Abstract

Background: Reducing care lapses for people living with HIV is critical to ending the HIV epidemic and beneficial for their health. Predictive modeling can identify clinical factors associated with HIV care lapses. Previous studies have identified these factors within a single clinic or using a national network of clinics, but public health strategies to improve retention in care in the United States often occur within a regional jurisdiction (eg, a city or county).

Objective: We sought to build predictive models of HIV care lapses using a large, multisite, noncurated database of electronic health records (EHRs) in Chicago, Illinois.

Methods: We used 2011-2019 data from the Chicago Area Patient-Centered Outcomes Research Network (CAPriCORN), a database including multiple health systems, covering the majority of 23,580 people with an HIV diagnosis living in Chicago. CAPriCORN uses a hash-based data deduplication method to follow people across multiple Chicago health care systems with different EHRs, providing a unique citywide view of retention in HIV care. From the database, we used diagnosis codes, medications, laboratory tests, demographics, and encounter information to build predictive models. Our primary outcome was lapses in HIV care, defined as having more than 12 months between subsequent HIV care encounters. We built logistic regression, random forest, elastic net logistic regression, and XGBoost models using all variables and compared their performance to a baseline logistic regression model containing only demographics and retention history.

Results: We included people living with HIV with at least 2 HIV care encounters in the database, yielding 16,930 people living with HIV with 191,492 encounters. All models outperformed the baseline logistic regression model, with the most improvement from the XGBoost model (area under the receiver operating characteristic curve 0.776, 95% CI 0.768-0.784 vs 0.674, 95% CI 0.664-0.683; $P<.001$). Top predictors included the history of care lapses, being seen by an infectious disease provider (vs a primary care provider), site of care, Hispanic ethnicity, and previous HIV laboratory testing. The random forest model (area under the receiver operating characteristic curve 0.751, 95% CI 0.742-0.759) revealed age, insurance type, and chronic comorbidities (eg, hypertension), as important variables in predicting a care lapse.

Conclusions: We used a real-world approach to leverage the full scope of data available in modern EHRs to predict HIV care lapses. Our findings reinforce previously known factors, such as the history of prior care lapses, while also showing the importance of laboratory testing, chronic comorbidities, sociodemographic characteristics, and clinic-specific factors for predicting care lapses for people living with HIV in Chicago. We provide a framework for others to use data from multiple different health care systems within a single city to examine lapses in care using EHR data, which will aid in jurisdictional efforts to improve retention in HIV care.

Introduction

Background

Retention in HIV care is an important step in the HIV care continuum for both public health efforts to end the HIV epidemic and for the individual health of people living with HIV [1]. The Centers for Disease Control and Prevention aims to reduce new HIV infections by at least 90% over the next 10 years [2]. Out of every 10 cases of HIV transmission, 8 are associated with people living with HIV who are not engaged in regular HIV medical care [2]. As part of the goal to reduce new HIV infections, it is important to ensure people living with HIV are receiving regular medical care. Currently, only 50.1% of people living with HIV in the United States are receiving continuous HIV care [3]. Therefore, increasing the percentage of people living with HIV retained in care is critical to ending the HIV epidemic in the United States.

Many methods to improve retention in care are being piloted across the United States [4]. In HIV clinical settings, the use of case managers to assist with appointment scheduling and health care navigation has been shown to improve retention [5]. Another initiative, Data to Care, is a strategy by public health departments to use HIV surveillance data to identify people living with HIV that have fallen out of care and attempt to relink them [6]. However, a study on the Data to Care program in Seattle and King County, Washington, found that only 50% of people living with HIV were successfully reengaged in care, suggesting a need for additional strategies to increase the number of people living with HIV in care [7]. One upstream intervention would be to identify people living with HIV who are more likely to fall out of care prior to lapsing in care, allowing them to be prioritized for intense case management and other retention interventions.

Prior Work

Previous studies have created predictive models to identify people who are likely to be at risk for lapses in HIV care. Ramachandran et al [8] used electronic health record (EHR) data from a single urban HIV clinic to predict retention in care. Similarly, Ridgway et al [9] used EHR data from multiple HIV clinics across the United States to predict retention in care. These studies identified factors associated with lapses in HIV care at the clinic or national level, but public health strategies to improve retention in care in the United States often occur at the city or county level. Local socio-structural factors may impact retention in care among people living with HIV within different cities in unique ways. To our knowledge, no prior studies have predicted which patients will lapse from HIV care within a single urban city (ie, using EHR data from multiple clinics within a single city or geographic region). Our study focuses on the city of Chicago, which is located in Cook County, Illinois, a priority jurisdiction for the Centers for Disease Control and Prevention's Ending the HIV Epidemic initiative [10]. The Chicago Department of Public Health (CDPH) is responsible for identifying and implementing HIV public health strategies, including the Ending the HIV Epidemic initiative, for both HIV prevention and HIV treatment within the city.

Goal of This Study

This study aimed to develop predictive models for determining which patients are at risk for lapses in HIV care in Chicago using the Chicago Area Patient-Centered Outcomes Research Network (CAPriCORN). CAPriCORN contains EHR data from a diverse group of 11 different health care systems in Chicago, including academic medical centers, community hospitals, and community health clinic networks [11]. Importantly, CAPriCORN contains data for 12.8 million people, including the majority of 23,580 diagnosed people living with HIV in the city of Chicago [12,13]. Data from CAPriCORN allowed us to follow people living with HIV who obtain HIV care across the different CAPriCORN health care facilities in Chicago. We used these data to identify those engaged in HIV care and to build predictive models to identify people living with HIV at risk for lapses in HIV care within the city of Chicago.

Methods

Study Population

We used deidentified EHR data obtained from 7 sites in CAPriCORN, selecting records from adults (aged 18 years and older) with encounters between January 1, 2011, and September 5, 2019. The hospitals included in the CAPriCORN research database use several different EHR systems, including Epic, Cerner, GE Centricity, eClinicalWorks, Sunquest, and Veterans Health Information Systems and Technology Architecture [11]. CAPriCORN was responsible for all harmonization of data across different EHR systems. Data from CAPriCORN are linked by using a hash-based data deduplication method, allowing researchers to identify and follow patients across the different Chicago health care systems [11]. All EHR data were provided at the encounter level, allowing us to incorporate changes to sociodemographic, medical diagnoses, and laboratory information over time. Data contained sociodemographic information, encounter information, diagnosis codes, laboratory data, and antiretroviral therapy (ART) medication or prescription drug orders. We used the following criteria to determine if an individual was HIV-positive: (1) a positive HIV laboratory test (confirmatory HIV antibody, p24 antigen, or HIV viral load > 20 copies/mL), (2) an HIV viral load test performed (regardless of results) and prescription for ART, excluding pre-exposure prophylaxis prescriptions, (3) an HIV diagnosis code (International Classification of Diseases [ICD] version 9 [ICD-9] codes 42, 079.53, 795.71, and V08; ICD version 10 [ICD-10] codes B20, R75, and Z21) and a prescription for ART, excluding pre-exposure prophylaxis, or (4) an HIV diagnosis code and 2 HIV viral load tests performed [14]. Individuals were only included in the study if they met one (or more) of the above criteria and had at least two HIV care encounters. An HIV care encounter was defined as an ambulatory encounter that was either (1) with an infectious disease (ID) provider (taxonomy code “207RI0200X” or “2080P0208X”), or (2) associated with an HIV viral load test or CD4 T cell test. This definition allowed for the inclusion of both people living with HIV who receive their HIV care from their primary care physician as well as those who receive HIV care from their ID physician. To avoid double counting of care visits, we considered visits and laboratory tests within 7 days of each other to be part of the same encounter.

Ethics Approval

This study was approved by the Chicago Area Institutional Review Board (IRB #00009693).

Outcome

The outcome of interest in all models was a lapse in HIV care, defined as not having a second HIV care encounter within 1 year after the original HIV care encounter. Because people living with HIV with stable viral loads may have longer time periods between their appointments (eg, from 6 to 9 months), a 1-year gap was chosen to distinguish between these patients and people living with HIV who had truly lapsed in care [9,15,16]. People living with HIV were censored from the study when <12 months of study time remained to ensure that all participants had the opportunity to be identified as having a lapse in care.

Predictor Variables

We initially created a list of 134 variables for inclusion in the models; however, 20 variables were excluded in the final models due to multicollinearity between these variables and those already in the model. Final models were built using 114 variables including patient demographics, history of lapse in care, site, provider specialty, insurance information, laboratory tests and results, ART medications, and patient diagnoses. Medical diagnoses were based on the presence of the ICD-9 and ICD-10 diagnosis codes. Specifically, we examined diagnoses of cancer, cardiovascular disease, diabetes, mental health disorders (including mood and anxiety disorders), obesity, sexually transmitted infections (STIs; ie, chlamydia, gonorrhea, hepatitis B, hepatitis C, and syphilis), as well as the use of alcohol, cannabis, opioids, sedatives, stimulants, and tobacco. CAPriCORN provided racial demographic information, with patients able to select more than one race. Laboratory test variables included HIV viral load, CD4 count, HIV genotype, STI tests, and other ID tests within the preceding 12 months. The complete list of variables, including those excluded due to multicollinearity, as well as their ICD-9 or ICD-10 codes, is available in Multimedia Appendices 1 and 2.

Model Development

Encounter data were randomly split into a training set (70% of total data) and a validation set (30% of total data). The split was performed while holding a constant ratio of the outcome variable. We created a baseline logistic regression model using only patient demographics and previous history of lapses in care allowing us to quantify how much more predictive capability was provided by including additional data related to laboratory tests and diagnoses. We then created 4 different predictive models: logistic regression, elastic net logistic regression, random forest, and XGBoost. The hyperparameters for the elastic net, random forest, and XGBoost models were tuned using a grid search and can be found in Multimedia Appendix 3. The hyperparameters were optimized using 5-fold cross-validation on the metric of the area under the receiver operating characteristic curve (AUC).

Model Performance

The performance of these 4 models was compared with each other and with the baseline logistic regression model. Model performance was evaluated using AUC via DeLong’s [17] method. Variable influence for each model was evaluated using the absolute value of the *t* statistic for the baseline and full logistic regression models, the value of coefficients for the elastic net logistic regression, the Gini index for the random forest, and the relative influence for the XGBoost model [18,19]. Each model can provide the association of variables; however, unlike the baseline regression, full logistic regression, and elastic net logistic regression models, the random forest and XGBoost models we created cannot provide the directionality of association. All analyses were performed using R (version 4.0.3; R Core Team).

Results

Study Population

The study population contained 16,930 people living with HIV with a total of 191,492 HIV care encounters during the study period. When examining the demographic information for participants based on information provided at their last HIV care encounter, people living with HIV in this study were predominantly male (75.2%, 12,733/16,930), Black (61.4%, 10,395/16,930), non-Hispanic or -Latino (84.2%, 14,249/16,930), and had all HIV care encounters at a single site within CAPriCORN (95.3%, 16,135/16,930). Based on each participant’s last 2 HIV care encounters, 25.1% (4257/16,930) of participants had a lapse in care (Table 1). Over the study period, 42.1% (7135/16,930) of participants had a change in their lapse in HIV care status (either from engaged to lapsed in care or vice versa). The different care sites served a wide range of number of patients; the smallest site served 224 unique people living with HIV, and the largest site served 10,035 unique people living with HIV. The proportion of lapses in care varied among sites. The worst-performing site was Site F, with 21.4% (61/292) of encounters resulting in a lapse in care. The best-performing site was Site G, with 3.7% (5283/141,864) of encounters resulting in a lapse in care. Over the study period, 94.4% (180,777/191,492) of HIV care encounters were followed by a second HIV care encounter within 1 year.

Table 1. Characteristics of people living with HIV in the Chicago Area Patient-Centered Outcomes Research Network in Chicago, Illinois, 2011-2019 (N=16,930).

Variable of interest and values	Frequency, n (%)
Lapses in HIV care	
No lapse in care	12,673 (74.9)
Lapse in care	4257 (25.1)

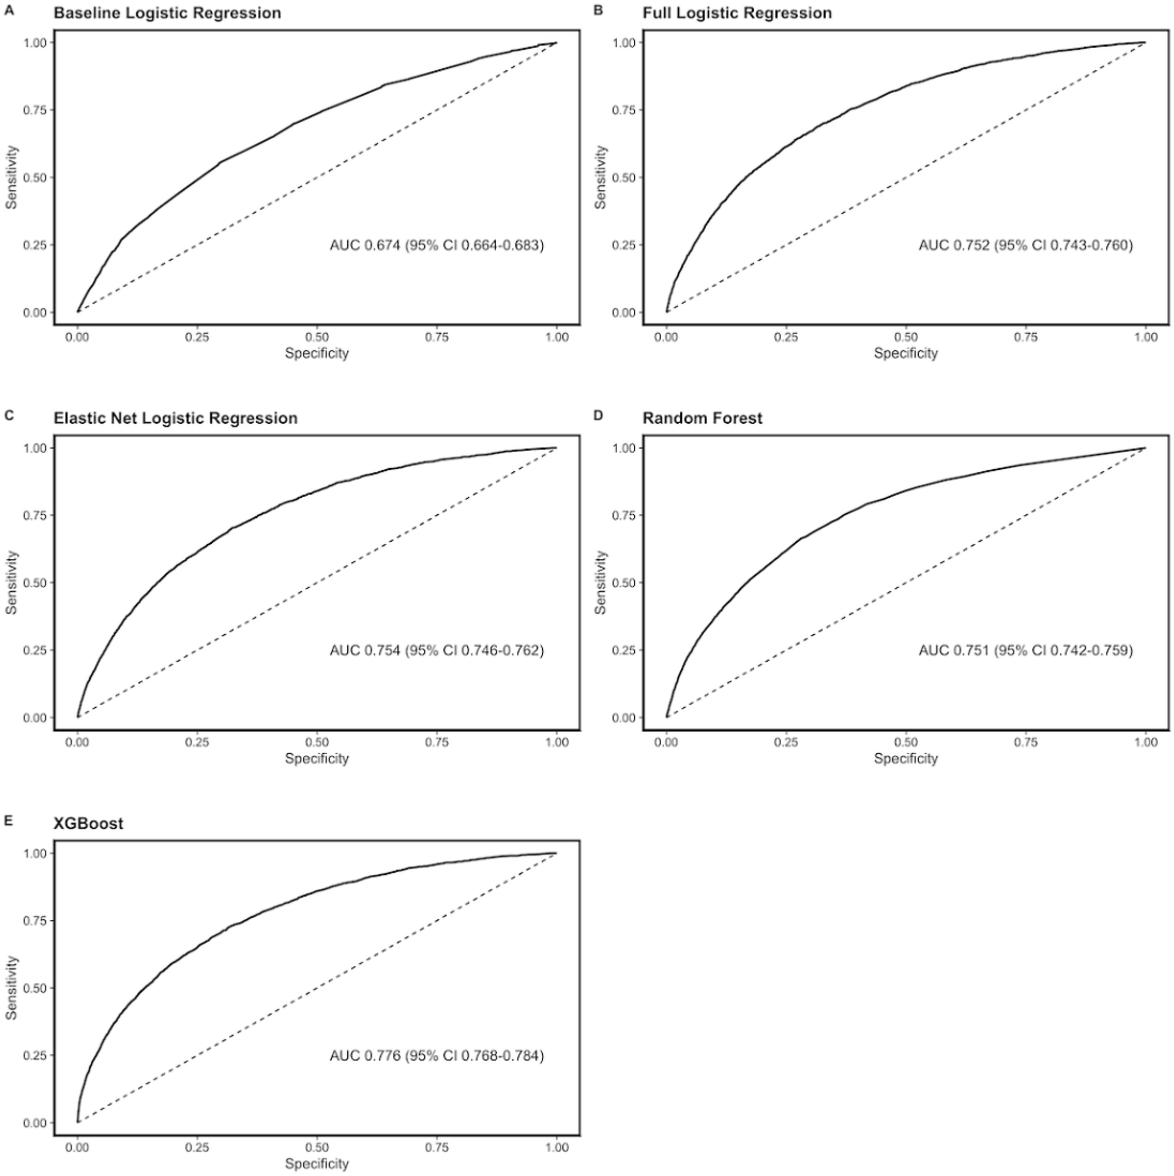
Variable of interest and values	Frequency, n (%)
Chlamydia laboratory test in the past year	
Yes	2419 (14.3)
No	14,511 (85.7)

Model Performance

Using our validation data set containing 57,447 encounters, all models created using 114 variables outperformed the baseline logistic regression model. The greatest improvement in AUC was seen with the XGBoost model (AUC 0.776, 95% CI 0.768-0.784 vs 0.674, 95% CI 0.664-0.683 for the baseline model; *P*<.001; Figure 1).

The XGBoost model had a significant difference in performance between the full logistic regression (AUC 0.776, 95% CI 0.768-0.784 vs 0.752, 95% CI 0.743-0.760; *P*<.001), elastic net logistic regression (AUC 0.776, 95% CI 0.768-0.784 vs 0.754, 95% CI 0.746-0.762; *P*<.001), and random forest (AUC 0.776, 95% CI 0.768-0.784 vs 0.751, 95% CI 0.742-0.759; *P*<.001) models. There was a significant difference in performance between the elastic net logistic regression model and the full logistic regression model (AUC 0.754, 95% CI 0.746-0.762 vs 0.752, 95% CI 0.743-0.760; *P*<.001); however, the magnitude of the difference between the 2 models was slight and may not be clinically meaningful. There was no significant difference in performance between the elastic net logistic regression model and the random forest model (AUC 0.754, 95% CI 0.746-0.762 vs 0.751, 95% CI 0.742-0.759; *P*=.43; Multimedia Appendix 4).

Figure 1. Prediction model receiver operator curves of lapses in care for people living with HIV in Chicago, Illinois, 2011-2019. AUC: area under the receiver operating characteristic curve.



Predictor Variable Importance

The top 10 most influential predictors in each model are listed in Tables 2 and 3. Although each model had slightly different results, common predictors included no lapse in care in the prior year, being seen by an ID provider (vs a primary care provider), and Hispanic or Latino ethnicity. Influential predictors for the full logistic regression model were no lapse in care in the prior year (adjusted odds ratio [aOR] 0.42, 95% CI 0.39-0.46; *P*<.001), being seen by an ID provider (vs a primary care provider; aOR 0.54, 95% CI 0.49-0.58; *P*<.001), age of 55 years or older (vs 25 years to less than 35 years; aOR 0.56, 95% CI 0.51-0.61; *P*<.001), Hispanic ethnicity (aOR 0.57, 95% CI 0.52-0.63; *P*<.001), age of 45 years to <55 years (vs 25 years to less than 35 years; aOR 0.68, 95% CI 0.63-0.73; *P*<.001), and site F (aOR 6.39, 95% CI 3.89-10.47; *P*<.001).

Table 2. Most influential variables for baseline logistic regression and full logistic regression models of lapses in care for people living with HIV in Chicago, Illinois, 2011-2019.

Model and variable	aOR[a] (95% CI)	*P* value
Baseline logistic regression		
No lapse in care in the prior 12 months	0.34 (0.32-0.36)	<.001
Hispanic ethnicity	0.32 (0.29-0.34)	<.001
Age of 55 years or older	0.53 (0.49-0.57)	<.001
Black race	0.41 (0.37-0.46)	<.001
Age of 45 years to less than 55 years	0.68 (0.63-0.73)	<.001
Unknown race	1.72 (1.52-1.94)	<.001
White race	0.63 (0.56-0.70)	<.001
Asian race	0.40 (0.31-0.51)	<.001
Age of 35 years to less than 45 years	0.86 (0.80-0.93)	<.001
Multiracial race	0.64 (0.41-0.99)	.047
Full logistic regression		
No lapse in care in the prior 12 months	0.42 (0.39-0.46)	<.001
Infectious disease provider	0.54 (0.49-0.58)	<.001
Age of 55 years or older	0.56 (0.51-0.61)	<.001
Hispanic ethnicity	0.57 (0.52-0.63)	<.001
Age of 45 years to less than 55 years	0.68 (0.63-0.73)	<.001
Site F	6.39 (3.89-10.47)	<.001
CD4 T cell percentage result greater than or equal to 28 in the prior 12 months	1.36 (1.25-1.48)	<.001
Gonorrhea laboratory test in the prior 12 months	0.35 (0.26-0.47)	<.001
Primary insurance unknown	0.56 (0.47-0.66)	<.001
Cancer diagnosis ever	0.78 (0.72-0.83)	<.001

[a] aOR: adjusted odds ratio.

Table 3. Top performing variables for elastic net logistic regression, random forest, and XGBoost models of lapses in care for people living with HIV in Chicago, Illinois, 2011-2019.

Model and variable	Variable importance score
Elastic net logistic regression	
Site F	1.575
No lapse in care in the prior 12 months	–0.835
Chlamydia laboratory test in the prior 12 months	0.815
Site A	0.814
Gonorrhea laboratory test in the prior 12 months	–0.769
Site C	0.649
Infectious disease provider	–0.583
Hispanic ethnicity	–0.512
Primary insurance unknown	–0.506
Emergency medicine provider	0.504
Random forest	
Primary insurance Medicaid	216.8
No lapse in care in the prior 12 months	205.9
Hypertension diagnosis ever	200.0
Age 35 years to less than 45 years	195.0
Tobacco diagnosis ever	194.5
Age of 45 years to less than 55 years	193.0
Mental health diagnosis ever	190.5
CD4 T cell percentage result less than 28 in the prior 12 months	184.1
Mood disorder diagnosis ever	172.5
Syphilis diagnosis ever	171.4
XGBoost	
Site G	0.089
No lapse in care in the prior 12 months	0.065
Infectious disease provider	0.045
Site A	0.038
Previous viral load result suppressed	0.031
Age of 55 years or older	0.019
Hispanic ethnicity	0.019
Primary insurance Medicaid	0.019
CD4 T cell percentage result greater than or equal to 28 in the prior 12 months	0.018
HIV viral load laboratory result unsuppressed in the last 12 months	0.017

Discussion

Principal Results

Our study found that 25.1% (4257/16,930) of patients experienced a lapse in care based on their last eligible HIV care encounter, which is lower than the CDPH estimate of 33.8% of people living with HIV in Chicago not accessing HIV care [13]. Our lower percentage is likely due to two factors: (1) a slightly different patient care population and (2) different definitions being used to determine who was not in care. We defined a lapse in HIV care as not having a second HIV care encounter within 1 year after the original HIV care encounter; however, CDPH defines a lapse in HIV care as not having at least one HIV laboratory test (CD4 or viral load) within a year [13]. Additionally, we only calculated lapses in care among patients with at least two HIV care encounters, rather than among all people living with HIV within the jurisdiction of Chicago identified in the enhanced HIV/AIDS Reporting System used by CDPH [13]. By limiting our study population to people with at least two HIV care encounters, we may have selected patients with a history of retention in care, resulting in a patient population less likely to experience a lapse in care.

In this study, we developed predictive models for lapses in care among people living with HIV using linked data that incorporated information from multiple health care systems across Chicago. Our XGBoost model outperformed our baseline model, which included only information about demographics and past lapses in care. Across the different models, we assessed various HIV health care and STI-related factors in predicting the likelihood of lapses in HIV care. In all models, prior lapses in care were among the most influential predictors of future lapses in care. This observation aligns with other studies that have found previous retention in care to be important in predicting future retention [8,9,20]. Our models also showed that higher CD4 T cell counts are associated with an increased risk of lapsing in care, supporting previous findings [21-23]. A previous suppressed HIV viral load laboratory result and an unsuppressed HIV viral load laboratory result in the prior 12 months were found to be associated with lapsing in care; however, the directionality could not be determined from the XGBoost model. A gonorrhea laboratory test in the last year was predictive of a decreased risk of lapsing in care in the logistic regression model and the elastic net logistic regression model. A chlamydia laboratory test in the last year was predictive of an increased risk of lapsing in care in the elastic net logistic regression model.

In addition to HIV-related factors, we also examined the ability of sociodemographic characteristics to predict lapses in HIV care. Since CAPriCORN covers the majority of people living with HIV in Chicago, this is a unique opportunity to view how these factors impact lapses in care in Chicago. We found that younger age is a predictor for lapses in care, which has been seen in other studies [9,21,22,24-26]. Hispanic or Latino ethnicity was associated with a decreased risk of lapsing in care in this study, a finding supported by some previous literature but contradicted by others [9,21,22,25-28]. Another predictor for not lapsing in care was the female sex, consistent with previous studies [22,28].

In terms of general medical and health care factors, we found that people living with HIV with chronic comorbidities, particularly cancer, are less likely to lapse in care, as others have also found [23]. This lower risk of lapsing in care may result from people with other comorbidities being more likely to follow up with both their chronic disease health care provider as well as their ID provider [9,29]. The comorbidity of hypertension (having hypertension or being hypertension-free) was also associated with lapsing in care [9,21]. Unfortunately, this result comes from the random forest model, so we cannot assess the directionality of the association. Finally, despite examining data from a single city, we found that the HIV care site was associated with a higher risk of lapsing in care. The HIV care sites included in our study ranged from a small percentage to almost a fifth of encounters resulting in a lapse of care, which could be due to a myriad of clinic-level factors, such as different patient demographics, acceptance of multiple insurance types, provider familiarity and trust, different neighborhood locations, and varying levels of resources available for identifying patients at risk for lapses in care and reengaging them. Additionally, structural racism and disinvestment in certain neighborhoods in Chicago have disproportionately impacted marginalized communities and the clinics that serve these communities, which may also be reflected in clinic site differences [30]. Our findings regarding the impact of chronic comorbidity and clinic-level factors on risk for lapsing in care suggest that public health departments may benefit from using data from city-wide research networks like CAPriCORN to better understand which people living with HIV have access to HIV care and are engaged in care.

Consequently, our model could allow public health agencies to identify which groups of people living with HIV within Chicago are at the highest risk of lapsing in care, allowing resources to be targeted toward these patients *before* they lapse in care. The integration of research data with city- or county-based HIV surveillance data can provide a more complete picture of access to and engagement with HIV care than either data source alone. For instance, CDPH, like most city public health departments, can follow the entire population of people living with HIV in Chicago due to mandatory laboratory reporting of HIV tests. CDPH also has precise knowledge of who enters or leaves the jurisdiction. This information was unavailable to us in the CAPriCORN health network. However, CAPriCORN contains a wide range of information derived from the EHRs of patients, encompassing their entire range of medical illnesses and test results, instead of the public health departments' relatively limited HIV-related medical information. City health departments typically use viral load and CD4 count laboratory tests as proxies for HIV care visits, whereas we gathered information from both laboratory and clinic visits, allowing us to capture the full range of HIV care encounters and providing a unique way to look at the city-wide continuum of care. For instance, using the CAPriCORN data, we were able to determine that most patients receive care from a single site; only 4.7% (795/16,930) of patients received care from more than one site within the research network. This is less than a study that found that 8% of people living with HIV in Philadelphia received HIV care from multiple sites [31]. Having the ability to determine this important information about the care continuum demonstrates the benefits of incorporating data from EHRs through research networks like CAPriCORN into public health surveillance for HIV care.

Limitations

There are several limitations to this study. In order to deidentify the data set and protect patient privacy, CAPriCORN removed specific dates of encounters. Therefore, we used patient age in days to determine the relative time between encounters. The lack of dates also means that we cannot account for study-wide temporal trends. Some of our sites also had incomplete data. For example, 1 site was missing HIV laboratory data, resulting in no eligible HIV care encounters, meaning that we were unable to incorporate this site into our models. This incompleteness of data shows a larger limitation of city-wide research networks. It is critical for cities using our framework to focus on incorporating high-quality data, ensuring the most accurate and complete data are available for tracking engagement in HIV care. Additionally, we determined that an HIV care encounter included primary care visits in which an HIV viral load test or

CD4 test were performed. However, it is possible that some primary care encounters were for HIV care but did not include performing an HIV viral load test or CD4 test leading to misclassifications. Similarly, we focused on 1 definition of a lapse in HIV care as our outcome, but there are multiple standards for defining a lapse in HIV care [32]. Future studies should compare different standards, such as the Health Resources and Services Administration HIV/AIDS Bureau measure [33]. As we did not have access to individual patient records for review of medical records, we used ICD-9/10 codes to identify diagnoses, which might lack sensitivity and specificity in identifying patients with medical comorbidities. However, ICD-9/10 codes provide a ubiquitous way for researchers to build predictive models using easily accessible data even if they lack the resources to carry out a review of medical records for every patient. Previous studies have shown that using ICD-9/10 codes can be effective at scaling up the rapid identification of people living with HIV [14,34]. Future studies should include social history variables and unstructured fields or free-text notes to see if they improve overall model performance. This model is possible because of the existence of the CAPriCORN research network. For this work to be extended in other settings, a deidentified, centralized data source from multiple hospital systems would need to be created in other jurisdictions. Our study is retrospective, so the performance of the model in a prospective setting should be tested in future studies prior to implementation.

Conclusions

We built predictive models for lapses in HIV care for people living with HIV from 7 different health care systems across Chicago and identified health care factors found in structured EHR data that are important for predicting lapses in care. Our models also serve as a proof of concept to show that differences in site-based practices (ie, laboratory tests ordered, diagnosis codes, different EHR systems, etc) do not prevent the ability to develop predictive models for lapses in care within a city. To our knowledge, this is the first time predictive models of lapses in HIV care have been built using EHR data from a large research network of health care systems within a major urban city with a high HIV prevalence rate. By focusing on data from patients served by a single public health department jurisdiction, findings from this study may inform HIV public health strategies for the city of Chicago. This model framework can also be adapted and used in clinics to identify patients most at risk for lapses in care who would benefit from tailored interventions or resources, thereby mitigating the number of people living with HIV who fall out of care and supporting efforts to end the HIV epidemic.

Abstract

Background: Risky sexual behaviors remain significant public health challenges among adolescents. Nearly 90% of adolescents live in low and middle-income countries (LMICs), but few studies have used standardized methodology to monitor the prevalence and trends of sexual behaviors among adolescents in LMICs.

Objective: This study aimed to assess the prevalence of sexual behaviors (ever had sexual intercourse, multiple sexual partners, and condom use) among adolescents aged 12 years to 15 years as well as the trends in prevalence between 2003 and 2017.

Methods: For this population-based study, we used recent data from the Global School-based Student Health Survey conducted in 69 LMICs from 2003 to 2017 to assess the recent prevalence of sexual behaviors by using complex analysis and a random effects meta-analyses method. Using the chi-square trend test, we also assessed the trends in the prevalence of sexual behaviors in 17 countries that had conducted ≥1 round of surveys from 2003 to 2017.

Results: We included 145,277 adolescents aged 12 years to 15 years (64,719/145,277, 44.5% boys) from the 69 LMICs that had conducted ≥1 survey and 80,646 adolescents aged 12 years to 15 years (34,725/80,646, 43.1% boys) from the 17 LMICs that had conducted ≥1 round of surveys. The recent global prevalence of ever had sexual intercourse was 6.9% (95% CI 6.2%-7.6%) and was higher among boys (10.0%, 95% CI 9.1%-11.1%) than girls (4.2%, 95% CI 3.7%-4.7%) and among those aged 14 years to 15 years (8.5%, 95% CI 7.7%-9.3%) than those aged 12 years to 13 years (4%, 95% CI 3.4%-4.7%). Among adolescents who had ever had sex, the recent global prevalence of having multiple sexual partners was 52% (95% CI 50.4%-53.6%) and was higher among boys (58%, 95% CI 56.1%-59.9%) than girls (41.4%, 95% CI 38.9%-43.9%) and among those aged 14 years to 15 years (53.5%, 95% CI 51.6%-55.4%) than those aged 12 years to 13 years (49.7%, 95% CI 45.9%-53.5%). Among adolescents who had ever had sex, the recent global prevalence of condom use was 58.1% (95% CI 56.2%-59.9%) and was higher among girls (59.2%, 95% CI 56.4%-61.9%) than boys (57.7%, 95% CI 55.7%-59.7%) and among those aged 14 years to 15 years (59.9%, 95% CI 58.0%-61.8%) than those aged 12 years to 13 years (51.6%, 95% CI 47.5%-55.7%). Between the earliest and latest surveys, the overall prevalence of ever had sexual intercourse (3.1% decrease) and condom use (2.0% decrease) showed downward trends. The overall prevalence of having multiple sexual partners increased by 2.6%.

Conclusions: We provide evidence and important implication for policymakers to develop targeted policy support systems to prevent and reduce risky sexual behaviors among young adolescents in LMICs with a high prevalence of risky sexual behaviors.

KEYWORDS

risky sexual behaviors; early sexual intercourse; multiple sexual partners; condom use; young adolescents; low and middle-income countries

Introduction

Adolescence is a period of rapid change in physical, psychological, emotional, and cognitive development, during which adolescents become more interested in sexual behaviors. Although sexual behaviors are widely considered a normative and physiological component of adolescent development, risky sexual behaviors including early initiation of sexual intercourse, having multiple sexual partners, and condom nonuse remain significant public health challenges among adolescents due to their potentially deleterious effects on later sexual and reproductive health [1]. Sexual debut is not deterministic of later sexual activities and risks, but sexual intercourse initiated at an earlier than normative age (typically defined as 15 years or younger) exposes adolescents, particularly adolescent girls, to a variety of risks such as HIV infection and other sexually transmitted infections (STIs) [2,3]. Girls who initiate sexual intercourse early were found to be at higher risk of reporting unintended pregnancies and STIs than those who delay intercourse until late adolescence [4,5]. Early sexual behavior is a public health concern among adolescents both in low and middle-income countries (LMICs) and high-income countries (HICs), but the adverse consequences of early sexual debut for adolescents in LMICs are more severe than for those in HICs. For example, previous studies have found that adolescent birth rates in LMICs are more than double that of HICs and most STIs occur in LMICs [6,7]. In addition, early sexual intercourse has been associated with reporting negative social and psychological outcomes (such as suicidal behaviors) [8] and subsequent higher-risk behaviors including alcohol or drug use during sex, lower levels of condom use, and forced sex [9,10].

Having multiple sexual partners is a common practice among young people. A review of data from the Global School-based Student Health Survey (GSHS) in 21 countries between 2010 and 2016 found that 53.1% of adolescents aged 12 years to 15 years who had sexual intercourse reported having multiple sexual partners [11]. Having multiple sexual partners is a risky sexual behavior that increases the risk of HIV and other STI transmission among adolescents [12]. A previous study indicated that the high prevalence of HIV/AIDS in sub-Saharan Africa is driven by high levels of multiple sexual partnerships [13].

Condom use has been acknowledged as an effective way to reduce the risk of gonorrhea, herpes simplex virus type 2, syphilis, and other STIs [14]. A review indicated that consistent use of condoms could effectively reduce the incidence of HIV/AIDS by 80% [15]. Meanwhile, condom use was associated with a lower risk of unintended pregnancy among adolescents, and the failure rate of male condoms for unintended pregnancy was about 2% [16]. Despite this, the prevalence of condom use among adolescents remains low. A study reported that nearly two-thirds of adolescents aged 15 years to 21 years did not use condoms during their last sexual intercourse [17].

Healthy sexuality is a key component of adolescent development. Nearly 90% of adolescents live in LMICs, and monitoring the prevalence and trends of sexual behaviors among adolescents in LMICs can help public health and education sectors design appropriate prevention and intervention strategies to promote sexual and reproductive health in adolescents. Although previous studies have reported the prevalence of sexual behaviors among adolescents aged 13 years to 15 years in some countries [18], as more countries have been released in the GSHS data set, there is an urgent need to analyze more up-to-date data and examine the difference in the prevalence of sexual behaviors among young adolescents. Differences in the prevalence of adolescent sexual behavior across countries may be influenced by race, religion, the society's culture, and economic status. Age and gender are also important factors to consider. However, few studies have used standardized questionnaires to examine and compare the age and gender differences in the prevalences of risky sexual behaviors among young adolescents in LMICs. More importantly, the most effective policies to prevent risky sexual behaviors may change over time; therefore, identifying trends in the prevalence of sexual behaviors is important for these countries to understand the effectiveness of previously developed policies in combating risky sexual behaviors among young adolescents and thus adjust intervention policies to fit the changes in policy needs and impacts. Therefore, it is imperative to analyze trends in the prevalences of risky sexual behaviors among young adolescents to provide evidence for the development of intervention programs. However, to our knowledge, few previous studies have assessed recent trends in the prevalences of risky sexual behaviors among young adolescents in LMICs.

Therefore, this study aimed to use recent data collected in the GSHS from 2003 to 2017 to assess the prevalences of sexual behaviors including ever had sexual intercourse, multiple sexual partners, and condom use as well as their age and gender differences among adolescents aged 12 years to 15 years in 69 LMICs. We also aimed to evaluate trends in the prevalences of sexual behaviors among adolescents in 17 LMICs between 2003 and 2017.

Methods

Study Design and Participants

This study used the latest GSHS data (2003-2017) publicly available on the websites of the US Centers for Disease Control and Prevention (CDC) and World Health Organization (WHO). Developed by the WHO and US CDC, the GSHS is a school-based self-administered survey for young adolescents aged 12 years to 15 years. The goal of the GSHS is to assess the health behavior risks and protective factors of middle-school students across countries and ultimately help countries develop and provide health care programs, resources, and policies that promote the health of adolescents [19]. To ensure the comparability of data across countries, the GSHS survey used the same standardized procedure (including sampling strategy, study methodology, and questionnaire) in each country; the GSHS questionnaire was translated into the local language, and each country was free to select question modules.

The selection of respondents in each country participating in the GSHS was based on a 2-stage random cluster sampling procedure. In the first stage, schools were randomly selected from all middle schools in each country by using the probability proportionate to size sampling method. In the second stage, classes were randomly selected from each selected school. All the students in each selected class were eligible to participate in this survey. Finally, based on the available data on sexual behaviors in the GSHS database, for the analysis of the prevalence of sexual behaviors, this study used the most recent GSHS data from 69 countries in 6 WHO regions (including 17 from Africa, 30 from the Americas, 1 from the Eastern Mediterranean, 2 from Europe, 5 from Southeast Asia, and 14 from the Western Pacific) that had conducted at least one survey between 2003 and 2017. To analyze the trends in the prevalences of sexual behaviors, we used the GSHS data from 17 countries in 4 WHO regions (5 from Africa, 7 from the Americas, 2 from Southeast Asia, and 3 from the Western Pacific) that had conducted more than one round of surveys between the earliest and latest surveys.

Outcomes and Definitions

Sexual intercourse was measured in this study using the question: “Have you ever had sexual intercourse?” The answer was dichotomized as “Yes” or “No.” Sexual partners were measured in this study using the question: “During your life, with how many people have you had sexual intercourse?” Multiple sexual partners were defined as having 2 or more sexual partners during their lifetime. Condom use was measured in this study using the question: “The last time you had sexual intercourse, did you or your partner use a condom?” The answer was also dichotomized as “Yes” or “No.” The prevalences of multiple sexual partners and condom use were calculated for those having sexual intercourse.

Statistical Analysis

The complex sampling command in SPSS Version 22.0 (IBM Corp) was used to conduct the statistical analysis. To adjust the sampling survey method and the differences between sampled students and national students, all complex sample analyses in this study were performed using 3 weighted variables included in each GSHS data set: strata, primary sampling unit, and weights. Weighted prevalences and corresponding 95% CIs of ever had sexual intercourse, having had multiple sexual partners, and condom use were calculated by region and country and by sex and age. ArcGIS software was used to map the prevalence of sexual behaviors among adolescents in each country. Chi-square analysis was used to test for differences in the prevalences between sexes and age groups, and *P* values <.05 indicated that the difference was statistically significant. The chi-square trend test was used to test the secular trend in the prevalences between the earliest survey and latest survey, and *P* values <.05 represented significant downward or upward trends in prevalences over time. Meanwhile, due to the significant heterogeneity between countries, we used the random effects model to calculate the pooled overall and regional prevalences of ever had sexual intercourse through the meta-analysis module in Stata Version 11.0.

Ethical Considerations

The ethics committee (usually the Ministry of Health or Education) of each country included in the GSHS survey reviewed and approved the study protocol. This survey was anonymous, and the answers were protected by privacy law. All participants and their parents gave their informed written or verbal consent for participation prior to the survey.

Results

Participants

As shown in Table 1 145,277 adolescents aged 12 years to 15 years were included from 69 countries in 6 WHO regions that had conducted at least one survey between 2003 and 2017. The sample sizes ranged from 218 in Nauru to 18,031 in Argentina. A total of 80,646 adolescents aged 12 years to 15 years were included from 17 countries in 4 WHO regions that had conducted more than one round of surveys between 2003 and 2017.

Prevalences of Sexual Behaviors in Young Adolescents

The overall prevalence of ever had sexual intercourse was 6.9% (95% CI 6.2%-7.6%) and was lowest in the Western Pacific and highest in the Americas (Table 2). Both gender and age differences were statistically significant in Africa, the Americas, and Southeast Asia. In Table S1 in Multimedia Appendix 1, nearly two-thirds (47 countries, 68%) of the 69 countries had a prevalence of ever had sexual intercourse >10%, while those in Europe and South Asia had a lower prevalence of <10% (Figure 1). Almost all countries had a higher prevalence for boys than girls, as well as for those aged 14 years to 15 years than those aged 12 years to 13 years.

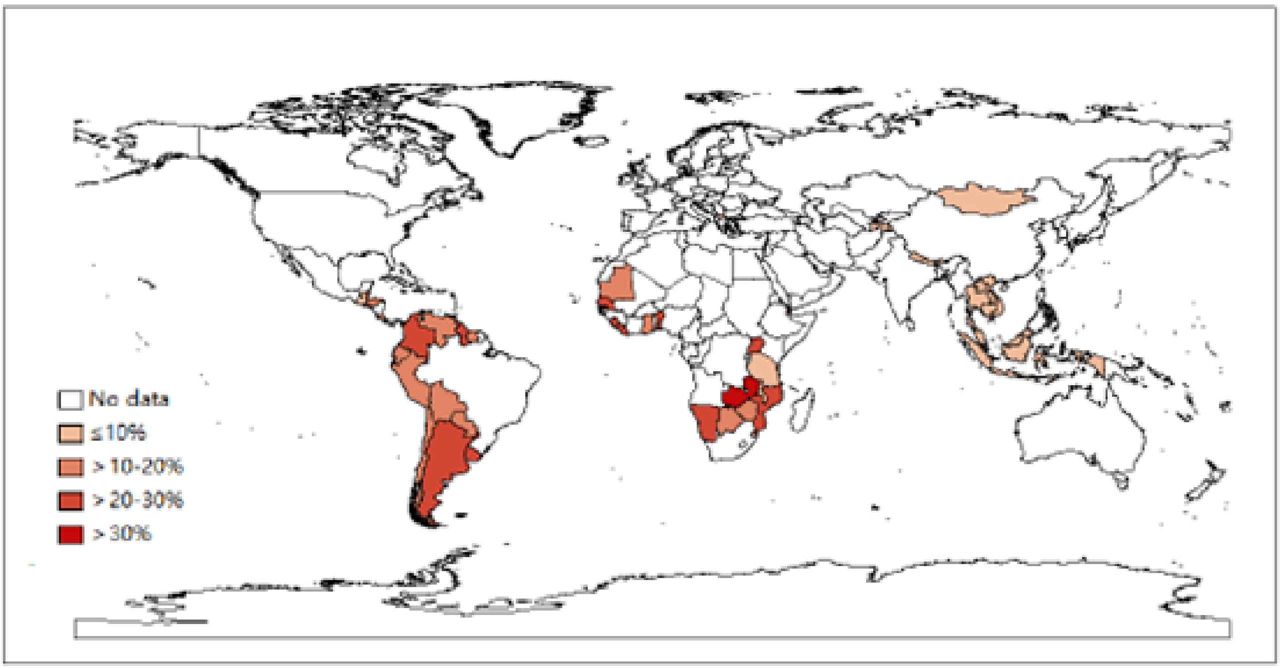
Figure 1. Prevalence of ever had sexual intercourse among young adolescents aged 12 years to 15 years based on the most recent Global School-based Student Health Survey from 69 countries, 2003-2017.



The prevalences of having multiple sexual partners and condom use among adolescents were based on those who ever had sexual intercourse. A total of 20,257 adolescents were included in the analysis of the prevalences of having multiple partners and condom use. The overall prevalence of having multiple sexual partners was 52.0% (95% CI 50.4%-53.6%) and was lowest in Western Pacific and highest in the Eastern Mediterranean (Table 3). The gender difference was statistically significant in all regions except for the Eastern Mediterranean, and the age difference was significant only in the Americas. In Table S2 in Multimedia Appendix 1, most (50 countries, 72%) of the 69 included countries had a prevalence of having multiple sexual partners >50% (Figure 2). The prevalence ranged from 2 times to 9 times higher among boys than among girls across countries, and the prevalence in adolescents aged 14 years to 15 years was higher than in those aged 12 years to 13 years in 47 of the 61 countries (data were unavailable for 8 countries in the Western Pacific).

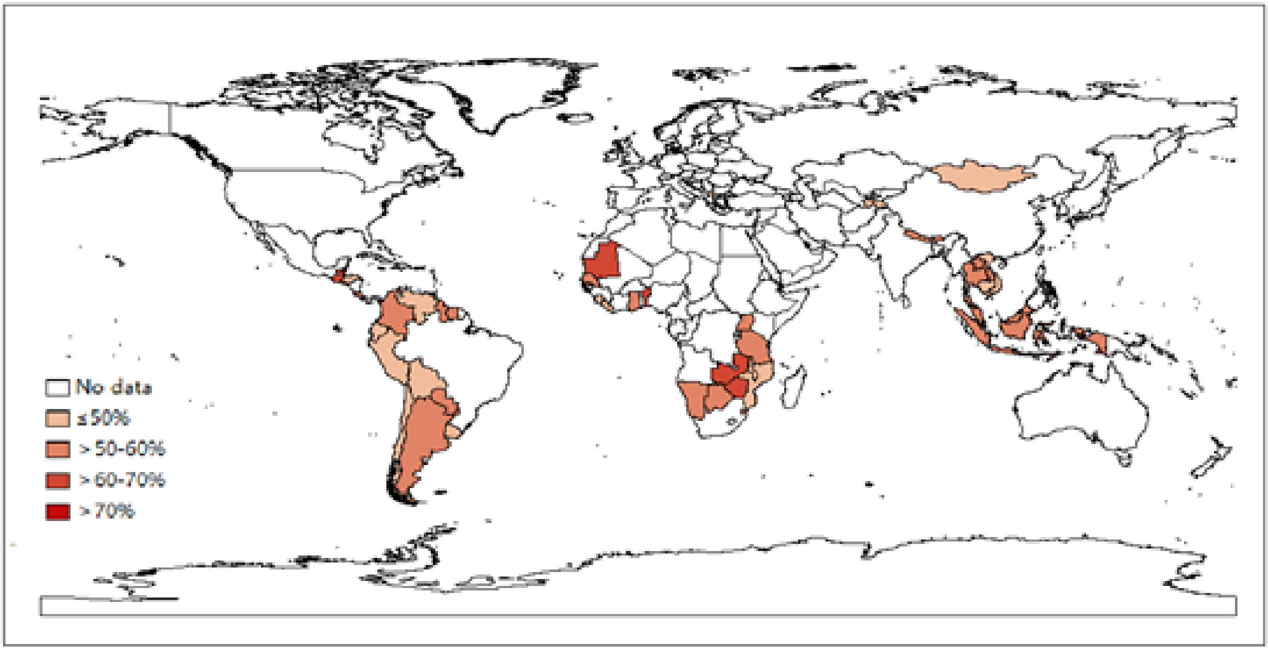
Figure 2. Prevalence of having multiple sexual partners among young adolescents aged 12 years to 15 years who ever had sexual intercourse based on the most recent Global School-based Student Health Survey from 69 countries, 2003-2017.



The overall prevalence of condom use at last sex was 58.1% (95% CI 56.2%-59.9%) and was lowest in the Western Pacific and highest in Europe (Table 4). The overall prevalence of condom use at last sex exceeded 50% in all regions, regardless of gender and age, except for among boys in Africa and the Western Pacific. In Table S3 in Multimedia Appendix 1, more than three-quarters (52 countries, 75%) of the included 69 countries had a prevalence >50% (Figure 3). In 38 of the 62 countries (data were unavailable for 7 countries in the Western Pacific), the prevalence in boys was higher than in girls, particularly in all countries in the Western Pacific. The prevalence in adolescents aged 14 years to 15 years was higher than in those aged 12 years to 13 years in 40 of the 62 countries, while all countries in Europe showed the opposite result.

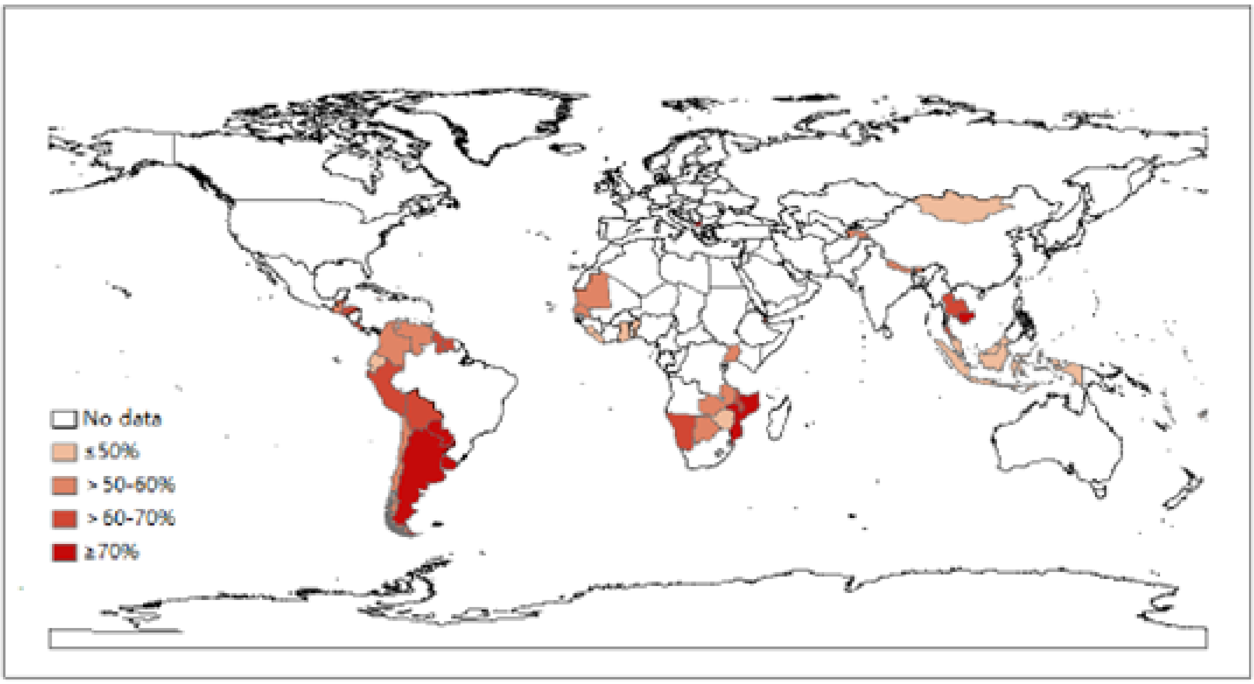
Figure 3. Prevalence of condom use at last sex among young adolescents aged 12 years to 15 years who ever had sexual intercourse based on the most recent Global School-based Student Health Survey from 69 countries, 2003-2017.



Trends in the Prevalences of Sexual Behaviors in Young Adolescents

As shown in Table 5, the overall prevalence of ever had sexual intercourse in young adolescents showed a downward trend over time between the earliest and latest surveys (3.1% decrease); a similar trend was observed by sex (boys, 3.9% decrease; girls, 2.5% decrease) and age group (12-13 years, 1.1% decrease; 14-15 years, 3.7% decrease). Specifically, in Table S4 in Multimedia Appendix 1, the prevalence of ever had sexual intercourse decreased in 9 countries (with the largest decrease of 24.6% in Samoa) and increased in 8 countries (with the largest increase of 7.9% in Seychelles).

Table 5. The trends in the prevalence of ever had sexual intercourse among young adolescents aged 12 years and 15 years between 2003 and 2017 or the earliest and latest surveys by World Health Organization region, sex, and age.

Region	Total sample, % (95% CI)	*P* value	Boys, % (95% CI)	*P* value	Girls, % (95% CI)	*P* value	12-13 years old, % (95% CI)	*P* value	14-15 years old, % (95% CI)	*P* value

A total of 13,051 adolescents were included in the trend analyses of the prevalences of having multiple partners and condom use. Table 6 shows that the overall prevalence of having multiple sexual partners increased by 2.6% over time; the upward trend was similar among girls and adolescents aged 14 years to 15 years (girls, 5.8% increase; age 14-15 years, 2.7% increase). All regions experienced an increase in the prevalence of having multiple sexual partners except for Africa. Specifically, in Table S5 in Multimedia Appendix 1, the prevalence of having multiple sexual partners increased in 9 countries (with the largest increase of 14.2% in Namibia), was unchanged in 2 countries, and decreased in 5 countries (with the largest decrease of 3.9% in Guyana).

Table 6. The trends in the prevalence of having multiple sexual partners among young adolescents aged 12 years to 15 years between 2003 and 2017 or the earliest and latest surveys by World Health Organization region, sex, and age.

Region	Total sample, % (95% CI)	*P* value	Boys, % (95% CI)	*P* value	Girls, % (95% CI)	*P* value	12-13 years old, % (95% CI)	*P* value	14-15 years old, % (95% CI)	*P* value

Discussion

Principal Findings

This study used the most recent GSHS data from 69 countries that had conducted at least one survey between 2003 and 2017 to assess the prevalences of sexual behaviors among adolescents aged 12 years to 15 years. Specifically, the overall prevalence of ever had sexual intercourse was 6.9%, and among adolescents who had ever had sex, the overall prevalences of having multiple sexual partners and using condom at last sex were 52.0% and 58.1%, respectively.

The prevalences of sexual behaviors among young adolescents varied widely across countries, and these differences may be due to several factors, including the social cultural environment, economic status, policy, race, and attitudes toward sex. For example, we found that the lowest prevalences of ever had sexual intercourse were in Indonesia, Malaysia, and Tajikistan, which can be explained by the religious culture embedded in these countries. Most people in these countries embrace Islam, which prohibits premarital sex and regards sexuality as a taboo and sensitive subject [20]. Especially in Indonesia, as the largest Islamic country with legal restrictions on pornography in the world [21], adolescents were generally considered to be more sexually conservative and bound due to the strict legal regulations and Islamic values.

The prevalences of sexual behaviors in boys were higher than in girls in most LMICs, which was consistent with previous studies in various countries, including HICs [22]. This finding may be due to the difference in sexual development between boys and girls. Previous studies have suggested that boys are more likely to report risky sexual behaviors and to initiate sexual intercourse earlier than girls [23,24]. Meanwhile, boys have more permissive attitudes about premarital sexual activity, while sexual intercourse in girls is often accompanied by trust, love, and a romantic relationship [25]. On the other hand, there are double standards in society for early sexual intercourse behaviors between boys and girls. Boys experience more sexual freedom, and sexual initiation in boys is regarded as a symbol of masculinity or rite of passage in some countries [26]. However, premarital sexual intercourse is stigmatized or labeled as indiscreet in girls, especially in Asian countries [23], and girls not only are bearing multiple social pressures but also have a higher risk of reporting unintended pregnancy and poor reproductive health. It is worth noting that the prevalence of condom use at last sex among boys in LMICs (57.7%) is lower than that from data obtained from HICs such as the United States (61% in those aged 13-19 years) and Australia (65.1% in those aged 10-12 years) and that future measures are needed to increase the use of condoms among not only girls but also boys in LMICs [27,28].

This study also provided evidence that the prevalences of sexual behaviors among adolescents aged 14 years to 15 years were higher than among those aged 12 years to 13 years in most countries, which has been shown in many previous studies [29]. This can be interpreted using the normal sexual development process. The expression of secondary sex characteristics is influenced by sexual-related hormones in puberty. A study showed that, during the ages of 12 years to 15 years, changes in hormones mature the reproductive system with age [30]. We speculated that sexual development may arouse sexual desire; thus, older adolescents are more likely to engage in sexual intercourse than younger adolescents.

Based on the GSHS data from 17 countries that had conducted more than one round of survey between the earliest and latest surveys, the overall prevalences of ever had sexual intercourse and condom use at last sex decreased over time, but the prevalence of having multiple sexual partners increased over time. To our knowledge, few studies have investigated the trends in sexual behaviors among young adolescents in LMICs, and this is the first study to explore the trends of sexual behaviors in young adolescents aged 12 years to 15 years in LMICs. An earlier study based on both the Youth Risk Behavior Survey (YRBS) and National Survey of Adolescent Males data found that the proportion of male adolescents aged 15 years to 17 years reporting sexual intercourse decreased by 9% from 1991 to 1997 and by 8% from 1988 to 1995 [31]. Another YRBS report based on recent surveillance data from the United States found that the percentages of high school students who ever had sex, had multiple sexual partners, or used a condom at last sex declined from 2009 to 2019 [32], with the downward trend in sexual intercourse and condom use at last sex consistent with our findings.

From a public health perspective, the decline in the prevalence of sexual intercourse among young adolescents aged 12 years to 15 years was a salutary trend, as sexual intercourse at an early age may put young adolescents at higher risk for poorer sexual and reproductive health outcomes. Most previous studies have identified factors influencing early sexual initiation from a static perspective, and only a few studies have explained the possible reasons for the decline in the prevalence of sexual intercourse. One study indicated that access to formal sexual education may reduce the number of adolescents younger than 15 years who have sexual intercourse [33]. Another study conducted in British Columbia suggested that the presence of protective factors (such as supportive schools and families, opportunities for community and school involvement) in adolescents' lives may contribute to declines in the proportion of adolescents in grades 7 to 12 who reported ever having sexual intercourse from 1992 to 2003 [34]. There is currently a lack of evidence explaining the change in adolescent sexual intercourse; future research should consider investigating factors that may affect changes in the prevalences of sexual behaviors among young adolescents.

The decreasing prevalence of condom use at last sex over time among young adolescents aged 12 years to 15 years is worrying. Previous studies have suggested that limited access to condoms (eg, restrictive laws or policies that provide contraceptives based on age or marital status) and the sociocultural environment (eg, the stigmatization of condoms) may be the main barriers to condom use among young people [35]. In addition, the decline in condom use at last sex among young adolescents might be explained by the lack of contraceptive knowledge, financial constraints, and the pursuit of sexual pleasure [36]. We found that the prevalence of having multiple sexual partners among adolescents who had ever had sexual intercourse increased over time, which was inconsistent with findings in HICs. The United States (2009-2019) and Canada (1992-2003) reported the prevalence of having multiple sexual partners decreased over time, by 5.2%, among high school students and, by 3.6%, among adolescents in grades 7 to 12 [32,34]. These previous studies conducted in Canada and the United States defined multiple sexual partners as having 3, 4, or more sexual partners during their lifetime, whereas the GSHS defined multiple sexual partners as having 2 or more partners in their lifetime, which may be one reason why the results of this study are inconsistent with previous results.

Implications and Contribution

Healthy sexual behaviors are an important component of adolescents' physical and psychological development. This study reported the prevalence and trends of sexual behaviors of young adolescents aged 12 years to 15 years in LMICs, which can provide evidence and important implications for policymakers to implement targeted programs that promote and improve the sexual and reproductive health of adolescents. The prevalences of adolescent sexual behaviors vary widely across countries, and there is an urgent need for the public health sector to develop targeted policy support systems to prevent and reduce risky sexual behaviors among young adolescents in LMICs with high prevalences of risky sexual behaviors. For example, the comprehensive sexuality education (CSE) intervention should be implemented, and its integration into the education system should be encouraged in countries where the prevalence of early sexual intercourse initiation is high or rising. Previous studies have indicated that CSE can increase sexual health knowledge and reduce risky sexual behaviors among young adolescents such as delaying the age of first sexual intercourse or ensuring that the age of sexual initiation is developmentally appropriate for the individual, increasing contraception use, and reducing the number of sexual partners [37,38]. The decline in condom use at last sex reported by some countries was a reminder that policymakers should continue to prioritize potential barriers to condom use among adolescents and explore solutions to these barriers. It is also important to consider gender and age differences among young adolescents when developing strategies to promote adolescent sexual health.

Limitations

This study also has several limitations. First, the prevalence of "having multiple sexual partners" or "condom use at last sex" among adolescents was based on those who have had sexual intercourse; the sample size of young adolescents who ever had sexual intercourse in some countries was extremely low, which may have caused selection bias and resulted in the lowest or highest prevalences of having multiple sexual partners and condom use in these countries. Therefore, the interpretation of the prevalences of having multiple sexual partners and condom use should be considered within the specific circumstances of the sample area. Second, the sexual behavior information was self-reported, which may have resulted in recall bias or intentional omission of key information. Although the interview questionnaire was anonymous and every effort was made to create a secure environment and maintain confidentiality of the respondents' information, the prevalences of sexual behaviors may still be underestimated or overestimated. Third, the GSHS was based on surveys of teenagers in school, which did not include those who did not attend school. Previous studies have shown that out-of-school students are more likely to initiate sexual behaviors than in-school students; thus, there may exist differences in sexual-related behaviors between these 2 groups, and the results of this study may not be suitable for generalization to all adolescents. Fourth, due to the data availability for each country, only 17 countries have conducted 2 rounds of surveys on sexual behaviors, and there are differences in the timing and length of surveys between countries. Although this can provide evidence for policy development in each country, our estimates for regional or global trends therefore need to be interpreted with caution. Finally, for some countries where sexual behavior surveys were conducted a long time ago (in the past decade or so), it is necessary to obtain data on recent adolescent sexual behaviors to identify recent trends.

Conclusions

In conclusion, this study found that the prevalences of sexual behaviors in young adolescents varied by country, region, sex, and age group. Over time, the overall prevalences of ever had sexual intercourse and condom use at last sex decreased, but the prevalence of having multiple sexual partners increased. This study can provide evidence and important implications for policymakers to develop a targeted policy support system to prevent and reduce risky sexual behaviors among young adolescents in LMICs with high prevalences of risky sexual behaviors.

Abstract

Background: Pre-exposure prophylaxis (PrEP) is proven to prevent HIV infection. However, PrEP uptake to date has been limited and inequitable. Analyzing the readability of existing PrEP-related information is important to understand the potential impact of available PrEP information on PrEP uptake and identify opportunities to improve PrEP-related education and communication.

Objective: We examined the readability of web-based PrEP information identified using search engines and on Twitter. We investigated the readability of web-based PrEP documents, stratified by how the PrEP document was obtained on the web, information source, document format and communication method, PrEP modality, and intended audience.

Methods: Web-based PrEP information in English was systematically identified using search engines and the Twitter API. We manually verified and categorized results and described the method used to obtain information, information source, document format and communication method, PrEP modality, and intended audience. Documents were converted to plain text for the analysis and readability of the collected documents was assessed using 4 readability indices. We conducted pairwise comparisons of readability based on how the PrEP document was obtained on the web, information source, document format, communication method, PrEP modality, and intended audience, then adjusted for multiple comparisons.

Results: A total of 463 documents were identified. Overall, the readability of web-based PrEP information was at a higher level (10.2-grade reading level) than what is recommended for health information provided to the general public (ninth-grade reading level, as suggested by the Department of Health and Human Services). Brochures (n=33, 7% of all identified resources) were the only type of PrEP materials that achieved the target of ninth-grade reading level.

Conclusions: Web-based PrEP information is often written at a complex level for potential and current PrEP users to understand. This may hinder PrEP uptake for some people who would benefit from it. The readability of PrEP-related information found on the web should be improved to align more closely with health communication guidelines for reading level to improve access to this important health information, facilitate informed decisions by those with a need for PrEP, and realize national prevention goals for PrEP uptake and reducing new HIV infections in the United States.

KEYWORDS

pre-exposure prophylaxis; PrEP; health literacy; health education materials; readability; prophylaxis; health information; electronic health education; HIV; infection; Twitter

Introduction

Pre-exposure prophylaxis (PrEP) is proven to prevent HIV infections [1-3], and using PrEP to prevent new HIV infections among vulnerable populations has been identified as a critical strategy in the Ending the HIV Epidemic initiative [4]. PrEP use increased more than 10-fold in the United States in just 5 years after its approval in 2012 [5]. However, inequitable PrEP uptake persists in the United States [6-8], especially in the southern United States and among Black and Hispanic residents in the United States. When those who need PrEP the most do not receive it, we lose opportunities to maximize reductions in new HIV infections. One potential explanation for lower uptake among vulnerable populations for HIV infections is the lower level of health literacy in these groups (ie, people in the southern United States, people living in poverty, younger people, and people of Black race or Hispanic ethnicity) [9,10]. Thus, analyzing the readability (ie, how difficult a text is to understand) of web-based information about PrEP would help understand the effectiveness of available web-based PrEP information and identify opportunities to improve the understandability of information for people who might benefit from PrEP.

Health literacy is an individual’s ability to obtain and understand health information to make informed health decisions [11]. The US Department of Health and Human Services (HHS) [12,13], the National Institutes of Health (NIH) [13,14], the American Medical Association (AMA) [15], and the US Food and Drug Administration (FDA) [16] recommend health information for the public be written at the ninth-grade reading level or lower to ensure that most people in the US population (ie, the general public) can make informed health decisions. However, researchers have consistently found evidence that text-based health information resources, including web-based resources, are too complex for the general public [17-25]. For example, patient education materials for electronic cigarettes [22], mental health [17], pediatrics [23], medical specialties [24], diabetes mellitus [18], clinical orthopedics [19], human papillomavirus immunizations [20], and cardiovascular diseases [21] were found to require higher literacy levels than that recommended by the NIH, AMA, FDA, and HHS. Moreover, health information available from commercially funded sources was significantly more difficult to read than the information available from government-funded sources for some health conditions, such as diabetes, hypertension, depression, high cholesterol, arthritis, asthma, heartburn, obesity, influenza, and erectile dysfunction [26], but not for electronic cigarette information [22]. This complexity often led to comprehension errors [27,28].

The readability of web-based PrEP information has also been reported [25], but the previous assessment was limited to 100 unique websites and did not include information circulated on social media. Additionally, the previous assessment did not stratify the assessment, which limits our understanding of how to improve the readability of educational materials. For information related to PrEP use, the increasing complexity of educational materials has been associated with lower uptake of PrEP [29,30]. There are other factors that can impact the understandability of PrEP information and accessibility to certain populations. For example, the format of the information (eg, brochure and website), the information source (eg, US government entities and for-profit organizations), and the intended audience could impact the readability of and trust in materials. Thus, different forms and sources of information should be examined for readability; these data should be interpreted in light of intended audiences who might require different levels of complexity. Analyzing updated content is also important because new PrEP delivery methods continue to gain approval and become available to consumers. For example, with the recent approval of injectable PrEP [31], readability studies of PrEP information need to be updated to include this new delivery method.

Assessments of readability should also include information disseminated through social media [32,33], which is an important source of passive information for many young people. However, many recent studies on the readability of health-related content on the web [17-25] have either focused solely on information obtained actively through search engines [17,18,20-22,24,25] or within popular websites for consumers [19,23]. It is important to examine health information that is obtained both actively via search engines and passively via social media channels. The latter is critical because >80% of Americans use at least one social media platform [34] and major health agencies, such as World Health Organization (WHO) and Centers for Disease Control and Prevention (CDC), regularly communicate via Twitter feeds. Social media content can include news releases as well as discussions on various health topics (eg, sexually transmitted infections, emergency situations [35,36], and preventive measures [33]).

We aimed to improve our understanding of the readability of publicly available web-based and social media–based PrEP information by analyzing it based on its information source, document format, communication method, PrEP modality, and intended audience. Our findings can be used to develop communication strategies that are tailored to the needs of different objectives and improve health literacy and the understandability of PrEP information for the general public.

Methods

Data Collection

We collected examples of both passively (eg, social media posts) and actively (information sought through user-initiated web searches) obtained information.

Collecting Passively Obtained Information

For passively obtained information, we collected PrEP-related information exchanged through Twitter. Twitter was chosen because many health organizations currently use Twitter to communicate health messages, including information about PrEP and HIV prevention, to the public [37,38]. About 22% of US adults use Twitter (45% of 18- to 24-year-olds); many (42%) check the platform more than once a day [39]. Tweets are short, being limited to 280 characters, but often refer readers to longer text information through embedded URLs. Thus, we investigated patient-level information sources (ie, brochures and websites) that were disseminated by URLs in tweets. We assessed and compared the readability of PrEP information based on the method used to obtain information (ie, passively or actively), information source (ie, organization type), document format (eg, brochures and websites), PrEP modality (ie, oral and injectable), and the intended audience (ie, patient, provider, and general).

To assess passively obtained information on PrEP, we used PrEP-related tweets with URLs as a starting point. Using Twitter API [40], we first collected PrEP-related tweets from July 2012, when the FDA first approved the PrEP indication for a pharmaceutical medication [41], to January 31, 2022, based on PrEP-related keywords that were used in a previous study [42] and a new set of keywords related to injectable PrEP [31] (Textbox 1). To emulate how users might search for information about PrEP on the web, we started from the Twitter URLs and further assessed the contents of external URLs that were embedded in the original URL (ie, manual web crawling). For each URL visited, PrEP information was manually and systematically collected (eg, text about PrEP) from the URLs. We repeated this process until all the relevant information linked to the original URLs and their referred external URLs were collected.

Textbox 1. Pre-exposure prophylaxis (PrEP)–related keywords for tweet collection.

PrEP keywords: [(truvada) OR (hiv AND PrEP) OR (preexposure AND prophylaxis AND hiv) OR (pill AND prevent AND hiv) OR (pill AND protect AND hiv) OR (pill AND protect AND AIDS)] [42]

Injectable PrEP keywords: [(Apretude) OR (cabotegravir) OR (inject AND prevent AND hiv) OR (inject AND protect AND hiv)]

Collecting Actively Obtained Information

To assess actively obtained information, a systematic search of PrEP was conducted using 5 popular search engines (ie, Google, Yahoo, Bing, DuckDuckGo, and Ask) from April to June 2022. We simulated the behavior of general consumers using the following various search terms and phrases: "PrEP," "PrEP information," "What is PrEP," "How to use PrEP," "Pre-exposure Prophylaxis frequently asked questions," "how does PrEP work in HIV prevention," "PrEP brochure," "PrEP facts," "HIV and PrEP," "Truvada PrEP," "PrEP side effects," "how much does PrEP cost," or "how to take prep" until a search result saturation was reached (ie, new information was not obtained). Then for comparison purposes, we specifically searched for "medication guide," "patient information," "info for people," "information for the patient," "information for the user," and "patient version" of known PrEP medications, (eg, Truvada, Descovy, Apretude, Vocabria, and cabotegravir).

For each of the 5 search engines, search results were collected from the first page for each search engine because most users rarely read past the first page of search results [43] and because our focus was to analyze the most frequently accessed web-based PrEP information. We did not include sponsored listings, as we wanted to focus on the most relevant and unbiased information. We manually verified search results to ensure that we only included web pages with PrEP information. We then systematically and manually web crawled these pages, using links from the search results as a starting point to emulate user behavior. Several false-positive links were excluded from the search results that were related to different acronyms or abbreviations (eg, Professional Research Experience Program). We also excluded documents without any PrEP-related information (eg, content about drugs used only for HIV treatment). We also excluded papers published in peer-reviewed journals that are not intended for the general public and would skew the readability results. Several documents were part of a much bigger document (eg, product monograph and prescribing information). Despite their relevance, if the overall PrEP information document exceeded 32,767 characters, we only included sections on PrEP that were written for the prescription drug prescribers in our analyses. We felt that this would most closely emulate how lay people would read this text. Duplicate sources obtained from more than one search path, educational videos, and descriptive figures and images were excluded and removed, and the web pages were converted to plain text for analysis.

Ethical Considerations

We only analyzed publicly available documents in this study and did not analyze identifiable private information or involve any direct or indirect interactions with individuals. Per UNC Charlotte's policy (citation 45 CFR 46 Definitions), the study is exempt from institutional review board requirements because it does not meet the regulatory definitions of human subject research.

Data Categorization

Information Source

We categorized information sources according to the originator of the document. The originator type was first determined with manual Google searches about organizations. This information was supplemented with information from the "about us" section of websites. We also used information in the web-based sources about affiliations, funding sources, and the Crunchbase [44] to finalize their organization types. Several websites still had no explicit indication of their affiliations or funding sources; we have denoted them as "N/A" and categorized them separately in our comparison analyses.

The information sources for this study included national and state governmental agencies (ie, US-located government entities; eg, CDC and California Department of Public Health), non-US governmental agencies (eg, National Health Service of the

United Kingdom), other public health organizations (eg, WHO and Joint United Nations Programme on HIV/AIDS), nongovernment organizations (eg, Mayo Clinic), and for-profit organizations (eg, Gilead Sciences).

Document Format and Communication Method

Communication methods were categorized as brochures, information sheets, or websites by manually assessing each document. To identify brochures, we first searched for the keyword "brochure" in the URLs, and then, we manually verified other documents with similar presentations of information. Brochures were distinguished from information sheets by their inclusion of images, figures, or pictures. To identify the information sheets, we searched for the keywords "factsheet" and "sheet" from the remaining URLs. Then, we manually labeled other information sheets by searching for similar presentations of information, which contained only text (ie, no images, figures, and pictorial descriptions). Other resources were categorized as websites because they were hosted on a web page and did not meet the criteria for either brochure or information sheet.

PrEP Modality

All documents were manually categorized based on PrEP modality (ie, delivery methods) to allow comparison by modality. We classified documents with one or more keywords—"oral," "tablet," "pill," "Truvada," "Descovy," "daily PrEP," "PrEP 2-1-1," and "PrEP on demand"—in the title as "oral PrEP." We classified documents with the keywords "Cabotegravir," "Apretude," "long-acting," "injection PrEP," and "injectable" as "injectable PrEP." If a document had both types of keywords in the title, we categorized it as "oral and injectable PrEP." For documents without these keywords in the title, the modality was categorized based on the content of the document. Documents without PrEP modality descriptions were categorized as general PrEP.

Intended Audience

The intended audience was manually determined for each document, that is, patient, provider, or general public. We used document titles and the first paragraph to determine the target audience. To identify documents written for patients, we looked for the following titles: "Patient Information," "Medication Guide," "Patient Medication Information," "Information for the user," "Information for the patient," and "Overview for Patients." Then, we read the first paragraph to ensure its intended audience was patient and checked if it had statements similar to the following. "Read this carefully before you start taking [Drug name] and each time you get a refill. […]." Similarly, documents written for providers were identified if they had these or similar titles: "Clinical Guide," "Provider Frequently Asked Questions," "Provider FAQs," "Clinician Guidance," and "Guide for Medical Providers." We also read the first paragraph to check phrases similar to "Review this guide when prescribing [Drug name]." The intended audience for documents not meeting the criteria for patient or provider documents was determined as intended for the general public.

Measuring Readability

We used the Flesch-Kincaid grade level [45], Simple Measure of Gobbledygook Index [46], Coleman and Liau Index [47], and Automated Readability Index [48] to calculate the text readability, which is defined here as the grade level required to comprehend the text in the US education system. These indices are widely used in previous readability studies [23,24,26,49-53], and we applied them to the entire data set. To computationally perform readability analysis, the readability scores were first calculated based on the 4 readability indices using the open-source Python *textstat* package [54]. Given that different readability indices can generate a range of results, we used the mean of the 4 readability indices in our analyses to increase the reliability of our results but also report results generated by all 4 indices (Multimedia Appendix 1). We then conducted 5 sets of pairwise independent sample *t* tests to compare readability scores based on the method of obtaining the information, information source, document format and communication method, PrEP modality, and intended audience. When necessary, *P* values were adjusted using the prespecified Hommel procedure [55] to account for multiple comparisons within each set.

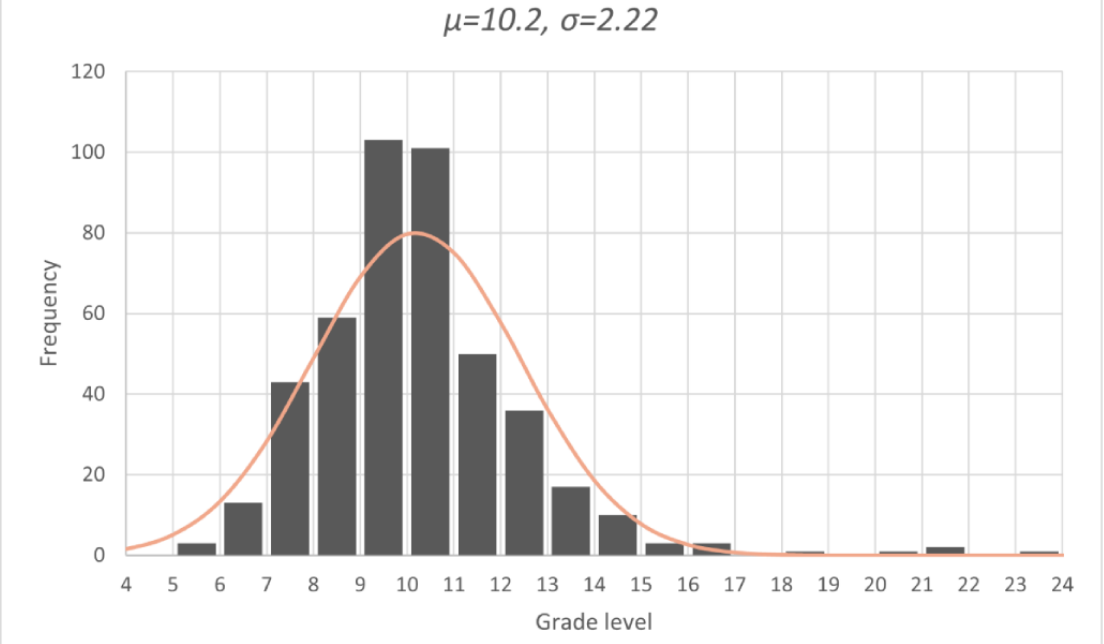
Results

Information Obtained Method

We collected a total of 463 documents, 194 from Twitter (ie, passively obtained information) and 269 from search engines (ie, actively obtained information). A total of 17 documents were duplicates. For analyses, we removed 1 set of the 17 duplicate documents. The documents were excluded in both sets, a total of 34 documents, when comparing the readability of documents based on methods for obtaining information. Using the average of the 4 reading level indices, the overall average reading level for web-based PrEP materials was a 10.20 grade level with an SE of 0.11. This is significantly above the recommended grade level of lower than ninth grade for the comprehension of health materials. The readability scores of materials retrieved from Twitter (9.8 grade level, SE 0.16) and search engines (10.5 grade level, SE 0.15) were significantly different (*P*=.002 by independent sample *t* tests).

We found that the distribution of readability scores for all documents was approximately normally distributed (ie, unimodal) with a slight skew to the right and a mode between the ninth and eleventh reading levels as shown in Figure 1. About 74% (n=328) of web-based sources required reading levels higher than ninth-grade.

Figure 1. The empirical distribution of the average readability level required for understanding web-based pre-exposure prophylaxis information.



Information Source

We found 172 documents from 45 for-profit entities (eg, Gilead Sciences and Nurx), 157 documents from 49 nongovernment organizations (eg, Mayo Clinic and Black AIDS Institute), 88 documents from 28 US governmental entities (eg, CDC and NIH), and 16 documents from 7 non-US governmental entities (eg, National Health Service of the United Kingdom and Health Service Executive-Ireland) or other public health organizations (eg, WHO and Joint United Nations Programme on HIV/AIDS). A total of 13 documents from organizations had no explicit indication of their affiliations or funding sources; they were excluded from our information source comparison analyses.

Some organizations and entities developed multiple PrEP-related documents, but they differed in content and topic. For example, some documents provided details about a particular PrEP drug (eg, Truvada and Descovy), while others provided information about accessing PrEP or PrEP cost. Still, others were different document types (eg, brochures). In our analyses, we treated each document as a separate data point.

Complete readability scores for each document are presented in Multimedia Appendix 1. The overall average grade reading level required to understand web-based PrEP information (10.2 grade level, SE 0.1) is considerably higher than the target grade level recommended by health agencies for health information. The mean grade reading levels and SEs (ie, of the 4 indices) from these organizations are displayed below and compared in Table 1. There was no significant difference in readability among organization types.

- Non-US government entities or other public health organizations: mean 10.6 (SE 0.7)
- For-profit entities: mean 10.4 (SE 0.2)
- The US-located government entities: mean 10.3 (SE 0.2)
- Nongovernment organizations: mean 9.9 (SE 0.2)

Table 1. Pairwise 2 sample *t* test of the average readability by source type.

Source type	*P* value	Adjusted *P* value
Non-US government entities or other public health organizations[a]	.22	.66
For-profit entities[a]	.04	.12
The US-located government entities[a]	.15	.46
Non-US government entities or other public health organizations[b]	.65	.74

[c] Versus for-profit entities.

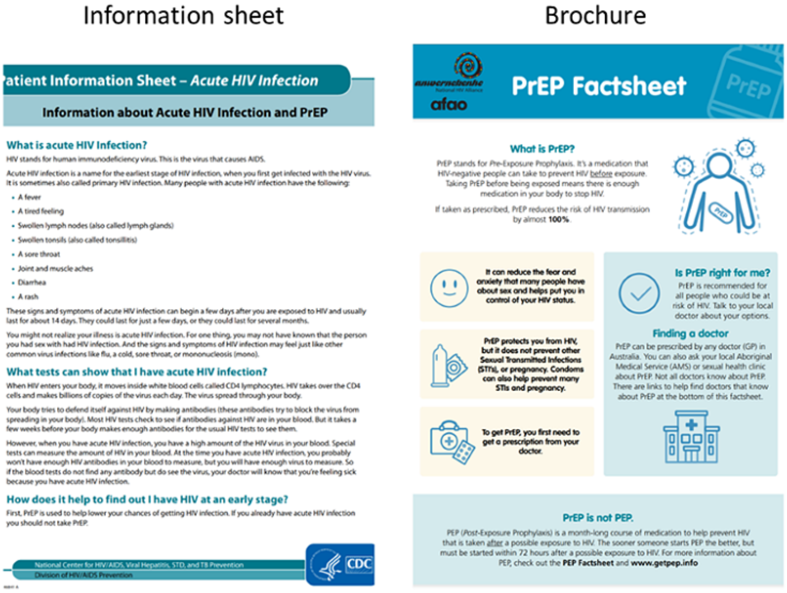
Document Format and Communication Method

The most common type of document was websites (n=384), including content from health organizations and health care professionals. Websites typically provide a comprehensive range of information on multiple related topics, such as HIV/AIDS and PrEP access, at a reading level of 10.2 grade (SE 0.46).

In our data set, information sheets (n=29) were in PDF file format and had titles containing phrases such as “Patient Medication,” “Medication Guide,” “Information for the user,” “Information sheet,” “Fact sheet,” “Facts,” and “Information booklet.” Compared to other document formats, they were also lengthy and detailed, including medication information and instructions for patient use. Most medication guides were written by the drug manufacturers (eg, Gilead Sciences and ViiV Healthcare) and FDA. Five information sheets were provided by nonprofit and non-US government health organizations. Information sheets were written at a reading level of 11.2 grade (SE 0.46).

Examples of each type of document are provided in Figure 2. Brochures (n=33) included user guides and leaflets containing commonly asked questions such as “What is PrEP” and “How to get PrEP.” Brochures were prepared by federal and state governmental organizations (n=15), non-US governmental organizations (n=2), nongovernmental organizations (n=10), and for-profit organizations (n=6). The 3 document types had significantly different readability levels: the readability of brochures was easier than both information sheets (adjusted *P*<.001) and websites (adjusted *P*=.003), with an average readability level at the recommended ninth grade level (SE 0.31).

Figure 2. Examples of document types used to disseminate pre-exposure prophylaxis (PrEP) information on the web: information sheet (top left), brochure (top right), website (bottom left), and website in a blog format (bottom right). More information about each document, including the source URL, can be found in Multimedia Appendix 1, rows 12, 272, 114, and 147. For a higher-resolution version of this figure, see Multimedia Appendix 2.



Information sheet

atient Information Sheet – *Acute HIV Infection*

Information about Acute HIV Infection and PrEP

What is acute HIV Infection?

HIV stands for human immunodeficiency virus. This is the virus that causes AIDS.

Acute HIV infection is a name for the earliest stage of HIV infection, when you first get infected with the HIV virus. It is sometimes also called primary HIV infection. Many people with acute HIV infection have the following:

- A fever
- A tired feeling
- Swollen lymph nodes (also called lymph glands)
- Swollen tonsils (also called tonsillitis)
- A sore throat
- Joint and muscle aches
- Diarrhea
- A rash

These signs and symptoms of acute HIV infection can begin a few days after you are exposed to HIV and usually last for about 14 days. They could last for just a few days, or they could last for several months.

You might not realize your illness is acute HIV infection. For one thing, you may not have known that the person you had sex with had HIV infection. And the signs and symptoms of HIV infection may feel just like other common virus infections like flu, a cold, sore throat, or mononucleosis (mono).

What tests can show that I have acute HIV infection?

When HIV enters your body, it moves inside white blood cells called CD4 lymphocytes. HIV takes over the CD4 cells and makes billions of copies of the virus each day. The virus spread through your body.

Your body tries to defend itself against HIV by making antibodies (these antibodies try to block the virus from spreading in your body). Most HIV tests check to see if antibodies against HIV are in your blood. But it takes a few weeks before your body makes enough antibodies for the usual HIV tests to see them.

However, when you have acute HIV infection, you have a high amount of the HIV virus in your blood. Special tests can measure the amount of HIV in your blood. At the time you have acute HIV infection, you probably won't have enough HIV antibodies in your blood to measure, but you will have enough virus to measure. So if the blood tests do not find any antibody but do see the virus, your doctor will know that you're feeling sick because you have acute HIV infection.

How does it help to find out I have HIV at an early stage?

First, PrEP is used to help lower your chances of getting HIV infection. If you already have acute HIV infection you should not take PrEP.

National Center for HIV/AIDS, Viral Hepatitis, STD, and TB Prevention
Division of HIV/AIDS Prevention

Brochure

PrEP Factsheet

What is PrEP?

PrEP stands for *Pre-Exposure Prophylaxis*. It's a medication that HIV-negative people can take to prevent HIV before exposure. Taking PrEP before being exposed means there is enough medication in your body to stop HIV.

If taken as prescribed, PrEP reduces the risk of HIV transmission by almost **100%**.

It can reduce the fear and anxiety that many people have about sex and helps put you in control of your HIV status.

PrEP protects you from HIV, but it does not prevent other Sexual Transmitted Infections (STIs), or pregnancy. Condoms can also help prevent many STIs and pregnancy.

To get PrEP, you first need to get a prescription from your doctor.

Is PrEP right for me?

PrEP is recommended for all people who could be at risk of HIV. Talk to your local doctor about your options.

Finding a doctor

PrEP can be prescribed by any doctor (GP) in Australia. You can also ask your local Aboriginal Medical Service (AMS) or sexual health clinic about PrEP. Not all doctors know about PrEP. There are links to help find doctors that know about PrEP at the bottom of this factsheet.

PrEP is not PEP.

PEP (*Post-Exposure Prophylaxis*) is a month-long course of medication to help prevent HIV that is taken after a possible exposure to HIV. The sooner someone starts PEP the better, but must be started within 72 hours after a possible exposure to HIV. For more information about PEP, check out the **PEP Factsheet** and **www.getpep.info**

GET TESTED FOR STIS AT HOME

Nurx offers at home test kits for common STIs for as little as $75 with insurance or $150 per month without insurance.

PrEP Modality

We identified 220 documents relating to oral PrEP only, 14 documents relating to injectable PrEP only, and 14 documents mentioning both oral and injectable PrEP. The rest of the documents (n=198, 44%) did not mention a specific PrEP delivery method (ie, "general PrEP"); these latter documents were excluded from analyses. On average, the content on injectable PrEP (12.7 grade level, SE 0.9) was more difficult to comprehend than the content on oral PrEP (10.2 grade level, SE 0.2). Information on both forms of PrEP was intermediate in readability (10.8 grade level, SE 0.6). The comparison analysis results are shown in Table 2.

Table 2. Pairwise 2 sample *t* test of the average readability by PrEP[a] modality.

PrEP modality	*P* value	Adjusted *P* value
Injectable PrEP[b]	<.001	<.001
Oral and injectable PrEP[b]	.30	.30
Injectable PrEP[c]	.09	.09

[a] PrEP: pre-exposure prophylaxis.

[b] Versus oral PrEP.

[c] Versus oral and injectable PrEP.

Intended Audience

Most documents (n=426, 95.5%) were categorized as "general public" because they did not specify their intended audience. We found 14 documents specifically written for PrEP users and 6 specifically written for providers.

The readability grade level indices of content intended for PrEP providers (15.6 grade level, SE 1.59) were significantly higher when compared to the content intended for patients (10.2 grade level, SE 0.3; adjusted $P<.001$) and the general public (10.1 grade level, SE 0.1; adjusted $P<.001$). The reading level of content written for PrEP users was similar to that of materials for the general public (adjusted $P=.84$).

Discussion

Principal Findings

Our study highlights the challenging task of effectively educating diverse audiences about PrEP. Our results are consistent with previous work [25], which found that web-based PrEP information is often difficult to understand. We add to this previous work by including data disseminated in social media and stratifying web-based PrEP documents by how the PrEP document was obtained on the web, information source, document format and communication method, PrEP modality, and intended audience. We found PrEP materials from Twitter were significantly easier to comprehend than those identified by web searches, despite the fact Twitter was merely posting URLs of web-based information. It is possible that organizations selectively identify more comprehendible materials to promote through Twitter. The readability of web-based PrEP information from different organizational groups was all higher than recommended, and there was no significant difference between them (Table 1). This contrasts with a previous study that focused on different health conditions [26]. Informational documents intended for providers had significantly higher reading levels than those intended for patients or the general public. However, the materials intended for the patients and the public were still higher than the recommended ninth-grade reading level.

Brochures were the only type of PrEP materials that achieved the HHS and NIH target of ninth-grade reading level [13]. Brochures have been used in successful public health campaigns for facilitating behavior change, knowledge increase, and self-efficacy for other health conditions [56]. Brochures may be effective means of PrEP communication for most people who are not medical providers. However, brochures were not a common mode of conveying information: there were only 33 brochures in 446 unique documents that we identified.

As PrEP regimens become more complex (eg, injectable PrEP and 2-1-1 PrEP), educational materials might become more difficult to comprehend. For example, we identified that a higher reading level was required to understand materials about injectable PrEP. Yet, there is great interest in injectable PrEP: in a National HIV Behavioral survey of 314 people, injectable PrEP was preferred by 3 times more respondents compared to oral PrEP [31]. This calls for attention to improving the readability of materials describing injectable PrEP because difficulty in understanding injectable PrEP information could discourage people who would otherwise be interested in the new PrEP route of administration.

Our findings suggest that there is a need for health communication strategies and policies that support the development and dissemination of clear and concise PrEP information. Our finding suggests that health communication strategies can be enhanced by using brochures and plain language, which may include avoiding jargon. Policies can also be improved to support this effort. For instance, governments could increase funding for research into PrEP literacy and the development of PrEP communication guidelines. Additionally, governments could mandate that health care providers receive training on how to communicate about PrEP in a clear and easy-to-understand way for a variety of audiences. Together, these communication strategies and policies can help individuals to have access to clear and easy-to-understand information about PrEP, which can help to increase PrEP uptake and reduce HIV transmission.

Limitations

Our findings should be understood in the light of their limitations. First, individuals accessing PrEP information on the web may be a select subgroup of those interested in PrEP and might have higher or lower health literacy than those who seek information from other sources. However, given that the internet has become an increasingly popular resource for health information [32,57] and groups potentially eligible for PrEP [58] tend to have high internet use [59], it is likely that a substantial proportion of potential and current PrEP users would seek PrEP information on the web. Second, current general-purpose readability indices alone may not be a perfect measurement of comprehension and reading level [60,61], especially for assessing documents with nontext content, such as charts, graphs, and videos. For instance, we noted that all brochures in our data set contained images. Pictorial and graphic representations of information have been shown to be more effective than text-only messages [62]. Similarly, we found that some websites also contain PrEP-related informational videos; videos have been shown to be effective in modifying health behaviors, including promoting HIV testing [63]. In this study, we focused on textual information as text remains the primary medium for health communication on the web [64] and relied on the average scores of 4 readability indices to minimize the lack of sensitivity or breadth of measurements from using a single metric. Third, our analysis, although systematic, was not exhaustive. The web-based PrEP information included in our study was collected from a variety of sources, yet it is possible that some important information was missed. We limited our search to English language materials, and the first page of the search result imitated users' web-based behavior [43]. Lastly, we did not use generic names of PrEP medications, thus potentially not including PrEP information that only might use the generic names.

Future Directions

Despite public guidelines for writing health education materials, readability levels of web-based health materials, even those written by public health organizations, have either become more difficult [65] or reflected no improvement [19] with few exceptions [66]. AMA guidelines suggest addressing health literacy concerns by avoiding unnecessary details and lengthy background information [15]. This recommendation is consistent with our finding that documents in the brochure format, which were assessed as most readable, were concise, focused more on patient needs, and provided less background information. Readability is only one measure of the impact of health information, for example, measures of health literacy are evolving to include measures of the extent to which materials increase decision-making ability [67]. Thus, future research on health literacy should extend to whether educational materials are helpful to clients in making informed decisions.

Social media platforms have been widely used for public health communication and education, but research focused on measuring the effectiveness of social media as a channel for public health information is limited (with a few notable exceptions [68]). A better understanding of social media platforms' effectiveness should improve public health communication and the development of an impactful campaign for facilitating behavior change, knowledge increase, and self-efficacy related to public health needs—including PrEP uptake. Inequitable PrEP uptake persists among racial, ethnic, and gender minority communities [6,7]. Follow-up studies should (1) optimize the effectiveness of web-based educational materials in making informed decisions among health equity populations and (2) tailor messaging to address the information needs of specific populations to address inequitable PrEP uptake.

Future studies of the readability of web-based PrEP information should consider the following points. PrEP use and HIV prevention are global concerns, and it is important to understand how people in other languages are accessing and understanding information about PrEP. Future studies should examine materials in other languages. To provide a more comprehensive picture of the range of available web-based PrEP information, future work can expand the data collection process by expanding the number of result pages, search keywords, search engines, and search locations and by applying various filters to narrow and rank the search results. In addition, future work should consider exploring other measures of comprehension, especially for materials that include images, videos, and other nontext elements. We believe that these measures will strengthen the findings and provide a more comprehensive picture of how people are understanding information about PrEP.

Conclusions

The overall reading level of PrEP information found on the web was above that recommended for most potential users; if unaddressed, other challenges to supporting PrEP use by those most likely to benefit might be made more difficult because of a gap in comprehension of web-based information. The readability of web-based PrEP information needs to be improved to comply with health communication recommendations, reduce the barrier of a health literacy gap, facilitate informed decisions by those with a need for PrEP, and counter the HIV epidemic.

Abstract

Background: Gay, bisexual, and other men who have sex with men (MSM) with a higher perceived risk of HIV are more aware of and willing to use pre-exposure prophylaxis (PrEP). PrEP is an effective HIV prevention strategy, but there is a lack of data on how PrEP use might moderate the relationship between sexual risk behavior and perceived risk of HIV. Moreover, most studies measure perceived risk of HIV via a single question.

Objective: We estimated the moderating effect of PrEP use on the association between sexual risk behavior and perceived risk of HIV, measured with the 8-item Perceived Risk of HIV Scale (PRHS), among Brazilian MSM.

Methods: A cross-sectional, web-based survey was completed by Brazilian Hornet app users aged ≥18 years between February and March 2020. We included data from cisgender men who reported sex with men in the previous 6 months. We evaluated the moderating effect of current PrEP use on the association between sexual risk behavior, measured via the HIV Incidence Risk Index for MSM (HIRI-MSM), and perceived risk of HIV, measured by the PRHS. Higher HIRI-MSM (range 0-45) and PRHS (range 10-40) scores indicate greater sexual behavioral risk and perceived risk of HIV, respectively. Both were standardized to *z* scores for use in multivariable linear regression models.

Results: Among 4344 cisgender MSM, 448 (10.3%) were currently taking PrEP. Current PrEP users had a higher mean HIRI-MSM score (mean 21.0, SD 9.4 vs mean 13.2, SD 8.1; $P<.001$) and a lower mean PRHS score (mean 24.6, SD 5.1 vs mean 25.9, SD 4.9; $P<.001$) compared to those not currently taking PrEP. In the multivariable model, greater HIRI-MSM scores significantly predicted increased PRHS scores ($\beta=.26$, 95% CI 0.22-0.29; $P<.001$). PrEP use moderated the association between HIRI-MSM and PRHS score (interaction term $\beta=–.30$, 95% CI –0.39 to –0.21; $P<.001$), such that higher HIRI-MSM score did not predict higher PRHS score among current PrEP users.

Conclusions: Our results suggest current PrEP users have confidence in PrEP's effectiveness as an HIV prevention strategy. PrEP's effectiveness, positive psychological impact, and the frequent HIV testing and interaction with health services required of PrEP users may jointly influence the relationship between sexual risk behavior and perceived risk of HIV among PrEP users.

Introduction

Tenofovir-based oral pre-exposure prophylaxis (PrEP) is highly effective in preventing HIV infection in gay, bisexual, and other men who have sex with men (MSM) [1,2]. Higher perceived risk of HIV has been shown to be associated with awareness and acceptability of [3,4], interest in [5], and willingness to use PrEP [6-8] and is influential in decisions to initiate [9-13], continue or discontinue [14-17], and adhere to PrEP [18]. Taking PrEP has in turn also been shown to be associated with lower perceived risk and perceived severity of HIV [19,20] and lower sexual anxiety [21-23].

While several studies have explored the impact of PrEP use on sexual risk behaviors, such as condomless anal intercourse (CAI) [17,22,24,25], few have considered how PrEP use may moderate the relationship between sexual risk behavior and perceived risk of HIV. Potential PrEP users in the PrEP Brasil study with a higher perceived risk of HIV were more likely to say that they would discontinue condom use if they took PrEP [26]. Another study found that a higher perceived risk of HIV among PrEP users correlated with lower condom use but higher PrEP adherence [18]. A study from Amsterdam found PrEP use was associated with a lower perceived risk of HIV while sexual risk behaviors, such as CAI, were associated with a higher perceived risk, but the influence of PrEP use on the relationship between sexual risk behavior and perceived risk of HIV was not considered [19].

Most research on the perceived risk of HIV and PrEP use has measured perceived risk using a single question [5,6,18-20,27-30]. However, single question measures may be inadequate, given that perceived risk of HIV is a complex, multidimensional concept [20,27,29,31]. To address this, the 8-item Perceived Risk of HIV Scale (PRHS) was developed and subsequently validated for use in European and Brazilian Portuguese [32-34]. The PRHS covers multiple dimensions of the perceived risk of HIV, including cognitive likelihood assessment (ie, the chance of infection), intuitive assessment (ie, worry about infection), and salience of risk (ie, having thought about infection) [32].

Among Latin American countries, Brazil is a middle-income country of 203 million people and was the first country in the region to offer free national access to PrEP to eligible populations under its public health system [35,36]. As of June 2023, there were more than 64,000 PrEP users in the country, 82% of whom were MSM [13,37]. One recent study found that more than half of PrEP users in Brazil thought they had no risk of acquiring HIV, but, as with most other studies, a single question was used to measure perceived risk of HIV and the association between sexual behavior and perceived risk was not considered [38]. In this study, we used the PRHS to evaluate the moderating effect of current PrEP use on the association between sexual risk behavior and perceived risk of HIV among Brazilian MSM in the year 2020.

Methods

Study Design and Population

We administered a cross-sectional, web-based survey to a convenience sample of users of Hornet, a geosocial gay social network app, between February and March 2020. The survey was administered via Alchemer [39] and contained 118 questions written in Brazilian Portuguese. Requests for survey completion were sent twice and responses were collected over a 35-day period, rather than defining a sample size a priori. Additional study design details were described previously [40].

The overall study population included Hornet users ≥18 years old living in Brazil with completed surveys. We excluded those who incorrectly answered any of the 5 attention questions, which asked respondents to select a specific answer: “This question is merely a check. Please select option A from the responses below” [41]. People living with HIV were excluded. Additionally, we focused on cisgender men who reported having sex with other men in the previous 6 months, excluding those who self-identified with other genders (eg, cisgender woman, transgender man, transgender woman, or nonbinary).

Variables

Sociodemographics

Age, race, sexual orientation, education level, monthly income, Brazilian state of residence, and residence in the state’s capital city metropolitan area were collected. Responses for race included White, Black, Pardo (mixed race), Indigenous, Asian (Japanese, Chinese, Korean, among others), or prefer not to respond. Income was asked in reference to the 2020 monthly minimum wage (MW) in Brazil (BRL1039, ~US $190), which was grouped into low-income (no salary, 1-2× MW), middle-income (2-6× MW), and high-income (>6× MW).

Sexual Health and Behavior

We asked about the timing of the most recent HIV test, which was categorized as within the last 6 months, more than 6 months ago, or never tested. Knowledge about HIV was measured via the HIV/AIDS Knowledge Assessment (HIV-KA) tool, which is scored 0 to 12, with higher scores indicating greater HIV knowledge [40,42,43]. Respondents indicated whether they had a steady partner and, if so, their steady partner’s HIV status. We also asked about each of the following over the previous 6 months: number of male sex partners, any male sex partners known to be living with HIV, receptive CAI, sexually transmitted infection (STI) diagnoses (syphilis, urethral or rectal gonorrhea, urethral or rectal chlamydia), transactional sex (sex for money or other good), or chemsex (see Table 2 footnote).

Level of engagement in sexual risk behaviors was estimated via the HIV Incidence Risk Index for MSM (HIRI-MSM) score, calculated based on respondent age and the following behaviors with men in the previous 6 months: number of sex partners, number of sex partners living with HIV, receptive CAI with any HIV-status partner, insertive CAI with a partner living with HIV, and use of stimulants (cocaine; crack, pasta básica, or oxy; ecstasy; methamphetamines; gamma hydroxybutyrate or gamma butyrolactone; poppers; or other inhalants) [44,45]. HIRI-MSM is scored from 0 to 45, and a score of >10 has been considered an indication that the respondents may benefit from PrEP.

PrEP Use

We asked respondents if they had ever heard of PrEP (awareness), and those who responded affirmatively were asked about PrEP use via the question “Are you taking or have you taken PrEP?” Options included “No, I have never taken PrEP,” “Yes, I took PrEP but stopped,” or “Yes, I am currently taking PrEP.” Respondents who were not aware of PrEP were grouped with never PrEP users. For this analysis, never and past PrEP use were grouped together as “no current PrEP use.” To evaluate the robustness of the results from the regression models, a sensitivity analysis was performed in which we excluded past PrEP users from the regression models. Current PrEP users were asked about adherence based on the number of days they had taken PrEP over the previous week, categorized as every day, 4 to 6 days, or 3 or fewer days.

Outcome

Perceived risk of HIV was measured via the PRHS [32,34]. The PRHS consists of 8 Likert-scale questions covering different dimensions of perceived risk, as described in the introduction. Prior work showed the scale to be valid for use among MSM in Brazil [34]. Total scores range from 10 to 40, with higher scores indicating greater perceived risk of HIV.

Statistical Analyses

The outcome of this analysis was the PRHS score, and our primary aim was to assess the effect of the HIRI-MSM score and current PrEP use as explanatory variables as well as their potential interaction. All analyses were performed using R Software for Statistical Computing (version 4.0.3; R Core Team). Categorical variables were described using proportions and continuous variables using mean with SD and median with IQR. Cronbach α was used to assess the internal reliability of the PRHS and the HIV-KA tool [46]. We present and compare mean PRHS scores across various demographic, sexual health, and sexual risk behavior variables using the Student *t* test (2 variable categories) or ANOVA *F* test (3 or more categories). The comparison of PRHS scores across sexual risk behaviors was stratified according to current versus no current PrEP use.

We used multivariable linear regression models to estimate the association between HIRI-MSM score and PRHS score and the moderating effect of current PrEP use on that association. Due to the small sample size for individual variable categories, respondents with missing data and those who identified their race as Asian or Indigenous were excluded from the regression model. For inclusion in regression models, PRHS, HIRI-MSM, and HIV-KA scores were standardized to *z* scores by subtracting the mean overall score from each participant’s score and dividing the difference by the overall SD. Multivariable models were created by first including HIRI-MSM as the explanatory variable, followed by current PrEP use, and then an interaction term between the two. Finally, a full multivariable model included variables for which prior work had shown an association with perceived risk of HIV, including race, education, Brazilian state, sexual orientation, HIV knowledge, steady partner, transactional sex, and timing of last HIV test [4,19,22,27,30,34,47-52]. Age was not included as a covariate in the final model since it is accounted for in the HIRI-MSM score. We verified the fitted model’s assumptions using standard diagnostic plots and observed no violations. To aid in the visualization of the moderating effect of PrEP, we present a graphical representation of the interaction between the HIRI-MSM score and PrEP use created using the “effects” package in R [53].

Ethics Approval

This study received approval from the human subjects ethics committee at Instituto Nacional de Infectologia Evandro Chagas of Fundação Oswaldo Cruz (#CAAE 01777918.0.0000.5262) and was exempt from review by the University of California, Los Angeles institutional review board. All participants provided electronic informed consent before survey initiation.

Results

A total of 4344 cisgender MSM who reported sex with other men in the previous 6 months were included (Figure 1). The overall sample had a mean age of 34.4 (SD 10.2) years (Table 1). Most reported White race (n=2624, 60.4%), identified as gay or homosexual (n=3643, 83.9%), and had a university or higher-level education (n=2992, 68.9%). Most respondents lived in the Southeast region of Brazil, with the Brazilian states of São Paulo (n=2284, 52.6%) and Rio de Janeiro (n=919, 21.2%) being the most common. More than two-thirds lived in their state’s capital metropolitan area (n=2963, 68.2%). The majority (n=2321, 53.4%) of respondents had tested for HIV within the previous 6 months, and knowledge about HIV prevention was high (median HIV-KA score 11, IQR 10-12; α=.61). Nearly all (n=3996, 92%) were aware of PrEP, and 448 (10.3%) were currently taking PrEP.

The PRHS had high internal reliability (α=.75). Mean overall PRHS score was 25.8 (SD 4.9). The mean PRHS score was higher among gay-identifying MSM compared to other sexual orientations (26 vs 24.9; *P*<.001) and among university-educated respondents compared to those with secondary- or lower-level education (26 vs 25.4; *P*<.001). There was no significant difference in PRHS score across age, race, income, or Brazilian state. PRHS scores were higher among those who were aware of PrEP, as compared to those not aware (25.9 vs 24.3; *P*<.001), but were lower among MSM currently taking, compared to not currently taking PrEP (24.6 vs 25.9; *P*<.001).

Current PrEP users had significantly higher mean HIRI-MSM scores compared to MSM not currently taking PrEP (21.0 vs 13.2; *P*<.001) (Table 2). Among MSM not currently taking PrEP, higher PRHS scores significantly correlated with reporting a greater number of sex partners (*P*<.001), a steady partner living with HIV or with unknown HIV status (*P*<.001), any sex partner living with HIV (*P*<.001), receptive CAI (*P*<.001), STI diagnoses (*P*<.001), chemsex (*P*<.001), and transactional sex (*P*<.001). Conversely, among MSM currently taking PrEP, the only sexual risk behavior significantly associated with higher PRHS score was having a steady partner living with HIV or with unknown HIV status (*P*=.03). Among MSM currently taking PrEP, having taken PrEP every day in the previous week, as compared to 3 or fewer days, was associated with a lower mean PRHS score (24.4 vs 27.2; *P*=.05).

Higher HIRI-MSM scores significantly predicted higher PRHS scores in bivariate linear regression (model 1: β=.19, 95% CI 0.16-0.22; *P*<.001), meaning a 0.19 higher standardized PRHS score per 1 SD increase in standardized HIRI-MSM score (Table 3). The magnitude of the β coefficient for the HIRI-MSM score increased when PrEP use was included in the model (model 2: β=.23, 95% CI 0.20-0.26; *P*<.001), and when the HIRI:PrEP interaction term was added as an explanatory variable (model 3: β=.27, 95% CI 0.24-0.30; *P*<.001). In the fully adjusted model, standardized HIRI-MSM score had a positive association (β=.26, 95% CI 0.22-0.29; *P*<.001) and current PrEP use had a significant negative association (β=–.36, 95% CI –0.48 to –0.23; *P*<.001) with standardized PRHS scores. The estimated β coefficient for the HIRI-MSM:PrEP use interaction term indicated a significant moderating effect on the association between HIRI-MSM and PRHS score by current PrEP use (β=–0.30, 95% CI –0.39 to –0.21; *P*<.001). Results were unchanged when past PrEP users were excluded from regression models (Table S1 in Multimedia Appendix 1). The graphical representation of HIRI-MSM:PrEP use interaction shows how among those not using PrEP, higher PRHS scores were associated with higher HIRI-MSM scores. In contrast, among those taking PrEP, PRHS scores were unchanged by higher HIRI-MSM scores (Figure 2).

Among covariates in the full adjusted regression model (Table 3), having a steady partner who was HIV-negative compared to no steady partner was associated with a lower PRHS score (β=–.24, 95% CI –0.31 to –0.18; *P*<.001). Conversely, having a university or higher-level education compared to secondary- or lower-level (β=.12, 95% CI 0.06 to 0.19; *P*<.001), increasing HIV-KA score (β=.12, 95% CI 0.09 to 0.15; *P*<.001), identifying as gay compared to other sexual orientations (β=.11, 95% CI 0.03 to 0.19; *P*=.007), having a partner living with HIV or with unknown HIV status (β=.16, 95% CI 0.05 to 0.28; *P*=.004), and testing for HIV more than 6 months ago (β=.08, 95% CI 0.01 to 0.15; *P*=.02) were all associated with higher PRHS scores.

[a] PrEP: pre-exposure prophylaxis.

[b] PRHS: Perceived Risk of HIV Scale.

[c] HIRI-MSM: HIV Incidence Risk Index for Men Who Have Sex With Men. The score is calculated based on respondent age and the following behaviors in the previous 6 months: number of male partners, number of male partners living with HIV, receptive condomless anal sex with any HIV-status partner, insertive condomless anal sex with a partner living with HIV, use of stimulants (cocaine; crack, basic paste, or oxy; ecstasy; methamphetamines [crystal or speed]; gamma hydroxybutyrate or gamma butyrolactone; poppers; or other inhalants). A score of >10 suggests the respondent may benefit from

pre-exposure prophylaxis.

[d] N/A: not applicable.

[e] Asked in reference to the previous 6 months.

[f] CAI: condomless anal intercourse.

[g] STI: sexually transmitted infection. The survey specified syphilis, urethral or rectal gonorrhea, and urethral or rectal chlamydia.

[h] Use of any of the following substances before or during sex: cocaine; crack, basic paste, or oxy; marijuana, hashish, or skank; ecstasy; methamphetamines (crystal or speed); gamma hydroxybutyrate or gamma butyrolactone; poppers; other inhalants; mephedrone; hallucinogens (LSD, mushroom tea, others); or others.

[i] Sex for money or some other good (eg, gifts, housing).

[j] Answered only by those currently taking PrEP (n=448).

Table 3. Linear regression models demonstrating the moderating effect of current PrEP use on the association between standardized PRHS and HIRI-MSM scores (n=4092).[a]

[a] Given small sample sizes, Asian (n=70), Indigenous (n=30), and respondents with missing data (n=152) were excluded.

[b] HIRI-MSM: HIV Incidence Risk Index-men who have sex with men.

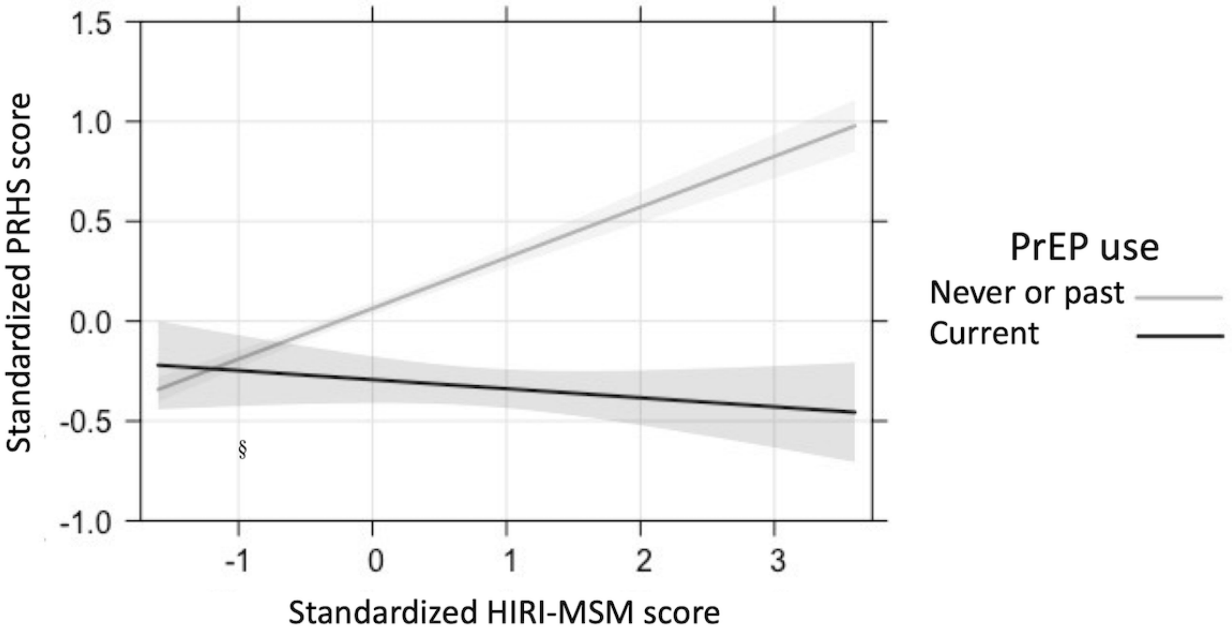
[c] PrEP: pre-exposure prophylaxis.

[d] N/A: not applicable.

[e] Reference categories are as follows: race: White; education: secondary or lower; Brazilian state: São Paulo; sexual orientation: other; steady partner: no steady partner; transactional sex: no; last HIV test: 6 months or less.

[f] HIV-KA: HIV/AIDS Knowledge Assessment.

Figure 2. Graphical representation of the joint effect of sexual risk behavior (measured via HIRI-MSM) and current PrEP use on perceived risk of HIV (measured via PRHS). The final model was adjusted for race, education, Brazilian state, sexual orientation, HIV knowledge, steady partner, transactional sex, and timing of last HIV test. HIRI-MSM: HIV Incidence Risk Index for men who have sex with men; PrEP: pre-exposure prophylaxis; PRHS: Perceived Risk of HIV Scale.



Discussion

Principal Findings

We found that current PrEP use among MSM in Brazil had a significant moderating effect on the association between sexual risk behavior and perceived risk of HIV. While there was an overall positive association between increasing HIRI-MSM and PRHS scores, the negative moderating effect of PrEP use resulted in no significant association between HIRI-MSM and PRHS scores among current PrEP users. Perceived risk of HIV was significantly positively associated with all sexual risk behavior variables among MSM not currently taking PrEP, but not among MSM currently taking PrEP.

One explanation for our findings is that Brazilian MSM who were taking PrEP were appropriately confident and optimistic about its effectiveness as an HIV prevention strategy. This understanding has been referred to as prevention optimism, which Holt and Murphy [54] define as “the belief that it is easier to avoid HIV infection or transmission because of PrEP and that it is more acceptable and safer to engage in condomless sex because the risk of HIV is reduced.” Prevention optimism could be a key mediator between sexual risk behavior and perceived risk of HIV and may be a useful adjunct to interpreting cross-sectional data [31,54]. While we did not specifically assess prevention optimism, future research could consider assessing agreement with statements such as “It is safe for me to have sex without condoms if I am using PrEP” [54]. There is a concern that the lower perceived risk of HIV among PrEP users may indirectly increase the risk of bacterial STIs via increased sexual risk behaviors, such as number of sexual partners and CAI [55], though data on the temporal relationship between PrEP use and changes in sexual behavior and STI acquisition are mixed [22,56,57]. Nevertheless, the lack of association between sexual risk behaviors and perceived risk of HIV among PrEP users in our study highlights the importance of including the prevention of bacterial STIs as a part of PrEP implementation policy. Other future considerations include the adoption of prophylaxis options for bacterial STIs to be taken by PrEP users [58].

Another important factor influencing the relationship between sexual risk behavior and perceived risk of HIV is the positive psychological impact of PrEP, which has been shown to be associated with reduced anxiety and fear related to sexual intercourse, and relatedly, increased sexual pleasure and intimacy [21-23,59-61]. PrEP use allows some MSM to engage in sexual behaviors that were previously the cause of anxiety and may facilitate connectedness within the MSM community [21,23]. Moreover, the ability of MSM taking PrEP to forgo condoms without worry about acquiring HIV can have a significant positive impact on sexual pleasure and satisfaction. In our study, we used a validated scale to capture PrEP’s impact on the multiple dimensions of the perceived risk of HIV, but future studies could more specifically consider the positive mental health impact of PrEP use among Brazilian MSM.

The frequent interaction with the health care system required of those taking PrEP may also influence an individual’s perceived risk of HIV and offer an opportunity for counseling interventions focused on reducing risk of bacterial STIs among PrEP users [4,22,56]. In Brazil, MSM receiving PrEP from the public health system must have appointments and HIV testing with their sexual health care provider every 3-6 months [62]. Regular HIV testing may contribute to lower perceived risk, since we found that those who had last tested for HIV within the previous 6 months had lower perceived risk of HIV. Additionally, the counseling provided at these visits could influence perceived risk by way of an improved understanding of how one's sexual behaviors relate to HIV risk and how PrEP may mitigate that risk [31]. Jaspal et al [4] proposed that perceived risk of HIV may mediate the pathway between HIV knowledge and sexual behavior. We previously found that PrEP use was associated with greater HIV knowledge among Brazilian MSM [40], and in this study we found greater HIV knowledge was associated with greater perceived risk of HIV among our overall sample. However, we did not explore the association among current PrEP users specifically, and future studies could compare the association between HIV knowledge and perceived risk of HIV stratified by PrEP use.

Like previous work from Brazil [47], we found higher education and reporting one's sexual orientation as gay to be associated with a higher perceived risk of HIV, whereas having a steady HIV-negative partner, compared to no steady partner, was associated with a lower perceived risk of HIV. Having tested for HIV more than 6 months ago, compared to within 6 months, was associated with a higher perceived risk of HIV among our sample, but findings from other studies have been mixed. MSM in the United States who had tested for HIV more than 1 year ago, compared to within the past year, were found to have lower perceived risk of HIV [27]. Another multicountry study found that as the years since the last HIV test increased, the perceived risk of HIV decreased among MSM in the United Kingdom but increased among MSM in Thailand [51].

Our use of the PRHS is unique among similar studies. Much of the prior research on perceived risk of HIV and PrEP use has measured perceived risk using agreement with a single Likert scale statement [6,18-20,27] or a single question with categorical responses of low, medium, and high risk [5,28-30]. The PRHS, in contrast, offers a more robust measure by assessing multiple dimensions of the perceived risk of HIV [32].

It is important to acknowledge that PrEP users are not a monolith, and the distribution of PRHS scores among PrEP users in our study demonstrated a range from low to high perceived risk of HIV. While we have demonstrated that PrEP use, on average, has a moderating effect on the relationship between sexual risk behavior and perceived risk of HIV, we did not study how this association may vary based on the type of PrEP user, and we did not have longitudinal data to assess how risk perception may change over time. Previous research has shown that PrEP users may fall into distinct groups depending on their perceived risk, sexual risk behaviors, and use of other prevention methods. A longitudinal study from France and Canada found that participants enrolled in the PrEP trial fell into distinct risk perception trajectories throughout the study follow-up, which they described as low-, medium-, and high perceived risk [18]. Similarly, a discrete choice experiment conducted among MSM in Singapore found that respondents fell into 3 different groups based on PrEP and condom preferences, and their perceived risk of HIV and STIs [63]. MSM PrEP-users from Australia fell into 4 distinct groupings based on a latent class analysis of risk behaviors and perceived risk of STIs, with highly variable views toward STI risk among the 4 groups [64]. Understanding the potential heterogeneity of PrEP users is critical in the implementation of future PrEP initiatives in Latin America and when considering interventions to reduce the risk of bacterial STIs among PrEP users.

Our study has several limitations. The cross-sectional nature of these data limited our ability to assert temporality between exposures of interest and perceived risk of HIV. These data were self-reported and may have been subject to recall or social desirability bias. We focused on cisgender MSM because of the small sample size of respondents reporting other gender identities; additional research is needed to characterize how PrEP use relates to sexual behavior and perceived risk of HIV among transgender, nonbinary, and gender-diverse individuals in Brazil. The majority of MSM in our sample were from either São Paulo or Rio de Janeiro, which may limit the generalizability of our findings, since previous research showed that perceived risk of HIV risk varies by region of Brazil [52]. Our findings are also specific to MSM who use Hornet and may not be generalizable to those who use other social networking app or those who do not have access. Additionally, the 10.3% of our sample who were taking PrEP at the time of this study may represent early adopters of PrEP and may not necessarily be representative of the population of MSM who will use PrEP as availability expands. The HIRI-MSM tool is a proxy measure of behavior risk of HIV, and other measures of sexual behavior may have different associations with perceived risk. Finally, the HIRI-MSM tool was developed for use in the United States and has not been specifically validated for use among Brazilian MSM, but we chose it because we preferred a continuous rather than dichotomous explanatory variable and because it has widespread familiarity among the HIV prevention research community and previous use among Brazilian MSM [52].

Conclusions

PrEP is highly effective at preventing HIV acquisition, and its use among MSM is associated with lower perceived risk of HIV compared to those not taking PrEP. We found that while higher HIRI-MSM scores were predictive of higher PRHS scores among our overall sample, the association was moderated by PrEP use, resulting in no significant association between sexual risk behavior and perceived risk of HIV among current PrEP users in Brazil. PrEP's objective efficacy, positive psychological impact, and the frequent HIV testing and interaction with the health care system required of PrEP users may jointly influence the relationship between sexual risk behavior and perceived risk of HIV, though additional research is needed to measure how each of these factors influences the moderating effect of PrEP. Future studies should explore the concept of prevention optimism and consider the temporal associations between PrEP use, sexual risk behaviors, and perceived HIV risk. Finally, the expansion of PrEP access in the Latin American region should consider how the lower perceived risk of HIV among PrEP users may necessitate targeted counseling on the risk of bacterial STIs as well as adjunct STI prevention modalities.

Acknowledgments

The abstract for this study was presented as a web-based poster presentation at the 24th International AIDS Conference, July 29, 2022, to August 2, 2022. This project was funded by the University of California Los Angeles' South American Program in HIV Prevention Research (SAPHIR) National Institute of Mental Health (NIMH) grant R25MH087222. This work was also supported by the UCLA Center for HIV Identification, Prevention, and Treatment Services (CHIPTS) NIMH grant P30MH58107. Abstract

Background: Emerging HIV drug resistance caused by increased usage of antiretroviral drugs (ARV) could jeopardize the success of standardized HIV management protocols in resource-limited settings.

Objective: We aimed to characterize pretreatment HIV drug resistance (PDR) among HIV-positive individuals and risk factors in China in 2022.

Methods: This cross-sectional study was conducted using 2-stage systematic sampling according to the World Health Organization’s surveillance guidelines in 8 provincial-level administrative divisions in 2022. Demographic information and plasma samples were obtained from study participants. PDR was analyzed using the Stanford HIV drug resistance database, and the Tamura-Nei 93 model in HIV-TRACE was used to calculate pairwise matches with a genetic distance of 0.01 substitutions per site. Logistic regression was used to identify and estimate factors associated with PDR.

Results: PDR testing was conducted on 2568 participants in 2022. Of the participants, 34.8% (n=893) were aged 30-49 years, 81.4% (n=2091) were male, and 3.2% (n=81) had prior ARV exposure. The prevalence of PDR to protease and reverse transcriptase regions, nonnucleoside reverse transcriptase inhibitors, nucleoside reverse transcriptase inhibitors, and protease inhibitors were 7.4% (n=190), 6.3% (n=163), 1.2% (n=32), and 0.2% (n=5), respectively. Yunnan, Jilin, and Zhejiang had much higher PDR incidence than did Sichuan. The prevalence of nonnucleoside reverse transcriptase inhibitor–related drug resistance was 6.1% (n=157) for efavirenz and 6.3% (n=163) for nevirapine. Multivariable logistic regression models indicated that participants who had prior ARV exposure (odds ratio [OR] 7.45, 95% CI 4.50-12.34) and the CRF55_01B HIV subtype (OR 2.61, 95% CI 1.41-4.83) were significantly associated with PDR. Among 618 (24.2%) sequences (nodes) associated with 253 molecular transmission clusters (size range 2-13), drug resistance mutation sites included K103, E138, V179, P225, V106, V108, L210, T215, P225, K238, and A98.

Conclusions: The overall prevalence of PDR in China in 2022 was modest. Targeted genotypic PDR testing and medication compliance interventions must be urgently expanded to address PDR among newly diagnosed people living with HIV in China.

Introduction

With the implementation of the “Treat all” program in 2016 in China, all people living with HIV are eligible to be treated, with their consent, regardless of their CD4 cell count and viral load level. Early treatment has been shown to effectively prolong the life span of people living with HIV and prevent secondary transmission. However, treatment of all individuals diagnosed with HIV has the potential to increase the prevalence of HIV drug resistance (DR) [1-4]. Pretreatment HIV drug resistance (PDR) refers to resistance that is detected among antiretroviral drug (ARV)–naive people initiating antiretroviral therapy (ART) or people with prior ARV drug exposure [5]. PDR may compromise the effectiveness of ART, increase mortality, and lead to secondary transmission of HIV [6]. Thus, assessing PDR levels is important for informing national policies on ARV and for improving ART programs and service delivery.

In China, individual ART plans are determined primarily by national standards for first- and second-line regimens, and potential DR is not a major consideration among individuals preparing to initiate ART. Due partly to resource limitations, individual HIV genotype resistance testing is not routinely conducted prior to the initiation of ART in China. This approach to developing individual ART regimens may be associated with DR [7]. A national meta-analysis indicated that PDR rapidly rose from 4.05% in 2011 to 5% in 2017. Specifically, resistance to nonnucleoside reverse transcriptase inhibitors (NNRTIs) increased from 2.15% to 3.81% from 2012 to 2017 [8]. However, it is important to note that PDR testing and prevalence varies widely by geographic region. Other surveys conducted on PDR in certain provinces of China showed that the prevalence of PDR was 10.5% in Chongqing, 9.1% in Shenyang, 4.1% in Beijing, 6% in Shenzhen, and 10.8% in Pu’er County of Yunnan [1,9-12]. The rates of PDR among HIV-positive individuals in China are comparatively lower than those in other countries, such as Cameroon (10.4%), Namibia (12.7%), Israel (12.1%), Mozambique (14.4%), Mexico (14.8%), the United States (22.5%), and Japan (12.5%) [13-19]. Yet China still lacks PDR surveillance methods that meet World Health Organization (WHO) standards. Assessing PDR prevalence with WHO standardized protocols will facilitate more accurate estimates of PDR prevalence in China, which will in turn better inform evidence-based ART policies in China.

Molecular transmission network analysis can be used to identify the maximum number of clusters and relatively active clusters based on genetic distance thresholds. Such methods have been used to evaluate the efficacy of ART on preventing secondary HIV transmission [20]. Moreover, our understanding of DR has been greatly enhanced by studies integrating analysis of transmission characteristics, DR strains, and molecular transmission networks [10,21].

The WHO has identified DR strategic surveillance of PDR as a very high priority in countries using efavirenz (EFV)/nevirapine (NVP) for first-line ART and recommends implementation or updates every 3 years [22]. Based on WHO PDR surveillance guidelines, the aim of this novel multicenter observational study is to investigate the prevalence of PDR and drug resistance mutations (DRMs) to partial pol regions, including protease (PR) and reverse transcriptase regions (RT), in diverse provinces in China.

Methods

Study Design and Study Population

We selected 8 provincial-level administrative divisions (PLADs) in China as the study area to conduct a large multicenter observational cross-sectional study. Two-stage systematic sampling in each PLAD was conducted according to the WHO PDR surveillance guidelines [23]. Provinces were stratified into the following 3 categories based on their HIV incidence rates: high (>2.00 cases per 10,000 individuals; included Sichuan Province, Chongqing Municipality, and Yunnan Province), moderate (0.52-1.99 cases per 10,000 individuals; included Jiangsu Province and Zhejiang Province), and low (<0.52 cases per 10,000 individuals; included Jilin Province, Hebei Province, and Hubei Province).

Guided by WHO PDR surveillance guidelines, we calculated the minimum necessary sample size by assuming the prevalence of PDR was 10% and the CI range was ±5%. We sampled 11-20 clinics in each PLAD according to the number of HIV-positive individuals starting or restarting ART in the past 12 months. The minimum sample size in each PLAD was 158-179 samples. To ensure a minimum necessary sample size, we assumed that 40% of collected specimens would be lost to factors such as laboratory failure and a design effect. Expected and actual sample sizes for each province are shown in Multimedia Appendix 1. Recruitment and specimen collection of HIV-positive individuals occurred in 2022 as individuals initiated ART.

The study eligibility criteria for individuals included the following: (1) tested HIV-positive, (2) ≥18 years old, (3) started or restarted first-line ART between January and June 2022 (includes women exposed to ARV drugs for preventing mother-to-child transmission of HIV, people who have received pre-exposure prophylaxis, and individuals reinitiating first-line ART), and (4) provided informed consent.

Data Collection

Each study participant was assigned a confidential and unique patient identifier used for linking basic epidemiological information and specimens. Basic sociodemographic data were collected, including age, sex, ethnicity, education level, marital status, occupation, route of infection, prior ARV exposure, time elapsed since HIV diagnosis, and PLADs. Clinical information included patients’ CD4 cell count before ART and HIV subtype.

Laboratory Tests

Viral RNA was extracted from 200 µL plasma samples using the QIAamp viral RNA mini kit (Qiagen, Hilton, Germany) according to the operational instructions. Extracted RNA was used for first-round polymerase chain reaction, and the products were used for second-round polymerase chain reaction amplification; both rounds were performed in 25 μL volume reactions to amplify the HIV pol gene region (HXB2: 2253-3553 nt). This covered the PR region (4-99 amino acids) and the partial RT region (1-251 amino acids) [24]. The amplified products were sequenced by Sanger sequencing.

Subtype and Drug Resistance Analysis

Sequencher (version 4.10.1, Gene Codes Corp) software was used to recombine and edit the original sequence fragments and nucleosides. BioEdit (version 7.0.9, Informer Technologies) software was used to realign the HXB2 reference sequence. The sequences were realigned, and some common reference sequences (including A to K) were used to identify the subtype by constructing neighbor joining phylogenetic trees in MEGA (version 7.0.26, MEGA Software). Subtypes with a bootstrap value higher than 70% were determined using HXB2 as the reference sequence. Sequences were realigned using the HIV database website [25]. Realigned sequences were uploaded to the Stanford Drug Resistance Database [26] to identify the degree of resistance of the 12 listed drugs that the WHO recommends for monitoring, namely, EFV, NVP, abacavir, zidovudine, lamivudine, tenofovir, emtricitabine, stavudine, didanosine, lopinavir/r, atazanavir/r, and darunavir/r. Corresponding DR mutant genes with levels of 1, 2, 3, 4, and 5 were classified as sensitive, potential resistance, low resistance, moderate resistance, and high resistance, respectively. Only mutations characterized as low, moderate, or high resistance were considered resistant. All possible sample mutual contamination, laboratory contamination, and other sequence quality controls were monitored by constructing neighbor joining phylogenetic trees and using the WHO HIVDR QC tool [27].

Construction of the Molecular Network

Realigned sequences were conducted to calculate pairwise genetic distances though the Tamura-Nei 93 model in the transmission cluster engine, HIV-TRACE [28]. Sequences no longer than 1000 bp or containing ≥5% ambiguities were excluded. A threshold genetic distance of 0.01 substitutions per site was used to observe transmission events that may occur within 5-6 years [29]. Each individual in the molecular network was represented by a node, and each node in the molecular transmission network represented HIV-positive individuals who were matched with epidemiological information. We then linked nodes to each other if their pairwise genetic distance was up to 0.01 substitutions per site. Web pages were used to visualize molecular networks, which were based on technical guides for HIV transmission network monitoring and intervention [30]. The results and subsequent molecular network diagram are accessible on the web [31]. Our previous studies used other software, such as HYPHY to calculate the pairwise gene distance and Cytoscape for visualization [20,32,33]. Clusters were defined as containing 2 or more nodes with HIV-positive individuals in the same cluster having potential for transmission.

Statistical Analysis

All quantitative data analyses were performed using the Statistical Analysis System version 9.4 (SAS Institute). Two-sided *P* values <.05 were considered statistically significant. All variables were assessed using univariate binary logistic regression. Variables significantly associated (*P*<.05) with the outcome were entered into a stepwise regression model to remove collinear variables. The remaining variables were entered into a multivariate binary logistic regression model to identify correlates of PDR. The *P* value of the final multivariate logistic regression model was <.05.

Ethical Considerations

This study was approved by the ethics committee of the National Center for AIDS/STD Control and Prevention, China Centers for Disease Control and Prevention (approval number X140617334).

Results

Characteristics of the Study Participants

A total of 2869 HIV-positive individuals were initially recruited into the study. After removal of 16 HIV-positive individuals who were younger than 18 years and 9 individuals who had not started ART, the penultimate sample size was 2844. PDR test results were available for 90.3% (n=2568) of participants in RT/PR regions, thus yielding a final sample size of 2568. Of the 2568 study participants with valid PDR results, 34.8% (n=893) were aged 30-49 years, 81.4% (n=2091) were male, 86.8% (n=2229) were of Han ethnicity, 30.5% (n=783) had a junior high school education, 37% (n=950) were single, 36% (n=924) were farmers, and 57.6% (n=1480) and 37% (n=951) were infected through heterosexual and homosexual intercourse, respectively. In addition, 3.2% (n=81) of participants had prior ARV drug exposure, 84.5% (n=2170) were diagnosed in 2022, and 37.5% (n=962) had CD4 cell counts of 0-199 cells/mm^3 prior to ART initiation (Table 1).

PDR and Mutations

Among the 2568 included study participants, PDR was detected in 7.4% (n=190). Table 2 shows the prevalence of overall PDR in Hebei (13/175; 7.4%), Jilin (19/206; 9.2%), Jiangsu (24/335; 7.2%), Zhejiang (34/385; 8.8%), Hubei (20/362; 5.5%), Chongqing (20/378; 5.3%), Sichuan (17/350; 4.9%) and Yunnan (43/377; 11.4%) in 2022. The prevalence of PDR in Yunnan (*P*=.002), Jilin (*P*=.047), and Zhejiang (*P*=.04) was much higher than that in Sichuan. Additionally, the prevalence of PDR in Yunnan was significantly higher than those in Chongqing (*P*=.002) and Hubei (*P*=.004).

Of the 2568 cases studied, the prevalence of PDR to NNRTIs, nucleoside reverse transcriptase inhibitors (NRTIs), and protease inhibitors (PIs) were 6.3% (n=163), 1.2% (n=32), and 0.2% (n=5), respectively. NNRTI-related DR to EFV and NVP was 6.1% (n=157) and 6.3% (n=163), respectively. There were 14 NNRTI-related resistance mutations; the most common mutations were K103N/S (n=81, 3.2%), followed by V179D/E/IL (n=39, 1.5%), and E138A/G/K (n=31, 1.2%). Among NRTI-related DR, the most frequent PDR drug was abacavir (n=19, 0.7%), followed by stavudine (n=17, 0.7%), emtricitabine (n=15, 0.6%), lamivudine (n=15, 0.6%), didanosine (n=13, 0.5%), zidovudine (n=10, 0.4%), and tenofovir (n=8, 0.3%). We detected 10 NRTI-related resistance mutations, of which M184V/I (n=13, 0.5%) was the most common. Even in the PR region, 0.2% (n=5) PI-related PDR to atazanavir/r and lopinavir/r was detected, including the PI-related DRMs L90M/IM (n=3, 0.1%), N88T/D (n=1, 0.1%), and V82IM (n=1, 0.1%) (Table 3).

Factors Associated With PDR

Table 4 lists the factors associated with PDR in PR/RT regions. Compared with participants without prior ARV drug exposure, those who had prior ARV drug exposure had 7.45 times greater odds of PDR (odds ratio [OR] 7.45, 95% CI 4.50-12.34). Compared to participants with the CRF07_BC subtype, those with the CRF55_01B subtype had 2.61 times greater odds of PDR (OR 2.61, 95% CI 1.41-4.83).

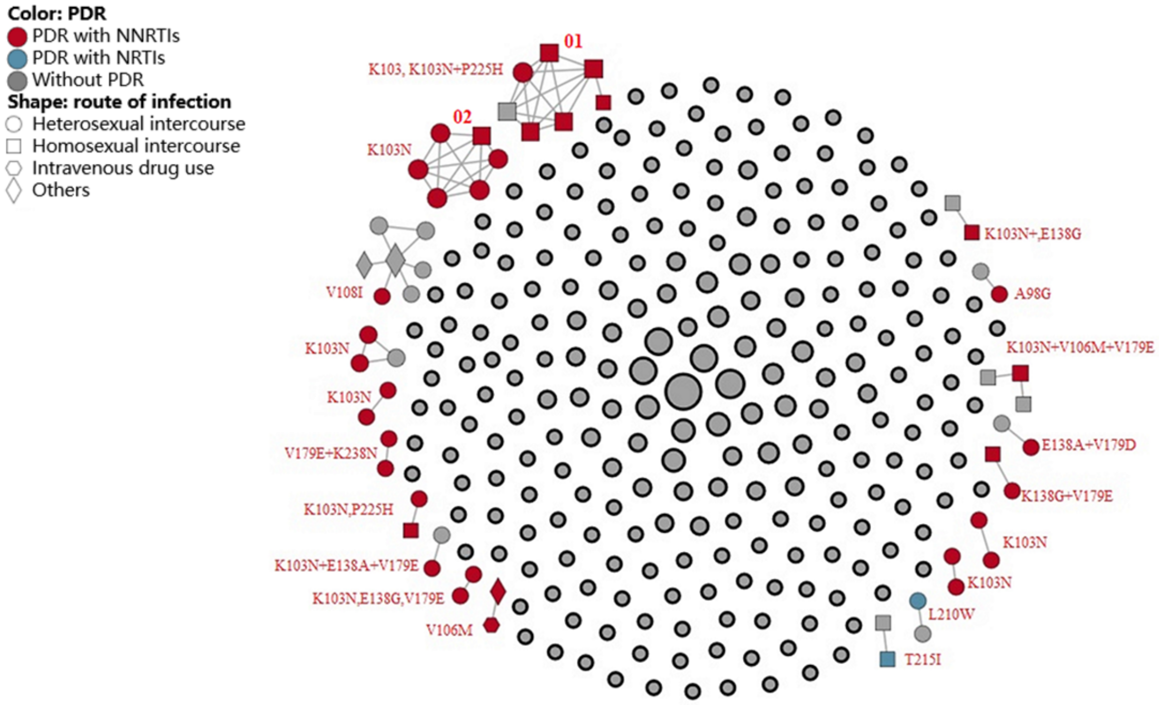
Molecular Transmission Network

Of the 2568 sequences in the PR/RT regions, 13 sequences were removed because the sequences in the PR/RT regions were shorter than 1000 bp or the number of mixed bases was >5%. Hence, a total of 2555 sequences in the PR/RT regions were used to construct a molecular transmission network. Under the optimal genetic distance threshold of 0.01 substitutions per site, 618 (24.2%) sequences (nodes) were linked to a total of 253 clusters (size range 2-13). We identified 38 sequences with PDR strains among 19 clusters. Most PDR strains linked to clusters had resistance to NNRTIs (36 of 38 sequences); DRM sites included K103, E138, V179, P225, V106, V108, L210, T215, P225, K238, and A98. Individual PDR status was not statistically significantly associated with belonging to a cluster. Cluster 01 with PDR consisted of 6 nodes in Jiangsu. Cluster 02 included HIV-positive individuals from 5 nodes in the same clinic sites in Zhejiang and 1 node in Hubei (Figure 1).

Figure 1. Molecular transmission network among HIV-positive individuals in 2022 in China.



Discussion

In 2022, a cross-sectional survey was conducted to examine the prevalence of PDR among HIV-positive individuals in 8 PLADs in China. The results showed that the overall prevalence of PDR was 7.4%. According to the WHO's qualitative classification of PDR prevalence levels, a prevalence below 5% is considered low, a prevalence between 5% and 15% is moderate, and a prevalence ≥15% is high [5]. Therefore, the overall prevalence of PDR in 2022 in China and those of 7 PLADs (all but Sichuan) were considered moderate. The prevalence of PDR in 13 PLADs and 31 PLADs in China was 6.8% and 4.4% in 2017 and 2018, respectively [34,35]. Monitoring and surveillance are needed to assess the extent to which resistant strains have spread, and new technologies and strategies should be applied to effectively curb the spread of PDR.

Our study revealed that the PDR rate of NNRTIs was 6.3%. However, the PDR NNRTI prevalence was 10.3% for Yunnan. We observed higher PDR rates in Zhejiang and Yunnan in 2022 compared to surveys conducted in 2018 (3.7% in Zhejiang and 3.8% in Yunnan) and this increase in PDR prevalence was driven mainly by NNRTI resistance. According to WHO ART guidelines developed in 2016, it is recommended to consider implementing supplementary first-line antiviral treatment plans when the prevalence of PDR is equal to or greater than 10% for NNRTIs in HIV-positive individuals who are starting first-line ART [36]. Further research is needed to identify the underlying reasons for the high NNRTI PDR rates in Yunnan. From 2014 to 2020, 21 of 30 countries that reported investigations to the WHO had an NVP or EFV PDR rate that exceeded 10% among HIV-positive individuals starting first-line ART [37]. In our study, we found that the prevalence of EFV and NVP DR was 6.1% and 6.3%, respectively. The main DRM sites identified were K103, E138, V179, and V106. These results are consistent with earlier surveys conducted in China in 2015 and 2018 [32,34]. Studies from Zimbabwe, Kenya, and Argentina have identified K103 as the most common DRM site for NNRTIs used as first-line antiviral drugs [38-40]. National HIV treatment strategies and regimens should be reconsidered given the high prevalence of NNRTI DR. In 2023, the *National Free HIV Antiviral Treatment Drug Treatment Manual* was released in China, and rilpivirine was added as the first-line treatment regimen [41]. The RPV resistance rate in our study was 5.3% (137/2568). The PDR after rilpivirine is applied to first-line treatment alternatives should be continuously monitored.

Our 2022 study indicated that PDR rates have increased in China over the past 7 years for NRTI DR (from 1.1% in 2015 and 0.8% in 2018 to 1.2% in 2022) and PI DR (from 0.02% in 2015 and 0.07% in 2018 to 0.2% in 2022) [34]. Nonetheless, PDR rates for NRTIs and PIs in China generally appear to be lower than the WHO's estimated regional PDR rates in Africa (NRTI PDR: 6.1%; PI PDR: 0.3%), the Americas (NRTI PDR: 6.4%; PI PDR: 0.8%), Southeast Asia (NRTI PDR: 3.1%; PI PDR: 0.4%), and the Western Pacific (NRTI PDR: 4%; PI PDR: 0%) [37].

Results of the multivariable analysis indicated that individuals who had prior ARV drug exposure had 7.45 times greater odds of PDR compared to those without prior ARV drug exposure. Such findings are consistent with research from Mexico, African countries, and Northeast China [42-44]. There was an increasing trend of the proportion of CRF55_01B samples, rising from 2.3% in 2015 to 3.9% in 2018 and 4.1% in 2022 in China [34]. Additionally, participants with the CRF55_01B subtype had 2.61 times greater odds of PDR (OR 2.61, 95% CI 1.41-4.83) compared to participants whose subtype was CRF07_BC. This may be due to association with V179 as a characteristic DR site of CRF55_01B, and V179 being frequently associated with E138G and causing low resistance to EFV and NVP [45].

Controlling the spread of CRF55_01B may be helpful for mitigating the proliferation of drug resistance. Furthermore, it is imperative to enhance the quality and effectiveness of intervention services for HIV-positive individuals.

In this study, we did not detect any statistically significant associations between having a PDR strain and belonging to clusters. Such results are similar with findings from Shijiazhuang city, Hebei Province and Liangshan region, Sichuan Province [46,47]. One possible explanation for these findings is that the transmission potential of DR strains is weaker than that of nonresistant wild strains [47,48]. The predominant subtype among the sequences in the molecular transmission network was CRF07_BC (representing 46.6% of strains), which is consistent with findings from a 2018 national molecular transmission network survey in China [32]. Clustered transmission of K103N DRMs in our study was observed in the molecular transmission network and is similar to findings from molecular transmission network studies in coastal Kenya [49]. It is worth noting that 6 DR strains in cluster 01 were from HIV-positive individuals at identical sites in Jiangsu Province. Epidemiological data indicated that all 6 were adult men aged younger than 30 years, of whom 5 reported homosexual transmission and 1 reported heterosexual transmission. Cluster 02 contained 6 samples with DR strains from HIV-positive individuals in the same clinic sites in Zhejiang Province, of whom 5 reported heterosexual transmission and 1 reported homosexual transmission, suggesting a possible clustered transmission of DR strains in that area.

Our study has several limitations. Due to sampling limitations, clinic sites were established in different counties and districts, and only 20-80 patients were enrolled in each site during a certain period of time. This may have resulted in smaller observable clusters (containing 2-13 nodes) in the molecular network and a lower network access rate. In addition, when detecting drug-resistant strains using genotyping, Sanger sequencing may not be able to detect up to 20% of less prevalent PDR strains [24]. This may have resulted in an underestimation of the PDR rate in HIV-positive individuals.

The findings from our 2022 PDR survey in China indicate a need to review and reconsider the standard ART protocol in some PLADs. Additional resources and strategies are needed in regions within China experiencing a higher prevalence of PDR. Possible interventions include extending pilot genotypic PDR testing to rapidly adjust medication regimens for HIV-positive individuals identified with PDR and targeted measures to improve medication compliance and prevention.

Acknowledgments

This work was supported by the Ministry of Science and Technology of China (grants 2022YFC2305205 and 2022YFC2305201), National Natural Science Foundation of China (grant 82260670), China Capital's Funds for Health Improvement and Research (grant 2022-1G-3011), Beijing Municipal Science & Technology Commission (grant D161100000416002), Guangxi Bagui Honor Scholarship, and Chinese State Key Laboratory of Infectious Disease Prevention and Control. The authors thank the study participants for their support and the staff at the clinical sites and provincial Chinese Center for Disease Control and Prevention for their help in collecting blood samples and data.

Authors' Contributions

HC, YR, HX, LL, YF, and YS were responsible for the study design and planning. HC, CS, YZ, XX, and ML were responsible for the statistics and figures. HC, J Hao, DL, XL, PX, DW, CS, J Hu, and JZ conducted the experiments and collected the data. HC, YR, and SWP drafted the manuscript. YR and HX guided the whole study and revised the article. All authors read and approved the final version of the manuscript.

Abstract

Background: Risky sexual behavior (RSB), the most direct risk factor for sexually transmitted infections (STIs), is common among college students. Thus, identifying relevant risk factors and predicting RSB are important to intervene and prevent RSB among college students.

Objective: We aim to establish a predictive model for RSB among college students to facilitate timely intervention and the prevention of RSB to help limit STI contraction.

Methods: We included a total of 8794 heterosexual Chinese students who self-reported engaging in sexual intercourse from November 2019 to February 2020. We identified RSB among those students and attributed it to 4 dimensions: whether contraception was used, whether the contraceptive method was safe, whether students engaged in casual sex or sex with multiple partners, and integrated RSB (which combined the first 3 dimensions). Overall, 126 predictors were included in this study, including demographic characteristics, daily habits, physical and mental health, relationship status, sexual knowledge, sexual education, sexual attitude, and previous sexual experience. For each type of RSB, we compared 8 machine learning (ML) models: multiple logistic regression (MLR), naive Bayes (BYS), linear discriminant analysis (LDA), random forest (RF), gradient boosting machine (GBM), extreme gradient boosting (XGBoost), deep learning (DL), and the ensemble model. The optimal model for both RSB prediction and risk factor identification was selected based on a set of validation indicators. An MLR model was applied to investigate the association between RSB and identified risk factors through ML methods.

Results: In total, 5328 (60.59%) students were found to have previously engaged in RSB. Among them, 3682 (41.87%) did not use contraception every time they had sexual intercourse, 3602 (40.96%) had previously used an ineffective or unsafe contraceptive method, and 1157 (13.16%) had engaged in casual sex or sex with multiple partners. XGBoost achieved the optimal predictive performance on all 4 types of RSB, with the area under the receiver operator characteristic curve (AUROC) reaching 0.78, 0.72, 0.94, and 0.80 for contraceptive use, safe contraceptive method use, engagement in casual sex or with multiple partners, and integrated RSB, respectively. By ensuring the stability of various validation indicators, the 12 most predictive variables were then selected using XGBoost, including the participants' relationship status, sexual knowledge, sexual attitude, and previous sexual experience. Through MLR, RSB was found to be significantly associated with less sexual knowledge, more liberal sexual attitudes, single relationship status, and increased sexual experience.

Conclusions: RSB is prevalent among college students. The XGBoost model is an effective approach to predict RSB and identify corresponding risk factors. This study presented an opportunity to promote sexual and reproductive health through ML models, which can help targeted interventions aimed at different subgroups and the precise surveillance and prevention of RSB among college students through risk probability prediction.

Introduction

Risky sexual behavior (RSB) is defined as sexual activities that are more likely to lead to the risk of sexually transmitted infections (STIs) and unwanted pregnancies [1], including sex without contraceptive use and sex with an ineffective or unsafe contraceptive method. It is a serious issue among college students worldwide, especially in low- and middle-income countries [2,3]. Among 5 types of contraceptive methods under the classification criterion from the World Health Organization (WHO) [4], condoms and hormonal contraceptive methods are regarded as safe and highly effective for adolescents [5]. Studies have shown that consistent condom use is low among college students [6]. In previous research, it was estimated that approximately 40% of students did not use a condom during their last sexual encounter [7]. Casual sex and sex with multiple partners have also been regarded as RSBs [8-10]. Nearly half of the college students had casual sex experience [11,12], and approximately 50.7% of students were sexually active, with 42.3% of students having multiple sexual partners [13]. Thus, to help reduce the influence of RSB, it is important to intervene and prevent it among college students by identifying relevant risk factors and making RSB predictions.

A number of association studies have focused on the risk factors for RSB. A systematic review of 30 papers summarized 11 aspects of risk factors of RSB including sociodemographics, gender roles, substance use, and partner characteristics [14]. It was widely validated that being male [15,16], drinking alcohol [17], experiencing poverty, and experiencing peer pressure [18] are significant risk factors for RSB [19,20]. Mental health has also been linked to RSB, with higher depression resulting in more RSB and STIs [20,21]. In addition, numerous public health and sociological studies have found that romantic relationship status [22,23], sexual knowledge [1], and sexual attitude have a significant influence on RSB [24,25]. However, few studies have fully used these identified factors to make RSB predictions.

Previous predictive studies on RSB have mostly been based on conventional regression models, which have high limitations of assumption and less ideal effects on RSB prediction. To fill such gaps, machine learning (ML) offers a possible alternative for factor identification and outcome prediction. In the past few years, a large number of studies have emerged using ML to predict the occurrence of STIs, which have achieved ideal performance [24,25]. However, RSB, as the main transmission route for STIs, has gained little attention from ML for prediction.

The objective of this study was to develop an ML-based model to precisely predict RSB in college students. Through a cross-province survey in China, this study aimed to develop a series of ML models to predict different types of RSB among Chinese college students. By comparison, we adopted the optimal model to identify key risk factors to help recognize and predict college students' engagement in RSB, thus facilitating more precise intervention and prevention.

Methods

Participants and Research Procedures

We conducted a large-scale and internet-based survey, the National College Student Survey on Sexual and Reproductive Health in 2020 (NCSS-SRH 2020), sponsored by the China Family Planning Association (CFPA). Through multistage sampling from November 2019 to February 2020, a total of 55,757 Chinese college students from 241 universities completed the questionnaire survey. Voluntary participants were recruited using snowball sampling, and informed consent was obtained from each participant before completing the survey.

Among all participants, 1177 (2.11%) were excluded for either failing the attention check questions, ignoring the informed consent, or being outside the age range for college students (15-24 years old according to a standard definition of late adolescence and young adulthood by WHO) [26,27]. Samples with duplicated answers and variables with missing values over 5% were deleted. For the remaining variables, missing values were imputed with the use of multiple imputation. Due to the constraint of sexual orientation and past sexual experience, 8794 (15.78%) self-identified heterosexual students with sexual intercourse experience were finally included in the analyses.

RSB Outcomes

We classified RSB from 4 perspectives: (1) whether contraception was used, (2) whether the contraceptive method was effective and safe, (3) whether participants engaged in casual sex or sex with multiple partners, and (4) the integration of the former 3 perspectives.

Contraception use was evaluated through 2 dimensions. Regarding frequency, contraception use was measured by the question "Do you use contraception while having sex every time you have sexual intercourse?" Regarding practices, contraception use was measured by the question "Did you/your partner use contraception the last time you had sex?" For both questions, a "no" response was considered to indicate RSB. According to WHO guidance, 4 contraceptive types with over 10 specific methods were investigated as contraception use: hormonal contraceptive methods, intrauterine devices, emergency contraception, and condoms [4].

The effectiveness and safety of contraception was mainly determined by the method of contraception. If someone reported using "emergency contraception," "external ejaculation," or a "safe period" for contraception, they were considered a member of the RSB group. The effectiveness and safety of contraception were also evaluated through the frequency and practice dimensions, which were, respectively, measured by the question of whether such approaches were taken every time or the last time of sexual intercourse.

Casual or multiple sex was assessed with the following questions: "Have you ever had sex through 'booty calls', ‘one-night stands’, ‘buying sex’, or ‘sex with multiple partners’?” As before, a “yes” response was considered RSB.

Finally, integrated RSB dimension was the combination of contraception use, the safety of contraception, and casual sex or sex with multiple partners. As long as 1 of these 3 types of behaviors occurred, we considered the student to have met the criteria for integrated RSB.

Predictors

We included 126 potential predictors, including baseline characteristics (sex, age, ethnicity, religion, income, parental information, etc), daily habits (exercise, appearance and popularity, mobile phone addiction, alcohol and tobacco consumption, etc), physical and mental health status, relationship status, sexual knowledge, sexual education, sexual attitude, previous sexual experience, experience of sexual harassment and assault, etc. Among them, the age of the participant, the age of the participant’s partner, the income and expenditure of the participant, and the frequency of sports were treated as continuous variables. Other variables, including the degree of agreement, the frequency of participation, and the order of evaluation, were treated as either binary variables or ordered categorical variables.

Continuous variables were standardized, and categorical variables were split into multidimensional Boolean values before applying ML models. For each type of RSB, we used ML models to select and identify key variables to predict RSB among college students.

Statistical Analyses

For descriptive statistics of baseline characteristics, continuous data were presented as the mean (SD) or the median (IQR), and the Student *t*-test or the Kruskal-Wallis test was applied depending on the normality distribution. Categorical data were presented in the form of counts with percentages, and the chi-square test or the Fisher exact test was applied. $P<.05$ in a 2-tailed test was considered statistically significant in these tests. In addition, we developed multivariable mixed models with a logit link function to learn the specific linear relationship between RSB and the key variables screened by ML. The results were presented in the form of point estimates of coefficients and corresponding 95% CIs, and statistical significance was accepted when $P<.05$.

Model Development and Validation

We used 8 ML approaches: multiple logistic regression (MLR), naive Bayes (BYS), linear discriminant analysis (LDA), random forest (RF), gradient boosting machine (GBM), extreme gradient boosting (XGBoost), deep learning (DL), and the ensemble model. The ensemble model used the average values of all other models’ predictive values to perform classification. The data set was split into a training set and a test set randomly in a ratio of 8:2, with 7035 (80%) samples in the training set and 1759 (20%) samples in the test set. Our models were built on the training set and then applied to the test set for RSB prediction. Model discrimination was assessed through the receiver operator characteristic (ROC) curve, and model performance was assessed through accuracy, precision, recall, F_1-score, the area under the receiver operator characteristic curve (AUROC), and the root-mean-square error (RMSE) calculated on the test set, which were presented in the form of the mean (SD).

Through comparison, we chose the optimal model for RSB prediction and included the most predictable variables in the model. The appropriate number of predictable variables was determined by the turning points of the model performance indicators. If all indicators did not change significantly through statistical testing when a new variable was added, we considered the turning point to have been reached.

To obtain the optimal performance for each model, we adopted the minimum distance (MD) method to select cut-off points to discriminate predictive values into 0 or 1. The MD method regarded the point closest to (0,1) on the ROC curve as the optimal cut-off point. To ensure the reliability and minimize the sensitivity of the results, we used a 10-fold cross-validation method to select the tuning hyperparameters as well as cut-off points. In addition, we repeated this process 10 times to minimize the influence of accidental circumstances.

All models were generated using R version 4.0.3 (R Core Team and the R Foundation for Statistical Computing). We used the *glmnet* package for MLR, the *e1071* package for BYS, the *MASS* package for LDA, the *randomForest* package for the RF, the *gbm* package for GBM, the *xgboost* package for XGBoost, and the *h20* package for DL.

Ethical Considerations

Ethical approval was obtained from the Institutional Review Board of Tsinghua University (IRB no. 20190083). All participants provided informed consent online, which was set before answering the questionnaire and emphasized the autonomy of participating and the ability to withdraw at any time. The privacy of personal information was protected throughout the study via anonymous data collection, and confidentiality was maintained by asking participants to provide honest answers. Eligible participation in this survey was voluntary and was not compensated.

Results

Baseline Characteristics

The baseline characteristics of the participants are shown in Table 1. Our sample covered all provincial-level administrative regions in China and achieved a relatively good balance in the sample division of eastern, central, western, and northeastern regions (n=4758, 54.11%, n=1484, 16.88%, n=2140, 24.33%, and n=412, 4.69%, respectively), as well as the sex ratio (males: n=3918, 44.55%; females: n=4876, 55.45%). A total of 8794 students were included, among which 3682 (41.87%) did not use contraception every time they engaged in sexual intercourse, 3602 (40.96%) did not use safe or effective contraceptive methods every time they engaged in sexual intercourse, 1157 (13.16%) had casual sex or sex with multiple partners, and 5328 (60.59%) had experience with at least 1 of those 3 former behaviors before. In addition, 307 (3.49%) participants did not use contraception and 2140 (24.33%) used ineffective or unsafe contraceptive methods during their last sexual intercourse, the details of which are shown in Multimedia Appendix 1. The distribution of basic characteristics differed greatly in terms of RSB. Between the 2 groups with and without integrated RSB, the region of residence, sex, age, ethnicity, religious beliefs, urbanization of hometown, left-behind experience, migration experience, and self-assessment of family finances were significantly different (*P*<.05) among college students.

Table 1. Baseline characteristics of participants (N=8794) grouped by different types of RSB[a].

Characteristics	Overall	RSB type 1 (nonuse of contraception)[b]	RSB type 2 (ineffective or unsafe contraceptive method)[c]	RSB type 3 (casual sex or sex with multiple partners)[d]	RSB type 4 (integrated RSB)[e]

[a] RSB: risky sexual behavior.

[b] Nonuse of contraception indicated that someone did not use contraception while having sex every time.

[c] Ineffective or unsafe contraception indicated that someone often used unsafe contraceptive methods (eg, emergency contraception, external ejaculation, and safe period).

[d] Casual sex or sex with multiple partners indicated that someone had engaged in casual sex or sex with multiple partners before.

[e] Integrated RSB was the combination of the former 3 types of RSB.

[f] P_1, P value of RSB type 1; P_2, P value of RSB type 2; P_3, P value of RSB type 3; P_4, P value of RSB type 4.

[g] Self-assessed gender role conformity is a 1-7–ordered categorical-scale question. We classified the responses into 3 groups: low conformity (1-2), middle conformity (3-5), and high conformity (6-7).

[h] CNY 1=US $0.145749.

[i] Self-assessment of family finances is a 1-7–ordered categorical-scale question. We classified the responses into 3 groups: low income (1-2), middle income (3-5), and high income (6-7).

Model Performance and Validation

To precisely identify RSB among Chinese college students, we used various ML models to execute RSB prediction on the test data set to choose the optimal model. The model performance for the 4 types of RSB is presented in Table 2, and the model performance for the other 2 types of RSB based on the last sexual intercourse is presented in Multimedia Appendix 1. Through the comparison from multiple rounds of experiments, it was obvious that some ML models had better efficiency than the traditional multilinear logistic regression model. Compared to the performance of MLR (for which the average AUROCs were 0.76, 0.71, 0.91, and 0.79, respectively), XGBoost, GBM, and the RF presented better performance in terms of accuracy, the F_1-score, and the AUROC.

To better understand model discrimination, we plotted ROC curves of all models on 4 types of RSB in Figure 1. Similarly, ROC curves of the other 2 types of RSB based on the last time of sexual intercourse are presented in Multimedia Appendix 1. It could be inferred that the curves of XGBoost and GBM were above the other curves, which suggests that these 2 models outperformed the others. Their average results were similar (average AUROCs were 0.77, 0.72, 0.94, and 0.80, respectively, in GBM and 0.78, 0.72, 0.94, and 0.80, respectively, in XGBoost). The ensemble model also played an effective role in predicting different types of RSB (average AUROCs were 0.77, 0.72, 0.93, and 0.80, respectively).

Table 2. Model performance among different types of RSB[a].

RSB	Model	Accuracy, mean (SD)	Precision, mean (SD)	Recall, mean (SD)	F_1-score, mean (SD)	AUROC[b], mean (SD)	RMSE[c], mean (SD)

[a] RSB: risky sexual behavior.

[b] AUROC: area under the receiver operator characteristic curve.

[c] RMSE: root-mean-square error.

[d] Nonuse of contraception indicated that someone did not use contraception while having sex every time.

[e] MLR: multiple logistic regression.

[f] BYS: naive Bayes.

[g] LDA: linear discriminant analysis.

[h] RF: random forest.

[i] GBM: gradient boosting machine.

[j] XGBoost: extreme gradient boosting.

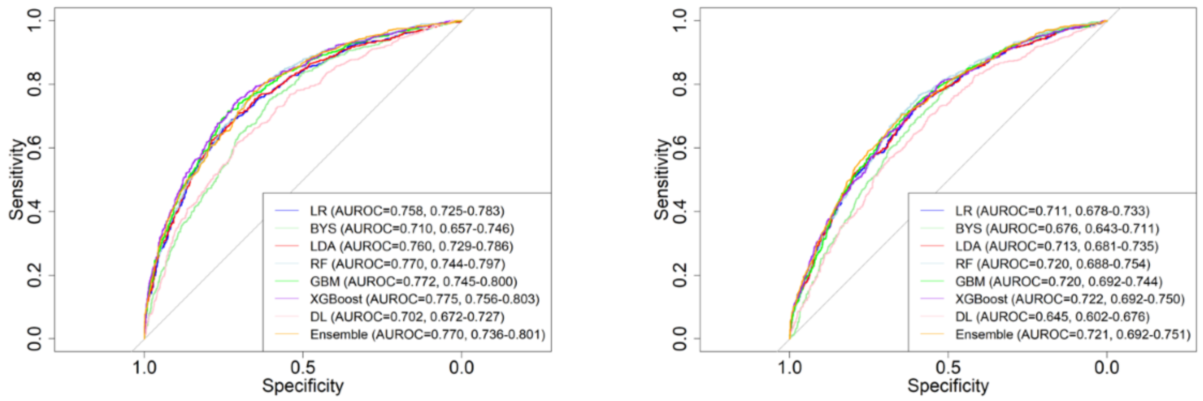
[k] DL: deep learning.

[l] Ineffective or unsafe contraception indicated that someone often used unsafe contraceptive methods (eg, emergency contraception, external ejaculation, and safe period).

[m] Casual sex or sex with multiple partners indicated that someone had engaged in casual sex or sex with multiple partners before.

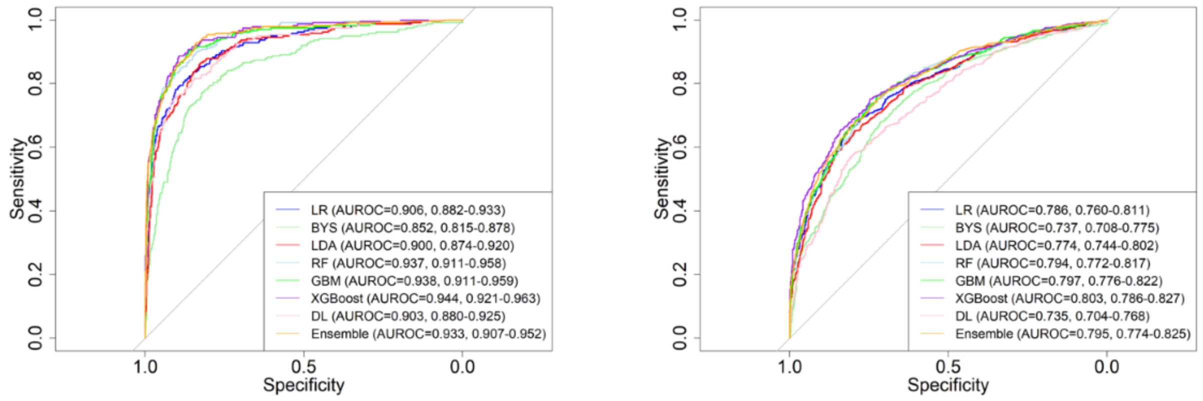
[n] Integrated RSB was the combination of the former 3 types of RSB.

Figure 1. AUROC curves among the different types of RSB. AUROC: area under the receiver operator characteristic curve; BYS: naive Bayes; DL: deep learning; GBM: gradient boosting machine; LDA: linear discriminant analysis; LR: logistic regression; RF: random forest; RSB: risky sexual behavior; XGBoost: extreme gradient boosting.



(a) Nonuse of contraception

(b) Ineffective or unsafe contraceptive method



(c) Casual sex or sex with multiple partners

(d) Integrated RSB

Variable Selection and Prediction for RSB

Through the comprehensive comparison of the evaluation indicators considering both efficiency and robustness, XGBoost was chosen to form the predicting model. To comprehensively predict RSB, we took integrated RSB as the outcome to select important variables, which were ranked in the order of importance according to the XGBoost model. Multimedia Appendix 1 shows the trend of 6 indicators as the number of variables increases, where points represent the average performance and lines represent the range. The turning points of the 6 indicators were 5th, 8th, 7th, 7th, 6th, and 12th, respectively. Thus, we finally chose 12 key variables for our prediction model, as presented in Figure 2. It could be inferred that RSB has multiple types of influencing factors, including relationship status, sexual knowledge, sexual attitudes, and previous sexual experience. The final prediction model we developed could estimate not only the probability of a student engaging in RSB but also the kind of RSB they were more likely to engage in.

To explore the specific association between the outcome variables and the predictive factors identified through XGBoost, we finally performed MLR, and the results of integrated RSB are presented in Table 3. It could be inferred that the lack of sexual knowledge and a liberal sexual attitude significantly increased the risk of RSB. In addition, regarding intimate relationship status, compared to the non-single group, the single group had a higher risk of RSB. Previous sexual experience also had a great influence on RSB. The greater the number of people participants had sexual intercourse with, the higher their risk of RSB. The more convenient the availability of contraceptives was, the less risk students would show RSB. The results of the other three types of RSB are shown in Multimedia Appendix 1.

Figure 2. The 12 most predictive variables selected by the XGBoost model. XGBoost: extreme gradient boosting.

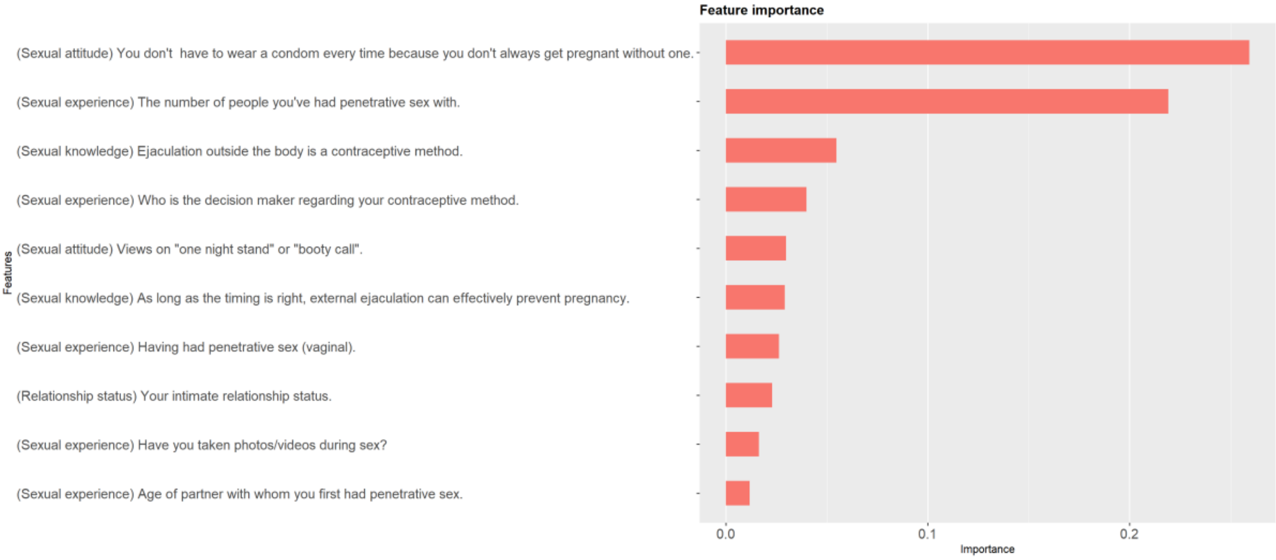


Table 3. Association between integrated RSB[a] and its key variables through MLR[b].

Variable and option	Coefficient estimate	SE	*Z* value	*P* value (>|*Z*|)
Sexual knowledge: ejaculation outside the body is a contraceptive method.

[a]RSB: risky sexual behavior.

[b]MLR: multiple logistic regression.

[c]N/A: not applicable as the baseline group.

Discussion

Principal Results

This study validated the effectiveness of ML models in predicting RSB among college students through comparisons of multiple models. Among various ML models, XGBoost performed the best in this task, with a higher accuracy, precision, F_1-score, and AUROC performance than others. Thus, we eventually used XGBoost to identify the 12 most predictive factors for total RSB, including relationship status, sexual knowledge, sexual attitudes, and previous sexual experience. This systematic process of data modeling as well as the accuracy of the final results indicated that ML approaches could have considerable value in RSB prediction and intervention among college students.

ML models were substantially superior to conventional regressions and should be recommended for more practical applications. Compared to the AUROC values of the MLR model (0.76, 0.71, 0.91, and 0.79 on the 4 types of RSB, respectively), XGBoost had a much higher effect in terms of AUROC values (0.78, 0.72, 0.94, and 0.80 on the 4 types of RSB, respectively). However, the capacity of explanation of MLR was nonnegligible. Thus, we finally used an MLR model again to investigate the linear association between outcomes and those important risk factors identified through XGBoost.

In this study, demographic characteristics and socioeconomic status were found to be significant factors of RSBs. Adolescents who were from an ethnic minority background, held religious beliefs, or had a lower family financial status tended to engage in more RSBs. This may be due to the lack of sexual education resources or specific religious customs. In addition, it was worth noting that students who had migration experience or were from rural hometowns were associated with increased RSBs. This finding was consistent with previous research and reflects the persisting gap in adolescent sexual and reproductive health between urban and rural areas [28,29]. Correlated with a lower level of education and socioeconomic status, rural-to-urban adolescents had less exposure to sexual knowledge and sex education [28,30].

In accordance with previous studies, romantic relationships were highly associated with RSB. It was found that college students with a romantic relationship had a significantly higher probability of using condoms during vaginal sex, oral sex, and anal sex [23]. On the one hand, students not in romantic relationships usually had fewer condom-carrying practices and a higher occurrence of unplanned sex. On the other hand, according to Rosenthal et al [31], rather than being concerned with the risk of STIs, students not in romantic relationships paid more attention to building intimacy through RSB, especially during casual sexual encounters. This is a worrisome mechanism since these students are more inclined to be unaware of each other’s health status, which could lead to a considerable risk of STIs.

This study also validated the role of sexual attitude in RSB. The more tolerant the students were toward condom nonuse and one-night stand, the higher their probability of engaging in RSB. In fact, it was widely validated that sexual attitude plays the most predictive influence in predicting RSB [32,33], which could be illustrated through the theory of planned behavior (TPB) that attitude is an activator of behavior [34]. Thus, sexual education should be facilitated to emphasize the importance and necessity of safe sex and dispel misunderstandings about it.

In addition, students’ previous sexual experience also had a large influence on the possibility of RSB, such as the number of sexual partners, the decision maker regarding the contraceptive method, and whether to take photos/videos during sex. This finding is also rational since well-practiced behavior would more likely recur due to the natural automation of initiates and controls [35].

Limitations

There are some limitations in this study. First, all outcomes and predictors were self-reported by participants, which may have caused recall bias and nonresponse bias. Since some questions were sensitive, participants may not have been willing to provide correct answers, such as on previous sexual experience, experience of sexual harassment, and assault. Second, the measurement of contraception use did not differentiate between the types of contraceptive methods used by the study population. Different contraceptive methods serve different functions. Condom use can prevent both STIs and unwanted pregnancies, while hormonal contraception is only effective for pregnancy prevention. Although the vast majority of participants used condoms for contraception, the predictive accuracy of contraceptive effectiveness may still have been obscured in this study because of the lack of differentiation across methods. Third, the definition of casual sex and sex with multiple partners was not well specified. Though these 2 types of behavior were undoubtedly validated as RSBs, the risks of contracting STIs and unwanted pregnancy can be kept relatively low with correct condom use. Fourth, although ML models have better predictive performance than traditional regression models, their explanatory performance is much weaker. We performed MLR to compensate for this drawback, but multicollinearity may exist among those selected risk factors, which could lead to inaccurate estimation. In particular, we had a large scale of many questions, with much similarity among them. Thus, questions could be divided into clusters to decrease the variable dimensions as well as strengthen the explanatory power. Fifth, since our model relied on a cross-sectional questionnaire, the outcomes and predictors were questioned concurrently. Under the same time window, it is difficult to identify the sequence of events. There may be causal inversion problems between predictors and outcomes, and thus, the prospective predictive efficiency of the model is hard to validate.

Comparison With Prior Work

There are considerable methodological, theoretical, and practical implications of this study. From the methodological aspect, we adopted a scientific and rigorous process to generate an RSB-predictive model using ML methods, which constitutes a research gap and urgent work to be done. The selection of the model, the adjustment of parameters, the comparison of indicators, and the finalization of variable numbers are of high reference value in the methodology. From a theoretical perspective, we identified a series of risk factors for RSB. We provided additional evidence for the association of demographic characteristics and socioeconomic status with RSB. Critical factors influencing RSB were also explored, including sexual attitude, sexual knowledge, relationship status, and sexual experience. Through the results presented, a comprehensive and evidence-based guideline was formed to facilitate more precise interventions and prevent RSB among adolescents and young adults. From a practical perspective, we developed a predictive model to help identify RSB among college students. Due to privacy concerns and the stigmatization of sexual behavior, it is often difficult to investigate the real prevalence of RSB among adolescents. Using the 12 predictors identified here, the model can predict not only the probability of a student engaging in RSB but also what kind of RSB they are more likely to engage in. With such a model, our study allows for more targeted intervention and prevention of RSB in students before they contract STIs, and thus, these students will be better able to avoid the various negative consequences of RSB, including STIs and unwanted pregnancy.

Conclusion

In summary, our study confirmed that ML approaches, especially XGBoost, have greater predictive effects for RSB than traditional regression models. Such ML-based assessment tools could generate new applications with considerable practical value, which would promote health at both the individual and the public level in the future.

Acknowledgments

The authors would like to express gratitude to the China Family Planning Association and the China Youth Network for their support in data collection and to all the students who participated in this survey.

Abstract

Background: Face mask wearing has been identified as an effective strategy to prevent the transmission of SARS-CoV-2, yet mask mandates were never imposed nationally in the United States. This decision resulted in a patchwork of local policies and varying compliance, potentially generating heterogeneities in the local trajectories of COVID-19 in the United States. Although numerous studies have investigated the patterns and predictors of masking behavior nationally, most suffer from survey biases and none have been able to characterize mask wearing at fine spatial scales across the United States through different phases of the pandemic.

Objective: Urgently needed is a debiased spatiotemporal characterization of mask-wearing behavior in the United States. This information is critical to further assess the effectiveness of masking, evaluate the drivers of transmission at different time points during the pandemic, and guide future public health decisions through, for example, forecasting disease surges.

Methods: We analyzed spatiotemporal masking patterns in over 8 million behavioral survey responses from across the United States, starting in September 2020 through May 2021. We adjusted for sample size and representation using binomial regression models and survey raking, respectively, to produce county-level monthly estimates of masking behavior. We additionally debiased self-reported masking estimates using bias measures derived by comparing vaccination data from the same survey to official records at the county level. Lastly, we evaluated whether individuals' perceptions of their social environment can serve as a less biased form of behavioral surveillance than self-reported data.

Results: We found that county-level masking behavior was spatially heterogeneous along an urban-rural gradient, with mask wearing peaking in winter 2021 and declining sharply through May 2021. Our results identified regions where targeted public health efforts could have been most effective and suggest that individuals' frequency of mask wearing may be influenced by national guidance and disease prevalence. We validated our bias correction approach by comparing debiased self-reported mask-wearing estimates with community-reported estimates, after addressing issues of a small sample size and representation. Self-reported behavior estimates were especially prone to social desirability and nonresponse biases, and our findings demonstrated that these biases can be reduced if individuals are asked to report on community rather than self behaviors.

Conclusions: Our work highlights the importance of characterizing public health behaviors at fine spatiotemporal scales to capture heterogeneities that may drive outbreak trajectories. Our findings also emphasize the need for a standardized approach to incorporating behavioral big data into public health response efforts. Even large surveys are prone to bias; thus, we advocate for a social sensing approach to behavioral surveillance to enable more accurate estimates of health behaviors. Finally, we invite the public health and behavioral research communities to use our publicly available estimates to consider how bias-corrected behavioral estimates may improve our understanding of protective behaviors during crises and their impact on disease dynamics.

Introduction

Human behavior plays a key role in infectious disease transmission [1,2]. Individuals' decisions to get vaccinated, reduce their contacts, or wear a face mask, for example, can have a tremendous impact on disease dynamics [3-5]. The COVID-19 pandemic has highlighted that we are grossly limited in our ability to accurately measure and predict human behavior in the face of a novel pathogen. Yet, knowledge of how human behaviors vary over time and space is critical to assess the effectiveness of mitigation strategies, to forecast disease surges, and to parameterize coupled disease-behavior models [6]. In particular, there is a paucity of data on how the frequency of face mask wearing varies across the United States over different phases of the pandemic. This lack of fine-scale spatiotemporal data has forced public health organizations to adopt an inefficient one-size-fits-all approach to encourage masking nationwide, rather than directing resources and messaging to areas with the lowest uptake. Here, we identify the spatiotemporal trends in self-reported data on mask-wearing behavior across the United States from a large survey distributed from September 2020 to May 2021.

Mask wearing has been identified as an effective strategy to reduce the transmission of SARS-CoV-2. At the individual level, masks decrease both the amount of viral particles dispersed by an infectious wearer and the amount of those inhaled by an uninfected wearer [7]. Modeling studies at the population level (eg, [4,8,9]) have suggested that mask wearing can limit SARS-CoV-2 transmission and COVID-19 deaths, including under scenarios where masks are not worn universally or are not completely effective at blocking transmission. Randomized controlled trials (eg, [10]) have also demonstrated that mask wearing is an effective community-level intervention against COVID-19. Despite limited information at the time, the Centers for Disease Control and Prevention (CDC) initially recommended mask wearing on April 3, 2020 [11]. Lack of a national mandate, though, resulted in a heterogeneous landscape of mask policies across states, counties, towns, and even individual businesses in the United States [12,13]. Compounded with this spatial heterogeneity in mandates is additional heterogeneity in compliance, documented by localized observational studies (eg, [14]). A collection of systematic, accurate data on mask-wearing levels across the United States is therefore essential to informing our understanding of the role of mask wearing in the US COVID-19 pandemic trajectory.

To address this gap, researchers and organizations have implemented extensive surveys on human behavior, including mask wearing (eg, [15-17]). These surveys hold exciting promise, yet they have contributed relatively little to our understanding of human behavior, due to significant sampling limitations. Larger surveys with sufficient power to detect trends at local geographic scales are often not designed to capture a representative sample of the population. Demographic biases arising from a nonrepresentative sample can be addressed with standard statistical tools, such as survey weights, but other forms of bias, particularly nonresponse and social desirability biases, are more challenging to correct. Surveys about salient public health issues are especially likely to suffer from response bias; COVID-19–cautious individuals may be overrepresented in a survey about COVID-19 behavior. However, without estimates of the proportion of individuals in a given region who are COVID-19 cautious, there is no way to use survey weights on this demographic. Likewise, respondents may be influenced by social desirability bias when self-reporting COVID-19–preventive behaviors, such as vaccination, social distancing, or mask wearing, so that they respond in a manner deemed favorable by society despite being inaccurate [18]. Without observational or ground-truth data to validate survey responses, quantifying this social desirability bias is difficult. Furthermore, it is critical that ground-truth data to correct biases in health behavior be used at a fine spatial and temporal scale to avoid further exacerbation of biases (eg, [19]).

The value of surveys on public health behaviors can be further restricted when data collection is at the national or state level. Coarse-grained spatiotemporal information about human behavior is of limited utility, providing only sparse insight into local trends. Collecting responses at the national or state level ignores spatial heterogeneity at these finer scales, preventing the identification of these local effects that can drive disease dynamics. Spatial heterogeneity in not only drivers of disease transmission, such as human behavior, but also disease prevalence has been well documented across pathogens (eg, [20-22]). For example, differences in connectivity between counties or states can affect the timing and geographic scale of disease spread, while national scale mobility data elide these key patterns [23,24]. Likewise, aggregation of vaccination data to the state level can hide spatial clustering of unvaccinated individuals, which undermines herd immunity and could drive sustained measles outbreaks in the United States [25,26]. Despite the importance of detailed local estimates on the drivers of disease incidence, few studies have analyzed human behavior during the COVID-19 pandemic nationally at these fine spatial scales. Furthermore, most surveys are not conducted for long enough to capture human behavior changes over time, leaving scant opportunity to assess the effects of changing public health messaging/guidance or disease prevalence on human behavior.

Here, we systematically characterize mask wearing across the United States at a fine spatiotemporal scale for 9 months using a national survey and account for the bias in this survey. By comparing survey demographics and vaccination statuses with accurate ground-truth data, we estimate and account for survey and response biases in our analysis of masking behavior. With these bias-corrected estimates, we characterize the spatiotemporal heterogeneity in masking behavior at the county-month level across the United States. Finally, we examine the differences between self-reported and community-reported estimates of masking using an additional survey question, seeking to understand whether these 2 measures are good predictors of one another. Our results are the most precise estimates of masking in the United States during the COVID-19 pandemic, providing insight into the local variation in behavior in response to public health messaging and changes in COVID-19 incidence.

Methods

Study Design

In this study, we sought to characterize the spatiotemporal heterogeneity in self-reported masking behavior in the United States from the fall of 2020 to the spring of 2021. Due to the small sample size in some counties, we used Bayesian binomial regression models to estimate mask-wearing proportions each month. Recognizing that surveys are subject to several types of bias, we used raking and resampling of responses to correct for unrepresentative samples and self-reported vaccination status compared to ground-truth vaccination data to quantify nonresponse and social desirability biases. With these estimates, we were able to identify spatiotemporal trends in bias-corrected masking behavior and compare these values to reported community levels of masking in a different survey question.

Survey Data and Processing

We analyzed self-reported mask-wearing survey responses for all 50 US states and the District of Columbia using data from the US COVID-19 Trends and Impact Survey (CTIS) [27]. The CTIS was created by the Delphi Research Group at Carnegie Mellon University and distributed through a partnership with Facebook. Beginning in September 2020, a random state-stratified sample of active Facebook users was invited daily to take the survey about COVID-19 and report how often they wore a mask in the past 5-7 days (the number of days changed from 5 to 7 on February 8, 2021). The answer options were (1) “All of the time,” (2) “Most of the time,” (3) “Some of the time,” (4) “A little of the time,” (5) “None of the time,” and (6) “I have not been in public in the last 5-7 days” (Multimedia Appendix 1, Figure S13). To dichotomize these responses for an analysis of the proportion of respondents wearing masks, we dropped respondents who had not been in public recently or did not respond to the masking question, and considered responses of “all of the time” and “most of the time” as masking, and all other responses as not masking. This cut-off is reasonable, considering the raw proportions of responses in each category for September through May (Multimedia Appendix 1, Figure S14). Due to sample size constraints, we aggregated these responses to the county-month scale. We ignored potential heterogeneity at smaller temporal (weekly) and spatial (zip code) scales due to the limited sample size.

By dichotomizing masking responses, we also lost information about the frequency with which people mask, though we expect the effect of this choice to be minimal (see Multimedia Appendix 1 for details).

Bayesian Binomial Regression Model

Due to the small sample sizes in some US counties, we used Bayesian binomial regression models to develop reliable estimates of the proportion of individuals masking in a given county-month. Population density was used as a fixed effect; masking behavior has previously been linked to population density, and this variable was easily available at the county scale [14,28]. We fit separate models for each month, allowing for a temporal trend without explicitly modeling it by specifying a parametric form. We defined M_i as the number of respondents masking in county *i* (eg, respondents who masked most or all of the time in the past 5-7 days), N_i as the total number of respondents in county *i* ($M_i \leq N_i$), and p_i as the county-level probability of a response consistent with masking. We used the following model to estimate and :

where $D_i = \log_{10}(\text{population density}_i)$ for county *i*. We ran the model using *brms* [29] with the *cmdstanR* [30] backend. We ran the sampler with 4 chains for 3000 iterations per chain. Sampler diagnostics indicated efficient exploration and that the model had converged, $n_{eff} < 0.25$, n_{eff} per iteration ≥ 0.25, ≤ 1.01, E-BFMI > 0.25, and no transitions hit the maximum tree depth. All Pareto-smoothed importance sampling leave-one-out (PSIS-LOO) k statistic values were below 0.71, indicating that the model was robust to the influence of individual observations, and the distribution of Pareto k statistics was uniform, indicating that the model captured essential features of the data [31]. Posterior predictive checks indicated a good model fit (Multimedia Appendix 1, Figure S15) as did the plots of observed versus predicted and residual values (Multimedia Appendix 1, Figures S16 and S17). We note that our binomial regression approach compensated for the small sample sizes in some county-months, but the resulting estimates depend on the validity of our model structure.

We also explored more complex model specifications that included state- or county-level random effects. However, both models suffered from a lack of convergence or overfitting and produced functionally similar results. Thus, we opted for the more parsimonious model presented earlier for our main findings; details of these additional models can be found in Multimedia Appendix 1 (Figures S20 and S21).

Survey Raking and Resampling

We were unable to use the provided weights for responses to the CTIS, due to spatial and temporal mismatch with the scales of our data analysis. Thus, we calculated county-month weights for each observation using the anesrake package [32] and the US Census American Community Survey’s 2018 5-year data on county age, sex, and education distributions. Age, sex, and education distributions were based on each county’s population over the age of 18 years to match the survey sample. We did not use race or ethnicity data in the raking scheme, as their inclusion substantially reduced algorithm convergence, but note that race/ethnicity was moderately correlated with education (Cramer's V>0.10). We then resampled from these responses using the calculated weights to estimate a raked masking proportion, which was fed into the binomial models, as described before. We excluded observations with missing age, sex, or education responses from the raking process and assigned equal weights to observations from county-months that did not converge (additional details in Multimedia Appendix 1).

Estimation of CTIS Masking Bias

Given the likelihood of sampling, nonresponse, and social desirability biases, we generated bias-corrected estimates of masking in the United States. In the absence of ground-truth masking data with which to calibrate these CTIS responses, we turned to a different survey question for which ground-truth data were available.

Beginning in late December 2020, the CTIS asked respondents whether they had received a COVID-19 vaccine. The response options were (1) "Yes, "(2) "No," and (3) "I don't know." Meanwhile, ground-truth vaccination data were collected by combining state-reported and CDC data to estimate the percentage of people vaccinated in each county in the United States [33,34]. A comparison of CTIS responses and ground-truth vaccination data revealed that the estimates of COVID-19 vaccination based on CTIS responses were much higher than true vaccination rates at the US county scale (Multimedia Appendix 1, Figures S18 and S19, [19,35]). Assuming that masking survey responses suffer from the same bias issues (in magnitude and direction) as vaccination responses, this result would suggest that CTIS responses also substantially overestimate masking behavior. Thus, we approximated survey bias by comparing the CTIS vaccination responses to the ground-truth vaccination data at the county level and incorporating this bias into the model of CTIS masking behavior.

Like the masking data, the CTIS vaccination response data suffers from small and unrepresentative samples in some counties. Thus, we resampled the responses from April and May 2021 according to the survey weights we generated before and then used a (frequentist) binomial generalized linear mixed-effects model to estimate p_i, the proportion of respondents who were vaccinated (assumed to be partial vaccination, with 1 of a 1-dose or 2-dose vaccine) at the county level each week (details in Multimedia Appendix 1).

Given these modeled CTIS county-level vaccination proportions, we compared them with the true vaccination data to calculate the expected bias in reported survey responses relative to ground-truth data in county *i*:

$$\text{bias}_i = \text{logit}(\text{CTIS estimated vaccination proportion}_i) - \text{logit}(\text{true vaccination proportion}_i)$$

To increase the stability of our bias estimates, we used a linear mixed-effects model. This mixed-effects model used random intercepts, which penalizes extreme coefficient estimates to the overall mean, and assumed that the residual error in the estimates was normally distributed. This model generated a penalized estimate of survey bias for each county from the difference in modeled reported vaccination and ground-truth vaccination:

This model was implemented using *lmer* in the *lme4* package [36]. If there were no responses in county *i* or a bias estimate could not be calculated, bias estimates for this county were imputed by taking the mean of surrounding county estimates.

We then incorporated these estimates into a Bayesian binomial regression model with an offset for bias to estimate the bias-corrected probability of reporting masking in county *i*. We defined M_i as the number of respondents masking in county *i* out of N_i total respondents and p_i as the county-level probability of a response consistent with masking. We used the following model to estimate and :

where D_i = $\log_{10}$(population density$_i$) for county *i*. The bias-corrected proportion of individuals masking, c_i, was calculated as

We ran the model using *brms* [29] with the *cmdstanR* [30] backend. We ran the sampler with 4 chains for 3000 iterations per chain. Sampler diagnostics indicated efficient exploration and that the model had converged: $n_{eff}>1000$, n_{eff} per iteration≥0.3, and ≤ 1.01.

Community-Reported Masking

Beginning November 24, 2020, the CTIS asked a question about masking in one's community: "In the past 7 days, when out in public places where social distancing is not possible, about how many people would you estimate wore masks?" The answer options were (1) "All of the people," (2) "Most of the people," (3) "Some of the people," (4) "A few of the people," (5) "None of the people," and (6) "I have not been out in public places in the past 7 days." We dichotomized these responses and aggregated them to the county-month the same way as the self-reported CTIS masking responses for December 2020 through May 2021. We then modeled these community masking estimates the same way we modeled the CTIS masking data using Bayesian binomial regression and resampling weighted by survey weights but without a bias offset.

Spatiotemporal Analysis

All analyses were completed in R version 4.1.3 (R Core Team and the R Foundation for Statistical Computing), and maps were produced using *choroplethr* [37]. Urban-rural classes were from the National Center for Health Statistics (NCHS) Urban-Rural Classification Scheme [38].

Ethical Considerations

This study was reviewed by the Institutional Review Board of Georgetown University and was determined not to be human subject research.

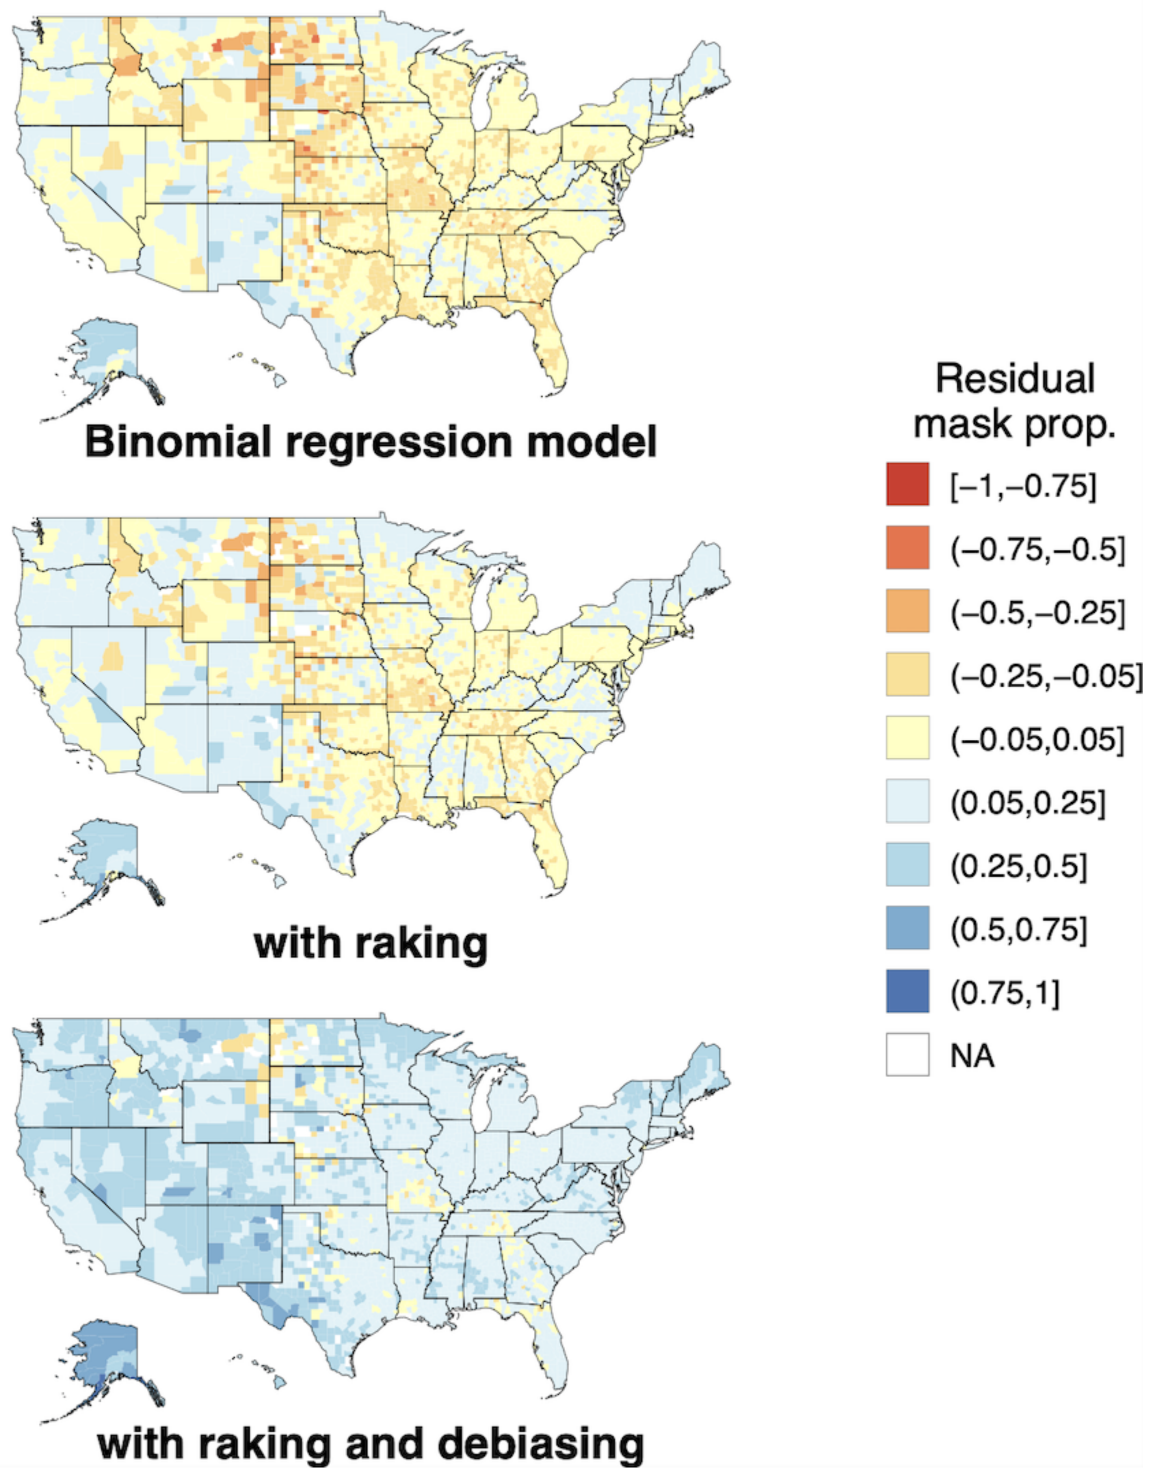
Results

To characterize the trends in the masking behavior in the United States during the COVID-19 pandemic, we used data from the CTIS conducted via Facebook from September 2020 through May 2021. Respondents self-reported how often they had worn a mask while in public in the past week (8,338,877 valid responses). We transformed these responses into a binary variable of masking or not masking and aggregated the responses to the county-month level to analyze spatiotemporal trends. To validate this data source, we analyzed a separate data set from Outbreaks Near Me and found consistent spatiotemporal patterns (Multimedia Appendix 1, Figures S1-S3), though both data sources suffer from issues of bias and small sample size. We addressed these issues in the CTIS data using binomial regression models to inform estimates of masking in counties with a small sample size, and raking and sample rebalancing on age, sex, and education to adjust for unrepresentative samples. Recognizing that CTIS responses to a question about vaccination overestimated the true vaccination rates, we quantified this bias for each county and used it to correct the estimates of masking behavior, assuming that vaccination and masking behavior responses were equally as biased. (Vaccination and mask wearing are both prosocial public health behaviors, which are socially desirable to report and are likely correlated [39-43].) We analyzed the overall spatial and temporal trends as well as fine-scale heterogeneity in the bias-corrected masking behavior estimates. Finally, we validated the bias-corrected CTIS values by comparing them to the respondents' estimates of the proportion of people masking in their community.

Spatially Heterogeneous Effects of the Binomial Regression Model, Survey Raking, and Debiasing

To demonstrate the spatially heterogeneous effects of our data-processing scheme, Figure 1 shows the difference between estimates from 3 separate models and the raw CTIS masking data. We refer to this difference as the residual, though it is only an indicator of model fit in Figure 1A. In Figures 1B and 1C, the residual values indicate where data corrections caused the largest changes in estimates compared to the original data. After modeling the data with binomial regression, estimates of masking proportions were higher than the observed values (Multimedia Appendix 1, Figure S4) in the central United States and slightly lower than the observed values in the Northeast, Northwest, and Southwest (Figure 1A). Adjusting for unrepresentative samples with raking and resampling and rerunning the binomial regression model had a minor effect on mask-wearing estimates, only exhibiting a slight decrease compared to the model without raking (Figure 1B). Correcting for survey biases using vaccination data in the binomial regression model run on raked survey responses systematically decreased masking proportions, as expected and denoted by increased residuals (Figure 1C). (A map showing the spatial distribution of these biases is given in Multimedia Appendix 1, Figure S19.) We refer to estimates from the model in Figure 1C as debiased or bias-corrected for the remainder of the paper. Our results reinforce that behavioral surveillance should be conducted carefully to limit bias initially.

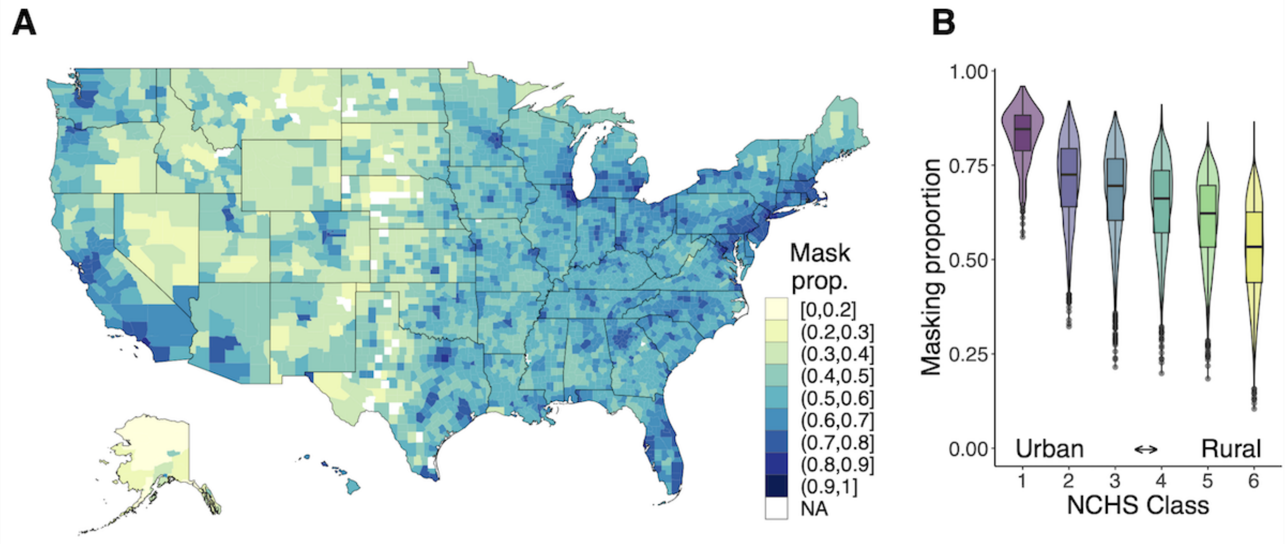
Figure 1. Visualization of spatially heterogeneous data-processing effects. (A) Residuals following the binomial regression model. (B) Residuals following the binomial regression model with raking/sample rebalancing. (C) Residuals following the binomial regression model with raking/sample rebalancing and an offset for bias. Residuals are defined as the difference between the modeled and the observed masking estimates at each analysis stage, where negative values indicate model estimates were higher than observed values and positive residuals indicate model estimates were lower than observed values. All maps are shown for February 2021. N/A: not applicable. See Multimedia Appendix 2 for a high-resolution image.



Masking Behavior Exhibits Spatial and Temporal Heterogeneity and Is Positively Associated With Population Density

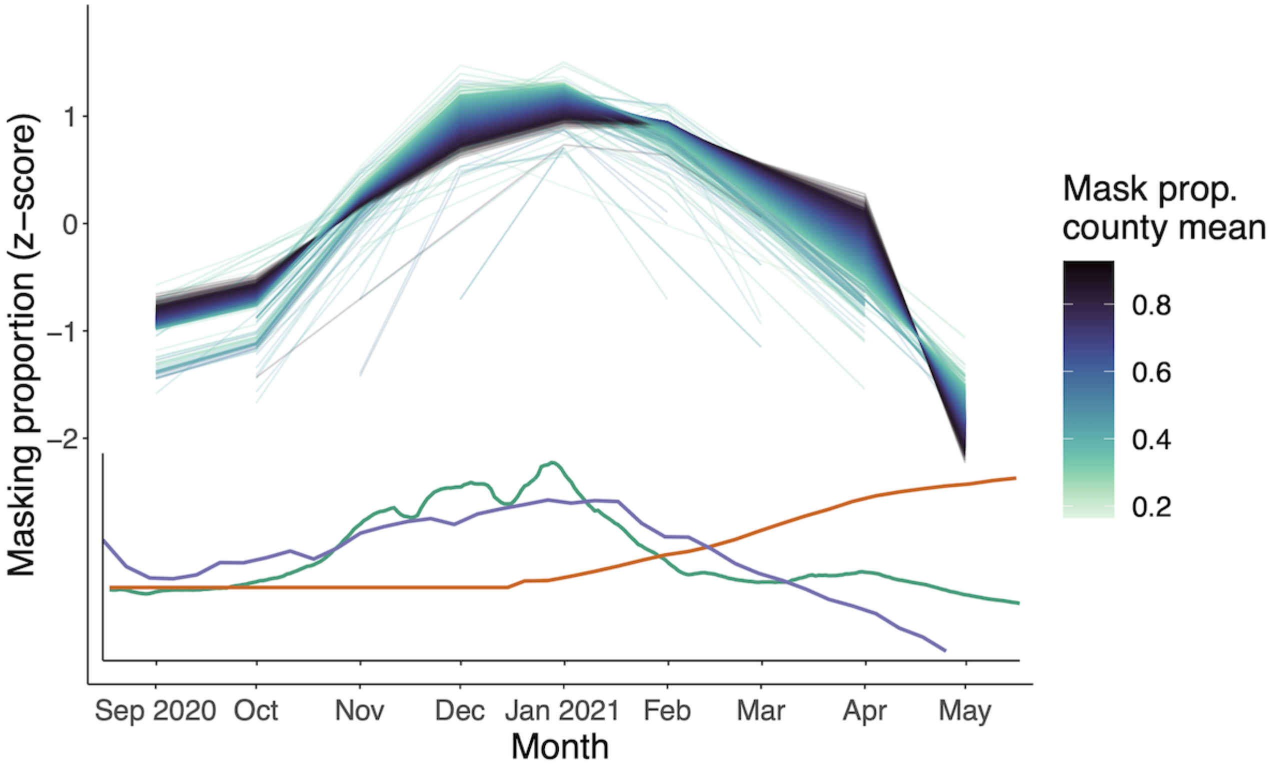
Using bias-corrected masking proportions from the CTIS, we found that masking behavior was spatially heterogeneous over all months (Moran's I between 0.68 and 0.70 for all months, Figures 2A and S5 in Multimedia Appendix 1). Bias-corrected masking proportions ranged from 0.11 to 0.96 and varied substantially within states, emphasizing the importance of analyzing masking behavior at finer scales than the state or Health and Human Services (HHS) region level. Masking proportions were closely linked to population density over the survey period: urban counties tended to have higher masking proportions than rural counties (Figure 2B). Although masking proportions ranged quite a bit within NCHS urban-rural classifications, all differences between NCHS classes were significant (Kruskal-Wallis and pairwise Wilcox test, n=27,842, all *P*<.001). Over all counties and survey months, the median fitted masking proportion in urban counties exceeded 0.8, while the median fitted masking proportion in the most rural counties was below 0.6.

Figure 2. Bias-corrected masking behavior is spatially heterogeneous and higher in urban areas. (A) Map of bias-corrected masking behavior in October 2020 reveals high spatial heterogeneity. Masking proportions vary substantially even within a single state. Spatial heterogeneity does not notably vary over time (Multimedia Appendix 1, Figure S5). A selection of other months in the study period are shown in Multimedia Appendix 1 (Figures S6-S8). (B) Breakdown of county masking proportions over all survey months by the NCHS urban-rural classification. A direct relationship between the median masking proportion and population density is observed. N/A: not applicable; NCHS: National Center for Health Statistics. See Multimedia Appendix 3 for a high-resolution image.



Masking behavior not only varied geographically but also temporally. Peak masking behavior was observed in January 2021, while the lowest masking proportions were observed in May 2021 (Figure 3). Counties with higher mean masking proportions fluctuated less than counties with lower mean masking proportions from September to April but experienced the largest differences from their mean values in May 2021. For context, we highlight that this decrease coincides with increasing proportions of vaccinated individuals in the United States (Figure 3, [33]), declining new infections [44], and decreasing reported worry about severe illness due to COVID-19 from the CTIS [27]. The policy context during this time was also shifting: On April 27, 2021, the CDC announced that fully vaccinated individuals no longer needed to wear masks outdoors [45], and on May 13, 2021, it announced that fully vaccinated individuals no longer had to wear masks indoors either [46]. Meanwhile, 49% of counties that ever had a mask mandate lifted it before May 1, 2021 (Multimedia Appendix 1, Figure S9). These announcements coincided with the observed decrease in masking in these months. Together, these analyses underscore the importance of tracking and analyzing mask wearing at fine spatial and across long temporal scales: further spatial and temporal aggregation of these data would have missed key heterogeneity previously not quantified and prevented future work from investigating the connection between policy and behavior change at appropriate granularity.

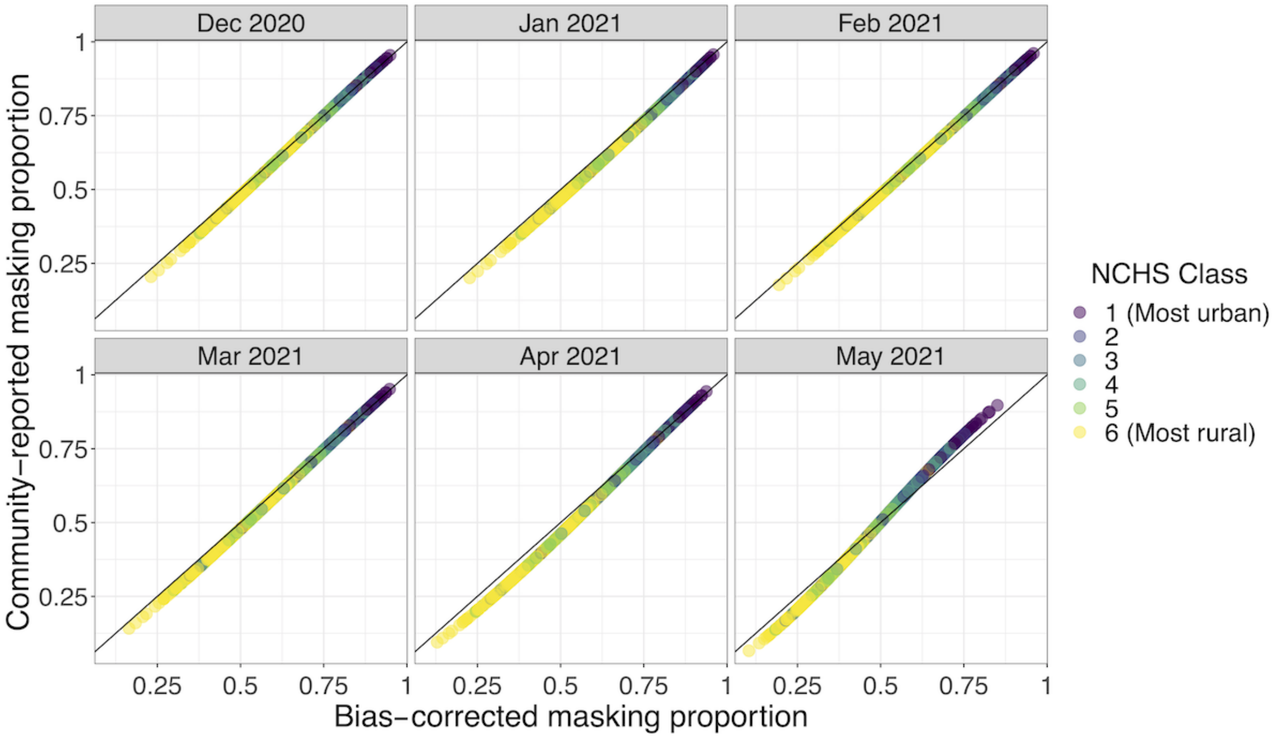
Figure 3. Bias-corrected masking behavior peaked in the winter of 2020-2021 and fell in the spring of 2021, mirroring new cases and increasing vaccinations. Top curves show the time series of the z-score of bias-corrected masking proportions for each county colored by the average masking proportion across the survey period. The inset plot shows z-scores of the 7-day rolling average of new cases (green), the proportion of individuals vaccinated nationally (orange), and the reported worry about severe illness from COVID-19 in CTIS respondents (purple). Z-scores are based on the mean and SD of each county's masking estimates over the survey period. CTIS: COVID-19 Trends and Impact Survey. See Multimedia Appendix 4 for a high-resolution image.



Community-Reported Masking Levels Are a Good Predictor of Bias-Corrected Self-Reported Estimates

Bias-corrected masking proportions were well approximated by modeled estimates of community-reported masking (Figure 4). The difference between the 2 mask-wearing proportion estimates ranged from –6% to 5% and became more apparent in April and May 2021, particularly in rural areas. In May 2021, though, community estimates in urban areas tended to overestimate bias-corrected individual masking estimates. This result is quantitatively affected by influential observations but is qualitatively robust (Multimedia Appendix 1, Figure S10). These results suggest that surveying participants about community masking may give less biased responses than asking individuals to report their own masking behavior, potentially reducing social desirability bias and capturing parts of the population that may be otherwise less likely to respond to the survey.

Figure 4. Community-reported masking gives a good estimate of bias-corrected self-reported masking. Community-reported masking refers to the CTIS question where individuals report how many people in their community are masking, which may decrease nonresponse and social desirability biases, compared to asking individuals to self-report their masking behavior. Point color denotes urban-rural classes. Comparisons of individual- and community-reported estimates at different analysis stages are shown in Multimedia Appendix 1 (Figures S11 and S12). CTIS: COVID-19 Trends and Impact Survey. See Multimedia Appendix 5 for a high-resolution image.



Discussion

Principal Findings

Despite the widespread adoption of face mask-wearing at points during the COVID-19 pandemic in the United States, the true prevalence of this behavior across temporal and spatial scales is largely unknown. Data on mask wearing have been collected through surveys, at varying spatiotemporal resolutions and with potentially varying survey biases (eg, [15-17]). Here, we characterized mask-wearing behavior across the United States using self-reported masking data from a large national online survey. We used Bayesian binomial regression models to remediate issues of small sample size, performed raking/sample balancing to address unrepresentative survey samples, and corrected for additional response biases using measurable bias in vaccination data. We observed substantial spatial heterogeneity in the masking behavior across urban versus rural counties, with some temporal changes in mean masking estimates at the county-month level, most notably a steep decline in masking in May 2021. We found that community-reported masking responses well approximated our bias-corrected masking estimates. Other work adds to this validation: Similar spatial heterogeneity was found in 2 other surveys, with some overlapping periods (Multimedia Appendix 1, Figures S1-S3, [17,47]), and our debiased estimates generally agree with those recorded in observational studies, including higher levels of masking in urban areas (Multimedia Appendix 1, Table S1, [14,28]). Our results reveal the landscape of the masking behavior across 3 distinct phases of the pandemic (presurge, surge during winter 2020-2021, and postsurge during the initial COVID-19 vaccination rollout). Our work also highlights the critical role that behavioral big data can play in the pandemic response, if such data are used with caution.

Implications

Our findings have several implications for the fields of infectious disease epidemiology and public health policy. We identified high spatial and moderate temporal heterogeneity in masking behavior at the county-level—patterns that are obscured if data are aggregated to the state or HHS region level. Contrary to our expectations, this level of spatial variability around the mean is consistent over time. Consequently, disease models should account for spatial variability in masking behavior but may only need to consider changes in masking dynamics over longer temporal scales. The high spatial heterogeneity we found in masking behavior also highlights the need for diverse and targeted public health approaches across the country rather than a single national program. Guidance set at the state level without regard for differences in local conditions may miss early opportunities to control disease spread, prematurely enforce public health restrictions, and contribute to fatigue with public health restrictions. Thus, we advocate for local behavioral data collection and geographically targeted public health policy for optimized resource use and efficient disease suppression.

Although county-level mask-wearing behavior varied across months, we observed little heterogeneity across counties in these temporal trends. The observed changes in masking behavior roughly correspond to national trends in new cases in the United States and self-reported worry about severe disease, as reported in the CTIS, though we did not determine causality or examine this relationship at the individual or county level. Because we modeled county-level averages, this observed correlation could be driven by a specific demographic group or subset of individuals modifying their masking behavior, rather than a uniform change in average mask uptake in a county's population. The sharp decrease in masking in May 2021 is contemporaneous with many states lifting mask mandates (Multimedia Appendix 1, Figure S9) and an announcement from the CDC that vaccinated individuals no longer have to wear masks outdoors (April 27, 2021 [45]) or indoors (May 13, 2021 [46]). It is plausible that these policy changes could have impacted masking behavior, both in vaccinated and in unvaccinated individuals, even though the change in CDC guidance did not apply to unvaccinated individuals [42,48]. More work is needed to explore the potential differences in mask wearing between vaccinated and unvaccinated individuals. Additional research could also focus on quantifying the impact of social norms on individuals' masking behavior at fine spatiotemporal resolution in the United States.

Recent work has highlighted the potential for big data sources to provide a measurement of spatially disaggregated social phenomena (eg, [49]), while other research points to the challenges of inferring high-quality estimates of behavior from such high-volume data sources [19]. In our work, we sought to steer away from "big data hubris" [50] by applying rigorous statistical methods to manage concerns about representativeness and bias and by conducting an internal validation of our model-based estimates [51]. In particular, we addressed representativeness by age, sex, and education to capture sociodemographic response bias. Motivated by an association between COVID-19–preventative behaviors [39], we debiased our masking estimates based on vaccination data to address additional nonresponse bias and social desirability bias. Finally, we internally validated our population-scale masking estimates of self-reported behaviors with responses of community behaviors, which may be subject to less nonresponse and social desirability bias compared to self-reporting questions [52]. We found that community-reported masking estimates agreed closely with bias-corrected self-reported masking behavior, highlighting that surveying participants about community behavior may be an avenue to reduce survey bias. We note, however, that this finding may not apply in all settings; self-reported masking behavior on a university campus closely matched observed masking levels, and questions about community masking were less accurate [53]. Although these implications for analysis of surveys on human behavior may not apply universally, similar results have been found in other infectious disease applications, including disease surveillance (using the CTIS data [27,54]) and early outbreak detection in social networks [55,56]. Our results further emphasize the promise of human social sensing going forward to make big data sources more meaningful [57].

Limitations

Nevertheless, our approach has some limitations that are important to consider. We were unable to deal with all representation or response biases, including the exclusion of individuals under 18 years of age; a lack of representativeness due to factors other than age, sex, and education; recall bias; dishonest responses; and other characteristics that may be predictive of nonresponse or social desirability bias, such as political leanings or belief in COVID-19 conspiracies [27]. Likewise, we could not account for how individuals with Facebook accounts may engage differently in COVID-19–preventive behaviors than non-Facebook users. It is unclear whether these biases that are unaccounted for would have a systematic or random effect on our results. However, we do expect their impact to be relatively small, particularly as our ground-truth–based debiasing approach adjusts masking estimates regardless of the source of nonresponse bias, and as supported by our community-reported masking analysis (since the community question captures some of the non-Facebook user population). We assumed that self-reported mask wearing is biased in the same magnitude and direction as the self-reported COVID-19 vaccination status—an assumption that should be tested in future research. Our approach also does not resolve issues of a small sample size; for example, the association we found between bias-corrected self-reported masking and community-reported masking is stronger between modeled estimates than between raw means. Although we attempted to correct for bias in our mask-wearing estimates, the point estimates for these values should be interpreted with caution. The goal of our work is not to produce point estimates of county-level mask-wearing behavior but instead to take advantage of the CTIS survey design and characterize the relative trends in mask-wearing behavior between and across counties. We advocate for additional observational studies with experimental designs that would allow for direct estimation of these quantities to improve behavioral surveillance estimates.

Conclusion

In summary, we produced the first accurate high-resolution spatiotemporal estimates of face mask wearing in the United States for the period from September 2020 through May 2021. Our work reveals that masking behavior is highly variable across the United States, suggesting that a one-size-fits-all approach to increasing mask-wearing behavior is likely to be ineffective. Instead, we identified regions of the country with higher and lower masking levels. These differences should be investigated going forward as public health organizations consider how to more effectively target these low-masking regions. For example, these communities may be more susceptible to mis- and disinformation regarding mitigation behaviors, which must be strategically confronted. Furthermore, this variability in behavior demonstrates the need to develop infectious disease dynamics models to analyze and predict how spatiotemporal trends in disease are affected by changes in human behavior, such as vaccination, contact patterns, and face mask wearing. Our analyses also address issues of survey bias, with the takeaway that, in the future, we should invest in a robust survey infrastructure that can recruit large representative samples with minimal bias, including using certain representative respondents as human social sensors to report on their communities.

Acknowledgments

The authors thank the Carnegie Mellon University (CMU) Delphi team for sharing the US COVID-19 Trends and Impact Survey (CTIS) data openly and freely and Alex Reinhart for his feedback on this work. We also thank the Outbreaks Near Me team at Boston Children’s Hospital and Momentive for data sharing and Benjamin Rader and John Brownstein for their feedback.

The research reported in this publication was supported by the National Institute of General Medical Sciences of the National Institutes of Health under award number R01GM123007. The content is solely the responsibility of the authors and does not necessarily represent the official views of the National Institutes of Health.

Data Availability

Data aggregated to the county-month scale and all code to analyze these data will be made available on GitHub [58]. Individual survey responses cannot be shared by the authors, but researchers can refer to Ref. [59] if they would like to enter an agreement for data usage with the Carnegie Mellon University (CMU) Delphi team.

Authors' Contributions

JCT performed analyses, interpreted results, and drafted and edited the manuscript. ZS designed and guided analyses and edited the manuscript. SB designed the study, guided the analysis, interpreted results, and edited the manuscript. All authors have read and approved the final manuscript.

Multimedia Appendix 2

Visualization of spatially heterogeneous data-processing effects. (A) Residuals following the binomial regression model. (B) Residuals following the binomial regression model with raking/sample rebalancing. (C) Residuals following the binomial regression model with raking/sample rebalancing and an offset for bias. Residuals are defined as the difference between the modeled and the observed masking estimates at each analysis stage, where negative values indicate model estimates were higher than observed values and positive residuals indicate model estimates were lower than observed values. All maps are shown for February 2021. N/A: not applicable.

[PNG File , 4292 KB - publichealth_v9i1e42128_app2.png]

Multimedia Appendix 3

Bias-corrected masking behavior is spatially heterogeneous and higher in urban areas. (A) Map of bias-corrected masking behavior in October 2020 reveals high spatial heterogeneity. Masking proportions vary substantially even within a single state. Spatial heterogeneity does not notably vary over time (Multimedia Appendix 1, Figure S5). A selection of other months in the study period are shown in Multimedia Appendix 1 (Figures S6-S8). (B) Breakdown of county masking proportions over all survey months by the NCHS urban-rural classification. A direct relationship between the median masking proportion and population density is observed. N/A: not applicable; NCHS: National Center for Health Statistics.

Multimedia Appendix 4

Bias-corrected masking behavior peaked in the winter of 2020-2021 and fell in the spring of 2021, mirroring new cases and increasing vaccinations. Top curves show the time series of the z-score of bias-corrected masking proportions for each county colored by the average masking proportion across the survey period. The inset plot shows z-scores of the 7-day rolling average of new cases (green), the proportion of individuals vaccinated nationally (orange), and the reported worry about severe illness from COVID-19 in CTIS respondents (purple). Z-scores are based on the mean and SD of each county’s masking estimates over the survey period. CTIS: COVID-19 Trends and Impact Survey.

[PNG File , 3253 KB - publichealth_v9i1e42128_app4.png]

Multimedia Appendix 5

Community-reported masking gives a good estimate of bias-corrected self-reported masking. Community-reported masking refers to the CTIS question where individuals report how many people in their community are masking, which may decrease nonresponse

and social desirability biases, compared to asking individuals to self-report their masking behavior. Point color denotes urban-rural classes. Comparisons of individual- and community-reported estimates at different analysis stages are shown in Multimedia Appendix 1 (Figures S11 and S12). CTIS: COVID-19 Trends and Impact Survey.

Abstract

Background: The COVID-19 pandemic and related lockdowns have impacted lifestyle behaviors, including eating habits and physical activity; yet, few studies have identified the emerging patterns of such changes and associated risk factors.

Objective: This study aims to identify the patterns of weight and lifestyle behavior changes, and the potential risk factors, resulting from the pandemic in Canadian adults.

Methods: Analyses were conducted on 1609 adults (18-89 years old; n=1450, 90.1%, women; n=1316, 81.8%, White) of the Canadian COVIDiet study baseline data (May-December 2020). Self-reported current and prepandemic weight, physical activity, smoking status, perceived eating habits, alcohol intake, and sleep quality were collected through online questionnaires. Based on these 6 indicator variables, latent class analysis (LCA) was used to identify lifestyle behavior change patterns. Associations with potential risk factors, including age, gender, ethnicity, education, income, chronic diseases, body image perception, and changes in the stress level, living situation, and work arrangement, were examined with logistic regressions.

Results: Participants' mean BMI was 26.1 (SD 6.3) kg/m^2. Of the 1609 participants, 980 (60.9%) had a bachelor's degree or above. Since the pandemic, 563 (35%) had decreased income and 788 (49%) changed their work arrangement. Most participants reported unchanged weight, sleep quality, physical activity level, and smoking and alcohol consumption, yet 708 (44%) reported a perceived decrease in eating habit quality. From LCA, 2 classes of lifestyle behavior change emerged: healthy and less healthy (probability: 0.605 and 0.395, respectively; Bayesian information criterion [BIC]=15574, entropy=4.8). The healthy lifestyle behavior change group more frequently reported unchanged weight, sleep quality, smoking and alcohol intake, unchanged/improved eating habits, and increased physical activity. The less healthy lifestyle behavior change group reported significant weight gain, deteriorated eating habits and sleep quality, unchanged/increased alcohol intake and smoking, and decreased physical activity. Among risk factors, body image dissatisfaction (odds ratio [OR] 8.8, 95% CI 5.3-14.7), depression (OR 1.8, 95% CI 1.3-2.5), increased stress level (OR 3.4, 95% CI 2.0-5.8), and gender minority identity (OR 5.5, 95% CI 1.3-22.3) were associated with adopting less healthy behaviors in adjusted models.

Conclusions: The COVID-19 pandemic has appeared to have influenced lifestyle behaviors unfavorably in some but favorably in others. Body image perception, change in stress level, and gender identity are factors associated with behavior change patterns; whether these will sustain over time remains to be studied. Findings provide insights into developing strategies for supporting adults with poorer mental well-being in the postpandemic context and promoting healthful behaviors during future disease outbreaks.

Introduction

On March 11, 2020, the World Health Organization (WHO) declared COVID-19 (SARS-CoV-2) a global pandemic. Between March 12 and 22, all Canadian provinces had declared a public health emergency, and individuals were asked to stay at home and nonessential businesses were closed, including restaurants and gyms. Indoor and outdoor gatherings were also prohibited in large provinces to avoid spreading of the disease. Indeed, the pandemic imposed a sudden disruption in people’s usual routine. Although many adopted telework practice, others, such as frontline workers, were required to work on-site with additional protective equipment. In May 2020, measures became less stringent and nonessential businesses across Canada reopened gradually [1]. COVID-19 vaccines in adults were under clinical trial investigation, when a second wave hit in September 2020, leading to the enforcement of a second lockdown across provinces [1,2].

Confinement inevitably disturbs lifestyle behaviors, such as eating habits, physical activity level, and sleep, to varying degrees among individuals [3]. Although some observational studies and surveys have reported more home cooking, better diet quality, and increased physical activity levels [4,5], others have observed decreased physical activity, increased energy and alcohol intake, binge eating, reliance on take-out foods, and overall decreased diet quality [6-8]. The combination of poor diet quality, low physical activity, and greater alcohol intake, BMI, and smoking represents an important risk for severe COVID-19 [9], COVID-19 mortality [10], and chronic diseases during the postpandemic period [11]. Accumulating evidence shows that particular groups, such as women and younger individuals, were more susceptible to higher levels of stress and depression during the pandemic, possibly due to changes in home life among others [12-15]. These factors, combined with limited access to grocery shops [8], restaurants, and food banks, restricted budgets due to sudden unemployment, and changes in living arrangements may have affected how people modified their lifestyle during the pandemic [16,17]. Yet, it remains unclear which factors are major determinants of overall lifestyle pattern adoption in times of the pandemic, and no study has examined the lifestyle pattern change of adults in Canada.

Therefore, the objectives of this study were to characterize the potential impact of the COVID-19 pandemic on the lifestyle habits of Canadians and to identify patterns of weight and lifestyle behavior change and associated risk factors. We postulated that individuals experiencing greater levels of stress, isolation, changes in their living situation and work arrangement, and decreased income adopted less healthy lifestyle behaviors. Findings from this study may inform strategies to cope with the effects of current and potential future outbreaks in promoting and maintaining a healthy lifestyle.

Methods

Study Population

The web- and mobile-based Canadian COVIDiet cohort study was initiated on May 29, 2020, toward the end of the COVID-19 pandemic’s first wave of infections. The primary objective was to provide longitudinal data on the impact of the pandemic on eating behaviors, diet quality, and related lifestyle behaviors of Canadian adults. Based on the Canadian population estimated at 31 million adults and considering a 5% margin of error, 95% CI, and 50% response distribution [18], 400 participants were required per age strata (18-45, 45-65, ≥65 years). Following power allocation relative to population size [19], the target sample size was 1920 participants. Until December 5, 2020, 2959 adults from across Canada were recruited using social media advertisement, professional societies, and institutional email lists and from community centers, including food banks. Efforts were made to recruit across age groups, regions, and gender (men and women). Regions were delimited as Ontario, Québec, British Columbia, Prairies (Alberta, Manitoba, Saskatchewan), Atlantic provinces (Nova Scotia, New Brunswick, Newfoundland and Labrador, Prince Edward Island), and territories (Northwest Territories, Yukon, and Nunavut). Interested individuals were invited to contact the study coordinator by email or visit the study website for more information and for eligibility screening.

Eligible participants were 18 years of age or older, were living in Canada at the time of study entry, were able to read English or French, owned a smartphone or tablet, and had access to the internet. Individuals living in care homes or other institutional environments; hospitalized, pregnant, or breastfeeding; or with an active and uncontrolled acute disease that interfered with usual food intake were excluded. The COVIDiet study participants were followed every 3 months for 1 year to capture the impact of the pandemic across waves of infections and for 1 year thereafter to evaluate the longer-term effect. The current analysis was conducted on baseline (May-December 2020) and retrospective data from the baseline questionnaire. Individuals who did not fill out the baseline questionnaire (n=904), provided implausible responses (n=8), and had missing data on changes in weight and lifestyle behavior (eating habits, alcohol consumption, physical activity level, sleep quality and smoking; n=442) were excluded. The final sample included 1609 participants (Multimedia Appendix 1, Figure S1).

Ethical Considerations

Data were collected with online encrypted surveys using AirTable [20] and deidentified using generated ID codes.

Participants were eligible to win a CA $250 (US $182) gift card when they enrolled in the study; 1 draw occurred at every 500 participants enrolled. All participants provided online informed consent. This study was approved by the McGill University Research Ethics Board (20-04-064) and was registered on ClinicalTrials.gov (NCT04407533).

Questionnaires

Baseline Sociodemographics and Medical History

Participants were asked to provide demographic characteristics and changes in lifestyle habits since the pandemic. They were asked to report on age, self-identified gender (women, men, others), ethnicity (White, South Asian, Chinese, Black, Filipino, Latin American, Arabic, Southeast Asian, West Asian, Korean, Japanese, Indigenous, other), usual occupation (full-time, part-time, occasional/seasonal, self-employed, student, unemployed, caregiver, volunteer, retiree), highest or current level of education (grade 8 or lower, grade 9 or 10, high school diploma, vocational school, college diploma , university certificate, bachelor’s degree, graduate studies), usual annual household income (<CA $20,000/<US $14,560, CA $20,000-$50,000/US $14,560-$36,400, >CA $50,000 -$100,000/>US $36,400-$72,800, >CA $100,000-$150,000/>US $72,800-$109,199, >CA $150,000/>US $109,199), usual household/living situation (living with parents, grandparents, brothers and sisters, host family, roommates, partner, children, alone), province, area (urban, suburban, rural), height (m or ft), usual weight (kg or lb), perceived body image (satisfied, somewhat satisfied, not satisfied), living with a chronic disease (hypertension, osteoarthritis, mood and anxiety disorder, osteoporosis, diabetes, asthma, chronic obstructive pulmonary disease, ischemic heart disease, cancer, dementia, other), and time since diagnosis. Questions were retrieved from the Canadian Community Health Survey (CCHS) 2020 [21]. As a measure of restrictive public health measures burden, the pandemic wave at the time of study enrollment was used. Participants who completed the Rapid Response - Healthy Living questionnaire before the second wave was declared on September 23, 2020 (May 26-September 22, 2020) [22] were classified within the “lenient restrictions” category, while those who started the study after this cut-off (September 23-December 14, 2020) were classified within the “strict restrictions” category.

Other Lifestyle Behaviors

Participants were also asked to report on physical activity (≥ or <150 minutes/week [23]) and its intensity, based on the CCHS 2020 questionnaire. We queried on alcohol consumption (≤1 drink/week, 1-3 drinks/week, 4-8 drinks/week, 9-14 drinks/week, >15 drinks/week) using an adapted CCHS 2020 questionnaire to better capture short-term changes in alcohol intake since the start of the pandemic. Smoking (daily, occasionally, no) and sleeping time (hours) and quality (very good, fairly good, fairly bad, very bad) were also retrieved from the CCHS [24]. Participants answered according to the current situation and from before the pandemic. The current anxiety level was assessed using the General Anxiety Disorder-7 (GAD-7) [25], and depression was assessed using the 10-item Center for Epidemiologic Studies Depression Scale (CES-D-10; ≥10) [26]. We also queried on the self-reported change in the stress level compared to before the pandemic. If participants reported having 1 or more chronic diseases, questions were asked on medication and medication changes during the pandemic.

For each question, participants were given the option to respond with “I don’t know” or “I prefer not to answer.”

Weight and Lifestyle Behavior Changes

Baseline (during) versus prepandemic changes in weight and lifestyle factor status were categorized into 3 levels. For weight, a difference greater than +/–3% was considered an increase or a decrease in weight, respectively; participants with 0%-2.9% or insignificant weight change were categorized as having unchanged weight. For alcohol consumption, an upward change in 1 or more categories (<1 drink/week, 1-3 drinks/week, 4-8 drinks/week, 9-14 drinks/week, ≥15 drinks/week) was categorized as increased consumption, a downward change as decreased consumption, or no change as unchanged consumption. For physical activity level, a change in adherence to the WHO recommendations (yes or no) was categorized as increased (no to yes), decreased (yes to no), or unchanged (yes to yes or no to no). For eating habits, a perceived change was reported as improved, unchanged, or worsened. For sleep quality, an increase or decrease in 1 or more categories (very bad, fairly bad, fairly good, very good) was categorized as increased or decreased sleep quality, respectively, or otherwise categorized as unchanged. For smoking status (daily or occasionally/never), a change was categorized as increased (no to yes), decreased (yes to no), or unchanged (yes to yes, or no to no).

Statistical Analysis

Baseline characteristics were reported as means and SDs, and counts and percentages, as applicable. Latent class analysis (LCA) was used to identify lifestyle behavior change patterns based on 6 indicator variables: change in weight, alcohol consumption, physical activity, perceived eating habits, sleep quality, and smoking status. Models with 1, 2, and 3 classes were tested, and improvement in test statistics chi-square goodness of fit, Bayesian information criterion (BIC), Akaike information criterion (AIC), and entropy were used for model selection. Differences between participants’ characteristics and sociodemographics by class membership were examined using the chi-square for proportions, and the *t* test and Mann-Whitney U test for normally and nonnormally distributed data, respectively. Potential risk determinants of class membership were examined using logistic regressions. Model 1 was adjusted for age, gender, ethnicity, province, and burden of restrictive measure, and model 2 was adjusted for model 1 covariates and for body image perception, anxiety level, depression, chronic diseases, and changes in income, stress level, living situation, and work arrangement. Given the oversampling of women, gender-weighted sensitivity analysis was performed applying the Canadian 2019 Census gender proportions (women: 50.6%, men: 49.3%) [27] to improve the generalizability of results. Unweighted stratified analyses by age (< and ≥55 years), baseline BMI (< and ≥25 kg/m^2), and restrictive public health measure burden subgroups were conducted. P<.05 was considered statistically significant in all analyses. LCA and logistic regressions were performed using R version 4.1.2 (2021-11) in RStudio (R Foundation for Statistical Computing). This study's program is available on GitHub [28].

Results

Participants Characteristics

In total, 942 (46%) of 1609 participants were recruited between the end of the first wave of infections and the beginning of the second wave, that is, when lenient restrictive measures were in place. The other participants (1105/1609, 54%,) were recruited during the second wave of the pandemic, during strict restrictive measures. Table 1 shows prepandemic sociodemographic and lifestyle characteristics of participants. Participants mostly self-identified as women, were aged 18-89 years (mean 40.2, SD 15.5 years), and had a mean BMI of 26.1 (SD 6.3) kg/m^2. The majority were White, had at least a bachelor's degree, and reported having a household income > CA $50,000 (US $36,400) per year.

Self-Reported Changes in Weight, Lifestyle, and Living Factors

Since the pandemic, 35.1% (565/1609) participants had a decreased income, 49.0% (788/1609) changed their work arrangement, and 94.3% (1518/1609) kept the same living situation (1295/1609, 80.5%, were living with others, and 223/1609, 13.9%, were living alone). Regarding mental well-being, 52.2% (840/1609) participants reported a worsened mood and 63.8% (1026/1609) reported increased stress levels compared to before the pandemic. Among lifestyle factors, most of the population reported either no change or insignificant weight gain or loss and no change in alcohol intake, physical activity, smoking, and sleep quality, yet 44.1% (709/1609) reported a decreased perceived quality of eating habits (Table 2).

Table 2. Self-reported changes in sociodemographic status, weight, and lifestyle factors. All reported values are unweighted.

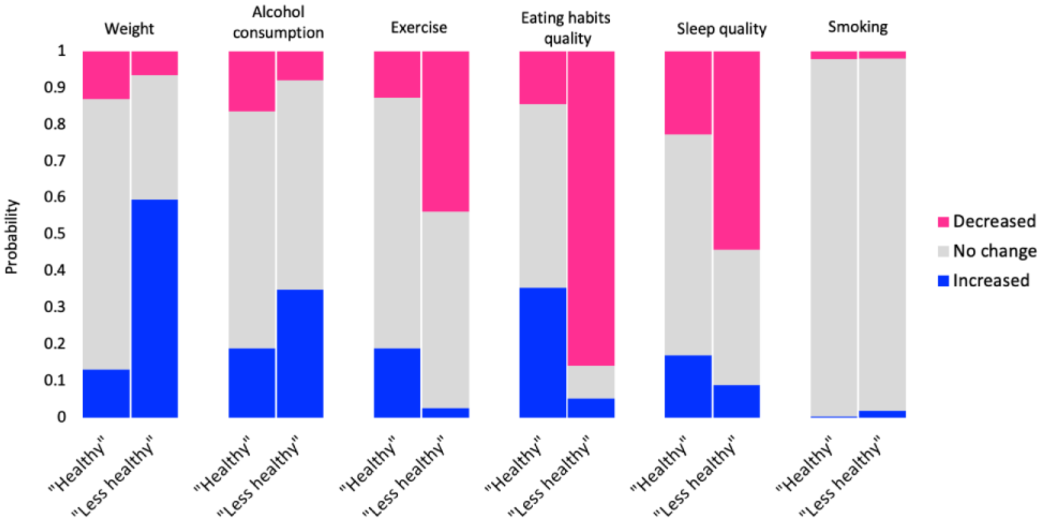
Factor	Increased, n (%)	Unchanged, n (%)	Decreased, n (%)
Weight	523 (32.5)	920 (57.2)	166 (10.3)
Perceived eating habit quality	369 (22.9)	531 (33.0)	709 (44.1)
Sleep quality	219 (13.6)	815 (50.7)	575 (35.7)
Physical activity level	196 (12.2)	1001 (62.2)	412 (25.6)
Smoking	17 (1.1)	1559 (96.9)	33 (2.1)
Alcohol consumption	412 (25.6)	991 (61.6)	206 (12.8)

Emergent Patterns of Change in Weight and Lifestyle Behaviors

Among the tested LCA models, the model with 2 emerging lifestyle behavior change classes had the best fit despite a slightly lower AIC compared to the model with 3 classes (Multimedia Appendix 2, Table S1) and was therefore selected for use. Participants with the class 1 membership (974/1609, 60.5%, population share probability) were more likely to report unchanged weight, sleep quality, smoking and alcohol intake, unchanged/improved eating habits, and increased physical activity. Participants with the class 2 membership (635/1609, 39.5%, population share probability) were more likely to report significant weight gain, deteriorated eating habits and sleep quality, unchanged/increased alcohol intake and smoking, and decreased physical activity. Class 1 was referred to as the healthy and class 2 as the less healthy pattern. Results from the LCA are presented in Figure 1.

Participants with the less healthy pattern were more likely to self-identify as women or a gender minority, to have a lower income prepandemic, and to live with 2 or more chronic diseases. They were also more likely to report a decreased income since the pandemic. Age, ethnicity, residential area, and change in the living situation did not differ between classes.

Figure 1. Two identified classes of change in weight and lifestyle patterns as a result of the pandemic. Classes were identified using LCA based on self-reported changes (prepandemic vs baseline) in weight, physical activity level, smoking, alcohol use, and sleep quality. LCA: latent class analysis.



Associations of Risk Factors With Identified Patterns of Lifestyle Behavior Change

Among risk factors, body image dissatisfaction (odds ratio [OR] 8.8, 95% CI 5.3-14.9), increased stress level (OR 3.4, 95% CI 2.0-5.8), depression (OR 1.7, 95% CI 1.2-2.4), and self-identifying as a gender minority (OR 5.5, 95% CI 1.3-22.3) were positively associated with adopting less healthy lifestyle behaviors in adjusted models (Figure 2 and Multimedia Appendix 2, Table S2). In addition, the province of Québec was inversely associated with less healthy lifestyle behavior changes (OR 0.51, 95% CI 0.33-0.80).

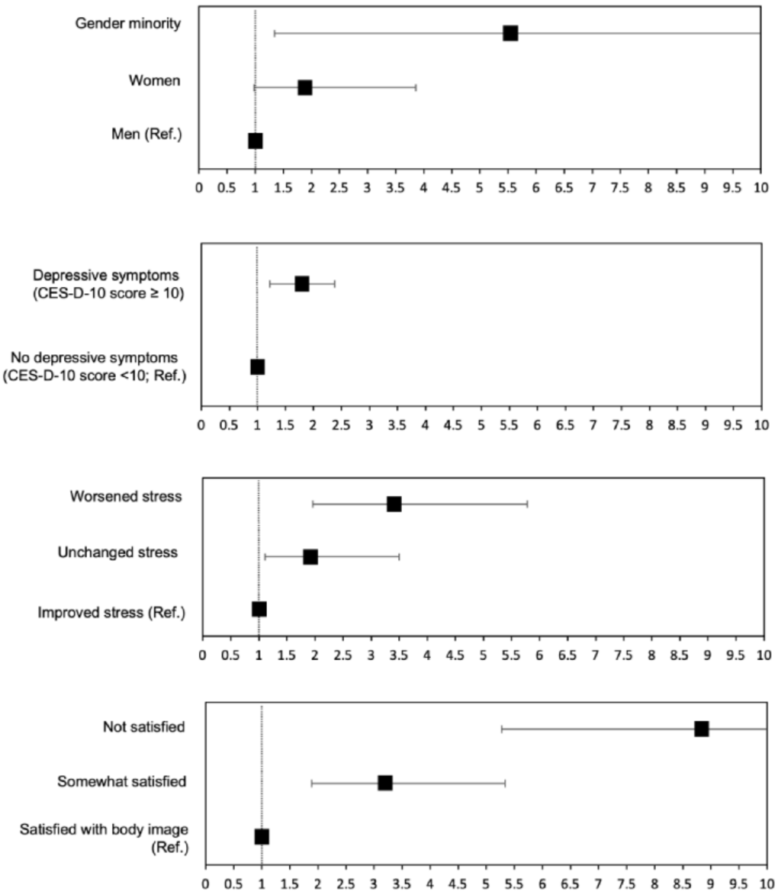
Gender-weighted sensitivity analysis showed a stronger positive association between women and the less healthy lifestyle behavior changes, and the association for gender minorities disappeared (Multimedia Appendix 2, Table S3). The results were otherwise consistent with the nonweighted analysis.

Stratified analysis by age group showed positive associations of body image dissatisfaction, symptoms of depression, increased stress, and women and minority genders with less healthy lifestyle behavior changes in younger adults (<55 years old) and positive associations of symptoms of anxiety and body image dissatisfaction with less healthy lifestyle behavior changes in older adults (Multimedia Appendix 2, Table S4). However, depressive symptoms, gender, and stress level were not determinants of lifestyle behavior change patterns in this subgroup. Living with a chronic disease was predictive of less healthy lifestyle behavior changes in older adults.

Stratified analysis by BMI group showed positive associations between body image dissatisfaction, symptoms of depression, increased stress levels, lenient restrictive measures at the time of enrollment, living with ≥2 chronic diseases, living situation change (lived with people and moved alone), and less healthy lifestyle behavior changes in those with a usual BMI of <25 kg/m^2 (Multimedia Appendix 2, Table S5). In participants with a usual BMI of ≥25 kg/m^2, increased stress levels, maintenance of the same work arrangement, and body image dissatisfaction were positively associated with less healthy lifestyle behavior changes. Living with ≥2 chronic diseases was predictive of less healthy lifestyle behavior changes in this population subgroup. Gender was not a determinant of the outcome within either BMI group.

Stratified analysis by the burden of restrictive measures at the time of enrollment showed body image dissatisfaction, symptoms of depression, and increased levels of stress to be positively associated with less heathy lifestyle behavior changes in both subgroups (Multimedia Appendix 2, Table S6). Living with ≥2 chronic diseases during lenient restrictive measures was predictive of less healthy lifestyle behavior changes. None of the participants recruited during lenient restrictive measures self-identified as a gender minority; gender was only significant within the subgroup of participants recruited during strict restrictive measures.

Figure 2. Unweighted adjusted ORs of the association between psychosocial factors and lifestyle pattern adoption (“less healthy” vs "healthy”). CES-D-10, 10-item Center for Epidemiologic Studies Depression Scale; OR, odds ratio; Ref., reference group. Tables S2 and S3 provide unweighted and gender-weighted ORs.



Discussion

Principal Findings

During the COVID-19 pandemic, more than half of the Canadian COVIDiet study adults reported no change in body weight, smoking status, exercise level, alcohol intake, and sleep quality; however, a dominant proportion (44%) reported worsened eating habits. Considering these lifestyle factors altogether, we identified 2 distinct lifestyle behavior change patterns: healthy and less healthy. The significant and independent determinants of a less healthy lifestyle behavior change pattern were body dissatisfaction, depression, increased stress levels since the pandemic, self-identifying as a gender minority, and the province of residence.

Several surveys have reported on changes in individual lifestyle factors during the pandemic in adults worldwide [10,29-40], but few observational studies have examined the overall lifestyle behavior change patterns and associated risk factors [41,42]. Similar to our findings and using comparable data-driven statistical approaches, one study found “favorable,” “unfavorable,” and “no change” lifestyle change groups in a French cohort [42], while another study identified “prohealthy,” “unhealthy,” and “constant” groups in a Polish population [41].

Adopting Healthy Lifestyle Behaviors

In this study, the healthy lifestyle behavior change pattern (974/1609, 60.5%) was mainly characterized by an increased physical activity level, unchanged or improved perceived eating habits, and stable weight, sleep quality, and smoking status. An increased physical activity level has also been reported in other countries [29,42]. It may have resulted from increased free time due to telework or from a desire to improve personal health in facing the disease outbreak. In addition, participants allocated to the healthy class were more active at baseline, which may have led them to coping with the pandemic-related stress with exercise [43], thus increasing their physical activity level, while decreasing stress levels. With regard to diet, stable and improved eating habits were observed in our study and elsewhere [4,29,42]. Staying at home may have favored the avoidance of less healthy food, such as fast food, and more frequent cooking for some individuals [4,29,42,44]. One study in the Canadian province of Québec (NutriQuebec study; N=853, with 87.2% women, 52.5% aged 50-69 years) showed a slight overall increase in diet quality (+1.1/100 points in the Healthy Eating Index-2015; 95% CI 0.6-1.5) during early lockdown (April-May 2020), especially in younger adults, in those with lower education, or in those with obesity [4]. Although not directly comparable, only 22.9% (369/1609) of the overall population reported improved eating habits and a larger proportion reported worsened eating habits (709/1609, 44.1%) in our study. In addition, only 35.5% (346/974) reported improved eating habits and the majority reported unchanged habits in the healthy lifestyle behavior change group. This suggests that the diet quality of Canadians may not have improved at a population level; in-depth dietary assessment will permit more robust conclusions. Lastly, the COVID-19 pandemic appears to have had disproportionate impacts on populations living with social inequalities [45]. Participants in the healthy pattern group were more likely to self-identify as men, to report higher and unchanged household incomes, to be satisfied with their body image, and to be living with less than 2 chronic diseases. The lifestyle behavior changes observed in this group may be reflective of social privilege.

Adopting Less Healthy Lifestyle Behaviors

Contrastingly, the less healthy lifestyle behavior change pattern (635/1609, 39.5%) was characterized by perceived worsened eating habits, decreased physical activity, decreased sleep quality, and weight gain. Similar patterns of lifestyle habit deterioration were observed in Canada, predominantly in British Columbia [46], and in other countries [47]. Another Canadian study (N=2338, with 90.2% women, February-April 2020) showed that although moderate-to-vigorous activity tracked with wearable devices returned to the prepandemic level 6 weeks after an initial decline in March 2020, the step count and light physical activity remained lower [48]. The lockdown imposed important modifications on daily physical activities, including work-related commuting interruption due to telework or unemployment, the prohibited practice of team sports, and the closure of fitness centers. Those at higher risk of complications and particularly worried of contracting COVID-19 possibly took extra isolation precautions and reduced their physical activity level. In addition, our data show that 1 independent determinant of the less healthy classification was increased levels of stress. Both objective and subjective measures of stress have been shown to hinder physical activity levels, especially in less active individuals [43]. Worsened eating habits may be explained by modified food supply and food choices due to more limited access to grocery stores, fresh food, and working from home. Increased snacking and sweet consumption have been reported in numerous global studies (reviewed in [49]) and may have contributed to participants' perception of worsened eating habits. In addition, the less healthy lifestyle behavior change class more likely reported increased alcohol intake. Altogether, these factors probably explain the observed body weight increase in this group. Comparably, in the NutriNet-Santé cohort study (France; N=37,252; weighted proportions: 52.3% women, 42.5% aged 25-50 years), among the 3 clusters identified, 1 reflected unfavorable changes that included decreased physical activity, increased snacking and sweet consumption, decreased vegetable and fruit consumption, and weight gain between March and May 2020 [50]. These changes were associated with being a woman, working from home, the presence of children at home, a lower income, and more depressive symptoms. In our study, individuals in the less healthy lifestyle behavior change group also more likely reported increased stress levels and anxiety and depressive symptoms and a greater proportion had more than 2 chronic diseases and reported a decreased income. A healthy lifestyle, including regular physical activity and high diet quality, were associated with reduced risk of chronic diseases [51] and mortality [52]. As a strategy to promote health during self-quarantine, the WHO regional office for Europe released physical activity and dietary guidelines [52]. However, none were made available in Canada in the early months of the pandemic. The impact of such guidelines on public health during the pandemic remains to be assessed.

Factors Associated With Lifestyle Behavior Changes

Among potential risk factors, body image satisfaction was the strongest determinant of lifestyle behavior change patterns during the pandemic, independent of several other factors, including gender, age, and income. Close to half of the studied population (707/1609, 43.9%) reported being not satisfied with their body image during the pandemic, a proportion higher than that observed in a population survey in Canada before the pandemic (15%) [53]. Body image dissatisfaction was also more frequent in those self-identifying as women and gender minorities, compared to men, which is typically observed in Western societies [54,55]. Evidence supports that individuals dissatisfied with their body image may have poorer mental health [56] and may engage in less healthy lifestyle behaviors, such as decreased physical activity [57]. A study showed an association of worsened body image dissatisfaction with increased psychological distress during the pandemic [58]. Yet, in our study, body image dissatisfaction was associated with less healthy lifestyle behavior changes independent of stress, anxiety, and depression. The reverse association is also possible, that is, those who adopted less healthy lifestyle behavior changes, including weight gain, may have experienced a greater level of dissatisfaction toward their body image. In our study, the majority of participants also reported increased stress levels since the pandemic (1026/1609, 63.8%), which was associated with less healthy lifestyle behavior changes. Compelling prepandemic evidence has supported an association of stress, anxiety, and depression with poorer lifestyle behaviors, including weight gain [59-63]. However, the pandemic appears to have exacerbated negative mental health in some individuals, putting them at risk of adopting poorer lifestyle behaviors [17] or vice versa [64].

Limited data of the impact of the COVID-19 pandemic on gender minorities have been collected and are available. In our study, self-identifying as a gender minority was associated with adopting less healthy lifestyle habits; although the sample size was small for this group (24/1609, 1.2%), the proportion was comparable to that reported in Canada (0.33% from Census data) [65]. Current evidence supports high rates of worsening physical and mental health outcomes during the pandemic among individuals belonging to gender minorities [66,67]. From stratified analyses, both self-identifying as a woman and self-identifying as a gender minority were associated with less healthy lifestyle behavior changes among younger participants (<55 years) only. Before the pandemic, women (compared to men) and gender-diverse individuals (compared to men and women) already reported poorer mental health in Canada. Since the beginning of social distancing, negative mental health has been reported in women and gender minorities in Canada [68] and elsewhere [58,69-71]. In people belonging to gender minorities, the lack or loss of access to community groups, stigmatization, and negative psychological outcomes of the pandemic may have contributed to the adoption of less healthy lifestyle behavior changes [66]. In younger women and gender minorities, the telework and at-home childcare arrangement may have further adversely impacted lifestyle behaviors [42,71].

Living in the province of Québec was significantly associated with adopting healthier lifestyle behaviors during the pandemic compared to Ontario and other large provinces. Yet, restrictive measures have been comparable across these provinces throughout the pandemic [1]. Some evidence suggests that the Québec population may have experienced healthier changes [4]. However, the association with healthier lifestyle behavior changes during the pandemic is most likely attributable to greater recruitment in this province during less stringent restrictive measures in our study (Québec: 301/576 during lenient and 71/1033 during strict restrictions; Ontario: 139/576 during lenient and 464/1033 during strict restrictions).

Strengths and Limitations

The strengths of this study include the overall large sample size and adequate representation across provinces. Another strength is the use of LCA, as opposed to using measures of central tendency, that allowed us to identify 2 classes and informed on distinct patterns within the population.

The study also has limitations. First, variations in restriction measures were observed across provinces between the start and the end of recruitment, which may have contributed to confounding residuals, although our models were adjusted for the pandemic phases during which participants responded to the questionnaire. Second, the use of self-reported lifestyle questionnaires may have introduced subjectivity to measurements. Third, the use of advertisement strategies combined with the nature of our study may have led to selection bias of more educated and healthier individuals. In addition, the over-/undersampling of specific groups of individuals, namely gender and age, may have limited the generalizability of our results to the Canadian population; however, our sensitivity analysis using gender-based calibration weights showed consistent results with our main analysis (Multimedia Appendix 2, Table S3). Fourth, although subgroup analysis by age, baseline BMI, and pandemic wave group was successfully conducted, it was not possible to examine the associations between risk factors and lifestyle behavior change patterns across ethnic and gender groups; further studies with a larger sample size within each, especially ethnic and gender minorities, are warranted.

Conclusion

Findings from this observational study showed that 39.5% (635/1609) of participants adopted less healthy lifestyle behaviors during the COVID-19 pandemic but that the majority (974/1609, 60.5%) adopted healthier behaviors. Factors such as body image perception, depression status, change in the stress level, and gender identity may have motivated these lifestyle behavior changes. It is yet to be determined whether the latter will sustain in the long term. In the postpandemic period, multidisciplinary strategies involving dietitians, psychologists, and kinesiologists may be considered to assist adults in (re)gaining mental and physical health. Lockdown-adapted public health recommendations and resources related to nutrition, physical activity, sleep, and smoking should be promoted during future outbreaks.

Acknowledgments

AJT, SC, and ASB elaborated the study design. SC, ASB, AIR, AM, CFG, CL, HY, SLB, and AJT contributed to participant recruitment. AM, CL, and AIR conducted the study and data collection. HY contributed to data preparation. AM and AJT contributed to table and figure preparation. AJT conducted statistical analyses and drafted the manuscript. SC obtained ethics approval and funding and supervised all activities. All authors have read, edited, and approved the final manuscript. This research was funded by McGill University.

Data Availability

The data sets generated and analyzed during the study are not publicly available due to ethical restrictions but are available from the corresponding author upon reasonable request.

Conflicts of Interest

None declared.

Multimedia Appendix 1

STROBE diagram showing the flow of participants in the Canadian COVIDiet cohort study. Inclusion criteria included reading and speaking English or French, owning a smartphone or tablet, and access to the internet. Exclusion criteria were living with an active and uncontrolled acute disease that interfered with usual food intake, being hospitalized, being pregnant, or living in care homes or other institutional environments.

Abstract

Background: Practicing healthy lifestyles can reduce the risk to develop noncommunicable diseases and the related mortality. Studies showed that practicing healthy lifestyles could enhance disease-free life expectancy and preserve bodily functions. However, engagement in healthy lifestyle behavior was suboptimal.

Objective: This study aimed to define individuals' lifestyle characteristics before and during COVID-19 and determine the factors associated with practicing a healthy lifestyle. This cross-sectional study was conducted using data from the 2019 and 2021 Behavioral Risk Factor Surveillance System surveys.

Methods: US individuals aged ≥18 years were interviewed via phone call. Healthy lifestyles were assessed through corresponding questions regarding the maintenance of optimal body weight, physical activity, daily consumption of at least five portions of fruits and vegetables, current smoking status, and alcohol consumption. Missing data were imputed using a package in the R statistical software. The effects of practicing a healthy lifestyle on cases without missing data and those with imputation were reported.

Results: There were 550,607 respondents (272,543 and 278,064 from 2019 and 2021, respectively) included in this analysis. The rates of practicing a healthy lifestyle were 4% (10,955/272,543) and 3.6% (10,139/278,064) in 2019 and 2021, respectively. Although 36.6% (160,629/438,693) of all 2021 respondents had missing data, the results of the logistic regression analysis for cases without missing data and those with imputation were similar. Of the cases with imputation, women (odds ratio [OR] 1.87) residing in urban areas (OR 1.24) with high education levels (OR 1.73) and good or better health status (OR 1.59) were more likely to practice healthier lifestyles than young individuals (OR 0.51-0.67) with a low household income (OR 0.74-0.78) and chronic health conditions (OR 0.48-0.74).

Conclusions: A healthy lifestyle should be strongly promoted at the community level. In particular, factors associated with a low rate of practice of healthy lifestyles should be targeted.

healthy lifestyle; health risk behaviors; habits; noncommunicable diseases; population surveillance; Behavioural Risk Factor Surveillance System; BRFSS

Introduction

Noncommunicable diseases (NCDs) are chronic health conditions including cardiovascular diseases and diabetes, which were responsible for approximately 74% deaths worldwide in 2019 [1]. Practicing a healthy lifestyle reduces the risk of NCDs and associated all-cause mortality [2-5]; it has been shown to reduce 78% and 42% of incident diabetes and hypertension, respectively [2,3]. The following 5 components determine a healthy lifestyle: optimal body weight, regular physical activity, healthy diet, smoking cessation, and limited alcohol consumption. Loef and Walach [4] conducted a meta-analysis of 15 studies and reported that strict adherence to most of these components could significantly reduce all-cause mortality (ie, from 26% to 68%). These findings were supported by the results of a cohort study involving 487,198 healthy adults; after a median follow-up of 10.2 years, Zhu et al [5] reported that practicing a healthy lifestyle could reduce up to 68% of the all-cause mortality and mortality rate associated with ischemic heart disease (58%), stroke (79%), and respiratory diseases (81%). A large-scale cohort study involving 111,562 participants with 28-34 years of follow-up showed that a healthy lifestyle could enhance disease-free life expectancy at 50 years of age by up to 31.1 years [6]. Another 3-year follow-up cohort study involving 3107 older adults found that practicing a healthy lifestyle could alleviate the deterioration of gait speed and cognitive function [7]. In brief, practicing a healthy lifestyle can reduce all-cause mortality, slow down the progression of NCDs, and preserve bodily functions. Accordingly, the World Health Organization (WHO) has recommended practicing healthy lifestyles to prevent the risk of NCDs across all age groups [8].

Despite this, engagement in healthy lifestyle behaviors has remained suboptimal, with some factors hindering individuals from pursing such lifestyles. Using a random sampling technique, Azizan et al [9] investigated adherence to a healthy diet among low-income individuals in Malaysia; only 34.8% of the 1450 participants followed a healthy diet. A low level of education and diabetes prevented individuals from following a healthy diet [9]. However, a cross-sectional study conducted in Iran comprising 500 patients with diabetes revealed that over 80% of the participants followed healthy diets and were physically active; the use of convenience sampling technique might be the reason of the high adherence rate of healthy diets and physical activity [10]. Another cross-sectional study conducted in Jordan, using random sampling, involving 1000 patients with hypertension reported that only 23% of the included participants practiced healthy lifestyles; being men and having a low level of hypertension knowledge prevented the participants from practicing healthy lifestyles [11]. On the other hand, fewer rural residents practice healthy lifestyles [12,13]. This might be why a higher mortality rate was noted in the rural areas [14]. Different sociodemographic conditions, comorbidities, and residential areas may influence individuals' decisions to practice healthy lifestyles.

A healthy lifestyle should be promoted at all ages. Studies have shown that practicing a healthy lifestyle may not always result in satisfactory outcomes and that many factors can influence individuals' decisions to pursue such lifestyles. However, COVID-19 has markedly altered our living environments and behaviors [15-17]. For example, a 3-month longitudinal study found that people spent less time visiting public places and became physical inactivity during COVID-19 [18]. Previous studies assessing healthy lifestyles were conducted at the community level and before the pandemic was announced. Our main objectives were to (1) define the individuals' characteristics and their practice of healthy lifestyles in 2019 and 2021 and (2) determine the factors associated with practicing a healthy lifestyle.

Methods

This cross-sectional study was reported in accordance with the Strengthening the Reporting of Observational Studies in Epidemiology guideline [19]. The study was performed using publicly available data from the Centers for Disease Control and Prevention (CDC).

Data Sources

Secondary analysis of data from the 2019 and 2021 Behavioral Risk Factor Surveillance System (BRFSS) surveys, which are national annual surveys that investigate health-related behaviors and health conditions of noninstitutionalized US adults aged ≥18 years, was performed [20]. The surveyor used the random-digit–dialing technique to generate random phone numbers for telephone and mobile phone interviews across 50 states in the United States, the District of Columbia, Guam, Puerto Rico, and the US Virgin Islands. The latest BRFSS survey was conducted in 2021. The median survey response rate of the 2019 BRFSS survey and 2021 BRFSS survey was 49.4% and 44%, respectively [20,21].

Study Population

Cases for which data regarding sociodemographic variables or chronic health conditions were missing and individuals who refused to answer questions were excluded from the study. We included 272,543/418,268 (65.2%) and 278,064/438,693 (63.4%) individuals from the 2019 and 2021 BRFSS 2021 surveys, respectively.

Variables

Sociodemographic Characteristics and Perceived Health

Following previous studies [9-12], several sociodemographic variables and the perceived health were extracted from the BRFSS surveys. Marital status, employment status, and housing were recategorized in this study, whereas the rest followed the categorizations from the BRFSS survey. In addition, some variables were recategorized in the logistic regression analysis, where perceived health was categorized as "fair or poor" (including the rating of fair and poor) and "good or better" (including the rating of good, very good, and excellent) and education level was recategorized as "high school or less" (including attended and graduated from high school) and "college and above" (including attended and graduated from college).

Healthy Lifestyle

A healthy lifestyle was defined by adherence to healthy behaviors and the avoidance of risky behaviors. Based on the items in the BRFSS and WHO recommendations [8], health behaviors were determined by three components: (1) optimal body weight, defined by a no response to the item “adults who have a body mass index greater than 25”; (2) physical activity, defined by the item “adults who reported doing physical activity or exercise during the past 30 days other than their regular job”; and (3) healthy diet, defined by the reports of the daily consumption of at least five portions of fruits and vegetables.

Following WHO recommendations [8], two risky behaviors were investigated: (1) current smoker status, which was directly surveyed using the BRFSS; and (2) excessive alcohol users, defined as heavy or binge drinkers.

Chronic Health Conditions

Several chronic health conditions, namely hypertension, high cholesterol, diabetes, asthma, chronic obstructive pulmonary disease, and depression, were assessed using the BRFSS survey data.

Statistical Analysis

Data were analyzed using the R statistical software (R Foundation for Statistical Computing). Logistic regression analysis was used to investigate which independent variables were associated with practicing healthy lifestyles (dependent variable). These independent variables included the sociodemographic characteristics, health status, and health-related behaviors. To inform future research, the latest 2021 data set was analyzed. Because the percentage of the excluded subjects was as high as 36.6% and the missing rate of outcome variables were associated with various covariates (missing at random instead of missing at completely random), multiple imputations were conducted to estimate the missing variables among the excluded subjects. Five imputed data sets were created by the *multiple imputation via chained equations (MICE)* package in R.

MICE imputation starts by a simple imputation such as mean imputations on all variables with missing value. Then, these imputed missing values are updated by running a series of regressions, whereby each variable with missing value is regressed upon other variables repeatedly until convergence. For cases with imputations, logistic regression analyses were performed for each of the imputed data sets. The regression coefficients were combined using the *pool()* function within the *MICE* package. In addition, we used the *detectseparation* package in R to check if there was any multicollinearity in our logistic regression analysis. The results of the 2021 data set logistic regression analyses were presented both for cases without missing data and for those with imputations. A *P* value <.05 was considered statistically significant.

Ethical Considerations

The surveys were conducted by US federal agencies where verbal consent was obtained from each participant prior to the data collection [20,21]. The BRFSS data set are allowed for secondary data analysis without permission required. No institutional review board approval or patient informed consent was required for secondary data analysis. The participants’ personal information had been deidentified in the data set prior to being publicly available [20,21].

Results

Individual Characteristics

We analyzed 550,607 respondents (272,543 and 278,064 from the 2019 and 2021 BRFSS surveys, respectively; Table 1). The majority of the respondents were female (n=284,876, 51.7%) and resided in urban areas (n=468,547, 85.1%); 35.2% (n=193,850) of the respondents were aged 65 years and older. Regarding health and related behaviors, 83% (n=456,846) of individuals were perceived to have a good or better health status. Hypertension (n=276,148, 50.2%) and high cholesterol (n=248,440, 45.1%) were the most commonly reported chronic diseases. The percentage of respondents who performed physical activity was greater in 2021 than in 2019 (214,943/278,064, 77.3% vs 204,733/272,543, 75.1%); in contrast, the percentage of smokers was lower in 2021 than in 2019 (36,983/278,064, 13.3% vs 38,662/272,543, 14.2%). The percentage of practicing a healthy lifestyle nonsignificantly decreased from 4% in 2019 to 3.6% in 2021.

Predictors of Practicing Healthy Lifestyles

Table 2 shows the results of the logistic regression analysis for cases without missing data in 2019 and 2021 who practiced healthy lifestyles; similar results were obtained for 2019 and 2021. In 2021, female individuals (odds ratio [OR] 1.95; *P*<.001) who had a high level of education (OR 1.99; *P*<.001), were single (OR 1.10; *P*=.02), unemployed (OR 1.10; *P*=.001), and had perceived good health (OR 1.62; *P*<.001) were found to have a higher likelihood of practicing healthy lifestyles. Compared with adults aged 65 years and above, young adults aged 18-64 years tended not to practice healthy lifestyles (OR 0.53-0.66; *P*<.001). Individuals with a low household income have a low likelihood of practicing healthy lifestyles (OR 0.72-0.79; *P*<.001).

Individuals with chronic health conditions had a low likelihood of practicing healthy lifestyles. The data in Table 2 show that individuals with NCDs such as hypertension and diabetes had a low likelihood of practicing healthy lifestyles (OR 0.48-0.83; *P*<.001).

For the cases with imputations, the weighted estimates of the logistic regression analysis results from 5 imputed data sets are presented in Table 3 (n=438,693). The rates of missing outcomes of healthy lifestyles in each variable are reported in Table S1 in Multimedia Appendix 1; briefly, the rate varied from 14.1% (61,858/438,693) to 27.3% (119,823/438,693). The weighted estimates were in line with those for cases without missing data (Table 2). Multicollinearity was not detected in all regression analyses.

Table 2. Logistic regression analysis of practicing a healthy lifestyle among complete cases without missing data in 2019 and 2021.

Discussion

Principal Findings

This study assessed the determinants of practicing healthy lifestyles at the national level using 2019 and 2021 BRFSS survey data. The distribution of sociodemographic variables and health and related behaviors were similar for both the surveys. However, the tendency to practice healthy lifestyles slightly decreased in 2021. The logistic regression analysis results indicated that female individuals residing in urban areas with a higher level of education were more likely to practice healthy lifestyles, whereas younger individuals with a low household income were less likely to do so. Although chronic health conditions hindered individuals from practicing healthy lifestyles, those with perceived good or better health were more likely to practice healthy lifestyles.

However, the overall rate of practicing a healthy lifestyle was still very low. Fang et al [22] analyzed 2013 BRFSS data and reported that only 1.7% of the assessed individuals with hypertension practiced healthy lifestyles. Other studies have shown that 2.1% of healthy adults and 6% of health care providers practiced healthy lifestyles [5,6]. Moreover, although more individuals performed physical activity, the percentage of individuals with optimal body weights and following healthy diets decreased. High BMI and unhealthy diet were major risk factors for disability and premature death worldwide [23,24]. In this study, we found that the individuals' residences considerably affected their decisions to practice healthy lifestyles. Rural residents reported that they received limited access to health-related information from health care providers [25]. Although the overall number of health care providers, such as physicians, nurse practitioners, and physician assistants, in the United States significantly increased between 2009 and 2017, the urban-rural disparities remained significant; the number and density of health care providers increased to a greater extent in urban areas than in rural areas [26]. Therefore, a healthy lifestyle should be strongly promoted, and urban-rural health disparities should be tackled urgently.

In concordance with previous studies [9,11,27], our results showed that individuals with a low household income, who were male, and had high school or lower levels of education were less likely to practice healthy lifestyles. Although married people were more likely to practice healthy lifestyles, results from another national survey revealed that such individuals were more likely to be overweight or obese [28]. In contrast, we found that young people (aged <65 years) were less likely to practice healthy lifestyles. Thus, early health promotion is required because the risk of developing NCDs exponentially increases after 50 years of age [29].

Practicing healthy lifestyles among individuals with hypertension were focused because hypertension has been the leading risk factor for global disease burden worldwide for a decade [23,30]. Although certain guidelines recommend healthy lifestyles and medical treatments to effectively control blood pressure [31-33], our analysis showed that individuals with hypertension were less likely to practice healthy lifestyles. A Finnish cohort study involving 41,225 participants followed up over 4 years reported that the initiation of antihypertensive treatment significantly decreased the tendency of individuals with hypertension to practice healthy lifestyles (OR 0.55-0.92) [34]. As blood pressure can indeed be controlled with medications, less attention has been paid to individuals with hypertension practicing healthy lifestyles. Approximately 82.3% of individuals with hypertension in the United States use antihypertensive medications [35]; they might not practice healthy lifestyles as their blood pressure is medically controlled.

Concern about around those with diabetes practicing healthy lifestyles have been raised, because these individuals showed the least likelihood of doing so. A healthy lifestyle has been indicated in various diabetes management guidelines [36,37]. However, our findings revealed that individuals with diabetes were the least likely to practice healthy lifestyle, showing the smallest OR among all variables. Individuals with diabetes have emphasized that education and support from health care providers can enhance their self-care tendencies [38]. Hence, new methods for diabetes care should be used.

Implications

Our study findings have strong implications for clinical practice, research, and policy making. The low likelihood of practicing healthy lifestyles highlights the need for strengthening current practices. Health education supported by printed materials, phone calls, and SMS text messaging may improve individuals' adherence to healthy lifestyles and medical treatments [39-43]. Given the rapid increase in smartphone ownership and advancing technologies [44], digital interventions such as website and smartphone apps have been shown to slightly improve adherence to a healthy lifestyle [45-47]. Supportive methods and digital interventions can be integrated into current health promotion activities to facilitate healthy lifestyles and widen the possibility of receiving health-related information and support from health care providers, especially for rural residents. Moreover, digital interventions can help overcome the barriers to public health measures caused by COVID-19 [18]. However, we noted that several sociodemographic characteristics can hinder individuals from practicing healthy lifestyles. Additionally, there may be associations between depression, ethnic background, and socioeconomic status [48]. Future studies can explore the associations and focus on developing specific interventions that promote healthy lifestyles among such individuals.

Rural residents showed a low likelihood of practicing healthy lifestyles; this highlights the need of support from policy makers. A cohort study of 25,014 middle-age and older adults with a 20-year follow-up revealed that performing any type of physical activity could significantly reduce the likelihood of hospitalization to a mean of 0.42 days per year; this reduced likelihood of hospitalization could reduce health care expenditures by approximately 7% [49]. Moreover, some amount of the saved health care expenditure could be granted as tax deductions to individuals who participate in healthy lifestyle programs and provide evidence of practicing such lifestyles (ie, reduced body weight). Such tax deductions can attract more people toward healthy lifestyles, further decreasing the overall health care expenditure. The shortage of health care providers may be managed through the use of digital interventions for providing education and support to residents in rural areas. However, more interventions should be developed to attract health care providers to work and remain in rural areas. For example, increased training in rural areas, the payment of locum relief, and loan repayment may help do so [50].

Limitations

This study has 4 key limitations. First, the variables in the secondary analysis were limited to the data set used. For example, only 1 question in the data set investigated the individuals' physical activity habits. Moreover, the question was rather general and inquired whether the individuals performed any type of physical activity or exercise during the past 30 days. Two essential components—frequency and intensity—were not explored. Thus, our study findings might not adequately represent the level of physical activity as recommended by the WHO [51]. Second, all variables were reported by individuals via phone call. Therefore, we might have encountered reporting biases arising from the participant's recall from memory, and the interviewers may have recorded the responses incorrectly. To address such issues, the CDC has created a program to identify errors or conditions of concern due to data entry by the interviewers [20,21]. Third, although the phone numbers used in each year were not repeated, it was unclear if some numbers would be used in the other survey years. Hence, it was possible that some people might have responded to both surveys in this study. Fourth, the overall rate of missing data was high at 36.6% in 2021, which could have impacted the generalizability of the results. However, we performed multiple imputations, and the pooled results of the imputed data were in line with those from the cases without missing outcomes. Hence, our imputed data provided an accurate estimation of the influence of sociodemographic variables and chronic health conditions on practicing healthy lifestyles and enhanced the generalizability of our findings.

Conclusions

Practicing a healthy lifestyle can have numerous health benefits across all age groups. We found that very few people practiced healthy lifestyles before and during COVID-19. Some sociodemographic variables and chronic health conditions were identified as significant factors affecting individuals' decisions to practice healthy lifestyles. Several interventions were suggested to strengthen the promotion of healthy lifestyles at the community level and to attract more health care providers to work and remain in rural areas.

Abstract

Background: The initial wave of the COVID-19 pandemic placed a tremendous strain on health care systems worldwide. To mitigate the spread of the virus, many countries implemented stringent nonpharmaceutical interventions (NPIs), which significantly altered human behavior both before and after their enactment. Despite these efforts, a precise assessment of the impact and efficacy of these NPIs, as well as the extent of human behavioral changes, remained elusive.

Objective: In this study, we conducted a retrospective analysis of the initial wave of COVID-19 in Spain to better comprehend the influence of NPIs and their interaction with human behavior. Such investigations are vital for devising future mitigation strategies to combat COVID-19 and enhance epidemic preparedness more broadly.

Methods: We used a combination of national and regional retrospective analyses of pandemic incidence alongside large-scale mobility data to assess the impact and timing of government-implemented NPIs in combating COVID-19. Additionally, we compared these findings with a model-based inference of hospitalizations and fatalities. This model-based approach enabled us to construct counterfactual scenarios that gauged the consequences of delayed initiation of epidemic response measures.

Results: Our analysis demonstrated that the pre–national lockdown epidemic response, encompassing regional measures and heightened individual awareness, significantly contributed to reducing the disease burden in Spain. The mobility data indicated that people adjusted their behavior in response to the regional epidemiological situation before the nationwide lockdown was implemented. Counterfactual scenarios suggested that without this early epidemic response, there would have been an estimated 45,400 (95% CI 37,400-58,000) fatalities and 182,600 (95% CI 150,400-233,800) hospitalizations compared to the reported figures of 27,800 fatalities and 107,600 hospitalizations, respectively.

Conclusions: Our findings underscore the significance of self-implemented prevention measures by the population and regional NPIs before the national lockdown in Spain. The study also emphasizes the necessity for prompt and precise data quantification prior to enacting enforced measures. This highlights the critical interplay between NPIs, epidemic progression, and human behavior. This interdependence presents a challenge in predicting the impact of NPIs before they are implemented.

Introduction

Spain was among the strongest-hit countries worldwide during the first wave, with officially 28,000 fatalities attributed to COVID-19 [1]. In terms of excess deaths, there was an alarming increase of 80% [2], coupled with an attack rate of about 5% [3]. In response to the rapidly rising case numbers, the Spanish authorities implemented stringent containment measures to control the spread of SARS-CoV-2.

The first case in Spain was reported on January 31. The first local transmission was reported on February 26. On March 8, all autonomous communities (Comunidades Autonomas [CCAA]) had reported local transmission. The fast-rising case numbers led the authorities to impose a national lockdown on March 15. Bars, hotels, and restaurants had to close, and individuals were only allowed to leave their homes for work and essential shopping. However, the national lockdown was foregone by various regional measures. On March 10, Madrid and Álava (Basque Country) closed the entire educational system. Other CCAA followed shortly afterward. Madrid and Andalusia closed the gastronomy sector on March 13 and 14, respectively. Additional local measures consisted of the cancellation of festivities and football matches.

The Spanish government declared a state of emergency on March 14, a day before the lockdown took effect. Despite the lockdown being in place, case numbers were still rising toward the end of March [1]. As a result, the national authorities intensified the lockdown between March 28 and April 12, during which all nonessential economic activities came to a halt. The lockdown was then gradually lifted from May 2 onward under the competence of the local authorities (CCAA).

In short, the nonpharmaceutical interventions (NPIs) issued by the national and local authorities, which came along with a strong reduction in mobility, were eventually sufficient to mitigate the daily infections. A thorough analysis of the series of events that shaped the epidemic evolution during the first wave, as performed in various countries [4-10], is essential to design future mitigation strategies of COVID-19 or other emerging respiratory diseases [11,12].

The imposed NPIs and voluntarily practiced social distancing caused a strong reduction in contacts that was reflected by a decrease in mobility. Different studies show that mobility is a robust indicator for the evolution of the epidemic and, hence, the reproduction number [6,9,13-17]. The relationship was most evident during the early phase of the epidemic, when there was no efficient contact tracing in place and only minor use of face masks [16]. Accordingly, a joint analysis of mobility and epidemiological data can provide valuable insight into the evolution of the first wave in Spain.

Moreover, a combined examination provides an opportunity to investigate the factors influencing epidemic trends beyond the implementation of NPIs. Numerous earlier studies that assessed the epidemic's progression assumed sudden shifts in transmission rates as NPIs were implemented [4,18,19]. This method may potentially exaggerate the effects of NPIs, as it does not account for the voluntary behavior modifications of the population that could impact the epidemic's trajectory. By addressing this issue, the integrated analysis presented here offers a more comprehensive perspective on the forces driving the dynamics.

More specifically, in this study, we first evaluate large-scale mobile phone data to show how mobility evolved in the face of rising case numbers and during the lockdown. In particular, we analyze whether there was any change in mobility prior to the introduction of the lockdown. To determine the impact of mobility on the epidemic dynamics, we then contrast the evolution of mobility with epidemiological data, such as case numbers, hospitalizations, and fatalities. More specifically, we blend a direct analysis of the epidemiological data [5,18] and model-based inference [10,19-21]. Furthermore, leveraging the model-based inference, we evaluate the evolution of the underreporting of infections over time. Finally, although most previous studies have focused exclusively on the impact of NPIs, this model-based approach allows us also to build counterfactual scenarios and quantify how the epidemic response that anticipated the lockdown substantially reduced the impact of SARS-CoV-2 in Spain during the first wave.

Methods

Mobility Data

The data were provided by the Ministry of Transport, Mobility and Urban Agenda (MITMA) [22]. The raw data stemming from 1 mobile network provider consisted of the anonymized individual trajectories of about 13 million individuals. Beyond the intrinsic limitation of mobile phone data, we assumed that the 13 million individuals would provide a reasonable sample of the Spanish population. By using additional information, such as land usage, sociodemographic indicators, the transport network and the schedule of the public transport, the raw data were transformed into an origin-destination matrix by the MITMA. We directly used the origin-destination matrices and did not have access to the raw data. More details can be found in the methodological note provided by the MITMA [23]. Trips are recorded on the level of municipalities and aggregated on an hourly basis. Additionally, trips are separated into 6 different distance classes. To calculate the mobility reduction on a national or provincial level, we summed up the number of trips and compared it to the corresponding day during the reference period (February 14-20).

Reconstruction of Exposure Times

We reconstructed the exposure times for different autonomous communities and regions (CCAA) by using a deconvolution process with the symptom onset data. This method allowed us to estimate the time individuals were exposed to the virus before they started exhibiting symptoms, providing a more accurate understanding of the transmission dynamics within each region. By tracing back the exposure times, we can gain valuable insights into the infection patterns and better assess the effectiveness of various interventions and public health measures implemented across the CCAA. This information can then be used to improve and refine epidemic models and guide future decision-making to better control the spread of the virus. More specifically, we used the backprojNP function [24] from the *surveillance* package [25,26] in R. The method, initially proposed by Becker et al [27], infers the expected number of exposures, given the probability mass function of the incubation period, through a maximum likelihood deconvolution approach.

Credible intervals were calculated based on a bootstrap procedure [28]. We fixed the smoothing factor k=6, which corresponds to a centered rolling average of days. The bootstrap procedure made use of 1000 samples (B=1000). The incubation period distribution was fixed as a gamma distribution with mean 5.2 and SD 2.8 days [29]. The time series with symptom onsets was provided by the Centro Nacional de Epidemiología [1].

Estimation of Rt

From the median incidence, obtained by the reconstruction of the exposure times, we estimated the evolution of Rt using the *EpiEstim* package [30,31]. For the infectivity profile, we chose the generation time estimated by Ganyani et al [32]. To be more precise, we assumed a generation time following a gamma distribution with mean 5.2 (95% CI 3.78-6.78) days and SD 1.72 (95% CI 0.91-3.93) days. This generation time distribution corresponds to the estimation by Ganyani et al [32] for Singapore, while assuming the same incubation period distribution [29] as we did in the reconstruction of the exposure times. We assumed SDs of 1.0 and 1.2 days for the mean and the generation time, respectively. However, we bound the values for the mean and SD by the estimations of Ganyani et al [32]. We fixed a centered rolling average of 7 days. To bootstrap the credible intervals, we took 100 samples of the generation time distribution and considered 100 posteriors for each of these samples (n1=100 and n2=100, respectively).

Identifying the Linear Segments of Rt

To identify the linear segments, we use the R package *segmented* [33,34]. The method proposed by Muggeo [33,34] implements a maximum likelihood approach using linear predictors. The credible intervals are obtained through bootstrapping. As previously pointed out, we assumed 3 segments of Rt. An initial constant value R1 as the disease was spreading freely in Spain, as well as 2 linear evolving parts corresponding to the decrease in Rt toward the lockdown and the constant decrease observed during the lockdown.

Model

An alternative method for investigating the evolution of Rt is to perform model-based inference [10,19,20]. By fitting a minimal model to daily fatalities and hospitalizations, we can compare the results with those derived from the reported number of infections and assess whether the early decrease in Rt can be attributed to saturation in testing capacity. This approach is more reliable as fatalities and hospitalizations are less susceptible to fluctuating reporting rates. However, daily fatalities experience significant underreporting. Although the official number of COVID-19 fatalities during the first wave is approximately 28,000, excess deaths amount to around 50,000 [2]. Nonetheless, the reported fatalities and excess deaths follow similar trends, with excess deaths exhibiting a slower decline (Figure S13, Multimedia Appendix 1). Consequently, we considered the reported fatalities to be a sufficiently robust data stream.

We opted for a discrete-time model, informed by empirically derived distributions for the generation time [32], incubation time [29], and time from symptom onset to hospitalization and death [35-37]. The time between symptom onset and hospitalization or death varies significantly by age [35] and region [36]. Since our data were aggregated by age and location, we did not incorporate age stratification or geographical heterogeneity through metapopulations.

Moreover, we assumed an instantaneous reproduction number Rt^M with a functional form. The notation Rt^M distinguishes this from the reproduction number inferred from reported infections, Rt. The functional form of Rt^M was inspired by the Rt inferred from the reported infections.

We divided Rt^M into 3 linear segments: the “free” spreading phase before restrictions (constant value R1), the initiation of the epidemic response (linear decrease at time BP), and the lockdown (constant value R2) on March 15. We referred to the intersection between R1 and R2, or the moment Rt^M began to decrease, as the breakpoint BP. Along with R1, R2, and the initial number of infected individuals I0, the initiation of the epidemic response remained a free parameter. The assumption that Rt^M would reach a constant value R2 upon lockdown implementation was re-evaluated in the sensitivity analysis. This framework allowed us to assess the plausibility of an early decrease around March 5/6, as found in the reported infections.

We decided against using intensive care unit (ICU) admissions as a data stream for our inference. During the first wave, some CCAA reported current occupancy, while others reported new admissions, and many changed their reporting criteria over time. Additionally, only in Madrid and Catalonia, the hardest-hit CCAA, did we observe an earlier peak in the 70-79-year age group compared to younger groups, followed by a rapid decrease in ICU admissions (Figure S14, Multimedia Appendix 1). This strongly suggests that ICU admission criteria were adjusted due to health care system overload. Another indication of this is that hospital admissions and ICU admissions peak on the same day, even though health authorities report a 3-day delay from symptom onset to ICU admission compared to hospital admissions (Figure S15, Multimedia Appendix 1). These factors suggest that ICU admissions data are not a reliable data stream.

Given the form of Rt^M, the generation time distribution w(t), and the size of the population N, the daily incidence I_t on day t evolves as [38]:

We used the same generation time distribution as that for estimating Rt [32]. From the daily incidence, we propagated the symptom onset as well as the daily fatalities through convolution [14,19]. Given the incubation time distribution P(t), and the distribution of time from symptom onset to hospitalization H(t) and to death D(t), the daily number of individuals developing symptoms S_t, the daily hospitalizations G_t, and the daily fatalities F_t evolve as:

Model Fitting

We fixed the incubation time distribution as that for the estimation of exposure times [29]. We fixed the infection hospitalization ratio (IHR) and the infection fatality ratio (IFR) by dividing the total number of hospitalizations and fatalities, respectively, by the total number of infected individuals. The latter was fixed through a nationwide seroprevalence study that found an attack rate of 5% by the end of April 2020 [39]. This led to an IHR and an IFR of 4.54% and 1.18%, respectively.

We assumed the times from symptom onset to hospitalization and to death to follow a gamma distribution. Since case line data were not available, we fixed the shape factor as 2.5 and 2.2, respectively, according to Hawryluk et al [35]. However, the health authorities published the median and IQR of these distributions [37]. They reported a median time from symptom onset to hospitalization and death of 6 (IQR 3-9) and 11 (IQR 7-17) days, respectively. We fixed the scale values by performing a least-squares fit with respect to these data. This resulted in a shape and scale parameter for time between symptom onset to hospitalization and death of 2.68 and 5.85, respectively.

We adjusted the model to the daily hospitalizations and fatalities through a Markov chain Monte Carlo (MCMC) approach—to be more precise, through Hamiltonian Monte Carlo [40]. For the log-likelihood, we chose a negative binomial distribution with a dispersion parameter that was left as a free parameter. Motivated by previous findings [13,19], we fixed the prior of R1 as a normal distribution with mean 4.5 (SD 1.0). The prior of R2 was a uniform distribution between 0.4 and 1.0. Similarly, the prior of BP was flat between and days before lockdown. The initial number of infected individuals I0 was uniform between and 5000. We set the prior for the dispersion as a normal distribution with mean 10.0 and SD 5.0. The daily fatalities were not accurately adjusted using directly the distribution received from the least-squares fit. Therefore, we added the scale and shape parameter of the distribution for time between symptom onset and death as a free parameter. We fixed the prior as a normal distribution with a mean as that found from the least-squares fit and SD 0.1. The form of the inferred distribution from symptom onset to death is shown in Figure S20, Multimedia Appendix 1. The model was implemented in Stan [41,42]. We ran 6 chains with 4000 iterations, where 2000 iterations were used for warm-up. Gelman-Rubin convergence statistics [43], that is, potential scale reduction factors, were all smaller than 1.001. Posteriors and trace plots are shown in Figures S21 and S22, Multimedia Appendix 1, respectively.

Counterfactual Scenarios

A common question when analyzing the pandemic's evolution retrospectively is, What would have happened if we had acted earlier or later? Several studies have examined the impact of an earlier or later lockdown [4,7,20]. These detailed modeling efforts allow us to address this question by considering a shift in the entire epidemic response [7,20]. If the reproduction number is initially constant, as was the case in our analysis, the effect of shifting the epidemic response is entirely determined by R1, that is, the initial doubling time. In other words, if one shifts the epidemic response by the number of days equivalent to the doubling time, the attack rate, hospitalizations, and fatalities double.

Here, however, we focused on the epidemic response that occurred before the lockdown implementation. This encompassed regional measures, individual awareness, nationwide educational system closures, and the lockdown announcement. Essentially, we moved the breakpoint BP by a specific number of days. If the shift surpassed the lockdown date, the BP remained fixed on March 15.

Sensitivity Analysis

The first part of the sensitivity analysis consisted of relaxing the assumption that the reproduction number would reach a stable value (R2) on March 15, the day the lockdown took effect. To do so, we introduced a second breakpoint BP2 that defined when Rt^M would reach R2. For BP2, we chose a flat prior from March 15 onward. The detailed results of the fit are shown in Figures S16-S18, Multimedia Appendix 1. The other estimated parameters, as well as the counterfactual scenarios, were robust. The median of BP2 was found half a day later than March 15, with a credible interval between March 15 and 17. This added plausibility to our assumption that Rt^M would reach R2 on March 15. Furthermore, we considered a second generation time distribution taken from Ferretti et al [44]. The generation time corresponded to a Weibull distribution, compared to a gamma distribution in the main text, with mean 5.0 and SD 1.9 days. The results did not substantially change and are presented in Figures S23 and S24, Multimedia Appendix 1.

Ethical Considerations

The Research Ethics Committee of Rovira i Virgili University deemed this study as exempt from ethics review (URV.F01.04.00 ALTRES-2023-PRD-0001). The mobility data from the mobile phone provider were anonymized and aggregated. Individual traces were not available. No other ethical considerations apply to this work.

Results

The Evolution of Mobility

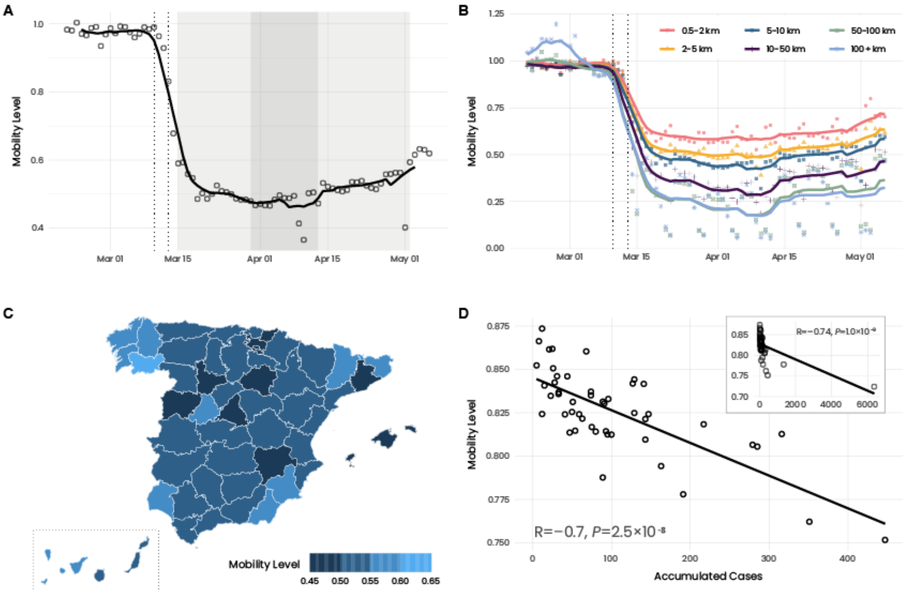
As highlighted previously, mobility is an indicator for the impact of NPIs. Here, we analyzed a data set provided by the MITMA that analyzed the evolution of mobility through anonymized mobile phone data from about 13 million users (see the Methods section for more details). The data indicated that already before the lockdown, there was a substantial reduction in mobility from March 10 onward (Figure 1A). The initiation of this decrease coincided with the first regional NPIs introduced in Madrid and in the Basque country. Furthermore, the early reduction was consistent with an increase in COVID-19–related searches on Google (Figure S1, Multimedia Appendix 1). During the lockdown, mobility was about 50% of the prepandemic level. Mobility increased from the end of the stronger lockdown toward the end of lockdown to about 60%.

Here, we referred to the aggregated, nationwide number of trips. However, the reduction in mobility was heterogeneous. For example, long-distance trips exhibited a much greater reduction than short trips, and long trips were only about 15%-20% of the prepandemic level (Figure 1B). A more detailed overview on the evolution of mobility during the lockdown is provided in Figures S2 and S3, Multimedia Appendix 1. Furthermore, there were regional heterogeneities. If we look at the provincial level (administrative subdivisions of CCAA), the strongest-hit province in terms of infections, Madrid, showed the highest reduction in mobility (Figure 1C). Similarly, highly affected provinces, such as Álava and Barcelona, were among the 5 provinces with the highest mobility reduction.

In fact, we found a pronounced correlation (R=–0.74) between the mobility level and the number of cases (Figure 1D) prior to the lockdown, which then substantially reduced during the lockdown (Figure S5, Multimedia Appendix 1). Interestingly, we observed a stronger correlation with the absolute number of cases than with the population size. The same held true for hospitalizations, ICU admissions, and fatalities (Figure S6, Multimedia Appendix 1).

We did not find regions with increased traffic on the days preceding the lockdown (Figure S7, Multimedia Appendix 1). In addition, the economic level or the fraction of individuals belonging to the working population did not seem to have been factors that determined the mobility level (Figures S8 and S9, Multimedia Appendix 1). However, we observed a general tendency that the reduction in mobility was greater in urban areas than in rural ones (Figures S8 and S9, Multimedia Appendix 1).

Figure 1. Evolution of mobility during the first wave. (A) Average, nationwide aggregated mobility before and during the lockdown. Dots indicate the data points, while the solid line shows a rolling centered 7-day average. Vertical dashed lines indicate the first NPIs introduced in Spain on March 10 (school closure in Madrid and Basque Country) and the announcement of the lockdown on March 13. The shaded area in light gray indicates lockdowns 1 and 3. In dark gray, we indicated lockdown 2, where, in addition, all nonessential economic activity was shut down. (B) Nationwide aggregated mobility but separating the distances of trips. Dots indicate data points, and the solid lines represent a rolling centered 7-day average. In general, long-distance trips showed a much higher reduction than shorter trips. (C) Mobility level during the lockdown (March 15-May 2) for the total number of trips in the provinces (administrative subdivisions of CCAA) of Spain. Ceuta and Melilla are not shown. Please note that the Canary Islands (islands at the bottom) were moved to be visible. (D) Correlation between the accumulated number of cases until the lockdown and the mobility level. Points represent the provinces of Spain. We excluded the provinces of Madrid and Barcelona since they represent statistical outliers due to their high number of cases. For completeness, the results with these provinces included are shown in Figure S4, Multimedia Appendix 1. The factor R and P denote the Pearson correlation coefficient and the associated *P* value. Similarly, the Spearman correlation coefficient was found to be –0.7 with *P*<.001. CCAA: Comunidades Autonomas; NPI: nonpharmaceutical intervention.



Estimation of Rt

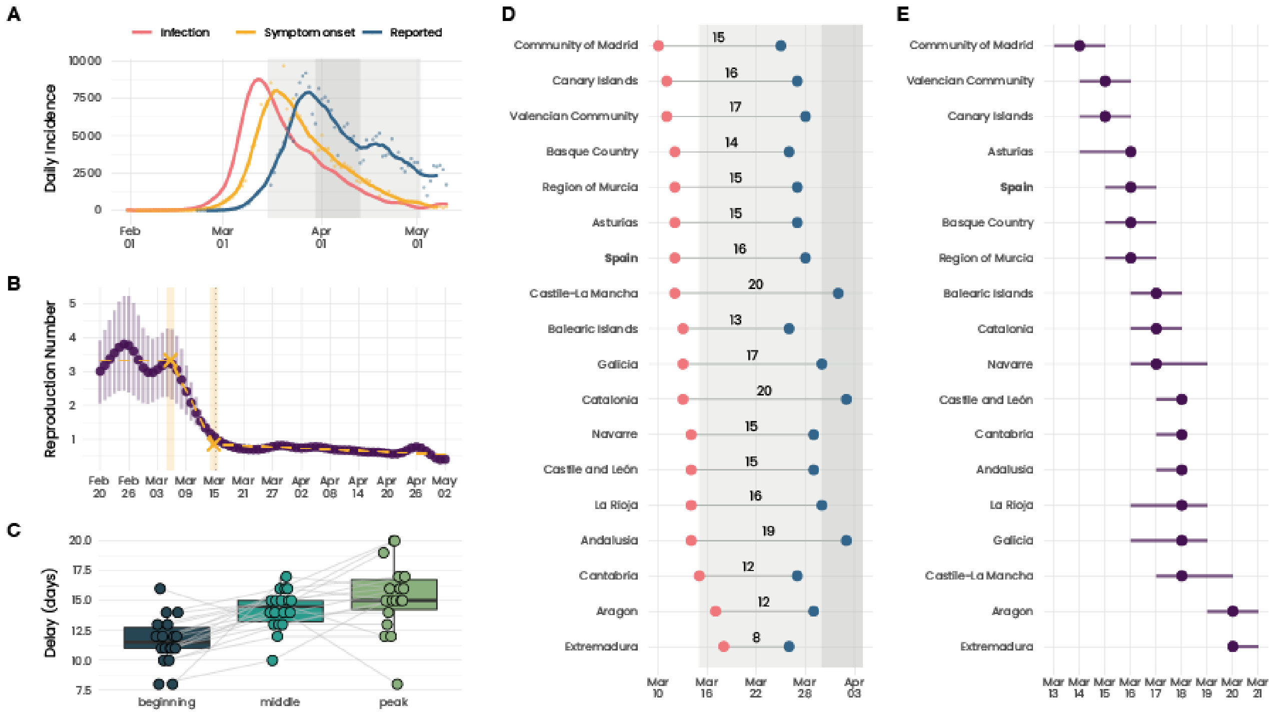
Figure 2A shows how the exposure times substantially anticipated the reported infections. The respective curves peaked with a delay of 16 days. In Figure 2B, we observe how the 3 linear segments capture the essential evolution of Rt. Additionally, we see a minimal variation in Rt during the lockdown, and the second breakpoint aligns with the lockdown implementation on March 15. Given that the average incubation time is about 5 days, this indicates a substantial delay from symptom onset until individuals were tested, results were received, and eventual positive cases were reported. We repeated the same analysis for each CCAA (Figure 2D and Figure S10, Multimedia Appendix 1). The delay ranged, among the CCAA, between 8 days in Extremadura and 20 days in Catalonia.

Given the exposure times, we inferred the reproduction number Rt shown in Figure 2B. We estimated that initially, the epidemic spread with a reproduction number of around 3. Rt started to decrease on March 5/6 according to the linear segments we identified. Furthermore, the first time Rt was below 1 was shortly after the beginning of the lockdown: between March 15 and 17. Repeating the same analysis for the regions, we observed that Rt dropped below 1 in all CCAA between March 13 and 21 (see Figure 2E). Please note that the nationwide data are strongly dominated by Madrid due to the high case numbers there. The evolution of the reproduction number in the CCAA is shown in Figure S11, Multimedia Appendix 1.

Although Rt dropping below 1 shortly after the lockdown was expected, the early decrease in Rt that was initiated on March 5/6 was rather surprising. At this point, no NPIs were in place and we did not observe any reduction in mobility. Furthermore, test-trace-isolate was implemented on such a small scale that it seems unlikely to have substantially contributed to the decrease. A possible explanation for this early reduction in Rt could be a saturation in testing capacity.

Looking at the temporal evolution of the delays between infection and reporting dates, we found an indication that the health care system was under increased strain to test and report infected individuals. The delay between infection and reporting continuously increased toward the peak in infections (Figure 2C). Although initially, we found a delay of 12 days, it increased steadily toward the peak of 16 days. Furthermore, this pattern was consistent across almost all CCAA. The only CCAA that showed a reduction in the delay toward the peak were Aragon and Extremadura (Figure S12, Multimedia Appendix 1). Interestingly, these were the CCAA with the lowest delay between the peak in infections and reported cases (Figure 2D) and were the last CCAA to have an Rt below 1 (Figure 2E). This further supports the hypothesis that there was a general overload on the testing facilities that impacted the evolution of Rt, which in turn may have led to the anticipated decrease in Rt.

Figure 2. Reconstruction of the exposure times and estimation of Rt. (A) Cases when they were reported (blue), onset of symptoms (yellow), and reconstructed exposure times. Dots indicate data points and the solid line a rolling centered 7-day average. The shaded area for the exposure times represents 95% credible intervals. (B) Estimation of Rt. Vertical bars indicate 95% credible intervals. The dashed yellow line represents the 3 linear segments we identified. The shaded yellow area shows the 95% credible interval for the 2 breakpoints. The 2 breakpoints are between March 5 (95% CI 4-6) and March 15 (95% CI 14-16), where the latter coincides with the implementation of the lockdown. (C) Delay between exposure time and reporting date. The position is defined with respect to the peak. To be more precise, we showed the time difference when both curves reached x% of their peak value. The 3 points (beginning, middle, and peak) correspond to 5%, 50%, and 100%, respectively, of daily infections compared to the peak incidence. Each point corresponds to a CCAA. Gray lines indicate how the delay evolves for each CCAA. We note that the delay steadily increased toward the peak in almost all CCAA. (D) Blue and red dots indicate the day the curves of the reported cases and exposure times reached their respective peaks. The number in between denotes the difference in days between these dates. (E) The day Rt was first below 1 in the different CCAA. Horizontal bars indicate 95% credible intervals. CCAA: Comunidades Autonomas.



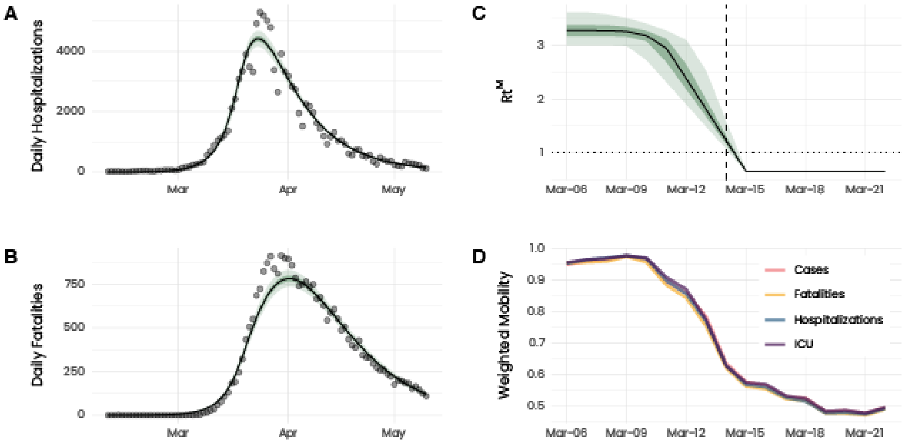
Model-Based Inference

Figure 3A,B shows the fit of the minimal epidemic model with respect to the fatalities and hospitalizations, respectively. The adjusted curve for the fatalities peaked slightly later compared to the real data. This could stem from the faster decrease in reported fatalities compared to the excess deaths. Looking at Rt^M, we found R1=3.27 (95% CI 3.01-3.61) and R2=0.66 (95% CI 0.64-0.67). Both R1 and R2 were consistent with the estimation from the reported cases, Rt. Given the generation time we used here, this resulted in a doubling time of 2.55 days (95% CI 2.32-2.78) during the free phase and a half lifetime of 9.11 (95% CI 8.72-9.56) days after the lockdown. The small doubling time suggests how the considerable delay between infection and reporting dates may have contributed to a substantial discrepancy between the actual epidemiological situation and the one that we could infer from the data. However, the low value of R2, together with the half-life time, shows the efficiency of the lockdown during the first wave and how it contributed to the low case numbers during the early summer months.

Let us turn now to the initiation of the epidemic response. The model adjustments yielded the initiation of the decrease in Rt^M on March 10 (95% CI 8-12), contrasting with the decrease in Rt on March 5/6. This suggests that the early decrease was due to an overload in the health care system, which eventually impeded testing infected individuals. The initiation of the decrease in Rt^M was consistent with the reduction in mobility. In Figure 3C,D, we contrast the reduction in mobility with Rt^M. Note that we weighted the mobility reduction by various daily epidemiological indicators—reported cases, fatalities, hospitalizations, and ICU admission—in the different provinces rather than by population. Hence, we accurately reflected the impact of mobility reduction on the evolution of the epidemic. Note that there was an additional, even though less rapid, decrease in mobility from March 15 onward. However, results from the sensitivity analysis (Figures S16-S18, Multimedia Appendix 1) suggest that the reproduction number reached a stable value timely after the lockdown. In this sense, the impact of the additional decrease in mobility on the epidemic seems not to have been substantial.

The eventual saturation of testing capacity also had consequences for ascertainment, that is, the fraction of cases that were detected compared to the total number of infections. We assumed our model output to be the total number of infections and compared it to the number of infections (exposure times) that we inferred previously. We noted that initially, ascertainment was only around 5% and subsequently increased. However, it then substantially dropped around May 5/6 before eventually starting to increase again. This substantial increase was consistent with the pronounced expansion in testing capacity in the middle of April (Figure S19, Multimedia Appendix 1) that enabled the detection of around 15% of the infections.

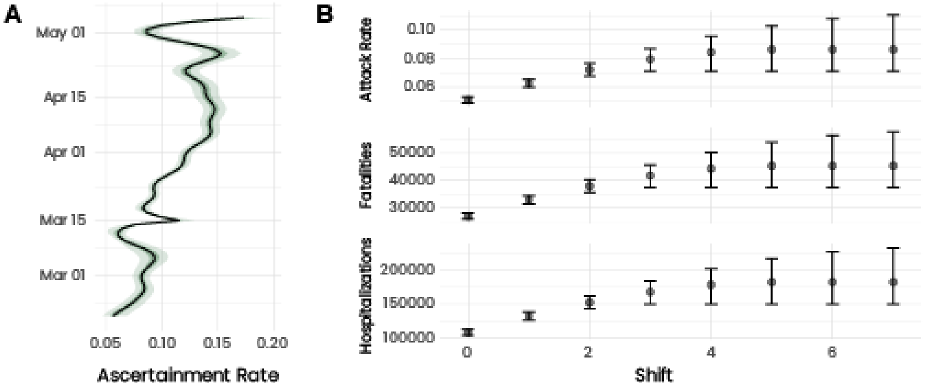
Figure 3. Model adjustment to epidemiological data. (A and B) Model adjustment to the daily hospitalizations and fatalities, respectively. The green and light-green shaded areas represent 50% and 95% credible intervals, respectively. The solid line represents the median. (C) Inferred evolution of Rt^M. The dashed vertical line indicates the implementation of the lockdown. (D) Aggregated mobility level of the Spanish provinces prior to the lockdown and shortly afterward. Instead of averaging by population size, we averaged by different daily epidemiological indicators to visualize the impact of mobility reduction on epidemic evolution. This is in analogy with the definition of Rt [31]. We observed that mobility and Rt^M started to decrease around the same time. ICU: intensive care unit.



Counterfactual Scenarios

The results of the counterfactual scenarios, shown in Figure 4B-D, indicate that the absence of an epidemic response before the lockdown would have resulted in an attack rate of 8.6% (95% CI 7.1-11.0), which is more than 50% higher than the actual value. The higher attack rate would then have resulted in 45,400 (95% CI 37,400-58,000) fatalities and 182,600 (95% CI 150,400-233,800) hospitalizations compared to 27,800 fatalities and 107,600 hospitalizations, respectively, that were reported. In other words, the results suggest that the pandemic response before the lockdown contributed substantially to limiting the impact of SARS-CoV-2 during the first wave in Spain.

Figure 4. Ascertainment and counterfactual scenarios. (A) Evolution of ascertainment in time. Ascertainment is defined as the ratio between the reported cases and the incidence from the adjusted model. We compared the date of infection (exposure time) instead of the reporting date. We noted a sudden decrease from March 5/6 toward the lockdown. Later, the testing capacity substantially increased, which increased ascertainment (Figure S19, Multimedia Appendix 1). (B) Counterfactual scenarios for the attack rate, death toll, and total number of hospitalizations. The counterfactual scenarios consist of shifting the breakpoint BP by x days. If the BP exceeded March 15 (ie, lockdown), no further shift was applied. We noted how the response before the implementation of the lockdown substantially contributed to limiting the impact of the epidemic.



Discussion

Principal Findings

Our analysis of large-scale mobility data revealed a significant reduction in mobility initiated before the lockdown. Additionally, we discovered a strong correlation between the decrease in mobility before the lockdown and the number of reported cases across Spanish provinces. Although the direct analysis of reported infections suggested a reduction in the reproduction number preceding the decrease in mobility, the model-based inference using hospital admissions and deaths primarily attributes this to a declining reporting rate as the epidemic progressed. The model-based inference indicates a simultaneous decrease in mobility and the reproduction number. According to our counterfactual scenarios, we estimate that the reduction in the reproduction number before the lockdown reduced the attack rate, hospital admissions, and deaths by over 30%.

The direct analysis of reported cases revealed a constant increase in the delay between exposure and notification as the epidemic peaked. An average delay of 16 days highlights the late testing of symptomatic individuals, a significant test turnaround time, and considerable notification delays. Studies have reported similar delays in other countries [17,20]. Such delays obstruct accurate evaluations of the epidemiological situation and hinder effective epidemic response management [45].

The increasing reporting delay also suggests a saturation in testing capacity. We hypothesized that the reduction in mobility before the decrease in Rt resulted from a worsening reporting rate. Our model-based approach supports this hypothesis, indicating an epidemic evolution consistent with the reduction in mobility, as found in other studies [15-17,46]. Moreover, ICU capacities seemed to have reached their limits. Specifically, ICU admissions among 70-79-year-olds peaked earlier than for younger age groups in the hardest-hit provinces, Madrid and Barcelona, indicating a change in admission criteria. These factors illustrate the immense pressure the Spanish health care system faced during the first wave.

The decrease in mobility began on March 9/10, 5-6 days before lockdown implementation. Linka et al [17] observed a similar decrease in mobility before lockdown introductions in other Western European countries. Identifying the exact cause of the early mobility decrease is challenging, as various factors are likely to have contributed to the decline. Worsening situations in many countries, reported in the media [47] and further disseminated through social networks [48], might have increased public awareness. In line with this increased awareness, the usage of SARS-CoV-2–related hashtags in Spain surged from March 9 onward [49]. We also found a significant correlation between mobility levels and the number of cases at the provincial level, suggesting the presence of risk-based individual awareness [50]. Other studies have identified risk-based awareness for SARS-CoV-2 [51,52], as well as for HIV [53] and measles [54].

The correlation between mobility and reported cases was especially high before lockdown implementation, as contact reduction mainly occurred voluntarily (Figure S5, Multimedia Appendix 1). However, the first autonomous communities announced educational system closure on March 9, with many others following suit. These factors are interconnected, as public awareness of COVID-19 influences voluntary social distancing, and individuals' attitudes toward the disease also impact authorities' decisions. Moreover, lockdown announcements can have similar effects as their implementations [55]. Our results should not be interpreted as lockdowns and NPIs being generally ineffective. Various studies have emphasized the impact of NPIs [18,56]. Our findings, however, highlight the complex interplay between risk-based and policy-induced behavioral changes and challenge a mechanistic understanding of NPIs, where any reduction in the reproduction number is solely attributed to policy [10,19]. In summary, studies analyzing the impact of public health policies should also account for voluntary behavioral changes beyond NPIs.

At the beginning of the model dynamics on February 10, we estimated around 1100 infectious individuals. In contrast, the first case of local transmission in mainland Spain was reported on February 26. This discrepancy underscores how SARS-CoV-2 initially spread silently through the population.

This observation aligns with the excess deaths attributed to influenza in February 2020 in Catalonia [57]. In line with this, the model consistently predicts more fatalities at the beginning of the epidemic than were reported.

Our counterfactual study demonstrates that the early decrease in mobility significantly contributed to mitigating the impact of the first wave in Spain. Our results suggest that if the epidemic response had started with the lockdown implementation on March 15, the attack rate would have been 8.6%, resulting in 180,000 hospitalizations and 45,000 fatalities, an increase of 60%-70% in these indicators. This finding indicates that in addition to the national lockdown, the combination of awareness and regional measures helped slow the spread of SARS-CoV-2 in Spain. Shifting the entire epidemic response, including the lockdown, would have led to twice/half as many infected individuals for every 2.5 days later/earlier. This emphasizes the importance of timely containment efforts in managing emerging epidemics [7,19,20,58].

Limitations

Several aspects of our analysis could be improved if more detailed data were available. For instance, the epidemiological model could be age-stratified if relevant data were available for Spain regarding symptom onset to hospitalization and death [36]. The same applies to geographical heterogeneity. If case line data were available at the regional level, autonomous communities could be treated separately [35]. In the absence of such data, age or location stratification is not feasible. Access to data that are not publicly available, unlike in other countries [4], would enable a more detailed and comprehensive analysis of the 2020 SARS-CoV-2 epidemic in Spain [11,12].

Conclusion

Summarizing, this study emphasizes that the behavioral response to an epidemic is multifaceted, driven by both voluntary decision-making and health authorities' policies. Although our results indicate that the reproduction number reached its lowest point during the lockdown in Spain, they also suggest a decrease before the implementation of any containment policies. Disentangling voluntary from policy-induced behavioral changes remains a future challenge, as this interplay involves individual psychology, societal dynamics, and pathogen spread [59]. However, understanding this complex interplay is crucial for designing better health policies and accurately assessing the need for public health interventions.

Abstract

Background: With the increasing enrollment scale of colleges, the number of students on campus has risen sharply in China. The number of students with tuberculosis (TB) and rifampicin-resistant TB in colleges has increased significantly. Preventive treatment of latent tuberculosis infection (LTBI) is an important means for TB prevention and control in colleges. At present, the acceptance of LTBI treatment among college students remains unclear. In addition, evidence shows stigma may be one of the key factors affecting acceptance of LTBI treatment. To date, there is little direct evidence on the gender-specific association between perceived stigma toward TB and acceptance of LTBI treatment among college students.

Objective: This study aimed to describe the acceptance of LTBI treatment among college students in an eastern province of China to explore the association between perceived stigma toward TB and acceptance of LTBI treatment and to examine the moderating effect of gender on the association.

Methods: Data were derived from the project on the evaluation of LTBI treatment and its effectiveness among college students in Shandong, China. In total, 1547 college students were included in the analysis. We considered covariates at the individual and family levels. Multilevel mixed-effects logistic regression was used to examine the moderating role of gender and also explore the association between perceived stigma toward TB and acceptance of LTBI treatment.

Results: The acceptance rate of LTBI treatment among the diagnosed college students was 46.7% (n=723). The proportion of female students (n=361, 51.5%) accepting LTBI treatment was higher than that of male students (n=362, 42.8%; *P*=.001). There was an interaction between perceived stigma toward TB and gender (OR 0.93, 95% CI 0.87-1.00; *P*=.06). Among college students with LTBI, perceived stigma toward TB was positively associated with acceptance of preventive treatment (OR 1.03, 95% CI 1.00-1.08, *P*=.05). Perceived stigma toward TB was positively associated with accepting LTBI treatment only among male students (OR 1.07, 95% CI 1.02-1.12; *P*=.005).

Conclusions: The acceptance rate of preventive treatment among college students with LTBI was low. Contrary to our expectations, perceived stigma toward TB was positively associated with acceptance of preventive treatment. Gender moderated this association; high perceived stigma toward TB was associated with acceptance of preventive treatment only in male gender. Gender-specific strategies are effective in improving the acceptability of LTBI treatment in colleges.

KEYWORDS

gender differences; perceived stigma; latent tuberculosis; treatment; acceptance; college students

Introduction

According to the Global Tuberculosis Report 2022, China has the third highest number of cases among 30 countries with a high burden of tuberculosis (TB). In China, the reported incidence of TB among students dropped from 20.6/100,000 enrolled students in 2010 to 13.4/100,000 in 2015 but increased to 17.5/100,000 in 2019 [1]. In 2019, TB cases in students accounted for 6.2% of all TB cases [2]. In recent years, the annual incidence of pulmonary TB among college students is higher than the national level for the same age group [3]. A systematic review and meta-analysis of TB outbreaks among students in mainland China showed that the incidence of TB was higher in colleges compared to high schools [4]. The number of students with TB and rifampicin-resistant TB increased significantly in China from 2015 to 2019, most of whom were college students [5]. With the expansion of national college enrollment and more schools being open, the prevention and control of TB in colleges have become challenging.

Latent tuberculosis infection (LTBI) is defined as a state of persistent immune response to stimulation by *Mycobacterium tuberculosis* antigens with no evidence of clinically manifest active TB [6]. Approximately 350 million people in China have an infection caused by *Mycobacterium tuberculosis* [7], which means that a considerable number of people are in the LTBI state. The population with LTBI is a large reservoir of TB and has a 5%-10% lifetime chance of developing active TB if LTBI is untreated [8]. LTBI treatment is one of the important interventions to finally meet the end TB targets. TB outbreaks still occur from time to time in Chinese colleges. LTBI treatment is an important means for TB prevention and control in colleges. The acceptance of LTBI treatment among college students remains unclear at present. Clarification of the LTBI treatment acceptance and identification of the key factors influencing it may be of great significance to implement this intervention among college students with LTBI.

Stigma is defined as “a social process, experienced or anticipated, characterized by exclusion, rejection, blame or devaluation that results from experience, perception or reasonable anticipation of an adverse social judgement about a person or group” [9]. TB-related stigma, including fear of infection, may be a barrier to initiation and successful completion of LTBI treatment [10,11]. A qualitative study in the Netherlands [12] found that the difficulty to differentiate LTBI from TB and the consequent fear of TB infection and disease had negatively impacted the screening or treatment of LTBI among asylum seekers and refugees. Another study in England [13] indicated that migrants in a college environment were reluctant to accept LTBI screening and treatment programs because they were concerned about reputational loss and stigma of being involved in a TB project. These findings indicate that stigma may be one of the key factors affecting acceptance of LTBI treatment. Based on existing findings, we hypothesize that perceived stigma toward TB is negatively associated with acceptance of preventive treatment among college students with LTBI.

Globally, many more adult men than women have been diagnosed with TB and have died from it [14]. A meta-analysis reported that men were disadvantaged in seeking and accessing TB care and suggested that men were a high-risk group requiring improved access to TB care [15]. In addition, studies found that substantial gender differences in the epidemiologic burden of TB were almost solely attributable to gender differences in disease incidence and treatment initiation, in both of which men were disadvantaged [16]. Studies in Nigeria and Australia showed that there were gender differences in TB diagnosis, treatment, and outcomes [17,18]. Gender differences in TB may be greater in China. The average male to female proportion in China was about 2.19:1, which was higher than the global average level (1.9:1) [19,20]. However, there are few studies on gender differences in LTBI-related aspects. We hypothesize that gender differences have an impact on the association between perceived stigma toward TB and the acceptance of LTBI treatment.

Given the importance of LTBI treatment, TB control in schools, and the critical role of stigma, the aim of this study was (1) to describe the acceptance of LTBI treatment among college students in an eastern province of China; (2) to explore the association between perceived stigma toward TB and the acceptance of LTBI treatment; and (3) to examine the moderating effect of gender on this association.

Methods

Study Setting and Participants

This study used data from the project on treatment and effectiveness evaluation of LTBI among college students in Shandong province, China. More information about procedures has been described in detail in our previous publication [21]. The study began in September 2020 and was conducted in 6 cities (Jinan, Qingdao, Yantai, Rizhao, Linyi, and Zibo) using a cluster random sampling method to select samples. We selected students aged ≥18 years with positive purified protein derivative test results (ie, induration diameter ≥10 mm or accompanied by blisters, papules, double circles, and lymphatitis) to participate in our questionnaire survey. We excluded patients previously diagnosed with active pulmonary TB or extrapulmonary TB as well as those with a history of mental illness or epilepsy. Respondents were instructed to fill out the electronic survey questionnaire by trained graduate students to ensure the quality of the questionnaire. In total, 1691 individuals were eligible, and 1631 completed the whole survey.

We used the following formula to calculate the sample size:

In this formula, *n*, δ, and *p* are estimations for sample size, allowable error, and population rate π, respectively. Because acceptance of LTBI treatment among college students with LTBI is not clear in China, we used the positive prevalence of the tuberculin skin test (TST) to calculate the sample size. The prevalence of positive TSTs in Chinese college students using 10mm cutoff value was 9%-49% [22,23]. We set $P=.09$, $\alpha=.05$ (2-tailed), and $\delta=0.009$. Considering the sampling method and the 20% lost follow-up rate, the TST screening sample was finally determined to include 20,330 people [21].

Ethical Considerations

This study protocol received ethics approval from the Ethical Committee of the School of Public Health in Shandong University (LL20200306). The investigation was conducted after the acquisition of written informed consent from all participants.

Measures

Acceptance of LTBI Treatment

Acceptance of LTBI treatment was measured by the question "Will you accept preventive treatment of latent tuberculosis infection?" The answer was divided into either accepting treatment or refusing treatment. We eliminated 84 samples whose answers were inconclusive. Finally, 1547 college students were included in the analysis.

Perceived Stigma Toward TB

Perceived stigma toward TB was assessed using 11 questions [24]. These problems originate in countries with a high burden of TB. More details about these questions are described in Multimedia Appendix 1. The answer to each question included "Yes" and "No." "Yes" indicated the presence of perceived stigma, and "No" indicated the absence of perceived stigma. The score ranged from 0 to 11. The higher the score, the higher the perceived stigma toward TB. The Cronbach coefficient was .880 in this study.

Covariates

In this study, gender was used as a moderating variable. Based on previous research [25,26], some other factors may also influence the acceptance of LTBI treatment. Therefore, we added covariates such as age (continuous), type of student (eg, medical students and nonmedical students), type of residence (eg, urban and rural), parents' levels of education (eg, primary school or below, junior high school, and high school or above), household income in 2019 (eg, quintile 1, quintile 2, quintile 3, and quintile 4), smoking (yes), current drinking (yes), physical activity level (eg, low, moderate, and high), exposure history of TB (eg, no, yes, or unknown), boarding experiences (yes), and knowledge of TB (continuous). Physical activity level was measured by the Chinese version of International Physical Activity Questionnaire Short Form [27]. The score of TB knowledge ranges from 0 to 45 (Multimedia Appendix 2). The higher the score, the higher the level of TB knowledge.

Statistical Analysis

First, a descriptive analysis was used to describe participants' characteristics with mean (SD) or median (IQR) values for continuous variables. Frequency and percentage values were used to describe categorical variables. Second, Pearson chi-square test (for categorical variables) and 2-tailed student *t* test or Wilcoxon rank-sum test (for continuous variables) were used to compare characteristics of male and female students. Then, since 1547 participants came from 6 cities and 16 colleges, multilevel mixed-effects logistic regression (Multimedia Appendix 3) was performed to examine the moderating role of gender. We added the multiplicative interaction term (perceived stigma toward TB × gender) in models. The association between perceived stigma toward TB and acceptance of LTBI treatment was also assessed by multilevel mixed-effects logistic regression. In model 1, no covariate was included. Model 2 was based on model 1, with additional adjusting for age, type of student, type of residence, father's level of education, mother's level of education, household income, smoking, current drinking, physical activity level, exposure history of TB, boarding experiences, and knowledge of TB. Odds ratios (ORs) and 95% CIs were presented as measures of effect. A 2-tailed $P<.1$ was considered as statistically significant. We conducted all analyses in Stata (version 14.2; Stata Corp).

Results

Table 1 shows the baseline characteristics of participants by gender. Of the 1547 participants, about 846 (54.7%) were male students. The average age of respondents was 18.5 (SD 0.8) years, and most of them were nonmedical students. The proportion of female medical specialty students was higher than that of male students ($P<.001$). In terms of lifestyle behaviors, male students had higher proportions of smoking and current drinking than female students ($P<.001$). The average TB knowledge score was 19 (SD 7.7). The level of TB knowledge in female students was higher than that in male students ($P=.05$). The median score of perceived stigma toward TB was 1 (IQR 0-4), with a statistical difference between male and female students ($P=.09$). A total of 723 (46.7%) students with LTBI were willing to accept preventive treatment. The proportion of female students accepting LTBI treatment was higher than that of male students ($P=.001$). Male students who accepted LTBI treatment had higher perceived stigma score compared to those who did not ($P=.02$; Multimedia Appendix 4).

The interaction between perceived stigma toward TB and gender and its effect on acceptance of LTBI treatment is shown in Table 2. After adjusting for covariates, there was an interaction between perceived stigma toward TB and gender (OR 0.93, 95% CI 0.87-1.00; $P=.06$).

Table 1. Participants' characteristics of latent tuberculosis infection (LTBI) college students by gender in Shandong, China, in 2020.

Variables	Total, n (%)	Male, n (%)	Female, n (%)	*P* value
Total	1547 (100)	846 (54.7)	701 (45.3)	
Age (years), mean (SD)	18.5 (0.8)	18.6 (0.8)	18.5 (0.8)	.25
Type of students, n (%)				<.001
Medical students	247 (16)	82 (9.7)	165 (23.5)

[b] TB: tuberculosis.

Table 2. The effect of gender on the cross-sectional interaction between perceived stigma toward tuberculosis (TB) and acceptance of latent tuberculosis infection (LTBI) treatment among college students in Shandong, China, in 2020.

Variables	Model 1[a]				Model 2[b]			
	OR[c]	SE	95% CI	*P* value	OR	SE	95% CI	*P* value
Perceived stigma toward TB	1.06	0.025	1.01-1.11	.005	1.07	0.025	1.02-1.12	.005
Gender (female)	1.80	0.261	1.36-2.39	<.001	1.94	0.300	1.43-2.62	<.001
Perceived stigma toward TB × gender	0.94	0.035	0.87-1.00	.07	0.93	0.035	0.87-1.00	.06

[a] Model 1 was unadjusted.

[b] Model 2 was adjusted for age, type of student, type of residence, father’s level of education, mother’s level of education, household income, smoking, current drinking, physical activity level, TB exposure history, boarding experiences, and knowledge of TB.

[c] OR: odds ratio.

Table 3 presents the relationship between perceived stigma toward TB and acceptance of LTBI treatment among male and female students. Perceived stigma toward TB was positively associated with acceptance of preventive treatment among college students with LTBI (OR 1.03, 95% CI 1.00-1.08; *P*=.05). Among male students, high perceived stigma toward TB was associated with accepting LTBI treatment when compared to low perceived stigma toward TB (OR 1.07, 95% CI 1.02-1.12; *P*=.005). However, there was no association between perceived stigma toward TB and acceptance of LTBI treatment among female students.

Table 3. Cross-sectional association between perceived stigma toward tuberculosis (TB) and acceptance of latent tuberculosis infection (LTBI) treatment among male and female students in Shandong, China, in 2020.

Variables	Model 1[a]				Model 2[b]			
	OR[c]	SE	95% CI	*P* value	OR	SE	95% CI	*P* value
Perceived stigma toward TB (n=1547)	1.04	0.019	1.00-1.07	.04	1.03	0.019	1.00-1.08	.05
Perceived stigma toward TB in male students (n=846)	1.06	0.025	1.02-1.11	.005	1.07	0.026	1.02-1.12	.005
Perceived stigma toward TB in female students (n=701)	1.00	0.029	0.94-1.06	.93	0.99	0.030	0.94-1.05	.87

[a] Model 1 was unadjusted.

[b] Model 2 was adjusted for age, type of students, type of residence, father’s level of education, mother’s level of education, household income, smoking, current drinking, physical activity level, exposure history of TB, boarding experiences, and knowledge of TB.

[c] OR: odds ratio.

Discussion

Principal Findings

In this study, only 723 (46.7%) college students diagnosed with LTBI were willing to accept preventive treatment. This figure is lower than what has been previously reported for other students’ acceptance rates of LTBI treatment, ranging between 63.9% and 87% in China [28,29]. The possible reason is that participants in this study were general college students, while previous research focused on students who had close contacts with TB and was related to the screening and management of students’ close contacts with TB [30]. For close contacts, schools actively organized screening and recommend LTBI treatments. Close contacts were more aware of TB than the student and more likely to accept LTBI treatment for fear of developing TB.

Our study observed a higher acceptance rate of LTBI treatment among female students than male students, contrary to previous studies in the United States and Canada [31]. One possible explanation for our findings is that female students have a higher level of TB knowledge than male students. Previous studies found that patients with LTBI who had low TB knowledge scores in student TB contacts or TB-designated hospitals were less likely to accept preventive treatment [28,32]. Students with higher knowledge of TB had some knowledge of the spread, harm, and prevention of TB. They wanted to reduce their risk of developing TB. When health workers recommended LTBI treatment, female students were more likely to accept it.

Our results showed that higher perceived stigma toward TB was positively related to acceptance of preventive treatment among college students with LTBI. This did run counter to our initial hypothesis, wherein we assumed that perceived stigma toward TB may be negatively associated with acceptance of LTBI treatment. No direct evidence has shown this association among college students, but prior studies found that TB-related stigma was negatively associated with LTBI treatment acceptance in other populations (eg, refugees and migrants) [12,13]. On the one hand, we speculate that the difference is due to people’s surroundings. College students live in a trustful and inclusive environment. College students did not score high on perceived stigma toward TB in our study, suggesting that they did not have embedded fears surrounding TB. Of course, it could also be that they did not know much about TB. After all, the TB knowledge score of college students in the study was 19.0 out of 45. However, TB stigma is relatively high in the community. Immigrants may feel singled out and stigmatized for other reasons [33,34]. One study in Eritrea [35] showed that restrained contacts due to fear of getting infected with TB, gossiping, and finger pointing in the community caused enacted and anticipated stigma among patients with TB. These findings indicate that the relationship between perceived stigma toward TB and acceptance of LTBI treatment may be quite opposite in different populations. On the other hand, LTBI is still different from TB infection. Although participants experienced enforced stigma, which could impede treatment initiation, their strong motivation to prevent becoming sick with TB resulted in acceptance of LTBI treatment.

It is worth noting that perceived stigma toward TB was positively associated with acceptance of LTBI treatment in male students, but there was no association between the stigma toward Tb and LTBI treatment acceptance in female students. Similar to previous studies on the impact of gender differences on TB epidemiological characteristics and access to services [15,16], we found gender differences played a part in the association between perceived stigma toward TB and acceptance of LTBI treatment. One possible factor that accounts for the disparity could be the different temperament and personality characteristics of male and female students. Women tend to be cautious, careful, worried, or pessimistic; men are more carefree, relaxed, and upbeat, even when most people are worried [36,37]. Therefore, male students may be more likely to accept LTBI treatment after feeling perceived stigma toward TB, whereas female students are not. Another plausible explanation is that the differences are related to men’s unhealthy behaviors, such as smoking and drinking. Studies found men were overrepresented in various pulmonary TB risk groups, notably alcoholic and tobacco smokers [16,38]. In this study, the proportion of male students who smoke and drink alcohol far exceeded that of female students. Despite higher perceived TB stigma, male students with LTBI were more likely to accept preventive treatment for fear of developing active TB. However, these pathways are speculative. Future research can explore the underlying mechanisms of the relationship between perceived stigma toward TB and LTBI treatment acceptance.

Perceived stigma toward TB was not associated with acceptance of LTBI treatment in female students. The reason may be that perceived stigma is not a key factor in female students accepting preventive treatment. In our study, the proportion of female medical specialty students was higher than that of male students. Moreover, female students have similar stigma scores but higher TB knowledge and LTBI treatment acceptance scores compared to male students. Of the added covariates, we found that exposure history of TB (Yes: OR 3.00, 95% CI 0.98-9.16; P=.05 and Unknown: OR 1.61, 95% CI 1.10-2.37; P=.02) and TB knowledge (OR 1.02, 95% CI 1.00-1.05; P=.08) were positively associated with acceptance of LTBI treatment among female students. In the future, research may focus on the factors influencing the acceptance of preventive treatment in women.

The current findings have some policy implications. Gender may be an important heterogeneous factor influencing the acceptance of LTBI treatment in colleges. It is recommended that colleges regularly and continuously carry out various forms of TB and LTBI knowledge publicity and education activities to raise students’ awareness of TB. The perceived stigma toward TB among male students needs to be addressed in improving their treatment acceptance. It is suggested that colleges provide suitable psychological counseling for male students. Overall, perhaps gender-specific management can improve the acceptability of LTBI treatment among college students.

This study has some limitations. First, the results were based on colleges in Shandong Province. Our findings were not necessarily generalizable to other settings within or outside China. Moreover, cross-sectional data used in this study were impossible to demonstrate the causality between perceived stigma toward TB and acceptance of LTBI treatment. Establishing and analyzing a multiyear longitudinal cohort of colleges covering different geographic regions in future studies could better elucidate the impact of gender on the relationship between perceived stigma toward TB and willingness for LTBI treatment.

Conclusions

In conclusion, we found that the acceptance rate of preventive treatment among college students with LTBI was low. The acceptance rate of female students was higher than that of male students. There were gender differences in the association between perceived stigma toward TB and acceptance of LTBI treatment. Only among male students, those with high perceived stigma toward TB were more likely to accept LTBI treatment. This study implies that gender-specific strategies in colleges may be effective in improving the acceptability of preventive treatment.

Acknowledgments

We are grateful to all participants for their effort. We thank the officials of local health agencies and staffs at the study sites for their cooperation.

This study was funded by the National Natural Science Foundation of China (grants 71974117 and 71774104), Cheeloo Youth Scholar Grant, and Shandong University (grants IFYT1810 and 2012DX006).

Abstract

Background: Comorbidity of psychiatric disorders such as depression and anxiety is very common among children and adolescents. Few studies have examined how comorbid anxiety and depression are associated with health risk behaviors (HRBs) in adolescents, which could inform preventative approaches for mental health.

Objective: We evaluated the association between HRBs and comorbid anxiety and depression in a large adolescent cohort.

Methods: We used data from 22,868 adolescents in the National Youth Cohort (China). Anxiety and depression symptoms were assessed using the 9-item Patient Health Questionnaire scale and the 7-item Generalized Anxiety Disorder scale, respectively. Comorbidity was determined by the coexistence of anxiety and depression. HRBs including poor diet, smoking, physical inactivity, and poor sleep, as well as the above HRB scores, were added to obtain the total HRB score (HRB risk index). Based on single and total HRB scores, we divided participants into low-, medium-, and high-risk groups. Potential confounders included gender, presence of siblings, regional economic level, educational status, self-rated health, parental education level, self-reported family income, number of friends, learning burden, and family history of psychosis. Correlation analysis was used to explore associations between single risk behaviors. Binary logistic regression estimated the association between HRBs and anxiety-depression comorbidity before and after adjusting for potential confounders.

Results: The comorbidity rate of anxiety and depression among Chinese adolescents was 31.6% (7236/22,868). There was a statistically significant association between each HRB ($P<.05$), and HRBs were positively associated with comorbid anxiety and depression in the above population. For single HRBs, adolescents with poor diet, smoking, and poor sleep (medium-risk) were more prone to anxiety-depression comorbidity after adjusting for confounders compared to low-risk adolescents. However, adolescents with all high-risk HRBs were more likely to have comorbid anxiety and depression after adjusting for confounders (poor diet odds ratio [OR] 1.50, 95% CI 1.39-1.62; smoking OR 2.17, 95% CI 1.67-2.81; physical inactivity OR 1.16, 95% CI 1.06-1.28; poor sleep OR 1.84, 95% CI 1.70-2.01). Moreover, in both unadjusted (medium risk OR 1.79, 95% CI 1.56-2.05; high risk OR 3.09, 95% CI 2.72-3.52) and adjusted (medium risk OR 1.57, 95% CI 1.37-1.80; high risk OR 2.33, 95% CI 2.03-2.68) models, HRB risk index, like clustered HRBs, was positively associated with anxiety-depression comorbidity, and the strength of the association was stronger than for any single HRB. In addition, we found that compared to girls, the association between clustered HRBs and anxiety-depression comorbidity was stronger in boys after adjustment.

Conclusions: We provide evidence that HRBs are related to comorbid anxiety and depression. Interventions that decrease HRBs may support mental health development in adolescence, with the potential to improve health and well-being through to adulthood.

Introduction

Adolescence is a transitional period from childhood to adulthood and also a critical period for the formation of lifestyle behaviors that can significantly impact immediate and long-term physical and mental health. During this period, under the influence of various pressures, such as study burden, life, and social interaction, some health risk behaviors (HRBs) are prone to occur [1]. The World Health Organization (WHO) defines youth HRBs as behaviors that directly, indirectly, or potentially threaten the current or future health of adolescents, mainly including physical inactivity, unintentional injury, and premature and unsafe behaviors [2]. However, many adolescents do not conform to specific health behavior guidelines, and the prevalence of unhealthy behaviors among adolescents ranges from 2.2% to 42.6% [3]. Of note, most adolescents' HRBs do not exist alone, but tend to cluster together [4]. The harm caused by clustered HRBs is larger than single HRBs. Therefore, identifying clustered HRBs may be more practical than studying single HRBs.

Adolescents are prone to many HRBs, and HRBs can lead to psychosocial disorders, physical illness, and other problems, particularly anxiety and depression [5]. Anxiety and depression, as the most common mental illnesses in adolescents, usually present a comorbidity pattern. Comorbid anxiety and depression is a global public health concern, as about 25% to 50% of depressed children and adolescents experience anxiety, and 10% to 15% of anxious children and adolescents have depression worldwide [6]. Evidence suggests that anxiety-depression comorbidity during adolescence is not only associated with immense personal and family suffering but also causes other adverse outcomes, such as academic failure, impaired cognitive function, poor interpersonal relationships, and even suicide [7]. Possible reasons for these psychosocial disorders include genetic predisposing factors [8], environmental factors [9], and personal behavioral factors such as HRBs [10]. Health behaviors have been highlighted as a potentially important factor that may support better mental outcomes throughout the life course, especially in adolescence. A study using data from a nationally representative sample of Australian adolescents showed that early-onset HRBs were strongly associated with mental health outcomes and varied by sex [11]. Moreover, a study examining the relationship between clustered HRBs and mental health status among US students identified clusters of HRBs, and the results showed participants who reported clustered HRBs were more likely to report poorer mental health [12].

Both HRBs and anxiety-depression comorbidity are common in adolescents, and there might be an association between them [13]. Thus, it is essential to delve into associations between HRBs and comorbid anxiety and depression in adolescents, as well as to compare the association in each sex. However, little research has examined how clustered HRBs affect the development of anxiety-depression comorbidity or gender-specific associations in adolescents, which could inform targeted interventions aiming to reduce harmful behaviors and improve long-term well-being. Furthermore, previous research has pointed to exercise, smoking, diet, and sleep as playing important roles in the prevention and treatment of mental disorders [14]. Therefore, our study aims to understand the prevalence of comorbid anxiety and depressive symptoms among Chinese adolescents and determine the extent of associations between HRBs (poor diet, physical inactivity, smoking, and poor sleep) and comorbid anxiety and depression by controlling confounders and identifying the influence of gender on these associations.

Methods

Setting and Study Design

Participants were enrolled in the National Adolescent Health Survey Cohort, which is a nationally representative, cross-sectional study designed to track behaviors, physical health, and mental health in Chinese adolescents from October to December 2021. A multistage cluster sampling method was applied to recruit participants. First, we selected first-line cities (Shenzhen, Chongqing, Zhengzhou, and Shenyang) and second-line cities (Kunming, Xuzhou, Taiyuan, Nanchang) according to regional economic levels. Second, each district selected 2 rural junior and senior high schools and 2 urban junior and senior high schools. The study enrolled 27 schools in total (5 of these schools were combined junior and senior high schools). Each school selected all students from 4 to 6 classes (with no less than 200 students in each grade) to conduct a questionnaire survey. There were no less than 600 students in each school and no less than 2400 students in each district.

In this survey, 24,500 questionnaires were actually distributed, and 1632 invalid returned questionnaires were excluded. Among these, 426 (1.7%) respondents were unwilling to participate in the survey, 367 (1.5%) were not in school on the day of the survey, and 839 (3.4%) did not complete the questionnaire (>15% missing data or obvious logical errors). Thus, 22,868 valid questionnaires were finally completed for an effective response rate of 93.3%.

Measures

Demographic Factors

Sociodemographic data were collected by a self-administered questionnaire, including gender (boy or girl), age, presence of siblings (yes or no), regional economic level (first-line or second-line) [15], residential area (rural or urban), educational status (junior or senior high school), parental education level (primary school and below, junior high school, or senior high school and above), self-reported family income (low, medium, or high), number of friends (≤2 or ≥3), learning burden (high, medium, or low), and family history of psychosis (yes or no). It is worth noting that "first-line" cities are considered the most important cities in China, with the most developed economies, the densest populations, and the highest urban radiation capacity (this refers to the ability of a city to influence the surrounding area and other cities); examples are Shanghai and Shenzhen. "Second-line" cities are mostly provincial capitals, economically strong cities in eastern regions, or economically developed regional central cities, such as Taiyuan and Nanchang.

Health Risk Behaviors

Dietary habits were assessed using a questionnaire adapted from the American Adolescent Health Behavior Monitoring System [16]. Dietary risk was assessed primarily by asking the adolescents about their frequency of consumption of fruits, vegetables, fast food, and soft drinks in the last week [17]. For fruit/vegetable consumption, replies of ≥3, 2, and ≤1 represent risk scores of 0, 1, and 2, respectively. For fast food consumption, replies of 0, 1-4, and ≥5 represent risk scores of 0, 1, and 2, respectively. For soft drinks, replies of ≤1, 2, and 3 represent risk scores of 0, 1, and 2, respectively. We then added the risk scores for a total score of 0 to 8, categorized into 3 groups: 0-2 (low risk), 2-3 (medium risk) and 4-8 (high risk). It is worth noting that the composite risk score could equal 2 only if (1) any 2 of the 4 components were medium risk (0 + 0 + 1 + 1) or (2) if any 1 of the 4 components was high risk (0 + 0 + 0 + 2). The former case was classified as low risk, whereas the latter was classified as medium risk. The reason for this was that adolescents with low dietary risk should not have any dietary component assessed as high risk.

Smoking status during the last month was assessed by a question in the American Adolescent Health Behavior Surveillance System Adaptation Questionnaire [16]: "During the last month, how many days did you smoke?" According to other similar studies [18], responses were categorized into 3 groups: less than 2 days (low risk), 3 to 19 days (medium risk), and 20 days or more (high risk).

Sleep duration during the last month was assessed using the Munich Chronotype Questionnaire Short Form (MCTQ-SF) [19]: adolescents reported their bedtime, fall-asleep time, and morning wakeup time; we then computed sleep duration. According to sleep duration recommendations proposed by the WHO and others, adolescents aged 13 to 18 years should sleep 8 to 10 hours per 24 hours on a regular basis to promote optimal health [20]; thus, responses were categorized into 3 groups, including low risk (8 to 10 hours), medium risk (7 to 8 hours, not including 8 hours, or 10 to 11 hours, not including 10 hours), and high risk (less than 7 hours or more than 11 hours).

The Physical Activity Rating Scale (PAR-3) was used to measure physical activity levels in adolescents [21]. This scale examines the amount of physical activity from 3 aspects: intensity, frequency, and time of participating in physical activity. Physical activity is rated as intensity times frequency times time. Intensity, duration, and frequency of physical activity were assessed by the questions "When performing physical activity, which of the following intensities are most likely to be selected?" "How many minutes at a time did the above intensity activity last?" and "How many times was the above activity performed?" respectively. Intensity and frequency were graded from 1 to 5 with 1 to 5 points, and time was scored from 1 to 5 with 0 to 4 points. The score range of the amount of physical activity was from 0 to 100. Physical activity risk assessment criteria were as follows: score >43 (low risk), score 20-42 (medium risk) and score <19 (high risk).

To evaluate the clustering effect of HRBs on comorbid anxiety and depression, we constructed an overall HRB index. To indicate overall HRB risk, single HRB factors were given weighted risk scores: 0 (low risk), 0.5 (medium risk), and 1 (high risk). They were then summed into an overall index ranging from 0 to 4. To study different levels of HRB risk, the HRB risk index scores were divided into 3 categories: low risk (total score 0-0.5), medium risk (total score 1-1.5), and high risk (total score 2-4). The index was termed HRB risk index.

Comorbid Anxiety and Depression

Anxiety symptoms were assessed using the Generalized Anxiety Disorder–7 (GAD-7). The GAD-7 is a 7-item self-reported measure used for screening and evaluating generalized anxiety disorder symptoms [22]. Respondents indicate how much they have been bothered over the last two weeks by each GAD-7 symptom using a 4-point Likert scale ranging from 0 (not at all) to 3 (nearly every day). GAD-7 score ranges from 0 to 21 with scores of 0-4, 5-9, 10-14, and 15-21 representing normal, mild, moderate, and severe levels of anxiety, respectively. According to the wide use of a cutoff value of 5, we classified GAD-7 scale scores ≥5 as indicating the presence of anxiety symptoms, and scores <5 as indicating the absence of anxiety symptoms.

The prevalence of depressive symptoms was measured using the Patient Health Questionnaire–9 (PHQ-9), which is used for screening and evaluating depressive symptoms [23]. Respondents indicate how much they have been bothered over the last 2 weeks by each PHQ-9 symptom using a 4-point Likert scale ranging from 0 (not at all) to 3 (nearly every day). The PHQ-9 score ranges from 0 to 27, with scores of 0-4, 5-9, 10-14, and 15-27 representing normal, mild, moderate, and severe levels of depression, respectively. Based on the suggested cutoff, participants who scored 5 points or more were considered to be at risk for depressive symptoms in our study.

An adolescent would be considered to have comorbid anxiety and depression if their GAD-7 scale score was ≥5 and their PHQ-9 scale score was also ≥5. Adolescents who met the above criteria were divided into a comorbid anxiety and depression group and a noncomorbid group.

The Chinese versions of the above questionnaires on adolescent demography, behavior, and mental health have good reliability and validity and have been verified in the Chinese adolescent population.

Confounders

We adjusted for a series of potential confounders; these were defined as measures that were associated with both the exposure and the outcomes but were not on the causal pathway between the two. Confounders mainly included statistically significant variables, including gender, presence of any siblings, regional economic level, educational status, self-rated health, parental education level, self-reported family income, number of friends, learning burden, and family history of psychosis.

Ethical Considerations

The studies involving human participants were reviewed and approved by the Ethics Institutional Review Committee of Anhui Medical University (20200573), and informed consent was obtained from the schools, students, and parents.

Statistical Analysis

Statistical analyses were carried out with SPSS (version 23.0; IBM Corp). Descriptive analyses investigated associations between HRBs, comorbid anxiety and depression, and confounders. Continuous variables with normal distribution in our study were represented as means and SDs, while categorical variables were summarized as frequencies (n) and percentages (%). Chi-square tests were used to assess demographic characteristics stratified by the presence or absence of comorbid anxiety and depression. Spearman correlation was used to assess the relationship between each HRB. Binary logistic regression was used to investigate the relationships between single HRBs, clustered HRBs, and comorbid anxiety and depression in adolescents before and after adjusting for confounders, and a correlation heat map was produced with Origin (OriginLab). For a sensitivity analysis, we explored whether associations varied by gender. All statistical tests were 2-sided and had a significance level set at $P<.05$.

Results

Participant Characteristics

The characteristics of the 22,868 participants (11,578/22,868, 50.6% boys and 11,290/22,868, 49.4% girls) included in the analysis are shown in Table 1. The mean age of the participants was 14.6 (SD 1.8) years. Among the 22,868 participants, the occurrence of comorbid anxiety and depression was 31.6% (7236/22,868). There were gender differences among adolescents with anxiety-depression comorbidity, and girls (4133/11,290, 35.7%) were more likely to have such mental health problems than boys (3203/11,578; 27.7%; $P<.001$). Moreover, not having siblings, living in a first-line economic city, being a senior high school student, having parents with an education level of primary school or below, having a lower self-reported family income, having ≤2 friends, having a higher learning burden, and having a family history of psychosis were all associated with comorbid anxiety and depression ($P<.05$).

Multimedia Appendix 1, Table S1 presents the risk index scores of single HRBs and clustered HRBs and their population distribution among the adolescents as indicated in the Methods section on HRB risk index scores.

Table 1. Characteristics of the study sample.

Variable	Comorbid anxiety/depression (n=7236), n (%)	No comorbid anxiety/depression (n=15,632), n (%)	Chi-square (*df*)	*P* value
Gender			171.56 (1)	<.001
Boys (n=11,578)	3203 (27.7)	8375 (72.3)

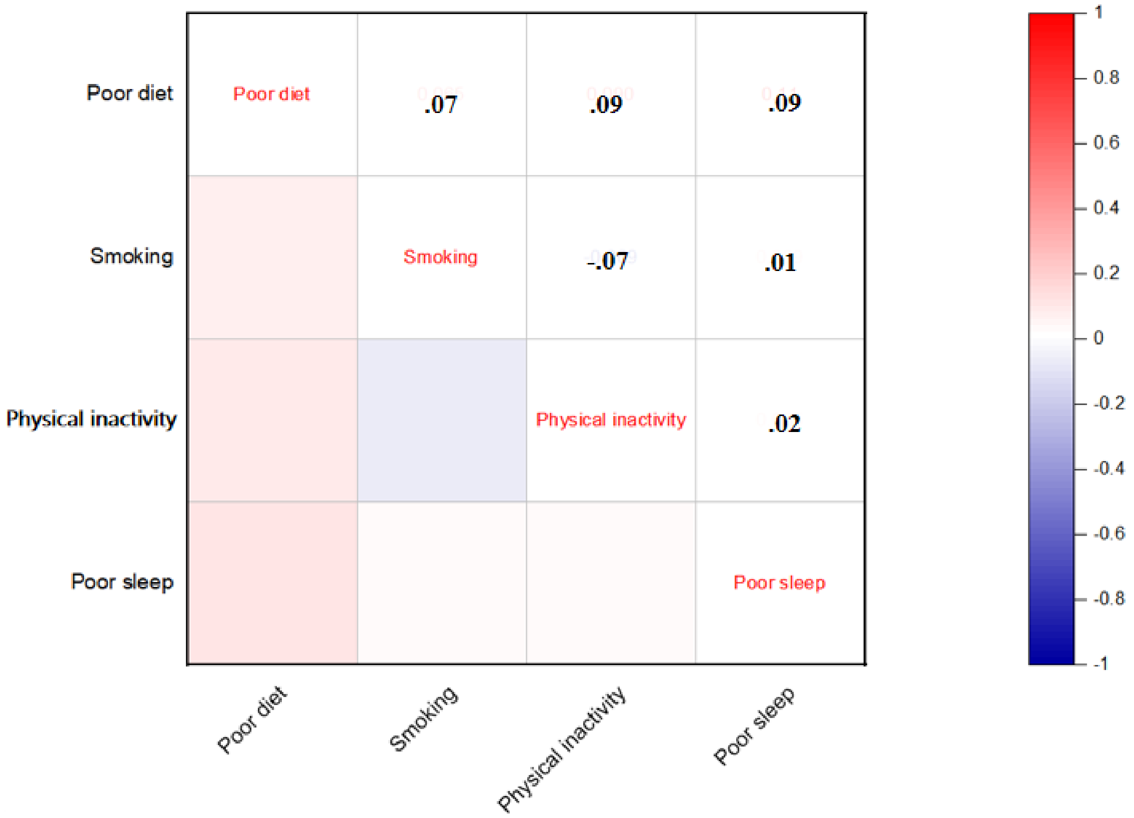
No (n=21,501)	6666 (31)	14,835 (69)		

Correlation of Various Health Risk Behaviors

Most studies have shown that HRBs often appear in clusters, which indicates there is usually a certain correlation between various HRBs. Thus, we also performed a correlation analysis of poor diet, smoking, physical inactivity, and poor sleep; the results are shown in Figure 1. There were statistically significant associations between each HRB (*P*<.05). Of note, there was evidence that other HRBs are positively related in addition to the negative correlation between physical inactivity and smoking. Furthermore, poor diet and poor sleep had the strongest correlation.

Figure 1. Correlation plot of health risk behaviors. Significant level: *P*<.05.



Association of Health Risk Behaviors With Comorbid Anxiety and Depression

Table 2 shows the chi-square associations between anxiety-depression comorbidity and HRBs in adolescents. There were statistically significant associations with anxiety-depression comorbidity for both single HRBs and clustered HRBs, all with a *P* value <.001. In terms of poor diet, physical inactivity, poor sleep, and clustered HRBs, we found that the higher the risk level of HRBs, the higher the likelihood of having comorbid anxiety and depression. However, the smoking medium-risk group had the highest rate of comorbid anxiety and depression compared to the smoking low-risk and high-risk groups.

Logistic regression analysis showed that HRBs were associated with comorbid anxiety and depression (Table 3). Regarding poor diet, adolescents in the medium-risk and high-risk groups were more likely to suffer from anxiety-depression comorbidity than those with low-risk HRBs. Adjusting for potential confounding factors partially attenuated these results, but comorbidity risk generally remained elevated with the increased risk of HRBs (medium risk OR 1.23, 95% CI 1.14-1.33; high risk OR 1.50, 95% CI 1.39-1.62). It is worth noting that the association between smoking and comorbid anxiety and depression was nonlinear, with a higher comorbidity rate in the medium-risk group (OR 2.74, 95% CI 2.14-3.51), whereas the comorbidity rate of anxiety and depression had a decreased tendency when risk increased (OR 2.17, 95% CI 1.67-2.81). The results were similar in the unadjusted model. Physical inactivity medium-risk and high-risk groups were associated with comorbid anxiety and depression without adjustment for any confounders, and the comorbidity rate increased with higher risk levels. However, results from the adjusted model confirmed evidence that there was a statistically significant association only in the high-risk group for physical inactivity (high risk OR 1.16, 95% CI 1.06-1.28). For poor sleep (medium risk OR 1.29, 95% CI 1.20-1.39; high risk OR 1.84, 95% CI 1.70-2.01) and clustered HRBs (medium risk OR 1.57, 95% CI 1.37-1.80; high risk OR 2.33, 95% CI 2.03-2.68), before and after adjusting the model, compared with the low risk group, other risk groups had a higher occurrence rate of anxiety-depression comorbidity, and the comorbidity rate increased as the risk level increased (*P*<.001).

On the basis of the above analysis, we performed a sensitivity analysis for gender stratification. After model adjustment, both OR values and 95% CIs were reduced (Multimedia Appendix 1, Table S2). For poor diet, physical inactivity, poor sleep, and clustered HRBs, boys at the same risk level had higher rates of anxiety-depression comorbidity than girls. Poor diet, poor sleep, and clustered HRB risk index were significant for both boys and girls before and after model adjustment, but no association of physical inactivity with anxiety-depression comorbidity was found for girls in the high-risk group before or after adjustment. It is worth noting that the comorbidity rate of anxiety and depression among girls based on smoking status (medium risk OR 3.94, 95% CI 2.24-6.90; high risk OR 5.00, 95% CI 1.77-14.12) was higher than boys (medium risk OR 2.49, 95% CI 1.88-3.28; high risk OR 2.07, 95% CI 1.58-2.72) at the same risk level, and the risk of smoking was nonlinearly associated with the comorbidity rate of anxiety and depression only in boys. Furthermore, logistic regression associations of clustered HRB risk index with comorbid anxiety and depression were stronger in boys than girls (Figure 2).

Table 2. Association of health risk behaviors with comorbid anxiety and depression.

HRBs[a]	Comorbid anxiety/depression, n (%)	No comorbid anxiety/depression, n (%)	Chi-square (*df*)	*P* value
Poor diet			234.88 (2)	<.001
Low risk (n=6082)	1519 (25)	4563 (75)		
Medium risk (n=7442)	2294 (30.8)	5148 (69.2)

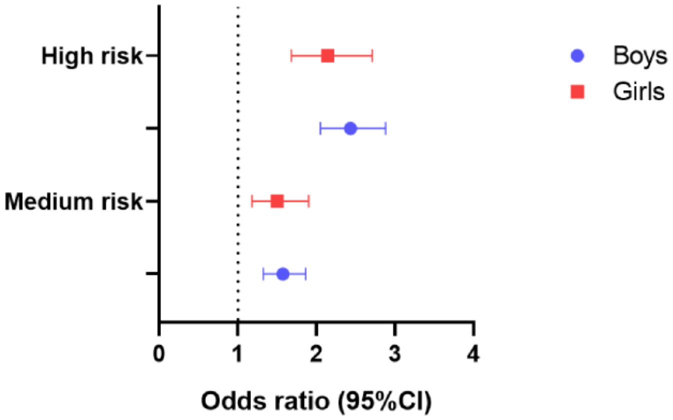
Table 3. Association between health risk behaviors and comorbid anxiety and depression. All reference groups were the low risk groups. Model 1 did not adjust for any variable; model 2 adjusted for demographically meaningful variables such as gender and parental education.

HRBs[a]	Model 1 odds ratio (95% CI)	*P* value	Model 2 odds ratio (95% CI)	*P* value
Poor diet				
Medium risk	1.34 (1.24-1.44)	<.001	1.23 (1.14-1.33)	<.001
High risk	1.74 (1.62-1.87)	<.001	1.50 (1.39-1.62)	<.001
Smoking				
Medium risk	2.42 (1.91-3.07)	<.001	2.74 (2.14-3.51)	<.001
High risk	1.93 (1.51-2.47)	<.001	2.17 (1.67-2.81)	<.001
Physical inactivity				
Medium risk	1.14 (1.03-1.26)	.01	1.07 (0.96-1.18)	.22
High risk	1.42 (1.30-1.54)	<.001	1.16 (1.06-1.28)	<.001
Poor sleep				
Medium risk	1.43 (1.33-1.53)	<.001	1.29 (1.20-1.39)	<.001
High risk	2.21 (2.05-2.37)	<.001	1.84 (1.70-2.01)	<.001
HRB risk index				
Medium risk	1.79 (1.56-2.05)	<.001	1.57 (1.37-1.80)	<.001
High risk	3.09 (2.72-3.52)	<.001	2.33 (2.03-2.68)	<.001

[a] HRB: health risk behavior.

Figure 2. Logistic regression association between health risk behavior risk index and comorbid anxiety and depression in adjusted model. The adjusted model was adjusted for the presence of any siblings, regional economic level, educational status, self-rated health, parental education level, self-reported family income, number of friends, learning burden, and family history of psychosis.



Discussion

Principal Findings

This nationwide study showed that HRBs (poor diet, physical inactivity, smoking, and poor sleep), especially clustered HRBs, were positively associated with higher odds of comorbid anxiety and depression among Chinese adolescents. Furthermore, we confirmed boys had a stronger association between clustered HRBs and comorbid anxiety and depression than girls.

Comparison With Prior Work

The prevalence of comorbid anxiety and depression found in our study (7236/22,868, 31.6%) is higher than in another Chinese study (20.9%) [24] and a previous study carried out with college students in Brazil (27.8%) [25]. However, the prevalence in our study is lower than the estimate in an Italian study (the prevalence of comorbid anxiety and depression was 47%) [26]. The reason for the differences in comorbidity among these different studies may be differences in study areas, survey tools, and subjects, but the above studies all showed high comorbidity of anxiety and depression symptoms. As we all know, comorbid anxiety and depression is common in adolescents. The etiology of comorbid anxiety and depression is usually different from single anxiety or depression. In the common etiological model of comorbidity, anxiety and depression are caused by common environmental risk factors, and the common risk factors interact to promote comorbidity. This may become the core etiological model for explaining comorbid anxiety and depression in the future [27,28]. Furthermore, as shown, common modifiable risk factors for HRBs may lead to anxiety-depression comorbidity, and anxiety-depression comorbidity in turn can easily lead to risk behaviors in individuals, which may be a bidirectional-interaction process [29].

Those with a high HRB risk index, who comprised 55.5% (12,687/22,868) of the sample in our study, were more likely to have comorbid anxiety and depression. The results nonetheless indicate a nonlinear association between smoking and comorbid anxiety and depression, with a slightly higher likelihood of having comorbid anxiety and depression among those with medium smoking risk compared with high smoking risk. This may be related to the age of the adolescents, as a past study showed that the frequency with which adolescents engage in these risk behaviors across development is not always linear [30]. In addition, the reasons for the stronger association between smoking and comorbid anxiety and depression after controlling for confounders need to be explored. Particular behaviors may play different roles in the development of comorbid anxiety and depression in adolescence. Overall, although the results were attenuated, significant differences remained after adjusting for confounders.

Substantial evidence suggests that a range of psychiatric conditions are associated with individuals with adverse health behaviors compared to healthy control subjects [31]. However, few studies have examined the direct association between HRBs and comorbid anxiety and depression, and a majority of studies have examined associations between HRBs and single anxiety or depression. A study of health behaviors and mental health found that the group with the highest clustered health behaviors had the lowest risk of depression, anxiety, and stress [32]. Additionally, participants with multiple HRBs showed significantly increased risk of depression (OR 2.21, 95% CI 1.83-2.67) and anxiety (OR 2.32, 95% CI 1.85-2.92) [3]. Mortality risk and risk of poor health-related quality of life also increase in a dose-response manner as the number of HRBs increases [33]. These results indicate that mental health problems in adolescence are associated with a greater risk of engaging in a host of behaviors that increase individuals' risk for poor physical and mental health over the course of their lifespan.

Achieving good diet habits, not smoking, having adequate physical activity, and sleeping for an appropriate length of time have been individually associated with better mental health among adolescents [34-37]. However, the fact that the above HRBs have been considered separately is concerning, because research has shown that these behaviors are codependent and should be considered together. For example, in addition to being a risk factor for mental disease in and of itself, it is likely poor sleep also acts synergistically to increase the disease burden related to other risk behaviors, with evidence suggesting associations between poor sleep and risks of smoking, poor nutrition, harmful alcohol consumption, and physical inactivity (SNAP); this association may be stronger in people with mental health conditions than those without mental health conditions [38]. Combinations of HRBs have been shown to pose greater morbidity risk than the sum of their individual effects, suggesting a synergistic relationship between risk factors. Multiple-behavior change interventions may therefore have a greater potential for a positive impact on comorbid anxiety and depression than single-behavior change interventions.

There is a close association between HRBs and comorbid anxiety and depression, which may involve biological mechanisms. Multisystem dysfunction, inflammation, oxidative stress, and biological aging are considered to be key pathways in the evolution of mood disorders. Evidence suggests that engaging in HRBs also affects developing adolescents' brains. Adolescents' brains are sensitive to nicotine, especially in the still-developing prefrontal cortex, which is important for executive function and attention, and nicotine use affects cognition by modifying information processing. Thus, adolescent smokers are at increased risk for poor mental health in adulthood [39,40]. Furthermore, mental health in adolescence also worsens with poor nutrition and insufficient physical activity. Physical activity provides various biological effects via multiple mechanisms seen in animal models, including increased levels of brain-derived neurotrophic factor (BDNF) [41] and enhanced neurogenesis [42]. With increased expression of serotonin in animal models as a result of increased physical activity [43], this is theorized to explain much of the antidepressant effect of exercise. A reduction in oxidative stress and inflammatory cytokines has also been found to occur as a result of a healthy lifestyle [44], and this immunological effect may reduce bad mood via effects on the psychoneuroimmunological nexus [45].

Strengths and Limitations

Strengths of our study include the use of a large, nationally representative sample of adolescents, which allowed for adjustment for potential confounding variables that may have made our findings more compelling. Multistage cluster sampling and weighted statistical analyses adjusted for avoidable bias and allow us to generalize our data to the population level. Moreover, HRBs often appear in clusters, but few studies have investigated the 4 HRBs examined here (poor diet, physical inactivity, smoking, and poor sleep) at the same time, and there are relatively few investigations that have examined clustering of behaviors, including sleep. Our study is thus the first large-scale study to simultaneously investigate and combine specific HRBs with comorbid anxiety and depression. Last, sensitivity analyses, such as gender stratification of HRBs, were carried out so as to enable gender-specific measures.

Nonetheless, we recognize the following limitations in our study: First, it was cross-sectional, a study design that limits determination of the causal relationship of HRBs and comorbid anxiety and depression among adolescents. Our research is still ongoing, and further longitudinal analysis will be performed in the future. Second, data on sleep patterns were based on subjective responses of the adolescents, and we could not prevent recall bias. Further studies should be undertaken that include more objective measures of sleep patterns, such as polysomnography and actigraphy. Third, anxiety and depression symptoms were self-reported, which may have led to variation, but the GAD-7 and PHQ-9 are valid instruments with high internal consistency, good test-retest reliability, and good convergence with other types of instruments. Finally, confounding factors that may have contributed to anxiety-depression comorbidity may not have been measured and included in our analyses; future studies should take this into account and incorporate it into the analysis.

Conclusions

The prevalence of comorbid anxiety and depression was 31.6% (7236/22,868) in this national sample of Chinese adolescents. Single HRBs, including poor diet, smoking, physical inactivity, and poor sleep, were all associated with comorbid anxiety and depression in adolescents. Furthermore, clustered HRBs increase the risk of comorbid anxiety and depression compared to single HRBs. These findings should be replicated in longitudinal studies to determine the direction of this association. Our study provides evidence that maintaining a healthy lifestyle pattern, such as maintaining high levels of physical activity and not smoking, is advantageous to healthy development in Chinese adolescents.

Acknowledgments

We are extremely grateful to all participants and their parents who took part in the National Adolescents Cohort (China). This study was supported by the National Natural Science Foundation of China (grant 82173542) and the Grants for Scientific Research Level Improvement Plan from Anhui Medical University (grant 2022xkjT004).

Data Availability

The data sets generated during and/or analyzed during this study are not publicly available because they contain information that could compromise the privacy of research participants, but are available from the corresponding author on reasonable request.

Authors' Contributions

XW and FT conceived and designed the experiments; ST, YW, TL, XM, YX, YZ, and MW performed the study; MW, YX, and YZ analyzed the data; MW wrote the paper.

Conflicts of Interest

None declared.

Multimedia Appendix 1

Table S1 (study population, distribution of main variables and risk scores) and Table S2 (association analysis of health risk behaviors with comorbidity of anxiety and depression by gender).

Abstract

Background: Sedentary time in workplaces has been linked to increased risks of chronic occupational diseases, obesity, and overall mortality. Currently, there is a burgeoning research interest in the implementation of multicomponent interventions aimed at decreasing sedentary time among office workers, which encompass a comprehensive amalgamation of individual, organizational, and environmental strategies.

Objective: This meta-analysis aims at evaluating the effectiveness of multicomponent interventions to mitigate occupational sedentary behavior at work compared with no intervention.

Methods: PubMed, Web of Science, EMBASE, and Cochrane Central Register of Controlled Trials (CENTRAL) databases were searched from database inception until March 2023 to obtain randomized controlled trials (RCTs) assessing the efficacy of multicomponent interventions on occupational sedentary behavior among office-based workers. Two reviewers independently extracted the data and assessed the risk of bias by using the Cochrane Collaboration’s risk of bias tool. The average intervention effect on sedentary time was calculated using Stata 15.1. Mean differences (MDs) with 95% CIs were used to calculate the continuous variables. Subgroup analyses were performed to determine whether sit-stand workstation, feedback, and prompt elements played an important role in multicomponent interventions. Further, the GRADE (Grading of Recommendations, Assessment, Development, and Evaluation) system was used to evaluate the certainty of evidence.

Results: A total of 11 RCTs involving 1894 patients were included in the analysis. Five studies were rated as low risk of bias, 2 as unclear risk of bias, and 4 as high risk. The meta-analysis results showed that compared with no intervention, multicomponent interventions significantly reduced occupational sitting time (MD=–52.25 min/8-h workday, 95% CI –73.06 to –31.44; *P*<.001) and occupational prolonged sitting time (MD=–32.63 min/8-h workday, 95% CI –51.93 to –13.33; *P*=.001) and increased occupational standing time (MD=44.30 min/8-h workday, 95% CI 23.11-65.48; *P*<.001), whereas no significant differences were found in occupational stepping time (*P*=.06). The results of subgroup analysis showed that compared with multicomponent interventions without installment of sit-stand workstations, multicomponent interventions with sit-stand workstation installment showed better effects for reducing occupational sitting time (MD=–71.95 min/8-h workday, 95% CI –92.94 to –51.15), increasing occupational standing time (MD=66.56 min/8-h workday, 95% CI 43.45-89.67), and reducing occupational prolonged sitting time (MD=–47.05 min/8-h workday, 95% CI –73.66 to –20.43). The GRADE evidence summary showed that all 4 outcomes were rated as moderate certainty.

Conclusions: Multicomponent interventions, particularly those incorporating sit-stand workstations for all participants, are effective at reducing workplace sedentary time. However, given their cost, further research is needed to understand the effectiveness of low-cost/no-cost multicomponent interventions.

KEYWORDS

sedentary behavior; workplace; multicomponent; systematic review

Introduction

For most working adults, the majority of their sedentary time is accrued during work time [1,2]. More sitting time was reported at work than in any other sitting activity such as watching television or using a computer at home on weekdays. Studies also revealed that the sitting time of work for full-time office workers accounted for approximately 60%-90% of the total daily sitting time in a workday [3,4]. In addition, there is evidence that working adults who spend long periods of time sitting at work do not necessarily compensate for their sitting by being more active outside work [5]. It is crucial to note that contemporary research indicates that excessive sedentary behavior is detrimentally linked to many health-related risks such as cardiovascular disease, unhealthy aging, musculoskeletal disorders, poor bone health, poor metabolic health, and all-cause mortality, especially when sedentary time accumulates in prolonged uninterrupted bouts [6,7]. The workplace has been highlighted by the World Health Organization as a vital setting for health promotion actions to reduce sedentary behavior [8].

According to 2 umbrella reviews, the utilization of electronic and mobile health tools such as mobile apps is associated with a reduction in sedentary behavior [9,10]. In addition, the recent umbrella reviews indicate that interventions targeting the physical environment, specifically the implementation of active workstations, represent the most efficacious category of interventions for mitigating sedentary behavior in workplaces [11,12]. Following the first randomized controlled trial (RCT) in 2013 [13], a surging multitude of subsequent RCTs has been undertaken to evaluate the efficacy of multicomponent interventions in mitigating sedentary behavior in workplaces among office-based employees [14,15]. The multicomponent interventions encompass a comprehensive amalgamation of diverse modalities, including individual strategies such as counselling, prompts, telephonic support, and motivational interviewing; environmental strategies such as active workstations, prompting posters, exercise sessions, and access to a gym; as well as organizational strategies such as workshops, site visits, consultations, and appointing team leaders, ambassadors, or management support. Currently, there is a burgeoning research interest for implementing multicomponent interventions aimed at mitigating sedentary behavior among office workers [16].

With the growing public health concerns surrounding sedentary behavior in the workplace among nonmanual employees, it is important to determine the effectiveness of multicomponent interventions for office-based workers. This is not only from a theoretical and best practice perspective but also due to the lack of a systematic summary on this topic. Multicomponent interventions are designed to address multiple levels of influence for sustainable behavior change, which aligns with the socioecological theory that emphasizes targeting multiple levels of influence [17]. Despite this, to date, evidence on the efficacy of multicomponent interventions has not been systematically summarized. Previous literature reviews on this topic have been constrained in their scope, as they have not concentrated specifically on the efficacy of multicomponent interventions in mitigating sedentary behavior. In addition, these reviews are outdated and have incorporated only a small number of RCTs in their analyses, which restricts the capacity to arrive at conclusive determinations regarding their impact [18,19].

Thus, this systematic review and meta-analysis includes newly published RCTs and aims to identify the effect of multicomponent interventions on sedentary workplace behavior based on more sedentary-related outcomes such as occupational sitting time, occupational standing time, occupational stepping time, and prolonged occupational sitting time. Furthermore, given that electronic and mobile health tools and physical environment interventions such as the implementation of an active workstation are independent and effective components affecting sedentary time, we performed subgroup analyses based on whether these components were included in the multicomponent interventions and attempted to identify the more effective components of multicomponent interventions.

Methods

Search Strategy

PubMed, Web of Science, EMBASE, and Cochrane Central Register of Controlled Trials (CENTRAL) databases were searched from database inception to March 1, 2023. The main search strategies were as follows: (occupation* or workplace* or employe* or office* or work-site or worker* or staff* or white-collar*) AND (sedentary or sitting or inactivity or "physical activity" or "physically active") AND (random* or blind* or singleblind* or doubleblind* or tripleblind* or RCT* or control*). The detailed search strategy is presented in Multimedia Appendix 1. In addition, the World Health Organization International Clinical Trials Registry Platform search portal, ClinicalTrials.gov, conference materials, and reference lists (backward and forward) of the studies identified using the above search strategy were searched manually for additional studies on March 1, 2023. We also searched relevant grey literature, including clinical guidelines, reports, and working papers through Google and grey literature databases [20].

Inclusion and Exclusion Criteria

Studies were included if they met all the eligibility criteria mentioned in Table 1.

Table 1. Inclusion and exclusion criteria for study selection.

	Inclusion criteria	Exclusion criteria
Participants	Workers aged ≥18 years who work in the office, do jobs that generally do not involve manual labor, or wear uniforms or work clothes were included	People working in the transportation industry (such as taxi drivers, truck drivers, bus drivers, and airline pilots) and those who operate heavy equipment (such as crane operators and bulldozer operators) were excluded
Intervention	Multicomponent interventions integrating individual strategies (eg, counselling, prompts, telephonic support, motivational interviews), environmental strategies (eg, active workstations, prompting posters, exercise sessions, access to a gym), and organizational strategies (eg, workshops, site visits, consultations, and appointment of team leaders, ambassadors, management support) aimed at changing sedentary behavior were eligible	Single-component interventions (such as implementation of a sit-stand workstation alone) or 2-level interventions consisting of only 2 types of strategies of the multicomponent intervention were excluded
Comparison	Usual work practices or waitlist	Other interventions such as single-component interventions, 2-level interventions, or multicomponent interventions were excluded
Outcome	Workplace sitting and activity outcomes during work hours: occupational sitting time, occupational standing time, occupational stepping time, and occupational prolonged sitting time as measured by self-report (eg, questionnaires) or using objective measures (eg, accelerometer) at the primary end point	Studies that reported daily sitting or activity outcomes during total waking hours rather than workplace sitting and activity outcomes specifically during work hours were excluded
Study design	Only studies with a parallel control (or treatment-comparison group) such as randomized controlled trials, controlled trials, cluster randomized controlled trials, or quasi-experimental studies were included in this review	Reviews, expert opinions, meta-analyses, or before-and-after studies were excluded
Language	English	Non-English

Study Selection and Data Extraction

Two independent reviewers performed title screening and data extraction of the retrieved studies, and any conflicts were resolved through a discussion. We used EndNote X9.1 software to omit duplicates. Subsequently, based on the inclusion and exclusion criteria, the 2 reviewers screened the titles and abstracts to discard irrelevant studies. Studies were removed from further review if both reviewers excluded them. Otherwise, full papers were obtained for a detailed review. We extracted the following data from the included studies by using a prespecified data form: general information (publication date, name of the first author, and study country/region), study population (age, gender, education, and employment status), multicomponent intervention (component, frequency, and duration of intervention; delivery mode; theoretical framework; status of sit-stand workstation installation; and inclusion of feedbacks and prompts), comparison intervention (waitlist or no intervention), outcomes (occupational sitting time, occupational standing time, occupational stepping time, and occupational prolonged sitting time [sitting time accumulated in bouts ≥30 minutes]), and follow-up time.

Risk of Bias Assessment

The Cochrane risk of bias tool was used to evaluate the quality of RCTs based on randomization and allocation concealment (selection bias), blinding of personnel and participants (performance bias), blinding of outcome assessment (detection bias), incomplete outcome data (attrition bias), selection of reported results (reporting bias), and sources (other bias), and the RCTs were evaluated as having low, high, or unclear risk of bias [21]. Studies were rated as having a low risk of bias if all items were low risk. When 1 item was high risk, the study was rated as having a high risk of bias. The studies that did not fall into the abovementioned categories were rated as having an unclear risk of bias [22-24]. In all the included studies, blinding of the participants or personnel to the intervention and allocation concealment was not possible in accordance with the nature and aim of the interventions, wherein intervention participants typically underwent changes in environment (such as installation of sit-stand workstation). Therefore, the performance bias item and allocation concealment item were excluded from the bias assessment. However, for the allocation concealment item, trials were assessed as high risk if there was a contamination between intervention and control group participants, that is, if participants from the same office or company ended up in different groups. Participants in the control group are more likely to be less sedentary under the influence of individuals in the intervention group in the same office, regardless of group allocation [25-27]. Studies were considered to have a low risk of bias if measures were taken to minimize contamination, such as using cluster trials or assigning intervention and control participants to separate floors in the same building. Studies were classified as unclear risk of bias if there was insufficient information to determine the presence of either of the above conditions. For studies with multiple publications, we reviewed all relevant papers, including protocol papers, to ensure that the quality of the trial was judged on all available information.

Data Treatment and Statistical Analysis

Data synthesis was based on the general recommendations from the Cochrane Handbook for Systematic Reviews of Interventions [28]. Both the adjusted mean difference (AMD) and its SD were extracted for studies that reported AMD for the intervention and control groups after the intervention or change (change from baseline or change score) for time spent in sedentary behavior. For studies that did not report AMD or change, the unadjusted MD and SD were calculated from the means and SDs at baseline and after follow-up in each group. Therefore, the AMDs and unadjusted MDs were pooled together using the inverse variance method. For studies with multiple intervention arms, estimates were combined into a single group as a weighted average using Cochrane formula for combining subgroups if all the intervention arms are multicomponent. If, in a multiple arm trial, an arm was not a multicomponent intervention, then we excluded that arm.

We used minutes per 8 hours of work time at the workplace as the standard unit in the main group and subgroup analyses because it was the most commonly reported unit of measurement in the included trials. We converted all the measurement units for sitting at work into min/8-h workday, where needed and possible and assumed the data referred to a 5-day work week if this was not reported. Therefore, studies that reported min/8-h workday were combined with studies that reported min/d, min/workday, h/d, and min/week to measure the overall minutes in sedentary behavior per workday.

MD value with 95% CI based on the inverse variance method was used as the summary statistic for continuous variables, including sitting time, standing time, stepping time, and prolonged sitting time. Heterogeneity was evaluated using the Higgins I^2 value, and values ≤50% and >50% were considered to indicate low and high heterogeneity, respectively. MD values and the corresponding 95% CIs were calculated. $P<.05$ was considered to indicate statistical significance [29]. All statistical analyses were performed using Stata version 15.1 (StataCorp LLC). The random effects model was used. As mentioned in the Introduction, electronic and mobile health tools and physical environment interventions, especially installation of active workstations, are independent and effective components affecting sedentary time. Therefore, we performed subgroup analyses to determine whether sit-stand workstations, feedbacks (individual feedback on sedentary behavior at baseline and following the monitoring of activity during the trial), and prompts (individual prompts to regularly break up sitting through email, telephone, computer software, or prompting app) played an important role in multicomponent interventions. With regard to the sit-stand workstation element, we divided the included studies into 2 subgroups based on whether individual sit-stand workstations were installed in the trial: multicomponent intervention with sit-stand workstation installment and multicomponent intervention without sit-stand workstation installation. Based on prior research highlighting the significant influence of availability on the utilization of sit-stand workstation [30], we made the decision to mandate the complete availability of the sit-stand workstation within the subgroup of multicomponent interventions that involved the installation of such workstations. To maintain categorization consistency, the studies including workplaces that provide some sit-stand workstations available for shared use were classified into the subgroup of multicomponent intervention without sit-stand workstation installment. In the case of shared active workstations, office workers were required to temporarily vacate their original workstations to utilize shared facilities. In these instances, shared sit-stand workstation interventions were paired with other environmental strategy interventions such as access to a gym and the provision of company bikes but not with individual sit-stand workstations. Sensitivity analyses were performed on the outcome indicators of ≥10 studies to explore their potential sources and assess the robustness of these results. Egger test was used to assess publication bias [31].

Certainty Assessment

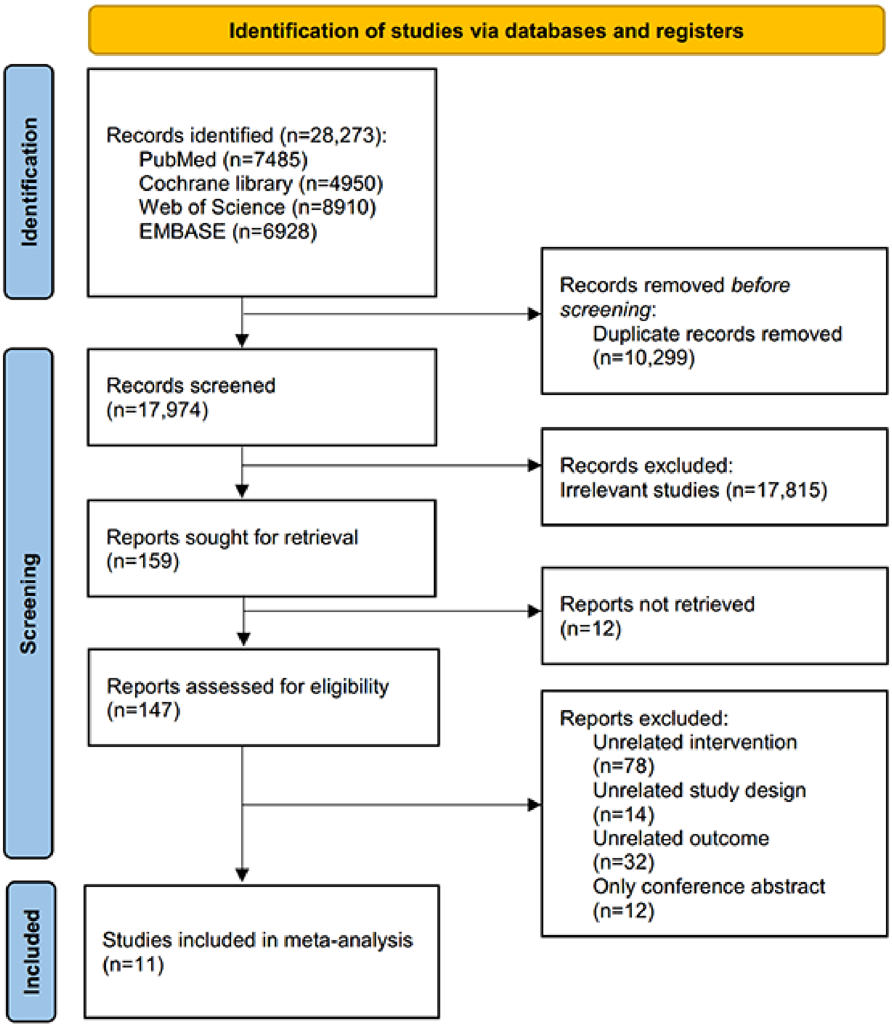
Two reviewers independently rated the certainty of evidence associated with specific outcomes and constructed a table summarizing the certainty of evidence findings using the GRADE (Grading of Recommendations, Assessment, Development, and Evaluation) system [32,33]. The GRADE approach uses 5 domains, namely, risk of bias, inconsistency, indirectness, imprecision, and publication bias, which are assessed to determine the degree of confidence in the estimate of effect or association derived from the meta-analysis. Prespecified level of certainty was initially considered based on the study design (eg, high certainty for RCTs). Correspondingly, following the rating by reviewers, the certainty of evidence was changed and divided into no downgrade (not serious), downgrade by 1 level (serious), or downgrade by 2 levels (very serious). Finally, the certainty of evidence of each outcome was judged as different levels of evidence, that is, high, moderate, low, and very low.

Results

Study Selection

A flow diagram of the literature selection process is shown in Figure 1. A total of 28,273 relevant records were initially identified, of which 10,299 were excluded because of duplication. The titles and abstracts were screened, and 17,815 were deemed unsuitable. After reading the full text, another 159 studies were excluded because of inappropriate study design or topic of research. Finally, 11 studies were included in this meta-analysis [13-15,34-41].

Figure 1. Flowchart of the selection of randomized controlled trials that assessed the effects of multicomponent interventions on the occupational sedentary behavior of office-based workers.



Main Characteristics of the RCTs

Of the 11 studies [13-15,34-41] included in this meta-analysis, 7 were cluster RCTs [15,34,35,37,39-41] and 4 were quasi-RCTs [13,14,36,38] (Multimedia Appendix 2). Regarding the location of the studies, 4 were conducted in Australia [13,14,36,37], 3 in England [34,35,39], and 1 each in Denmark [15], Taiwan [38], Sweden [40], and the Netherlands [41]. The studies were published between 2013 and 2022. All the trials compared the multicomponent intervention with no intervention among office-based workers. Multicomponent interventions aiming at reducing sedentary time in the workplace consisted of individual strategies, environmental strategies, and organizational strategies. In Multimedia Appendix 3 [13-15,34-41], a detailed account of the constituent elements and implementation particulars of multicomponent interventions implemented in each of the trials is presented. Seven of the 11 studies [13-15,34-37] had environmental components that implemented interventions to install sit-stand workstations, whereas the other 4 [38-41] did not. The studies included 1894 participants (1127 and 767 in the intervention and control groups, respectively) with a mean age ranging between 37.3 and 49.5 years. The sample size largely varied among the studies and ranged between 25 and 756. The intervention and follow-up periods varied from 1 month to 12 months. Seven studies [13, 14, 34, 35, 37, 39, 41] assessed sedentary behavior outcomes using the activPAL accelerometer, 3 studies [15, 36, 40] used the ActiGraph accelerometer, and only 1 [38] study used self-reported methods (ie, a self-efficacy scale). The dropout rates in the studies ranged from 1.98% to 35.52%.

Risk of Bias Assessment

As shown in Figure 2, the risk of bias was high in 4 studies [13,36,38,40], unclear in 2 [14,39], and low in 5 [15,34,35,37,41]. Regarding the random sequence generation assessment, 3 studies [13,36,38] did not adhere to random sequence generation, and thus we judged them to have a high risk of bias. Additionally, 1 trial [14] was assessed as unclear risk of bias because it gave no information about how randomization was done. For allocation concealment, 1 trial [36] was assessed as high risk due to contamination between the intervention and control group participants. Regarding outcome assessment, 1 trial [38] was rated as high risk of bias because its outcome measures were self-reported. Regarding incomplete outcome data, 1 study [40] was assessed as high risk of bias due to attrition rates of more than 25%. Regarding selection of the reported results, 4 trials [13,36,38,39] were assessed as unclear risk of bias due to there being no available trial registration or published protocol.

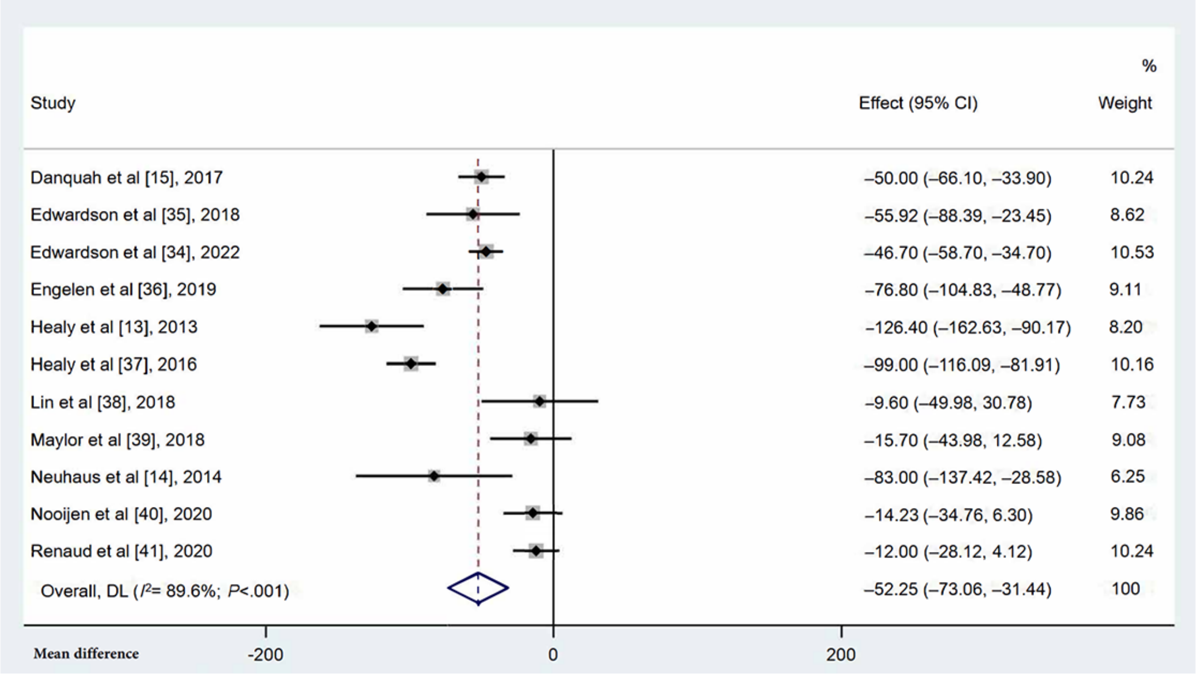
Summary of the Intervention Effects

Occupational Sitting Time

All 11 included studies, with the multicomponent intervention and control groups including 1127 and 767 individuals, respectively, measured occupational sitting time (Figure 3). Participants in the multicomponent intervention groups had significantly shorter occupational sitting time than those in the control groups (MD=–52.25 min/8-h workday, 95% CI –73.06 to –31.44; I^2=89.6%; P<.001). Sensitivity analysis showed that no single study significantly affected the overall heterogeneity.

Figure 3. Forest plots for the effects of multicomponent interventions on occupational sitting time in office-based workers compared with usual practices [13-15,34-41]. Note: Weights are from random-effects model. DL: DerSimonian-Laird approach.



Study	Effect (95% CI)	% Weight

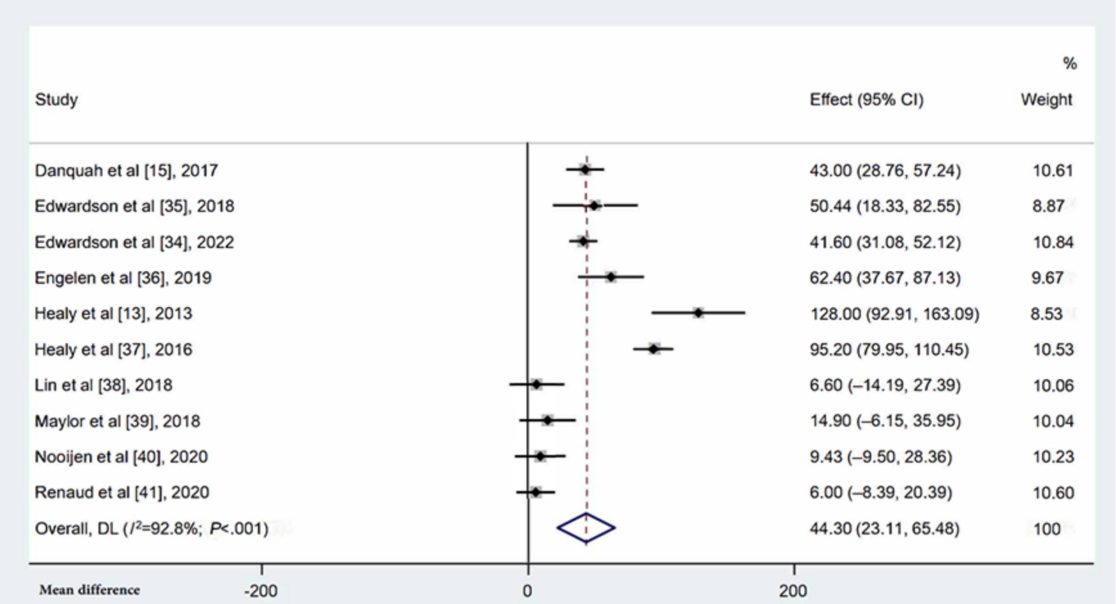
Occupational Standing Time

A total of 10 studies [13,15,34-41] with the multicomponent intervention and control groups including 1115 and 754 individuals, respectively, measured occupational standing time at the workplace (Figure 4). Participants who were in the multicomponent intervention group had significantly increased standing time compared with those in the control group (MD=44.30 min/8-h workday, 95% CI 23.11-65.48; I^2=92.8%; P<.001). Sensitivity analysis showed that no single study significantly affected the overall heterogeneity.

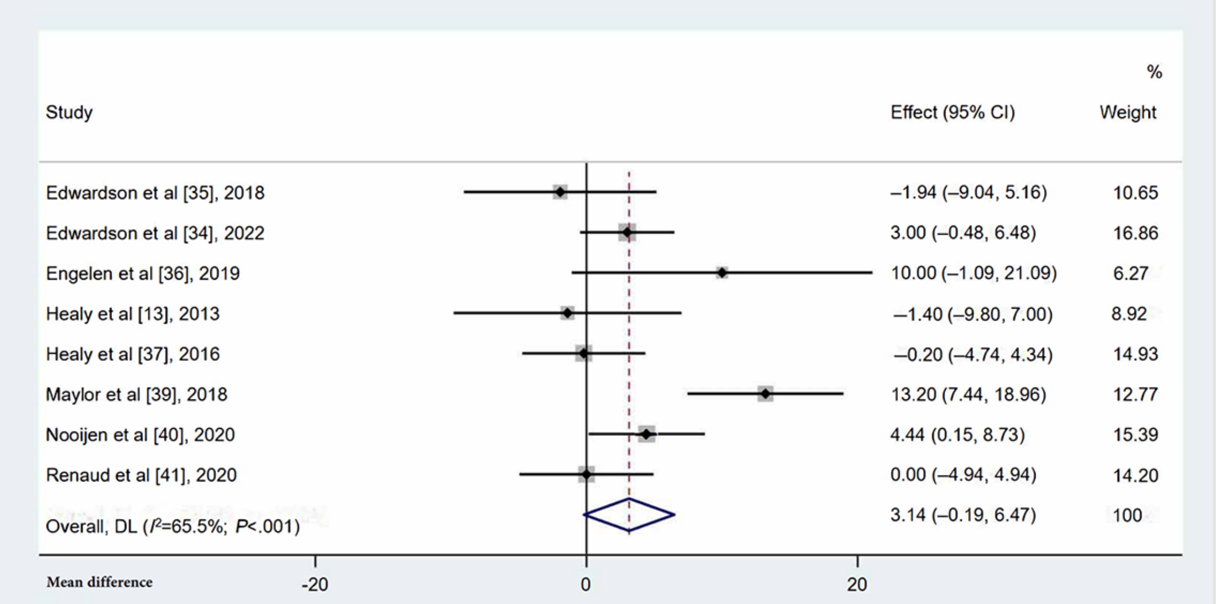
Figure 4. Forest plots for the effects of multicomponent interventions on occupational standing time in office-based workers compared with usual practices [13,15,34-41]. Note: Weights are from random-effects model. DL: DerSimonian-Laird approach.



Occupational Stepping Time

Of the 11 studies [13-15,34-41], 8 [13,34-37,39-41] reported the occupational stepping time of individuals (Figure 5). No statistically significant difference in occupational stepping time was observed between the 2 groups (MD=3.14 min/8-h workday, 95% CI –0.19 to 6.47; I^2=65.5%; P=.06).

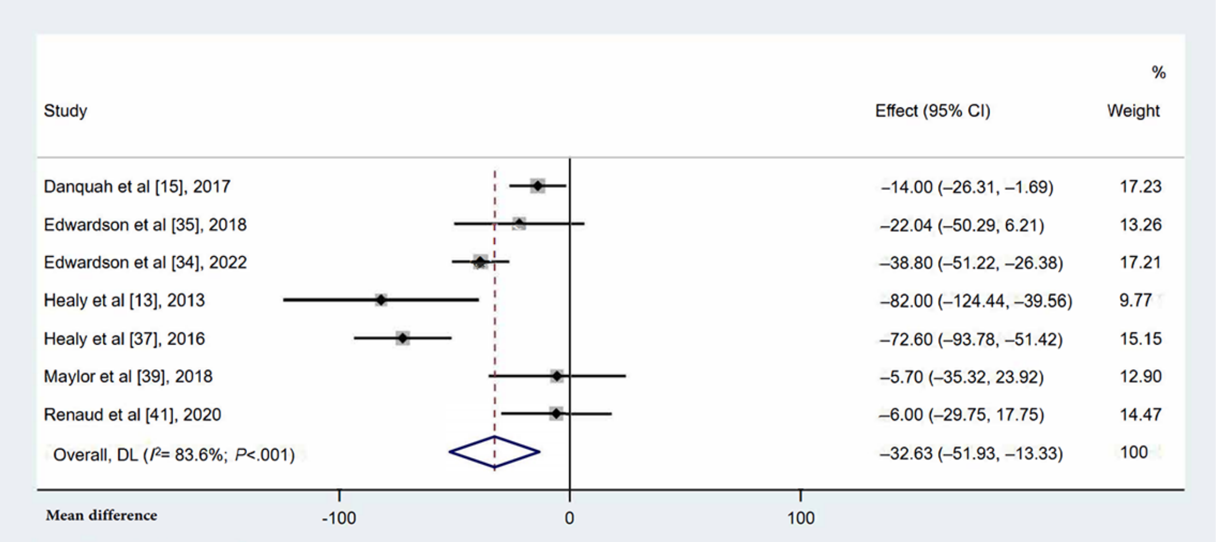
Figure 5. Forest plots for the effects of multicomponent interventions on occupational stepping time in office-based workers compared with usual practices [13,34-37,39-41]. Note: Weights are from random-effects model. DL: DerSimonian-Laird approach.



Occupational Prolonged Sitting Time

Seven studies [13,15,34,35,37,39,41] reported a reduction in occupational prolonged sitting time at work following multicomponent interventions (Figure 6). Multicomponent interventions significantly reduced prolonged sitting time (MD=–32.63 min/8-h workday, 95% CI –51.93 to –13.33; I^2=83.6%; P=.001).

Figure 6. Forest plots for the effects of multicomponent interventions on occupational prolonged sitting time in office-based workers compared with usual practices [13,15,34,35,37,39,41]. Note: Weights are from random-effects model. DL: DerSimonian-Laird approach.



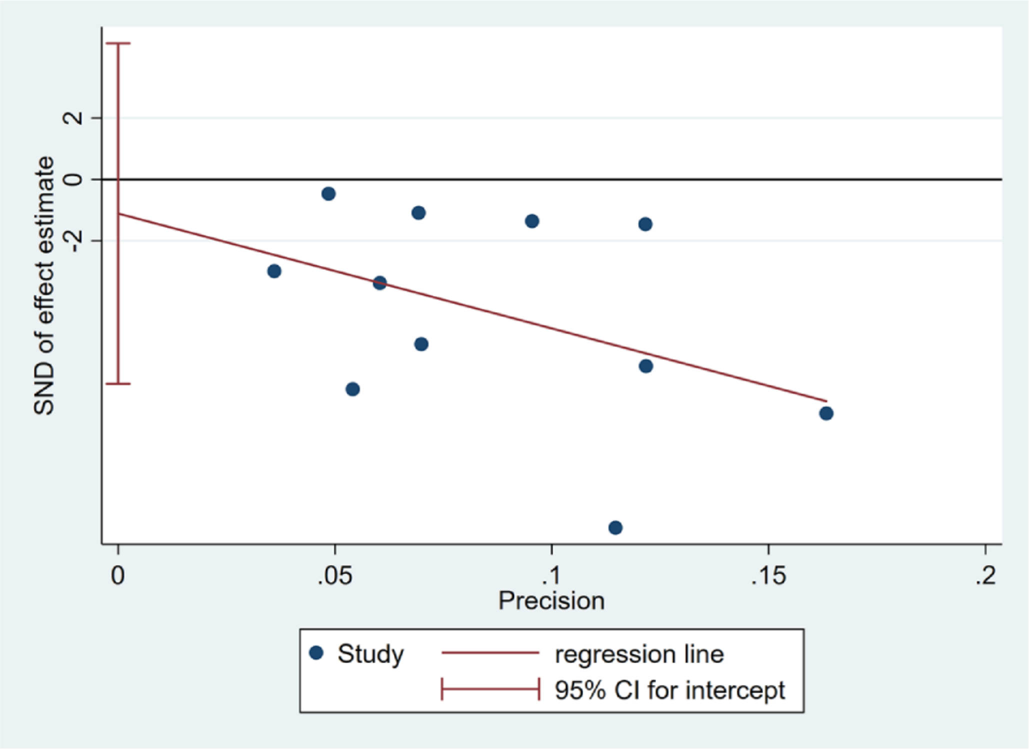
Subgroup Analyses

In the subgroup analyses for installment of sit-stand workstations during multicomponent interventions, the multicomponent intervention subgroup with sit-stand workstation installment showed considerable reduction in the occupational sitting time (MD=–71.95 min/8-h workday, 95% CI –92.94 to –51.15; I^2=84.2%; *P*<.001); however, the multicomponent intervention subgroup without sit-stand workstation installment showed a smaller reduction in the occupational sitting time (MD=–14.25 min/8-h workday, 95% CI –22.78 to –5.72; I^2=0%; *P*=.001). Furthermore, the results showed no heterogeneity in the subgroup without the installment of sit-stand workstations. The multicomponent intervention subgroup with the sit-stand workstation installment showed a great increase in the occupational standing time (MD=66.56 min/8-h workday, 95% CI 43.45-89.67; I^2=89.9%; *P*<.001), but the multicomponent intervention subgroup without the sit-stand workstation installment showed no such effect (MD=6.82 min/8-h workday, 95% CI –0.09 to 13.67; I^2=0%; *P*=.06). The results showed no heterogeneity in the subgroup analysis without the installment of sit-stand workstations. Further, the multicomponent intervention subgroup with the installment of sit-stand workstations showed a considerable reduction in occupational prolonged sitting time (MD=–47.05 min/8-h workday, 95% CI –73.66 to –20.43; I^2=88.7%; *P*=.001), but the multicomponent intervention subgroup without the installment of a sit-stand workstation showed a smaller reduction (MD=–11.49 min/8-h workday, 95% CI –22.78 to –0.19; I^2=0%; *P*=.04). On the contrary, the multicomponent intervention subgroup with the installment of sit-stand workstations showed no significant difference in stepping time (MD=1.53 min/8-h workday, 95% CI –0.90 to 3.96; I^2=5.8%; *P*=.22), but the subgroup without the installment of sit-stand workstations showed increased occupational stepping time (MD=5.22 min/8-h workday, 95% CI 0.31-10.13; I^2=74.9%; *P*=.04). On performing subgroup analysis based on inclusion of prompt and feedback elements in multicomponent interventions, no significant differences between subgroups were observed overall (Multimedia Appendix 4).

Publication Bias

A funnel plot based on Egger test was constructed, and no publication bias was found (*P*=.68) (Figure 7).

Figure 7. Egger publication bias plot for assessing publication bias among the 11 included randomized controlled trials. SND: standard normal deviation.



Certainty Assessment

The GRADE evidence summary of certainty showed that all 4 outcomes were rated as moderate certainty (occupational sitting time, occupational standing time, occupational stepping time, and occupational prolonged sitting time). The main reason we downgraded the certainty of evidence was limitations in study design, that is, high risk of bias in the studies, including nonrandomized allocation sequence, possible contamination between the intervention and control groups, self-reported outcome measures, a high rate of loss to follow-up, and unclear risk of bias in the studies, including no information about random allocation sequence generation, trial registration, or published protocol (Multimedia Appendix 5).

Discussion

Principal Findings

In this meta-analysis of RCTs, we included 11 studies [13-15,34-41] involving 1894 participants from 6 countries. The analyses showed, with moderate certainty of evidence, that multicomponent interventions were effective in reducing occupational sitting time, increasing occupational standing time, and reducing occupational prolonged sitting time. We did not find a statistically significant difference in the occupational stepping time outcome between the groups. Based on subgroup analysis results, multicomponent interventions with the installment of sit-stand workstations were significantly more effective in decreasing both occupational sitting time (*P*<.001) and occupational prolonged sitting time (*P*<.001) while increasing occupational standing time (*P*<.001). Conversely, the subgroup without the sit-stand workstation installment demonstrated only marginal reduction in occupational sitting time and occupational prolonged sitting time but demonstrated a minor increase in occupational stepping time. Minimal differences were observed between multicomponent intervention subgroups with the presence and absence of feedbacks and prompts in occupational sitting time, standing time, stepping time, and prolonged sitting time. More RCTs are still needed to strengthen the evidence body.

Potential Interpretations of the Findings

These findings may be explained by multicomponent interventions implemented in the included studies, which reduced sedentary behavior primarily by increasing sitting-to-standing transitions by using a sit-stand workstation rather than by increasing stepping [42]. Multicomponent interventions may primarily reduce occupational sitting and occupational prolonged sitting time and increase occupational standing time by promoting the use of sit-stand workstations among office workers in their environmental strategies through individual and organizational strategies. The provision of a sit-stand workstation permits continued work at a computer while standing as opposed to encouraging regular ambulation [43]. Therefore, sit-stand workstation installation may be required to significantly reduce occupational sitting time. However, the subgroup without the installment of sit-stand workstations exhibited only slight reductions in both occupational sitting time (MD=–14.25 min/8-h workday) and occupational prolonged sitting time (MD=–11.49 min/8-h workday) and a minor increase in occupational stepping time (MD=5.22 min/8-h workday). In addition, it should be noted that the increase in occupational stepping time associated with an 8-hour workday is minimal, and the effect size is negligible. Furthermore, the increased occupational sitting time only constitutes a small fraction of the overall reduction in occupational sitting time. The impact of increased occupational stepping time on reducing sedentary behavior in the workplace is limited. Consequently, we deduce that some multicomponent interventions implementing measures such as step/pedometer challenges, walking routes and resources, walking meetings, and lunch walks to reduce sedentary behaviors demonstrated limited effectiveness in increasing the stepping time of participants because most of these measures were of secondary and facilitative nature throughout the multicomponent intervention [35,44]. Moreover, the effectiveness of these measures may also be limited by space, feasibility, and convenience. Specifically, all interventions reduced the occupational total sitting time and prolonged sitting time, and most increased occupational standing time by using sit-stand workstations. These changes occurred across the workday among participants, although there was a wide individual variability in these changes [45,46].

This explanation can also be confirmed by Danquah et al [15], who suggested that the multicomponent intervention was effective in reducing sitting time and prolonged sitting time and in increasing the number of sit-to-stand transitions among office workers who already have sit-stand workstations (which is a standard equipment at most Danish workplaces, introduced for ergonomic considerations) [15]. In addition, Renaud et al [41] concluded that the multicomponent intervention had little to no effect in reducing occupational sitting time, which may be because of the relatively low intensity of the intervention, that is, it only involved the replacement of 25% of sitting workstations with sit-stand workstations. In addition, Michaud et al [47] conducted a cluster-RCT comparing multicomponent interventions with and without the incorporation of a sit-stand workstation and reported that the former intervention, with the installment of a sit-stand workstation, resulted in a reduction in occupational sitting time as well as total sitting time, thus strongly supporting our findings. Therefore, we believe that sit-stand workstations play a central role in multicomponent interventions and that the other components play a role in facilitating and increasing the effect.

Comparisons With Other Reviews

Our findings on the effects of multicomponent interventions are consistent with several other systematic reviews in this area, which have demonstrated the benefits of such interventions in reducing sedentary time among office workers [18,19]. However, in comparison with previous systematic reviews and meta-analyses that investigated the effectiveness of multicomponent interventions, we included 3 more outcomes (occupational standing time, occupational prolonged sitting time, and occupational stepping time). In addition, subgroup analyses, including the installation of sit-stand workstations, feedbacks, and prompts, were conducted to investigate the significant constituents of multicomponent interventions, predicated on the inclusion of sit-stand workstations, feedback, and prompt elements, which were found to be independent and efficacious factors influencing sedentary time in previous studies. In brief, we included 11 RCTs with 1894 participants, which was almost 3 times the number of RCTs and participants included in the previous meta-analyses. Nonetheless, we observed similar results suggesting that multicomponent interventions are effective in reducing sitting time. With a more robust analysis, we could conclude that multicomponent interventions are also effective in reducing prolonged sitting time and increasing standing time. Furthermore, we used the GRADE method to assess the certainty of the evidence for the effectiveness of multicomponent interventions in reducing occupational sitting time and occupational prolonged sitting time and increasing occupational standing time and occupational stepping time among office workers.

Assessment of Evidence Quality

Although the results of this meta-analysis are based on rigorously designed RCTs, they should be interpreted with caution because of the risk of bias. The 5 study designs [15,34,35,37,41] identified to have a low risk of bias met all standards. The remaining 4 studies [13,36,38,40] were deemed to have a high risk of bias, and 2 [14,39] were considered to have unclear risk of bias. This was mainly demonstrated in the fact that the allocation sequence was not randomized; there was possible contamination between the intervention and control groups; there was a high rate of loss to follow-up; and there was no available information about random allocation sequence generation, trial registration, or published protocol. This may have affected the authenticity of the reported results. Allocation concealment and blinding of participants and personnel was not possible once the study was underway because of the open plan nature of the environmental strategies in multicomponent interventions. However, 1 trial was assessed as high risk because of contamination between the intervention and control group participants; in this trial, participants from the same office or company were placed in different groups [36]. Participants in the control group were likely to be less sedentary because of the influence of the intervention group participants in the same office [25-27]. Therefore, while allocation concealment and blinding are not possible, the certainty of evidence was also downgraded 1 level to moderate due to the other limitations in the study design, such as the allocation sequence not being randomized, possible contamination between the intervention and control groups, a high rate of loss to follow-up, and no information about random allocation sequence generation, trial registration, or published protocol. These methodological limitations underscore the importance of future clinical trials adhering to robust study design principles and implementation guidelines. RCTs with rigorous randomization procedures should be prioritized to minimize bias and increase the validity of findings [48]. Additionally, adopting the CONSORT (Consolidated Standards of Reporting Trials) as the reporting standard can significantly improve study quality and transparency [49]. CONSORT guidelines provide a structured framework for reporting essential aspects of trial design, conduct, and analysis, thereby enabling readers to evaluate the study's validity and replicate the findings. To further enhance the scientific quality and reliability of RCTs, investigators should consider utilizing the Cochrane quality assessment tool [21]. This tool allows researchers to conduct a comprehensive self-examination of the study design, hypothesis formulation, data collection and analysis methods, and risk of bias assessment. By critically evaluating these aspects, researchers can identify and address potential limitations, thus strengthening the overall methodological rigor of the trial. Furthermore, the preregistration of studies and publishing research protocols can be beneficial for improving the transparency and trustworthiness of the evidence generated [50,51]. This practice helps reduce the risk of selective outcome reporting and ensures that the reported findings align with the initial study plan.

Strengths and Limitations

This review was based on RCTs with real-world data. We conducted a comprehensive systematic search of 4 primary databases. Any differences between reviewers during screening, data extraction, risk of bias assessment, and evidence certainty grading were resolved through a discussion. We used 4 outcome measures to assess the effects of multicomponent interventions on sedentary behavior in the workplace. Estimates from the fully adjusted models in each study were used in our analyses to reduce the potential for confounding. We used the GRADE approach to assess the certainty of evidence, which will allow the readers to clearly understand the uncertainty in results. Furthermore, we conducted sensitivity analyses to test the robustness of the results. No evidence of publication bias was found. However, when interpreting the results, the following limitations should be considered. First, the countries included in this review were mainly high-income countries, thereby limiting the generalizability of the results. Office workers in high-income countries pay more attention to physical health than those in low-income countries; accordingly, participants may have shown higher motivation during the trial. Second, differences among office workers may affect the reliability of the evidence obtained in this study, such as job type, length of work, levels of physical and cognitive loads across sectors and industries, and workload. Third, the limited sample size observed in certain studies, coupled with variations in measurement units, likely exerted an influential impact on the wide CIs, leading to imprecise estimations of effect sizes. Furthermore, some included studies have been evaluated to possess high and unclear risk of bias due to limitations in study designs. In the future, more high-quality cluster-RCTs with large sample sizes are needed to strengthen the evidence body. Fourth, a substantial degree of heterogeneity was evident in the findings. However, we found no heterogeneity in the multicomponent intervention without the installment of a sit-stand workstation, whereas the multicomponent intervention with the sit-stand workstation installment showed heterogeneity. A high degree of heterogeneity was still observed in the subgroup of multicomponent intervention with the sit-stand workstation installment. Therefore, we speculate that the installment of a sit-stand workstation as well as its specific type and function (eg, whether it was electronically regulated) constituted the primary sources of heterogeneity. Regrettably, due to inadequate description of these parameters in the included studies, we were unable to conduct more comprehensive subgroup analyses or meta-regression analyses to further explore the origins of heterogeneity.

Conclusions

Multicomponent interventions are indeed effective in reducing sedentary behavior in workplaces. In particular, multicomponent interventions including the component of sit-stand workstation installation are more effective in reducing sedentary behavior in workplaces. The reduction in sitting time was mainly replaced by standing time, which we presume primarily resulted from the increased use of the sit-stand workstation. Thus, the sit-stand workstation may be a key component of multicomponent interventions. Therefore, future research will benefit from assessing the relative contribution of different individual and organizational components for mitigating sedentary behavior in workplaces through factorial designs or multiple arms. Moreover, future studies should add detailed cost-effectiveness and time-of-day effect analyses while reporting multicomponent interventions. Further research to understand the effectiveness of low/no-cost multicomponent interventions is needed.

Acknowledgments

This research was supported by the National Natural Science Foundation of China (72074103), the Fundamental Research Funds for the Central Universities (lzujbky-2021-ct06, lzujbky-2021-kb22), and the Gansu Special Project of Soft Science (20CX9ZA109). Abstract

Background: Online grocery delivery services (OGDSs) are a popular way of acquiring food. However, it is unclear whether OGDS use is associated with the healthiness of purchases and whether there are sociodemographic differences in OGDS use. If so, the increased prevalence of OGDS use may have implications for population diet, and differential OGDS use could contribute to diet inequalities.

Objective: This study aimed to examine whether OGDS use varies by sociodemographic characteristics and is associated with the amount and types of groceries purchased.

Methods: Item-level take-home food and drink purchase data (n=3,233,920 items) from households in London and the North of England were available from the 2019 UK Kantar fast-moving consumer goods panel (N=1911). Purchases were categorized as being bought online or in-store. We used logistic regression to estimate the likelihood of an above-median frequency of OGDS use by sociodemographic characteristics. We used Poisson regression to estimate the differences in energy and nutrients purchased by households that had above- and below-median OGDS use and the proportion of energy purchased from products high in fat, salt, and sugar (HFSS) online versus in-store among households that used both shopping methods (n=665).

Results: In total, 668 (35%) households used OGDSs at least once in 2019. Of the households that used OGDSs, the median use was 5 occasions in 2019. Households were more likely to have above-median use in London versus in the North of England (odds ratio 1.29, 95% CI 1.01-1.65) and if they had a higher annual household income (odds ratio 1.56, 95% CI 1.02-2.38 for ≥£50,000 [US $64,000] vs <£20,000 [$25,600]). Households with above-median OGDS use had a higher weekly mean purchase of energy by 1461 (95% CI 1448-1474) kcal per person compared with households with below-median OGDS use. For households that used a combination of in-store and online shopping, HFSS products made up a lower proportion (–10.1%, 95% CI –12% to –8.1%) of energy purchased online compared to in-store.

Conclusions: Differences in grocery purchases between households with above- and below-median OGDS use could have positive or negative consequences. The extra energy purchased among households with above-median OGDS use could lead to overconsumption or food waste, which has negative consequences for population and environmental health. Alternatively, this extra energy may be replacing out-of-home purchasing, which tends to be less healthy, and may be beneficial for the population diet. Households made fewer HFSS purchases when shopping online compared to in-store, which may be due to differences in the shopping environment or experience, such as fewer promotions and advertisements when shopping online or not having to transport and carry purchases home. As higher-income households used OGDS more frequently, the implications of this sociodemographic pattern on dietary inequalities must be explored.

Introduction

There has been an increasing interest in whether the use of digital platforms to purchase foods impacts on the type of products purchased and, therefore, population diet and health. Much of this research has focused on the purchase of takeaway foods [1-3], but fewer studies have explored the use of online services for grocery purchases. The use of online grocery delivery services (OGDS) is an increasingly popular method of purchasing food and drink products for preparation and consumption at home. Although online delivery services have been available for over 20 years, they have grown rapidly in the past decade, with recent consumer adoption and growth in the use of these services further accelerated by the COVID-19 pandemic [4,5]. These services enable groceries to be ordered online for home delivery or to be picked up through "click and collect," where purchased products are selected and packed in-store ready for collection by the consumer. The industry predicts further growth, with around half of those who used OGDS for the first time during the pandemic intending to continue [6].

OGDS may plausibly have positive and negative impacts on dietary behaviors [7-10]. Positive impacts might arise through changes in the shopping experience compared to traditional in-store purchasing. For example, products are presented symbolically in online channels rather than physically in stores, which may decrease their vividness and reduce consumers' desire to purchase [11]. OGDS also increase the lag time between product choice and food acquisition [12]. It is theorized that people make more healthful food choices when the outcome (ie, acquisition or consumption of food) is further into the future [9], as there is a decreased focus on immediate gratification [11,12]. OGDS may also improve access to food, thereby potentially increasing access in communities with poor availability or quality of local food shopping opportunities or enabling those with poor access to transport to take advantage of home delivery [13-15]. Almost all households in Great Britain are covered by at least 1 supermarket delivery service, with 3 of the major supermarkets each providing coverage to over 98% of households [15].

There may also be negative effects on dietary behaviors. Sizing of products may be more difficult to determine online, leading to over- or underpurchasing. One UK study found that there were differences in the size of products, fewer price promotions, and less front-of-pack labeling for products available online when compared to similar products in-store [16]. Online delivery may also be more appealing for larger, heavier items and increase bulk buying (leading to overconsumption and waste), while consumers may be less inclined to purchase healthier perishable goods such as fresh fruit and vegetables [10].

Who accesses these services and what they purchase online may be influenced by sociodemographic characteristics, which could also plausibly influence dietary inequalities [8]. For example, many OGDSs have minimum spend requirements and delivery fees, meaning that more affluent households may have greater access to and use of these services compared to more disadvantaged households [10]. OGDS use may also be affected by household size, composition, age, and other sociodemographic characteristics. Similar differences have been observed for online delivery services for takeaway foods, where the use of these services was more likely among adults who were younger, male, from an ethnic minority background, highly educated, or had children [1]. Such differences may have implications for dietary inequalities if OGDS use influences purchasing behavior [7,8,11].

Whether OGDS affects the dietary quality of purchases has not been well studied. Some limited evidence from the United States suggests that the share of consumer expenditure on healthy products is higher when grocery purchases are made online compared to in-store [9,11,12,17]. From intervention studies that use online delivery services to improve diet and nutrition, including in low-income populations, there is some evidence that they can improve the healthiness of purchases [18,19].

Overall, the evidence on who uses OGDS and how the use of these services may have either positive or negative effects on dietary behaviors is limited. A deeper understanding of the ways that OGDSs are associated with purchasing behavior could help inform future policies and interventions aiming to improve population diet and reduce dietary inequalities. This study, using large-scale consumer panel data from England, aims to generate evidence in this area by (1) exploring the sociodemographic correlates of OGDS use and (2) exploring whether the use of OGDS is associated with overall grocery food and drink purchases and purchases of unhealthier products that are high in fat, salt, and sugar (HFSS).

Methods

Study Design

We used data on household take-home grocery food and drink purchasing from the 2019 Kantar fast-moving consumer goods (FMCG) panel. FMCG are products sold quickly and at a relatively low cost, including food and drink. Kantar, a commercial consumer data company, continually recruits around

30,000 households in the United Kingdom to a live panel via email and post using quota sampling. The households largely reflect the key sociodemographic characteristics of the geographical region they have been sampled from. The data available for this analysis were from a study examining the association between outdoor HFSS food and drink advertising restrictions in London and household food and drink purchases [20]. Households in our analysis were randomly selected from Kantar households in London or the North of England (North West, North East, and Yorkshire and the Humber regions). The included households (N=1911) recorded individual food and drink purchases (n=3,233,799 items) from December 31, 2018, to December 29, 2019. Our findings are reported in accordance with the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) guidelines (Multimedia Appendix 1).

Ethical Considerations

Ethical approval was not required for the analysis of anonymized secondary data. Upon joining, participants agreed to the terms and conditions of the Kantar FMCG panel, which state that their data may be used for research purposes. Panelists receive around £100 (~US $128) worth of vouchers for their participation per year.

Purchases and Nutrient Data

Participating households recorded all food and drink items purchased and brought into the home using a handheld barcode scanner. Nonbarcoded products, such as loose fruits and vegetables, were recorded using bespoke barcodes. Kantar provided nutrient data based on direct assessment of product nutrient labels in outlets twice a year or using product nutrient label images provided by Brandbank, an FMCG product database. Where this nutritional information was not available, Kantar obtained nutritional values from similar products or an average value for the product type was used.

We used nutrient data provided by Kantar to assess the healthiness of products by categorizing purchases as HFSS or non-HFSS, based on the UK's nutrient profiling model (NPM), which was developed by the Food Standards Agency in 2004/2005 [21]. We chose this classification as it has been used in policies and regulations in the United Kingdom previously [22,23]. An NPM score for each product was calculated by adding points for energy, sugar, sodium, and saturated fat and subtracting points for protein, fiber, fruit, nut, and vegetable content. Information on the energy, sugar, sodium, saturated fat, protein, and fiber content of each purchase was provided by Kantar. Kantar categorizes product markets as high, mixed (medium) or low in fruit, nuts, and vegetables, which we then used to assign individual products with 5 (>80%), 1 (>40% and ≤80%), or 0 (≤40%) points for fruit, nut, and vegetable content. The higher the final NPM score, the less healthy the product. We used the recommended cut-offs of ≥4 for foods and ≥1 for drinks to classify a product as HFSS. We additionally split purchases into 35 food groups based on (1) product market and submarket classifications provided by Kantar and (2) whether products were healthier (non-HFSS) or less healthy (HFSS). These food groups have been used in other studies and are described in Table S1 in Multimedia Appendix 1 [24].

Sociodemographic Characteristics

Sociodemographic data are collected by Kantar annually. We had access to data on sex, age (years), and occupational social class of the main food shopper, number of adults and children in the household, and household income. Occupational social class was based on the National Readership Survey social grade [25]. We categorized occupational social class as high (AB—higher and intermediate managerial, administrative, and professional occupations), middle (C1C2—supervisory, clerical and junior managerial, administrative, and professional occupations), and low (DE—semiskilled and unskilled manual occupations and unemployed, including retired). Gross annual household income bands were available for 1608 (84.1%) households (<£20,000, £20,000-£29,999, £30,000-£39,999, £40,000-£49,999, and ≥£50,000 [A currency exchange rate of £1=US $1.28 is applicable.]). Height and weight were self-reported by 1544 (80.8%) of the main food shoppers and used to calculate BMI (kg/m^2).

Outcomes

Mode of Purchase

Panelists reported the type of store each purchase was from, including whether purchases were made through the internet. Purchases were determined to be online or in-store purchases according to this information. Click and collect services were included in OGDS, as store type information was based on where purchases were made rather than how they were delivered.

Purchases

Household purchases, stratified by online or in-store, were summed over the 1-year study period. We then divided this by household size and the 52 study weeks to obtain means per person per week for outcomes: energy (kcal), fat (g), saturated fat (g), sugar (g), salt (g), items (packs), and expenditure (£). To account for energy purchased, we also looked at mean weekly outcomes per 100 kcal purchased for fat (g/100 kcal), saturated fat (g/100 kcal), sugar (g/100 kcal), salt (g/100 kcal), and expenditure (£/100 kcal). We further explored the proportion of purchases that were HFSS and the proportion of energy purchased from HFSS products and from each of the 35 food groups.

Statistical Analyses

All items purchased on the same day using the same mode of purchase (online or in-store) were considered as having been purchased in the same shopping occasion. The use of OGDS was highly skewed (Figure S1 in Multimedia Appendix 1). Most households did not use OGDS in 2019, and many households that did use them did so infrequently. Among households that used OGDS, the median use was 5 occasions in 2019. We explored differences in purchases between households that used OGDS above and below the median as we theorized that households with very low OGDS use (eg, 1-2 occasions in a year) would not be representative of typical users.

Using a logistic regression model, we examined the association between sociodemographic characteristics (sex, age group, region, occupational social class, household income, number of adults in the household, and presence of children in the household) and OGDS use (above- or below-median). Using Poisson regression models, we explored the association between OGDS use and total purchases of energy, nutrients (overall and per 100 kcal), items, and expenditure (overall and per 100 kcal). Marginal effects were obtained, and pairwise comparison was used to estimate the difference in mean purchases per person per week. We also examined the association between OGDS use and the proportion of purchases that were HFSS using linear regression models. For households that used both online and in-store purchasing methods (n=665), we compared the mean proportion of energy purchased from HFSS products and the 35 food groups through the 2 shopping methods. To examine the associations between OGDS use and purchases independent of household sociodemographic characteristics, all models were adjusted for sex, age, and occupational social class of the main food shopper, region, household income, and proportion of household members that were children (number of children divided by household size). The logistic regression model used to investigate the association between sociodemographic characteristics and OGDS use was also mutually adjusted for other sociodemographic characteristics. All analyses were conducted in Stata SE 16 (Stata Corp).

Sensitivity Analyses

As the cut-offs for categorizing households by the frequency of OGDS could have been made in several ways, we also explore the differences between regular users (which we defined as households using OGDS ≥26 occasions in 2019) and nonregular users (<26 occasions) to see if our results were sensitive to changes in cut-off. As only 147 households were regular OGDS users, we did not use this as our main analysis due to reduced statistical power. We also ran the analyses comparing households that had any OGDS use (n=668) with those that had no OGDS use (n=1243). As mentioned above, we did not use this as our main analysis as we theorized that households with very low OGDS use would not be representative of typical users. Using a subsample of households where the main food shopper's BMI was known (n=1544), we also reran our analyses, additionally adjusting for BMI—a potential confounder of the relationship between OGDS use and purchasing behavior—to see if this changed our findings. BMI was categorized into 2 groups: not overweight (<25 kg/m^2) and overweight (≥25 kg/m^2).

Results

Study Population and OGDS Use

In total, 1911 households were included in our analyses (Table 1). Most households had a female main food shopper (n=1391, 72.8%), were in the middle social class group (n=1133, 59.3%), had 2 adults (n=1062, 55.6%), and had no children (n=1358, 71.1%). Households varied in their household income and age of the main shopper. Of the 1911 included households, 668 (35%) used OGDS at least once in 2019. Almost all households that used OGDS also shopped in-store (n=665, 99.6%). Of households that used OGDS, the median use was 5 (IQR 1-22) occasions in 2019. When stratified by above- (≥5 occasions) and below- (<5 occasions) median OGDS use, there were 353 (18.5%) households above and 1558 (81.5%) below the median including households that did not use OGDS at all. Without adjustment, female main shoppers, younger main shoppers, households in London, households with higher annual income, and households with children were more likely to have above-median OGDS use.

[a] OGDS: online grocery delivery service.

[b] A currency exchange rate of £1=US $1.28 is applicable.

Food and Drink Purchases

Overall, households purchased a median of 9808 (IQR 6988-13,375) kcal and spent £21.40 (IQR £14.20-£31.40) per person per week (Table 2). Most food and drink items were purchased in-store, with 2,891,843 (89.4%) items purchased in-store and 341,956 (10.6%) items purchased online. HFSS purchases accounted for 1,231,882 (38.1%) of total items purchased and households purchased a median of 4.8 (IQR 3.2-6.9) HFSS items per person per week. Without adjustment, households with above-median OGDS use had higher purchases of energy and salt, purchased more items and spent more compared to households with below-median OGDS use. Households with above-median OGDS use also purchased marginally more salt per 100 kcal, spent more per 100 kcal purchased, and purchased marginally less sugar per 100 kcal compared to households with below-median OGDS use in our unadjusted analysis.

Table 2. Unadjusted sample purchases of energy, nutrients, items, and expenditure per person per week for households with above- and below-median online grocery delivery service (OGDS) use.

	Total users (N=1911), median (IQR)	Above-median OGDS users (n=353), median (IQR)	Below-median OGDS users (n=1558), median (IQR)	Chi-square (*df*=1)	*P* value

Sociodemographic Correlates of OGDS Use

In our adjusted models, households where the main shopper was female were marginally more likely than those with male shoppers to have above-median OGDS use (odds ratio [OR] 1.38, 95% CI 1.04 to 1.83; Table 3). London households were more likely to have above-median OGDS use than households in the North of England (OR 1.29, 95% CI 1.01-1.65). Households in the highest 2 income groups (£40,000-£49,999 and ≥£50,000) were more likely to have above-median OGDS use than households with an income <£20,000 (OR 1.70, 95% CI 1.09-2.66 and OR 1.56, 95% CI 1.02-2.38, respectively). No difference was observed by age group of main shopper, occupational social class, number of adults, or the presence of children in the household.

Table 3. Sociodemographic differences in online grocery delivery service (OGDS) use (N=1911) using a logistic regression model adjusted for sex and age of the main food shopper, occupational social class, household income, the proportion of household members that were children, and region.

Association Between OGDS Use and Total Food and Drink Purchases

After adjustment for sociodemographic and household characteristics, households with above-median OGDS use had higher mean purchases of energy (1461 kcal, 95% CI 1448-1474 kcal), fat (64.8 g, 95% CI 62.1-67.6 g), saturated fat (28.5 g, 95% CI 26.8-30.2 g), sugar (63.9 g, 95% CI 61.1-66.7 g), salt (6.1 g, 95% CI 5.4-6.9 g), and items (3 items, 95% CI 2.5-3.5 items) per person per week (Table 4). These households also spent more on groceries per person per week (mean £6.30, 95% CI £5.70-£7.00) than those with below-median OGDS use. However, there was no difference in nutrients purchased per 100 kcal between the 2 groups. When food products and drink products were separated, food accounted for most of the differences observed, although the significant associations were the same for both food and drink (Table S2 in Multimedia Appendix 1).

Table 4. Incidence rate ratio (95% CI) and predicted difference in adjusted weekly mean (95% CI) purchases of energy, nutrients, items per person, and expenditure on groceries per person between households with above- and below-median online grocery delivery service (OGDS) use using a Poisson model adjusted for sex and age of the main food shopper, occupational social class, household income, the proportion of household members that were children, and region.

	Incidence rate ratio (95% CI)	Predicted outcome for above-median OGDS use (n=353), mean (95% CI)	Predicted outcome for below-median OGDS use (n=1558), mean (95% CI)	Predicted difference, mean (95% CI)
Energy (kcal)	1.14 (1.14 to 1.14)	11,927 (11,916 to 11,939)	10,466 (10,461 to 10,471)	*1461* (*1448* to *1474*)[a]

Association Between OGDS Use and Purchases of HFSS Products

There were no differences in HFSS purchases between households that had above- and below-median OGDS use in our adjusted models (Table 5). At a more disaggregated level, households with above-median OGDS use purchased more or the same amount as households that had below-median use across healthier and less healthy food groups (Table S3 in Multimedia Appendix 1).

Table 5. Coefficient (95% CI) and predicted difference in adjusted weekly mean (95% CI) energy; nutrients; items from high in fat, salt, and sugar purchases as a proportion of all grocery food and drink purchases; and expenditure on products high in fat, salt, and sugar as a proportion of all food and drink grocery expenditure between households with above- and below-median online grocery delivery service (OGDS) use using a linear regression model adjusted for sex and age of the main food shopper, occupational social class, household income, proportion of household members that were children, and region.

	Coefficient (95% CI)	Predicted outcome for above-median OGDS use (n=353), mean (95% CI)	Predicted outcome for below-median OGDS use (n=1558), mean (95% CI)	Predicted difference, mean (95% CI)

Association Between Mode of Shopping and Purchases Among OGDS Users

Among households that used both online and in-store shopping methods (n=665), the mean proportion of energy purchased from HFSS products was –10.1% (95% CI –12% to –8.1%) lower in online compared to in-store shopping occasions (43.3%, 95% CI 41.4%-45.2% vs 53.3%, 95% CI 52.5%-54.1%) in the adjusted model. When stratified by food group, online purchases had proportionately more energy from vegetables (1%, 95% CI 0.2%-1.8%), healthy nonmilk-based drinks (1.6%, 95% CI 0.7%-2.4%), and alcohol (1.2%, 95% CI 0.4%-2.1%) and proportionally less energy from some HFSS food groups, including puddings and biscuits (–3.3%, 95% CI –4.1% to –2.5%), chocolate and confectionery (–1.5%, 95% CI –2.2% to –0.7%), and savory snacks (–0.8, 95% CI –1.3% to –0.2%; Table S4 in Multimedia Appendix 1). Healthy nonmilk-based drinks were nonalcoholic and not milk-based (eg, milkshakes and coffee drinks). Examples of nonmilk-based drinks included carbonated drinks and juice drinks. Healthy refers to non-HFSS according to the UK nutrient profiling model. The proportion of energy was also lower from carbohydrate food groups (healthy bread: –3.1%, 95% CI –3.7% to –2.5%; less healthy bread: –0.7, 95% CI –0.8% to –0.5%; morning goods: –0.6%, 95% CI –0.8% to –0.4%), dairy products (reduced fat milk: –0.9, 95% CI –1.2% to –0.6%; high fat milk: –0.4, 95% CI –0.6% to –0.2%; less healthy cheese: –1.2, 95% CI –1.7% to –0.7%, healthy cheese: –0.01, 95% CI –0.02% to 0%), protein (–0.6%, 95% CI –1.1% to 0%), and ready meals (healthy: –1.2%, 95% CI –1.6% to –0.8%; less healthy: –0.7, 95% CI –1.2% to –0.2) for online shopping occasions.

Sensitivity Analyses

The difference in total grocery purchases between regular OGDS users and nonregular users was larger compared to the main analysis (2208 kcal, 95% CI 2188-2228 kcal vs 1461 kcal, 95% CI 1448-1474 kcal; Table S5 in Multimedia Appendix 1). There were no qualitative differences in the proportion of HFSS purchases between regular OGDS users versus nonregular users and above- versus below-median users (Table S6 in Multimedia Appendix 1). The association between households with any versus no OGDS use and total purchases was in the same direction as the main analysis, but the magnitude of difference was smaller (756 kcal, 95% CI 746-766 kcal vs 1461 kcal, 95% CI 1448-1474 kcal; Table S7 in Multimedia Appendix 1). Although the point estimates for HFSS purchases were similar for any versus no OGDS use and above- versus below-median use, a marginally higher proportion of energy, fat, and saturated fat from HFSS products was observed among households that had any OGDS use compared to households with none (Table S8 in Multimedia Appendix 1). Adjusting for BMI did not qualitatively change the association between OGDS use and total food and drink purchases (Table S9 in Multimedia Appendix 1) or OGDS use and HFSS purchases (Table S10 in Multimedia Appendix 1).

Discussion

Summary of Main Findings

Overall, in our sample, 35% (n=668) of London and the North of England households used OGDS at least once, with OGDS users having a median use of 5 occasions in 2019. Almost all households that used OGDS also purchased foods in-store. Higher-income households, households with a female main food shopper, and households in London versus the North of England had a higher likelihood of above-median OGDS use. Households with above-median OGDS use had higher mean purchases of groceries per person per week, in terms of energy (1461 kcal), number of food and drink items (3 items), and expenditure (£6.30). Nutrients purchased per 100 kcal, expenditure on purchases per 100 kcal, and the proportion of total purchases that were HFSS were similar in both groups. However, households that used both shopping modes purchased a 10.1% (95% CI 8.1%-12%) lower proportion of energy from HFSS products from their online compared with in-store purchases.

Interpretation of Findings

Almost no households in our sample exclusively used OGDS for their grocery shopping. OGDS use therefore appears to complement, rather than substitute, in-store grocery shopping. The extra energy purchased among households with above-median OGDS use, compared with below-median OGDS use, could lead to overconsumption or food waste, which has negative consequences for population health and environmental health. Alternatively, more energy purchased for in-home consumption could be because these households eat out less. If this is the case, additional grocery purchases may be beneficial for population diet as consuming out-of-home food is associated with weight gain and higher intakes of energy, fat, salt, and sugar [26,27].

No significant differences in the healthiness of purchasing between households according to their OGDS use were observed, with households with above-median OGDS use purchasing greater amounts of both HFSS and non-HFSS products. However, there was a difference in the healthiness of purchasing within households, with their online purchases having fewer HFSS products than their in-store purchases. This means that households made healthier choices online or preferentially purchased their healthier products online. As our analysis was a comparison within households, the differences observed here cannot be due to household characteristics and are likely due to factors that influence the shopping experience (eg, vividness of products, time lag between shopping and receiving items, exposure to promotions and front-of-pack labeling, preference for purchasing some items online or in-store, and ability to browse products online vs in-store) and, in turn, purchasing behavior [11,12,28]. Online shopping environments have been found to be more supportive of healthier diets through fewer advertisements and promotions and a lack of product placement to encourage HFSS purchases. A healthier food environment in an online setting, compared to a physical setting, is supported by studies from the United States, which found OGDS to be associated with purchasing healthier food [9,11,12,17]. The higher proportion of energy from fruit and vegetables in households' online shops suggests that households were not deterred from purchasing perishable goods without being able to choose products personally, which was a concern highlighted in previous research [10]. Differences in the online food environment, compared to the physical food environment, may have implications for population health, especially as OGDS use prevalence increases. Therefore, further research is needed to understand why households choose OGDS and how it relates to in-store purchasing and out-of-home purchasing to give us a better understanding of total food purchases. With the COVID-19 pandemic having encouraged greater use of OGDS [4,5], future studies should examine short- and long-term changes in food purchasing behaviors and their associations with population diet.

While we have some understanding of, and are trying to regulate, aspects of the in-store food environment [29], less is known about how online platforms influence purchases and whether and how these should (or should not) be regulated. Some studies have shown positive results for interventions that manipulate the online food environment to encourage healthier purchasing [28,30,31]. The online food environment could be used to increase access to fresh food, improve access to nutritional information, and reduce exposure to HFSS advertising [10,19]. While there are fewer promotions online compared to in-store in the United Kingdom (24% of products vs 32% of products), front-of-pack labeling was only found for 42% of products online compared to 74% in-store [16]. Regulations could be helpful in harnessing the elements of OGDSs that may improve population health while limiting the elements that may have negative impacts.

Strengths and Limitations

While online platforms for grocery purchasing have been available for many years, little is known about their association with food and drink purchasing behavior in the United Kingdom. Our findings contribute to the evidence base on OGDS use and food purchasing behavior. Purchase data are a good indicator of food and drink consumption [32,33]. However, they do not tell us about the intrahousehold distribution of purchases, which we assumed to be equal across all household members, including children. This, of course, will not have been the case and provides only an estimate, which likely underestimates purchased energy and nutrients per adult for households with children. Purchase data also do not tell us about food waste. Having data at the item level with the day on which purchases were made and whether this was online or in-store allowed us to establish OGDS use by number of occasions. However, it is unknown whether households may report online and in-store purchases differently. Households may also have forgotten to report purchases or chosen to not report less healthy purchases due to social desirability. The lower average weekly household grocery food expenditure in this analysis (£21.40) compared to the UK's Living Costs and Food Survey (£32.12) may be explained by the inclusion of only 2 UK regions in our study and the unweighted nature of our data, which limits its accuracy in reflecting population-level averages [34]. We were able to compare online and in-store purchases for households that used both modes of shopping, which removed potential confounding from household characteristics. However, we were only able to assess purchases brought into the home and could not consider out-of-home purchases, so we were unable to capture overall household food purchasing. We were also unable to equivalize household income as we did not have information on the age of the children in the household. However, all models were adjusted for the proportion of household members that were children. Errors in the nutrient data, imputed values where data were missing, and the crude estimation of fruit, nut, and vegetable content may have affected the accuracy of our categorization of products as HFSS or non-HFSS. We were unable to explore how online shopping interacts with other forms of food acquisition.

Conclusions

In this study, OGDS use was greater among higher-income and London households. Households that had above-median OGDS use purchased a mean of 1461 kcal more energy per person per week through their grocery purchases. The differences in grocery purchases between households with above- and below-median OGDS use could have positive or negative consequences. The extra energy purchased through groceries among households with above-median OGDS use could lead to overconsumption or food waste, a problem for population health and the environment. Alternatively, more energy purchased for in-home consumption could plausibly replace out-of-home consumption, which may be beneficial to population diet, as out-of-home food tends to be less healthy. Households purchased fewer HFSS purchases when shopping online compared to in-store, which may be due to differences in the shopping environment or experience, such as fewer promotions and advertisements when shopping online or not having to transport and carry purchases home. As higher-income households used OGDS more frequently, the implications of this sociodemographic patterning on dietary inequalities need to be explored. Further research is needed to investigate the relationship between OGDS use and the healthiness of purchasing in different population subgroups. With the online food environment becoming an increasingly important retail channel for household food purchasing, it should be an important consideration when designing food system policies and interventions that aim to improve population diet and reduce dietary inequalities.

Abstract

Background: Long-acting injectable cabotegravir (CAB-LA) for preexposure prophylaxis (PrEP) has proven efficacious in randomized controlled trials. Further research is critical to evaluate its effectiveness in real-world settings and identify effective implementation approaches, especially among young sexual and gender minorities (SGMs).

Objective: ImPrEP CAB Brasil is an implementation study aiming to generate critical evidence on the feasibility, acceptability, and effectiveness of incorporating CAB-LA into the existing public health oral PrEP services in 6 Brazilian cities. It will also evaluate a mobile health (mHealth) education and decision support tool, digital injection appointment reminders, and the facilitators of and barriers to integrating CAB-LA into the existing services.

Methods: This type-2 hybrid implementation-effectiveness study includes formative work, qualitative assessments, and clinical steps 1 to 4. For formative work, we will use participatory design methods to develop an initial CAB-LA implementation package and process mapping at each site to facilitate optimal client flow. SGMs aged 18 to 30 years arriving at a study clinic interested in PrEP (naive) will be invited for step 1. Individuals who tested HIV negative will receive mHealth intervention and standard of care (SOC) counseling or SOC for PrEP choice (oral or CAB-LA). Participants interested in CAB-LA will be invited for step 2, and those with undetectable HIV viral load will receive same-day CAB-LA injection and will be randomized to receive digital appointment reminders or SOC. Clinical appointments and CAB-LA injection are scheduled after 1 month and every 2 months thereafter (25-month follow-up). Participants will be invited to a 1-year follow-up to step 3 if they decide to change to oral PrEP or discontinue CAB-LA and to step 4 if diagnosed with HIV during the study. Outcomes of interest include PrEP acceptability, choice, effectiveness, implementation, and feasibility. HIV incidence in the CAB-LA cohort (n=1200) will be compared with that in a similar oral PrEP cohort from the public health system. The effectiveness of the mHealth and digital interventions will be assessed using interrupted time series analysis and logistic mixed models, respectively.

Results: During the third and fourth quarters of 2022, we obtained regulatory approvals; programmed data entry and management systems; trained sites; and performed community consultancy and formative work. Study enrollment is programmed for the second quarter of 2023.

Conclusions: ImPrEP CAB Brasil is the first study to evaluate CAB-LA PrEP implementation in Latin America, one of the regions where PrEP scale-up is most needed. This study will be fundamental to designing programmatic strategies for implementing and scaling up feasible, equitable, cost-effective, sustainable, and comprehensive alternatives for PrEP programs. It will also contribute to maximizing the impact of a public health approach to reducing HIV incidence among SGMs in Brazil and other countries in the Global South.

Introduction

Background

In 2021, there were approximately 960,000 people living with HIV in Brazil [1]. In recent studies, the HIV prevalence rate was estimated to reach approximately 23% among Brazilian gay men, bisexual men, and other men who have sex with men (MSM) [2] and surpass 30% among *travesti* and transgender women (TGW) in some cities [3,4]. Young MSM aged ≤30 years are among the few populations with an increasing number of new HIV infections in Brazil, whereas HIV incidence has stabilized in the overall population [2]. Since December 2017, oral tenofovir disoproxil fumarate (TDF) and emtricitabine (FTC) HIV preexposure prophylaxis (PrEP) have been freely available in Brazil through the national public health system (*Sistema Único de Saúde* [SUS]) [5]. As of October 2022, there were 566 health facilities across all Brazilian states providing oral PrEP to approximately 46,886 individuals [6]. Although 85% of current PrEP users in Brazil are MSM, PrEP use remains well below the initial projections [5].

Tenofovir-based oral PrEP has been effective in dramatically reducing population-level HIV incidence in multiple regions [7-11]. However, to realize the protective benefits of PrEP, individuals need to both initiate PrEP and remain on PrEP during periods of HIV vulnerability [12,13]. Among the individuals who initiated PrEP in the Brazilian SUS, discontinuation was common among MSM (approximately 40%) and TGW (>50%) [6]. PrEP Brasil, a daily oral PrEP demonstration study, found that although 74% of all participants had protective concentrations of tenofovir diphosphate at week 48, young participants and TGW participants had decreasing rates of protective drug concentrations throughout the study [14]. In addition, data from the ImPrEP study, which aimed to evaluate the feasibility of same-day PrEP initiation for MSM and TGW within the public health contexts of Brazil, Mexico, and Peru, identified lower PrEP adherence among TGW and individuals aged ≤30 years [15,16].

Owing to user adherence challenges, PrEP has not decreased HIV incidence among some population, particularly among populations with higher susceptibility (youth, racial and ethnic minorities, and TGW) [17-20]. Although HIV incidence in the ImPrEP study population was relatively low (0.85/100 person-years), it was higher among TGW, participants from Peru, those aged 18 to 30 years, Black or mixed-race participants, and those who were nonadherent to daily oral PrEP [15,16]. These disproportionately worse outcomes reinforce the potential of PrEP agents that do not require daily or planned oral dosing to increase their effective use among the most susceptible populations.

In multiple studies, reasons for discontinuing or never initiating daily oral PrEP include low HIV perceived risk, concerns about medication side effects, desire not to take a daily pill, stigma, competing life events, and challenges accessing the medication [13,21-23]. Long-acting PrEP agents may potentially address some of these concerns by providing consistent protection through infrequent, discrete administration, avoiding the need for daily adherence to an oral regimen and the related need for disclosure to sex partners and acquaintances [24].

Long-Acting Injectable Cabotegravir

Long-acting injectable cabotegravir (CAB-LA) is an integrase strand-transfer inhibitor, and its effectiveness for PrEP has been demonstrated in phase 2b/3 studies (HIV Prevention Trials Network [HPTN] 083 and HPTN 084) [25,26]. HPTN 083 was a double-blind double-dummy randomized controlled trial that assessed the effectiveness of CAB-LA for PrEP compared with oral tenofovir disoproxil fumarate (TDF) and emtricitabine (FTC) PrEP among 4566 cisgender MSM and TGW under high susceptibility to HIV. The blinded phase of the study showed the superiority of CAB-LA, with a 66% reduction in new infections in the cabotegravir arm compared with the active TDF and FTC arm. Similarly, HPTN 084 observed impressive reductions in HIV infections in the CAB-LA arm compared with the TDF and FTC arm among cisgender women in Africa, with an 89% reduction in new infections in the cabotegravir arm when compared with the active TDF and FTC arm. Data from both studies led to the regulatory approval of CAB-LA for HIV prevention in the United States, Australia, South Africa, Malawi, and Zimbabwe. Approval is currently being sought in numerous countries, including Brazil. In July 2022, a recommendation for CAB-LA PrEP was issued by the World Health Organization (WHO) [27].

Although it is reassuring that CAB-LA has demonstrated comparable effectiveness among youth, Black MSM, and TGW in large clinical trials, the advantages of bypassing daily adherence behavior may not be realized if individuals cannot access injectable PrEP or do not return for repeat injections. Implementation studies are needed to provide crucial information about how interventions that are proven efficacious under randomized clinical trial conditions can be optimized for delivery within real-world service settings. The ImPrEP CAB Brasil implementation study aims to generate critical evidence to inform national policies and program implementers about how injectable CAB-LA PrEP can be provided to MSM, nonbinary persons, and transgender persons within public health PrEP services in Brazil. Its implementation objectives are to describe the facilitators of and barriers to integrating CAB-LA into routine public health clinics and to evaluate whether a mobile health (mHealth) intervention optimizes decision-making on the best PrEP regimen among PrEP users and WhatsApp text messaging improves the uptake of and adherence to CAB-LA injection appointments. The primary clinical objective is to evaluate the effectiveness of CAB-LA PrEP in reducing the risk of HIV acquisition in a study cohort of participants in a context where participants can exercise choice in their HIV prevention method (injectable CAB-LA PrEP or daily oral PrEP).

Methods

Study Design

The ImPrEP CAB Brasil (Figure 1) is an implementation study of CAB-LA PrEP among 1200 young adult (aged 18 to 30 years) sexual and gender minorities (SGMs) in 6 Brazilian cities: Rio de Janeiro, São Paulo, Manaus, Salvador, Florianópolis, and Campinas (Figure 2). Each participating site provides PrEP service as a part of the Brazilian SUS.

This is a type-2 hybrid implementation-effectiveness open-label cohort study with a convergent mixed methods approach (quantitative and qualitative). A type-2 hybrid design examines both effectiveness and implementation strategies within the same study [28]. The study will draw on selected implementation science constructs from the theoretical framework for acceptability (TFA) [29], the Reach, Effectiveness, Adoption, Implementation, and Maintenance framework [30], and the framework of Proctor et al [31] to assess the implementation outcomes for the different study objectives outlined earlier. Relevant outcomes and their level of evaluation will include the following: acceptability at the individual health provider and participant levels, reach (choice and uptake) at the individual participant level, effectiveness at the individual participant level, implementation at the setting level (overall delivery), maintenance at the individual participant level, and feasibility at the setting level.

Individuals may participate in up to 4 different steps (Figure 3). In step 1, PrEP naive individuals who come to the study sites seeking PrEP will be exposed to education and counseling about HIV prevention and be informed of the availability of both oral and injectable PrEP. Half of the enrolled participants that tested negative for HIV will receive standard of care (SOC) prevention counseling, and the other half will be exposed to an mHealth education and decision support intervention in addition to SOC prevention counseling. Participants who choose to use injectable PrEP and with an undetectable HIV viral load will enroll in step 2 on the same day, whereas those who choose to use oral PrEP will be referred to the Brazilian Public Health PrEP program at the same clinic. Of the participants who enroll in step 2 and receive a CAB-LA injection, half will be randomized to receive a digital appointment reminder using WhatsApp (Meta Platforms, Inc; the most common messaging app in Brazil). Participants in step 2 who may decide to discontinue CAB-LA during the study follow-up will be invited to step 3 and switch to oral PrEP (TDF and FTC) or keep off PrEP with HIV and sexually transmitted infection (STI) monitoring and counseling for 1 year. Participants from either step 2 or step 3 who are diagnosed with an HIV infection during follow-up will be invited to be enrolled in step 4, where antiretroviral therapy (ART) effectiveness and ART resistance will be monitored for 1 year.

Figure 1. ImPrEP CAB Brasil logo.

Figure 2. Site distribution for the ImPrEP CAB Brasil study.

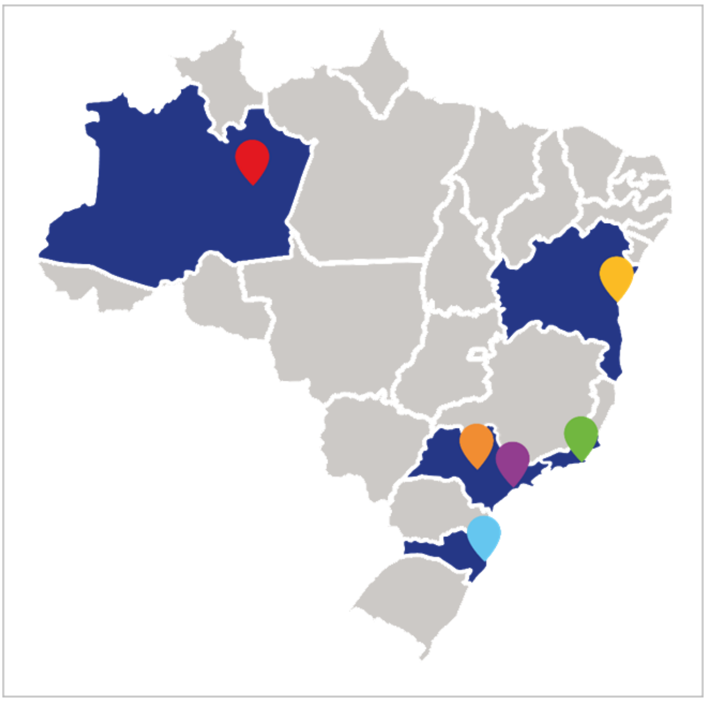

Figure 3. Overview of the study design and enrollment scheme. Only HIV-negative participants will perform standard of care (SOC) or mobile health (mHealth). Individuals living with HIV will be referred for antiretroviral therapy. CAB-LA: long-acting injectable cabotegravir; CT: Chlamydia trachomatis; NAAT: nucleic acid amplification testing; NG: Neisseria gonorrhea; PrEP: preexposure prophylaxis; VL: viral load.

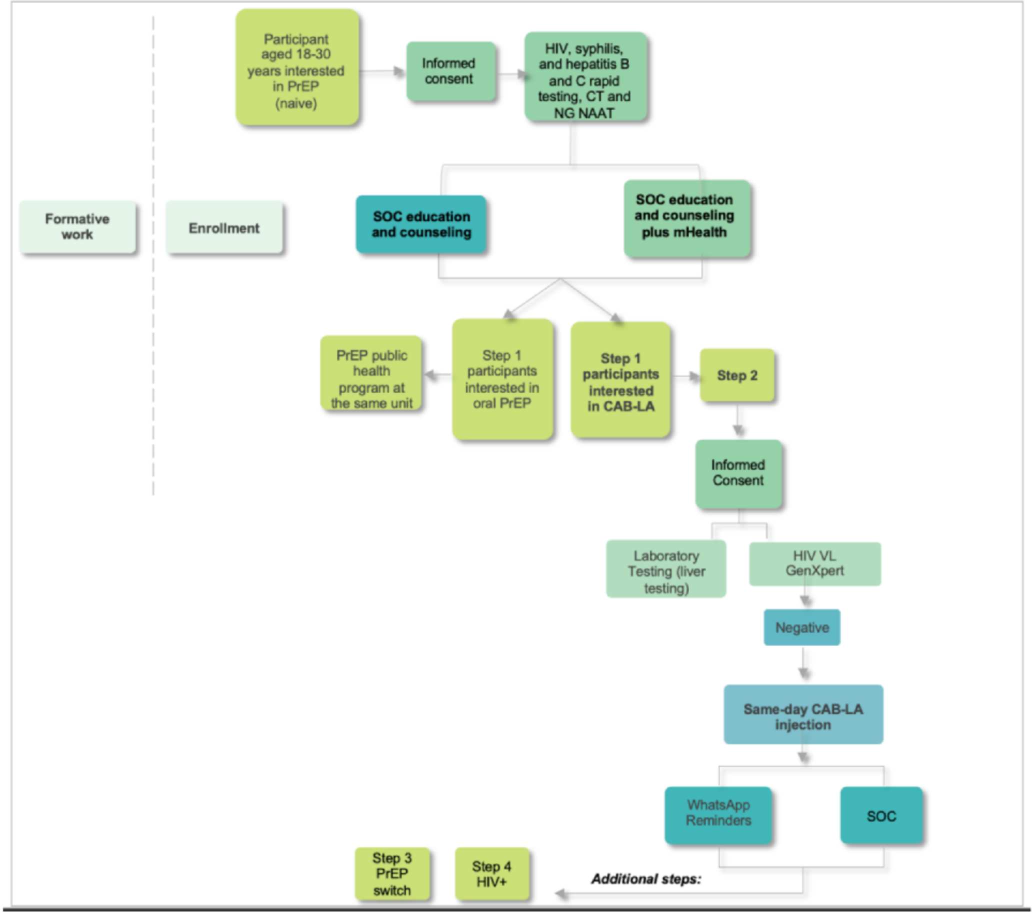

Eligibility Criteria

Participants will be included if they (1) are MSM, nonbinary person (assigned as male at birth), TGW, or transgender men; (2) are aged 18 to 30 years; (3) attend one of the study clinics looking for PrEP; (4) are CAB-LA and TDF and FTC PrEP naive; (5) are willing and able to provide written informed consent and adhere to the study requirements; (6) have nonreactive or negative HIV test results, including both third-generation HIV rapid tests and an undetectable HIV RNA at enrollment for individuals choosing injectable CAB-LA; (7) have no report of hepatic dysfunction; and (8) are willing to undergo all required study procedures. The full list of exclusion criteria is described in Multimedia Appendix 1. The study team will provide checklists to aid the site teams in accessing the inclusion and exclusion criteria.

Study Procedures

Formative Work

We will conduct formative work using participatory design methods [32] to develop an initial implementation package for CAB-LA PrEP. Training modules will be developed in collaboration with health providers at the 2 sites that have had experience with CAB-LA PrEP as part of HPTN 083 (Rio de Janeiro and São Paulo) and will include slides, learning activities, and job aids (eg, education, and counseling scripts).

Process mapping [33,34] at each site will facilitate planning for optimal PrEP client flow, that is, for ensuring that PrEP users can move most efficiently and effectively through the various clinical steps needed to receive services while minimizing the work burden on health care providers and maintaining service quality. Engaging clinical staff in the process mapping exercise prompts the identification of anticipated facilitators and barriers associated with each step of service delivery as well as planning for barrier mitigation strategies. Thus, process maps can facilitate the development of "readiness" exercises once PrEP CAB-LA is approved and ready for scale-up in Brazil and elsewhere. Finally, process maps will also be used at the end of the study to guide health care providers' reflections on the facilitators of and barriers to different components of PrEP delivery. Guidelines for developing process maps and process map examples will be included in the implementation package. The implementation package developed in collaboration with providers from the CAB-LA–experienced sites will be used to prepare health care providers at the remaining 4 sites and will be revised based on their feedback.

Focus group discussions (FGDs) will be held with health care providers experienced in CAB-LA PrEP and members of the young SGM community to gather their input for the adaptation of an mHealth education and decision support tool. This tool, intended to be accessed via an electronic tablet with self-guided instructions, will be designed to convey information about both oral and CAB-LA PrEP in an engaging way, describing the benefits and drawbacks of each method, to help participants decide whether and which PrEP method may be appropriate for them. A preliminary storyboard will be developed and shared with FGD participants, and they will be asked to provide feedback on images, content, and sequence. Feedback will be incorporated into the programming of the mHealth education intervention. FGD participants will be also asked to review and refine the content of WhatsApp appointment reminders and provide input regarding the best timing for receiving the WhatsApp reminders. In addition, FGD participants will be asked about barriers and facilitators for CAB-LA PrEP implementation. Health care providers at the 2 study sites with experience in CAB-LA PrEP will be inquired about frequent questions asked by CAB-LA PrEP users about the medication as well as examples of education and counseling strategies they have used previously to facilitate CAB-LA user comprehension.

Step 1: mHealth Intervention

Overview

Step 1 focuses on evaluating the mHealth intervention and participants' choice of PrEP method (Table 1). Potential step 1 participants include individuals who come to a study clinic looking for PrEP, are PrEP naive, and have expressed an interest in taking PrEP (see eligibility criteria). All individuals accessing the service for PrEP will be assessed for study eligibility by a designated study staff member. Eligible participants will be asked whether they are interested to assess educational and counseling interventions for PrEP choice.

After signing step 1 informed consent, participants will undergo rapid tests for HIV, syphilis, and hepatitis B and C. Rectal, oral, and urine swab samples will be collected for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* nucleic acid amplification testing. If a reactive or positive result is obtained for HIV test, the respective person is deemed ineligible to receive PrEP. Additional testing to confirm suspected HIV infection will be performed in accordance with local guidelines. If an HIV infection is confirmed, the participants will receive counseling and be immediately referred for HIV treatment and care. All participants will be evaluated for signs or symptoms of a possible acute HIV infection. Those with suspected acute HIV infection will be referred for follow-up investigation within the public health system.

Participants at each site will receive counseling and education on the use of PrEP options per the local SOC from a health care provider until 100 participants indicate that they would like to start CAB-LA PrEP and enroll in step 2. Additional participants will receive an mHealth education and counseling intervention plus the SOC education and counseling until 100 participants exposed to both SOC and the mHealth intervention enroll in step 2 of the study at each site (200 participants enrolled per site).

Upon completing their exposure to SOC or SOC plus mHealth, participants will be asked to complete a brief survey administered by a study member that will capture the following information: (1) participants' knowledge and beliefs about the dosing, advantages, and disadvantages of the 2 PrEP options, (2) their method of choice for HIV prevention, and (3) the reasons for their preference for oral or CAB-LA PrEP. Participants who received the mHealth intervention will be asked additional questions about its acceptability and its value in supporting decision making on PrEP choice.

[l] ALT: alanine aminotransferase.

[m] CT: *Chlamydia trachomatis*.

[n] NG: *Neisseria gonorrhea*.

[o] ISR: injection site reaction.

Qualitative Interview

A small subset of step 1 participants from each site (8 SOC participants per site and 12 SOC plus mHealth participants per site) will be asked to participate in a qualitative interview to evaluate their perceived advantages and disadvantages of different PrEP products and reasons for their choice. Those who received SOC plus mHealth will be asked to share their feedback on the acceptability of the mHealth intervention. Audio recordings will be transcribed *verbatim* by study staff.

PrEP Choice and Administration

Following the completion of step 1 procedures, participants will be asked by a health provider whether they choose oral PrEP or CAB-LA PrEP. Participants who indicate a preference for oral PrEP will be referred to receive it in the routine HIV prevention service and will not be navigated by the study team. The study team will not actively follow-up on these participants but will retain their participant ID in case they express interest in switching to CAB-LA PrEP later in the study period. Participants who choose CAB-LA PrEP will be invited on the same day to participate in step 2 of the study and will undergo additional consent, screening, HIV viral load testing, enrollment, and data collection procedures.

Step 2

Overview

Step 1 participants who chose CAB-LA PrEP after receiving either SOC counseling or SOC counseling plus mHealth will be eligible to participate on the same day in step 2 (Tables 1 and 2). Step 2 aims to understand the safety and effectiveness of CAB-LA PrEP in an environment of choice, assess an implementation strategy (WhatsApp appointment reminder) for improving adherence to CAB-LA injections, evaluate HIV testing strategies, evaluate the acceptability of STI sample self-collection and HIV self-testing, and understand the facilitators of and barriers to the integrated delivery of CAB-LA PrEP in the existing oral PrEP services.

HIV viral load testing will be performed in step 2 participants using the GeneXpert platform to confirm their eligibility. With a detectable HIV result, the person will be deemed ineligible to receive PrEP and will be referred to treatment and care through the public health system. Those who do not have detectable HIV results and do not meet any other exclusion criteria will receive their first CAB-LA injection.

The first follow-up visit will happen in 1 month, and the subsequent follow-up visits will happen once in every 2 months. At every follow-up visit, sites will perform HIV testing using the third-generation (antibody) HIV rapid tests before providing the next CAB-LA injection. Blood-based HIV self-testing will be performed by the study participant 24 hours before all follow-up visits, and the results will be reported by the participant during the study visit. If a participant does not bring the HIV self-testing report, the test will be performed at the clinic in a private space and before the study visit procedures. Regularly, additional HIV testing with stored samples will be conducted retrospectively, in batches, with fourth-generation HIV rapid test, Abbot ARCHITECT HIV Ag/AB combo assay, and the HIV-1 and HIV-2 RNA Viral Load COBAS 5800 platform. For positive or inconclusive results, the Geenius HIV1/2 confirmatory assay will be used. In all study visits, samples will be stored for additional retrospective HIV testing at the study central lab at INI-Fiocruz, as necessary. At any point of the study follow-up, participants with suspected HIV infection will be referred for follow-up investigation under study protocol. If HIV infection is confirmed at any point, CAB-LA injection will be stopped, and the participant will be immediately linked to care and ART initiation (according to the Brazilian guidelines) and will be invited to maintain a 1-year follow-up in the study with quarterly visits (step 4). Resistance testing will also be performed (if feasible, based on the number of viral copies).

Randomized Injection Reminders via WhatsApp

As part of the consent process for enrollment in step 2, participants will be informed that they may be selected to receive a WhatsApp appointment reminder 2 days before each scheduled injection visit. Participants will be randomly assigned (1:1) to either the SOC (verbal communication and paper appointment slip letting participants know when they should come back to the clinic) or SOC plus WhatsApp arm using simple or block randomization and will be informed of which arm they are assigned to during the step 2 enrollment visit. During the month 5 visit, participants who were randomized to receive WhatsApp appointment reminders will be asked to complete a brief participant survey to assess the acceptability of receiving WhatsApp appointment reminders. If a participant does not return for their month 5 visit, the survey will be administered at their next clinic visit.

Switching From Oral TDF and FTC PrEP to CAB-LA PrEP

Step 1 participants may choose to switch from oral TDF and FTC PrEP to CAB-LA PrEP only once during the study period. These participants will undergo all step 2 procedures prior to receiving the first CAB-LA injection. Individuals with hepatitis B surface antigen–positive results and indication of hepatitis B treatment will be counseled to remain on oral TDF and FTC for PrEP. If hepatitis B treatment is not indicated and the individual chooses to switch to CAB-LA, enrollment will be allowed unless exclusionary hepatic criteria are identified (alanine aminotransferase ≥5 × upper limit of normal).

Specific Visit Procedures

Participants included in step 2 to receive CAB-LA PrEP who decide to discontinue participation before completing the minimum 1 year and maximum 2 years of study follow-up will complete early discontinuation visit procedures (Table 3). These participants will be invited to participate in a 12-month extension follow-up to safely monitor the CAB-LA “tail” phase and will be offered oral PrEP (TDF and FTC). Some of them will be invited to participate in a qualitative interview to describe their experience with CAB-LA PrEP and the reason for decision to discontinue CAB-LA PrEP.

If a participant misses an appointment but wishes to continue with CAB-LA PrEP, reloading with CAB-LA may be necessary, and the participant will need repeat HIV rapid tests before receiving a new CAB-LA injection. Oral bridging with TDF and FTC will be offered to participants who anticipate not being able to attend their scheduled injections (planned missed injections) in the +7 or −7-day window, starting approximately 2 months after the last injection dose of CAB-LA.

ART[u] initiation			✓		
TDF[v] and FTC[w] PrEP[x]	✓[y]	✓[y]			

[a] Any discontinuation occurring before the anticipated final study visit and not related to seroconversion.

[b] STI: sexually transmitted infection.

[c] AE: adverse event.

[d] Depending on the scenario that presents itself at the time of the final study visit.

[e] If pregnancy is suspected.

[f] HIVST: HIV self-test.

[g] If available.

[h] PCR: polymerase chain reaction.

[i] If HIV infection is suspected.

[j] HBV: hepatitis B.

[k] HCV: hepatitis C.

[l] ALT: alanine aminotransferase.

[m] Interim visits performed because of suspected hepatic adverse events should collect liver function tests.

[n] ClCr: creatinine clearance.

[o] If oral preexposure prophylaxis is initiated.

[p] CT: *Chlamydia trachomatis.*

[q] NG: *Neisseria gonorrhea.*

[r] Only for transgender men.

[s] ISR: injection site reaction.

[t] Interim visits performed because injection site reactions should follow specific protocol instructions.

[u] ART: antiretroviral therapy.

[v] TDF: tenofovir disoproxil fumarate.

[w] FTC: emtricitabine.

[x] PrEP: preexposure prophylaxis.

[y] In a final study visit or an early discontinuation visit, if the participant chooses to switch to oral preexposure prophylaxis, they will be followed in the 12-month follow-up study.

Study Step 3

Participants from step 2 will be invited to participate in step 3 if they meet the following eligibility requirements: (1) the participant decides to switch from CAB-LA to oral TDF and FTC during study follow-up or (2) the participant decides to early discontinue CAB-LA injections but does not want to start oral PrEP.

Participants who choose to switch from CAB-LA to oral TDF and FTC will need to complete the procedures related to the daily oral TDF and FTC enrollment visit (Table 3). The procedures are the same as those specified under both the early discontinuation visit and the final study visit, plus creatinine dosage and estimated creatinine clearance. Once enrolled in step 3, the follow-up consists of visits scheduled for the following intervals: month 1, month 4, month 7, month 10, and month 13 or year 1 (Table 4).

Participants who choose to keep off PrEP will be invited to be followed up in step 3. Participants will have quarterly visits with sexual risk assessment, HIV and STI testing and counseling, and the provision of condoms and lubricants.

Table 4. The ImPrEP CAB Brasil step 3 procedures: daily oral preexposure prophylaxis.

[h] CT: *Chlamydia trachomatis.*

[i] NG: *Neisseria gonorrhea*.

[j] PrEP: preexposure prophylaxis.

[k] TDF: tenofovir disoproxil fumarate.

[l] FTC: emtricitabine.

Step 4

Overview

Participants who are diagnosed with HIV while using CAB-LA during study follow-up will perform the procedures related to the *seroconversion visit* (Table 3) and will be invited to join step 4. HIV treatment will be initiated in accordance with the Brazilian guidelines. The participant will be requested to come to the study clinic for quarterly visits for 1 year. HIV RNA polymerase chain reaction will be evaluated in all visits. If a participant is identified with suspected virological failure, a new resistance test will be performed, and a new ART regimen will be selected based on the resistance test results.

Qualitative Assessments During the Study

At month 7, a select set of participants will be invited to participate in a semistructured qualitative interview guided by the TFA to understand their experiences with CAB-LA PrEP and with the clinic services, including WhatsApp appointment reminders and HIV self-testing. Up to 16 participants will be interviewed at each site. The aim is to sample approximately 8 individuals who continually adhered to their injection schedule, approximately 4 individuals who needed to reload, and 4 individuals who discontinued CAB-LA injections. Interviews will be conducted in Portuguese and audio recorded. Interviewers will complete a debriefing report summarizing the key points of the interview within 12 hours of completing the interview. Audio recordings will be transcribed *verbatim* by study staff.

Health Care Provider Survey

At the end of the implementation study, health providers will be asked to complete an in-depth interview on their experiences integrating CAB-LA in the existing PrEP services and their views on the mHealth tool and WhatsApp reminders. The interview questionnaire will seek to understand the facilitators of and barriers to CAB-LA service delivery and will be informed by implementation science constructs drawn from the TFA (affective attitude, burden, ethicality, intervention coherence, opportunity cost or relative advantage, perceived effectiveness, and self-efficacy) [29], Reach, Effectiveness, Adoption, Implementation, and Maintenance (implementation) [30], and Proctor et al [31] (feasibility). The definitions of the constructs are summarized in Multimedia Appendix 1. During these interviews, health care providers will also be asked to review their most recent process mapping, describe changes that happened with CAB-LA implementation, and describe ongoing “pain points." Short Likert-scale surveys will also be embedded in the questionnaires to gather quantitative data on acceptability.

Major Outcomes

The major clinical and implementation outcomes, levels of analysis, methods, and timing are described in Table 5.

Table 5. Summary of major clinical and implementation outcomes.

Major outcomes	Level	Methods and timing
Clinical		
HIV incidence (effectiveness)	• Individual	• HIV test completed at each visit and interim analysis after 12 months of enrollment and upon the completion of the study
Resistance to CAB-LA[a] or oral TDF[b] and FTC[c] PrEP[d] (effectiveness and safety)	• Individual	• HIV genotyping test at the time of seroconversion or suspected viral failure at any time during the 12-month follow-up
Implementation		
mHealth[e] intervention acceptability (from TFA[f])	• Individual participant (client or potential PrEP user)	• Survey of all participants receiving mHealth intervention immediately upon the completion of SOC[g] or SOC and mHealth education and counseling • Qualitative interview (12 participants per site who receive mHealth and SOC) during the enrollment period for step 1
mHealth intervention effectiveness (from RE-AIM[h])	• Individual participant (client or potential PrEP user)	• Knowledge survey of all participants receiving mHealth intervention immediately upon the completion of SOC or SOC and mHealth education and counseling • Qualitative interviews of 8 participants per site who receive SOC counseling and 12 participants who receive SOC and mHealth education and counseling about their knowledge and beliefs about oral and CAB-LA PrEP in relation to their choice • Adherence data at the end of the study
mHealth tool acceptability (TFA) and feasibility (from Proctor et al [31])	• Individual provider and clinic setting	• Interviews at the end of the study including questions that will generate both qualitative and quantitative data
WhatsApp appointment reminder acceptability (TFA)	• Individual client or PrEP user	• Brief survey given to each participant who received WhatsApp appointment reminders at their month 5 visit • Qualitative interviews (16 participants per site) conducted at month 7
WhatsApp appointment reminder effectiveness (from RE-AIM)	• Individual client or PrEP user	• Study adherence data at the middle and end of the study • Qualitative interviews (16 participants per site) conducted at month 7
WhatsApp appointment reminder feasibility (Proctor et al [31]) and implementation (RE-AIM)	• Individual provider and clinic setting	• Interviews at the end of the study including questions that will generate both qualitative and quantitative data • WhatsApp appointment reminder program data files
Acceptability (TFA) of STI[i] self-test	• Individual client or CAB-LA PrEP user	• Qualitative interviews (16 participants per site) conducted at month 7
Acceptability (TFA) and feasibility (Proctor) of STI self-test	• Individual provider and clinic setting	• Qualitative interviews at the end of the study
Acceptability (TFA) of HIV self-testing	• Individual client or CAB- LA PrEP user	• Qualitative interviews (16 participants per site) conducted at month 7
Implementation: barriers to and facilitators of the integrated delivery of CAB-LA PrEP in the existing oral PrEP services	• Individual participant (client or CAB-LA PrEP user) • Individual provider and clinic setting	• Qualitative interviews (16 participants per site) conducted at month 7 • Interviews at the end of the study including questions that will generate both qualitative and quantitative data
Feasibility of CAB-LA PrEP in public clinic PrEP services	• Individual provider and clinic setting	• Interviews at the end of the study including questions that will generate both qualitative and quantitative data • Review of routine study documentation

Major outcomes	Level	Methods and timing
Maintenance	Individual participant (client or CAB-LA PrEP user)	Adherence to injection visits at the middle and end of the study
Reach	Individual participant and cohort characteristics	Survey of all participants receiving mHealth intervention immediately upon the completion of SOC or SOC and mHealth education and counseling about the rationale for their PrEP choice Qualitative interview (12 participants per site who receive mHealth and SOC) during the enrollment period for step 1 that will include questions about the rational for their PrEP choice Study data on the number of participants enrolled and pace of enrollment and demographic data

[a] CAB-LA: long-acting injectable cabotegravir.

[b] TDF: tenofovir disoproxil fumarate.

[c] FTC: emtricitabine.

[d] PrEP: preexposure prophylaxis.

[e] mHealth: mobile health.

[f] TFA: theoretical framework for acceptability.

[g] SOC: standard of care.

[h] RE-AIM: Reach, Effectiveness, Adoption, Implementation, and Maintenance.

[i] STI: sexually transmitted infection.

Statistical Analysis

Our major clinical outcome (primary analysis) will adopt an intent-to-treat approach and compare HIV incidence (and 95% CI) among individuals in the CAB-LA cohort with HIV incidence (and 95% CI) among individuals on daily PrEP within the Brazilian SUS. We will estimate the rate of HIV incidence with 95% CI in each group using Kaplan-Maier statistics. We will use a Cox proportional hazard model to assess the relative hazard (hazard ratio with 95% CI) between the 2 groups, overall and by site, age category, and gender.

It is anticipated that there will be an average follow-up of 1.5 years per person with at least 75% retention each year (N=1350 person-years of follow-up) and that incidence will be higher than that observed in HPTN 083 in Latin America (0.60 per 100 person-years). If the observed incidence is approximately 50% higher than that observed in HPTN 083, the study will be able to estimate an incidence of 0.85 (95% CI of 0.47-1.42) per 100 person-years (Table 6). If the observed incidence is approximately twice as high as that observed in HPTN 083, then the study will be able to estimate an incidence of 1.18 (95% CI of 0.72-1.82) per 100 person-years. If the comparison group is of similar size, then the incidence would need to be 2.2 to 2.5 times higher to observe statistically significant differences between CAB-LA and oral PrEP. However, if the comparison group is 3 times larger, then the incidence would need to be 2 to 2.2 times higher to observe statistically significant differences between CAB-LA and oral PrEP.

To reach the primary implementation objective, we will report descriptive statistics (numbers, proportions, and medians) of Likert-scale responses to the TFA constructs (affective attitude, burden, ethicality, intervention coherence, opportunity costs, and perceived effectiveness and self-efficacy) among health care providers.

Table 6. Observable differences given potential HIV incidence in intervention and comparison groups.

Group	Incidence (95% CI)
Intervention: CAB-LA[a]PrEP[b]	
1350 py[c] incidence/100 py	
8 cases	0.59 (0.28-1.13)
12 cases	0.89 (0.48-1.51)
18 cases	1.19 (0.71-1.88)
Comparison: oral PrEP in the Brazilian health system	
1350 py[c] incidence/100 py	
24 cases	1.78 (1.17-2.61)
30 cases	2.22 (1.53-3.13)
36 cases	2.67 (1.90-3.65)
2700 py incidence/100 py	
43 cases	1.59 (1.17-2.13)
54 cases	2.00 (1.52-2.59)
66 cases	2.44 (1.91-3.09)
4050 py incidence/100 py	
60 cases	1.48 (1.14-1.89)
78 cases	1.93 (1.53-2.39)
94 cases	2.32 (1.89-2.83)

[a] CAB-LA: long-acting cabotegravir.

[b] PrEP: preexposure prophylaxis.

[c] py: person-years.

Ethics Approval

The study protocol and informed consent forms were reviewed and approved by the Evandro Chagas National Institute of Infectious Diseases (INI), Fundação Oswaldo Cruz (Fiocruz) institutional review board (August 25, 2022; #CAAE 59166522.7.1001.5262) and the Research Ethics Review Committee at the WHO with respect to scientific content and compliance with applicable research and human participants' regulations. The protocol, site-specific informed consent forms, participant education and recruitment materials, and any requested documents and their subsequent modifications were also be reviewed and approved by the ethical review bodies responsible for the oversight of the research conducted at each of the study sites. Informed consent will be obtained in 2 study steps. In step 1, consent will be obtained from participants who visit the site looking for PrEP. In step 2, the participants will provide consent for the use of injectable CAB-LA PrEP. This study may be paused or stopped at any time by the local institutional review board or the study's principal investigator.

Results

During the third and fourth quarters of 2022, we obtained regulatory approvals; programmed data entry or management systems; trained sites; and performed community consultancy, process mapping, and formative work. Study enrollment is anticipated to happen in the first quarter of 2023. The planned activities are presented in Table 7.

Table 7. Planned activities for the ImPrEP CAB Brasil study (2022-2024).

Discussion

Principal Findings

ImPrEP CAB Brasil is the first study to evaluate CAB-LA PrEP implementation in Latin America. Latin America is one of the regions where PrEP scale-up, as well as the reduction of inequalities in PrEP access, is most needed. We hereby describe the study protocol, providing details of the study's objectives, procedures, outcomes, and statistical analysis to aid researchers from Brazil, Latin America, and other regions during CAB-LA implementation within public health systems.

To date, no clinical or implementation results are available for injectable PrEP with CAB-LA in real-life settings. We expect the acceptability of CAB-LA in Brazil to be high. Data from a web-based survey and descriptive choice experiment have shown that injectable PrEP was preferred over other PrEP modalities in Brazil [35-37]. Our results regarding PrEP choice among individuals seeking PrEP in health units will increase this body of evidence. For instance, in the field of contraception, the increased availability of options and informed decision-making in the choice of contraception have improved the uptake and persistence of the methods used [38]. It is likely that expanding the method options for PrEP will similarly improve uptake and persistence.

Our study will also contribute to the expansion of the knowledge on the best HIV testing algorithm to be implemented in low- and middle-income countries when using CAB-LA for PrEP, which is a major need.

This study is coordinated by INI-Fiocruz, an internationally recognized research institution and the leading reference center in Latin America for infectious diseases. INI-Fiocruz has been working closely with the Brazilian Ministry of Health (BMOH), the Pan American Health Organization, Unitaid, and the WHO to address evidence gaps and identify key learnings to inform the introduction of injectable CAB-LA PrEP among the most susceptible populations. The INI-Fiocruz team has extensive experience in engaging SGMs in demand creation, providing HIV combination prevention services that foster PrEP uptake and retention and advocating for enhanced HIV prevention policies [39,40]. In addition to being a recognized academic institution, INI-Fiocruz is the largest HIV prevention and treatment center in Rio de Janeiro, Brazil, with over 1000 SGMs tested per year [41]. The INI-Fiocruz study team was responsible for planning, designing, and implementing the PrEP Brasil study [14], which provided critical evidence to support the BMOH in the incorporation of PrEP as a public health policy. The team also coordinated the ImPrEP study, which provided information for PrEP surveillance in Brazil, and PrEP implementation in Mexico and Peru [16].

This study is poised for informing policy makers, building public health staff capacity, and creating environments for successfully implementing the proposed prevention strategies in collaboration with the BMOH. Moreover, we expect the mHealth component to be highly acceptable and possibly implemented within the Brazilian public health system.

Conclusions

The ImPrEP CAB Brasil study will contribute to the generation of valuable information to inform the design of programmatic strategies for implementing CAB-LA PrEP in Brazil, maximizing the public health impact of PrEP in reducing HIV incidence among young SGMs in Brazil, Latin America, and other countries in the Global South.

Acknowledgments

This project was made possible thanks to Unitaid’s funding and support. Unitaid accelerates access to innovative health products and lays the foundation for their scale-up by countries and partners. Unitaid is a hosted partnership of the World Health Organization. ViiV Healthcare will provide the study medication. BG and TST are funded by the National Council of Technological and Scientific Development and Carlos Chagas Filho Foundation for Research Support in the State of Rio de Janeiro. The authors would like to thank the Ministry of Health of Brazil for their support.

The contributors associated with ImPrEP CAB Brasil Study Group are as follows: Anna Hellstrom, Alessandro Farias, Marcus V Lacerda, José Valdez Madruga, Josué N de Lima, Ronaldo Zonta, Roberta Trefiglio, Renato Lima, Antonio Carvalho, Sandra Wagner Cardoso, Débora Marra Faber Barreto, Egydio Sampaio Pessanha, Sandro Nazer, Carla de Barcellos Rocha, Claudio Gruber Mann, Nilo M Fernandes, Cristina Jalil, Lucilene Freitas, Eduardo Carvalheira Netto, Mônica Derrico, Flávia Lessa, Larissa Vilela, Laylla Monteiro, Josias Freitas, Toni Araújo, Daniel R B Bezerra, Luana M S Marins, Robson Pierre N. Silva.

Data Availability

This manuscript is a description of a study protocol; therefore, no data are available.

Conflicts of Interest

None declared.

Abstract

Background: Adverse drug reactions (ADRs) are unintended consequences of medication use and may result in hospitalizations or deaths. Timely reporting of ADRs to regulators is essential for drug monitoring, research, and maintaining patient safety, but it has not been standardized in Australia.

Objective: We sought to explore the ways that ADRs are monitored or reported in Australia. We reviewed how consumers and health care professionals participate in ADR monitoring and reporting.

Methods: The Arksey and O'Malley framework provided a methodology to sort the data according to key themes and issues. Web of Science, Scopus, Embase, PubMed, CINAHL, and Computer & Applied Sciences Complete databases were used to extract articles published from 2010 to 2021. Two reviewers screened the papers for eligibility, extracted key data, and provided descriptive analysis of the data.

Results: Seven articles met the inclusion criteria. The Adverse Medicine Events Line (telephone reporting service) was introduced in 2003 to support consumer reporting of ADRs; however, only 10.4% of consumers were aware of ADR reporting schemes. Consumers who experience side effects were more likely to report ADRs to their doctors or pharmacists than to the drug manufacturer. The documentation of ADR reports in hospital electronic health records showed that nurses and pharmacists were significantly less likely than doctors to omit the description of the drug reaction, and pharmacists were significantly more likely to enter the correct classification of the drug reaction than doctors. Review and analysis of all ADR reports submitted to the Therapeutic Goods Administration highlighted a decline in physician contribution from 28% of ADR reporting in 2003 to 4% in 2016; however, within this same time period, hospital and community pharmacists were a major source of ADR reporting (ie, 16%). In 2014, there was an increase in ADR reporting by community pharmacists following the introduction of the GuildLink ADR web-based reporting system; however, a year later, the reporting levels dropped. In 2018, the Therapeutic Goods Administration introduced a black triangle scheme on the packaging of newly approved medicines, to remind and encourage ADR reporting on new medicines, but this was only marginally successful at increasing the quantity of ADR reports.

Conclusions: Despite the existence of national and international guidelines for ADR reporting and management, there is substantial interinstitutional variability in the standards of ADR reporting among individual health care facilities. There is room for increased ADR reporting rates among consumers and health care professionals. A thorough assessment of the barriers and enablers to ADR reporting at the primary health care institutional levels is essential. Interventions to increase ADR reporting, for example, the black triangle scheme (alert or awareness) or GuildLink (digital health), have only had marginal effects and may benefit from further improvement revisions and awareness programs.

KEYWORDS

pharmacovigilance; adverse drug reactions; primary care; digital health

Introduction

The World Health Organization defines pharmacovigilance (PV) as “the science and activities related to the detection, assessment, understanding and prevention of adverse effects of medications” [1]. Many harmful adverse drug reactions (ADRs) resulting from medication use go undetected or unreported to regulatory authorities [2]. The underreporting of ADRs remains a major threat to patient safety and is a substantial burden to established health care systems [2,3]. Most PV schemes are based on spontaneous and voluntary reporting [4]. In Australia, the Therapeutic Goods Administration (TGA) receive suspected ADRs reports from health care professionals (HCPs; physicians, pharmacists, nurses, etc) and the general public (consumers, patients, carers, members of the legal system, etc) [5,6]. The TGA regularly reviews available information originating from submitted ADR reports, and this informs drug safety decisions [4]. International studies have stated that less than 5% of ADRs are reported, including in jurisdictions where ADR reporting is mandatory [7]. Without a robust PV systems, ADRs may remain undetected for years, exposing patients to unanticipated health risks, and is a detriment to the health care system and taxpayers [8]. For example, the anti-inflammatory drug rofecoxib (Vioxx) was withdrawn from the market for high risk of myocardial infarctions after population exposures had reached millions, emphasizing the need for early detection of drug safety signals to ensure global health safety[7].

In Australia, approximately 400,000 consumers present to hospital emergency departments each year with medication-related problems [3,9]. Furthermore, about 7.2% to 11% of hospital admissions are specifically related to ADRs, of which approximately 50% are preventable [9,10]. Globally, it has been reported that 3.6% to 15.6% of hospital admissions are related to ADRs [11,12]. Complications related to ADRs may increase the mean length of hospital stay from 8 to 20 days [13]. According to the Pharmaceutical Society of Australia’s medication safety report (2019), health care expenditure for medication-related problems is estimated at AUD $1.4 billion (US $900,207) per annum [14]. Despite its limitations, spontaneous reporting remains the most common method for generating safety signals; however, it is estimated that only 6% of all ADRs that occur are reported [7,15,16]. The reasons for ADR underreporting have previously been described [10,17-19]; these may include limited knowledge and awareness of PV, reluctance to report by consumers or HCPs due to time constraints, and nonsupportive workplace structures. Although various interventions to improve ADR reporting have been implemented [20], ADR underreporting remains a limitation of the current PV system [10,21].

Previous studies have evaluated the effects of interventions for improving ADR reporting rates; however, the perspective of ADR reporting and handling within the Australian health care system remains largely unexplored [20-22]. There remains little integrative and collective knowledge on ADR reporting, monitoring, and handling in the Australian health care context [21]. This scoping review aimed to provide a comprehensive landscape of PV and ADR reporting, monitoring, and handling in Australia. This review may stimulate further research, policy makers, regulatory authorities, or software vendors to make decisions that may promote ADR reporting and improve patient safety within the Australian context.

Methods

Overview

The Arksey and O’Malley methodology framework was adopted for conducting this scoping review [23,24]. This framework uses a rigorous process of transparency that enables the replication of the search strategy, which increases the reliability of the study findings. The framework has six stages as follows.

Stage 1: Identifying the Research Question

The focus of this scoping review was to explore ADR reporting in the Australian health care system and the extent of participation by consumers or HCPs and to describe the different reporting systems. The core questions are (1) How are ADRs monitored, reported, and handled in the Australian health care system? and (2) What is the extent of participation by consumers or HCPs?

Stage 2: Identifying the Relevant Studies

The search strategy was developed by authors JFT and RAY. Six scientific databases were searched (Web of Science; Scopus; Embase; PubMed, including MEDLINE; CINAHL; and Computer & Applied Science Complete) for research articles published in English between 2010 to 2021. Furthermore, a reference list search (ie, backward reference search) and a cited reference search (ie, forward reference search) were carried out based on the full-text papers that met the study selection criteria. The reference search was repeated on newly identified papers until no additional relevant papers could be found. Multimedia Appendix 1 presents the full search strategy for each database.

Stage 3: Selecting Studies

The inclusion and exclusion criteria are presented in Textbox 1.

Five authors (JFT, RAY, THD, RM, and NW) independently screened the titles and abstracts of the studies to identify the ones for potential inclusion. Disagreements about exclusions were discussed until a consensus was reached. The full texts of the articles were then independently reviewed by 2 authors (JFT and RAY), who decided whether or not they met the selection criteria. In the case of disagreement, a third author (NW) made the final decision.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Adverse drug reactions (ADRs) in the Australian health care system (medication management context)
- Cross-sectional or survey-based studies

Exclusion criteria

- Not related to drugs
- Not related to ADR reporting, monitoring, or handling (eg, efficacy or effectiveness of a study's design)
- Not related to patients' reporting (eg, a safety study in animals)
- Qualitative studies, review manuscripts, editorials, letters, and news

Stage 4: Charting the Data

Two reviewers (JFT and RAY) identified characteristic data sets to describe the articles, which included the author(s), year of publication, setting (where the study was conducted, eg, hospital and community pharmacy), study population (eg, physicians), gender, age, intervention, and reporting rates. The data were represented in a logical and descriptive manner in line with the objectives of this review. As per guidelines, scoping reviews do not exclude research based on the research quality but rather identify areas that are lacking in research [23,24]. Therefore, methodological quality or risk of bias of the included articles were not needed [23,24].

Stage 5: Collating, Summarizing, and Reporting Results

The information extracted were summarized, organized, and discussed. A PRISMA (Preferred Reporting Items for Systematic reviews and Meta-Analyses) flow chart was developed to summarize the identified literature and study selection steps. The narrative and a numerical summary of the characteristics of the included studies were tabulated. In the conceptual analysis, the study aimed to describe 2 main themes: (1) how ADRs are monitored, handled, or reported in the Australian health care system and (2) the extent of participation by stakeholders. The results of the first theme are presented in Multimedia Appendix 2 as the type of reporting or intervention, PV system used, and the focus of the surveillance. The results of the second theme are presented by the study population, setting, and reporting rates.

Stage 6: Consultation Exercise

The last stage was to engage in a consultation exercise with stakeholders to discuss, inform, and validate the results of the study [23,24]. This scoping review was interdisciplinary [23,24]; the overall expertise covered medicine, clinical pharmacy, PV, epidemiology, public health, health informatics, and statistics. The participation of all the authors throughout the research process served the purpose of constant consultation and provided the rigor and strength to the study findings and conclusions.

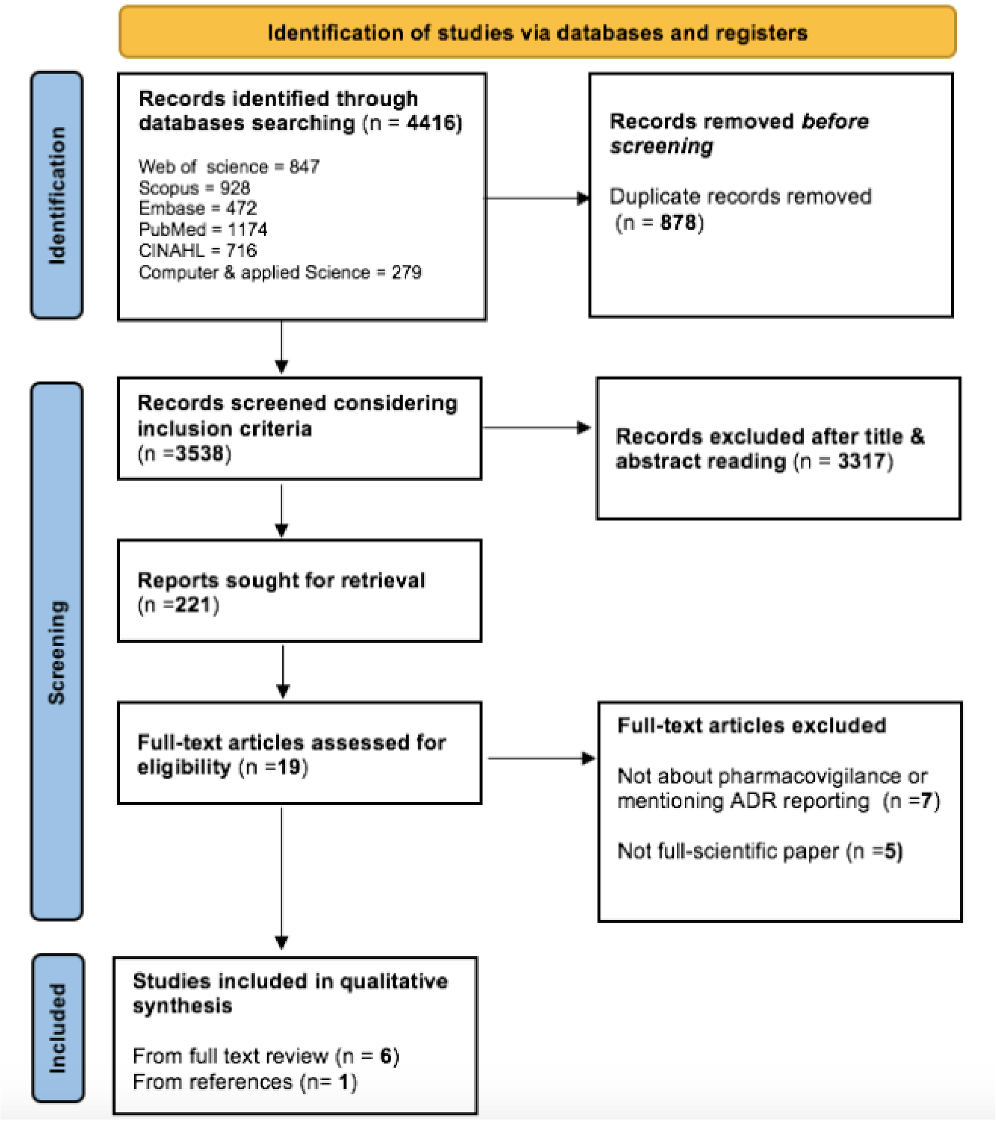
Results

Overview

Figure 1 (PRISMA flow chart) depicts the full review process and shows the number of citations excluded at each step. A total of 3538 citations were retrieved from the scientific electronic databases after duplicates (n=878) were removed. We screened the titles, abstracts, and full texts using the exclusion criteria and resulted with 6 citations to be included. The reference lists of the selected studies were also manually searched, and 1 article was identified; in total, 7 citations were relevant to the research question and included in the flow chart (stage 3). Multimedia Appendix 3 presents a list of the included studies.

The selected studies were published between 2013 and 2021. Among the studies, 2 focused on consumers and patients, 2 on health care providers, and 3 on information systems. In all, 5 of the 7 studies were in the hospital settings, and the rest were in the community. The findings of the selected studies are presented in 2 themes that relates back to the research questions, "ADR reporting, monitoring, and handling in the Australian health care context" and "participation." The characteristics of the studies' findings are summarized in Multimedia Appendix 2.

Figure 1. PRISMA (Preferred Reporting Items for Systematic reviews and Meta-Analyses) flowchart of study selection and inclusion criteria. ADR: adverse drug reaction.



ADR Reporting, Monitoring, and Handling in Australia

Regulatory Monitoring of ADR

The Australian National Safety and Quality Health Service provides statements for accreditation and include standards for ADR management. Health services are required to have processes for documenting medication allergies and ADRs within the health care records and in the organization-wide incident-reporting system, as well as for submitting major or rare ADRs to the TGA. Providing written ADR information to both the patient and their general practitioner (GP) is a requirement in Australian hospitals [25]. However, despite national and international guidelines for ADR reporting and management, there is no established national protocol for reporting ADRs at the individual health care facility level [26]. As such, there exists substantial interinstitutional variability with respect to the timing and nature of ADR reports [26]. The responsibility for the timely collection and reporting of drug safety information mainly rests with the marketing authorization holder due to mandatory reporting requirements from regulatory agencies [27,28].

ADR Handling

An Adverse Drug Reaction Review Committee (ADRRC) is an internal hospital committee comprising of a multidisciplinary team that includes a senior pharmacist and a specialist clinician from at least one of dermatology, immunology, clinical pharmacology, infectious diseases, and general medicine [25,26]. The committee meets every 2 weeks to review all ADR reports; verify diagnoses, if required; organize allergic clinical referrals; and provide further risk mitigation measures through written recommendations to the clinicians involved as well as the patients and carers. Relevant ADR reports are forwarded to the national database at the TGA [26]. In the study of patient satisfaction with an ADR warning card at a tertiary hospital during the period between January 2013 and April 2016 (n=241), patients with suspected ADRs received a wallet-sized paper card titled “Temporary ADR warning card” with the name of the drug thought to be the causative agent. The ADR pharmacist collated the supporting evidence for the case including notes from the inpatient stay and information from the Australian

Database of Adverse Event Notifications. The collated evidence was sent to the ADRRC clinicians who reviewed the case and determined an outcome. If the ADR was confirmed, the patient was sent a letter containing the details of the reaction and a laminated card titled “Permanent ADR warning card,” and a copy of the letter was sent to the patient’s GP [25].

ADR Reporting Schemes

The Adverse Medicine Events Line is a telephone reporting service that was introduced in Australia in 2003 to allow consumers to report suspected ADRs to the TGA and receive advice about side effects [27]. In June 2014, a pharmacy software vendor, GuildLink, created a web-based Adverse Events Recording module that integrated directly into the TGA ADR web service. This integration allows community pharmacists to report ADRs directly to the TGA from their professional service program instead of having to manually complete a separate ADR reporting form. In 2018, the TGA introduced a black triangle scheme on the packaging of newly approved medicines to alert HCPs and consumers, serving as a prompt to report any ADRs associated with that medicine [28]

Participants and Extent of Involvement

Patient and Consumer

Direct consumer and patient reporting of ADRs to the TGA has been possible since 1964, and since 1990, there had been fewer than 7000 consumer ADR reports [27]. In 2009, there was a spike in consumer ADR reporting (1307/13,298, 9.8%) that was associated to influenza vaccines due to the H1N1 pandemic; however, consumer reporting fell to 3% in 2011 [27]. A study of consumer awareness to ADR reporting between September and October 2012 used 2 methods to survey respondents: a computer-assisted telephone interview (n=2484) and a Pureprofile web-based survey (n=2497). From the 2 groups combined, 46.3% of consumers indicated that side effects of prescription medicines were very common (88.4%) [27]. The awareness of consumer reporting schemes among the whole study group was low (10.4%) [27]. Among 217 respondents who had experienced a side effect and were aware of consumer reporting schemes, 46 (21.2%) reported the ADR, using one of the reporting schemes [27]. Consumers were more likely to report ADRs to their doctors or pharmacists than to the pharmaceutical industry [27,28]. Among the consumer who had experienced a side effect, 84.6% reported the event to an HCP, most often a GP [27]. In the study of patient satisfaction with an ADR warning card at a tertiary hospital during the period between January 2013 and April 2016 (n=241), 85% notified their doctor, 67% notified their family, and 40% notified their community pharmacist [25]. The likelihood of the causative agent being available in community pharmacies determined if participants were more likely to consider it necessary to inform their regular community pharmacist of the new ADR (P=.001) [25]. The majority of ADRs experienced by participants fell within 3 drug classes: antibiotics (32%), iron infusions (14%), and contrast media (13%) [25].

HCPs’ Participation

In the review and analysis of all ADR reports submitted to the TGA, 28% out of 10,981 reports received in 2003 and about 7% out of the 14,400 reports received in 2011 were from GPs [27]. In 2016, the TGA national PV data also highlighted that hospital and community pharmacists were a major source of ADR reporting, at a much higher rate than doctors (physicians; ie, 16% for pharmacists vs 4% for physicians) [26]. In fact, in their submission for the 2015 TGA review of Australian Medicines and Medical Devices regulations, the Consumers Health Forum argued for mandatory requirements for doctors and pharmacists to report ADRs [28]. However, the Royal Australasian College of Physicians expressed the need for Australian physicians to receive payment for completing ADR reports [27]. In the review of voluntary ADR reports by HCPs to an ADRRC from 2012-2016, of the 555 ADR reports, 471 (84.8%) were reported by hospital pharmacists, 52 (9.4%) by doctors, and 32 (5.7%) by other HCPs. The median time from the date of onset of an ADR to submission of an ADR report (ie, to the TGA) was 3 days [26]. In the study of knowledge and perspectives of ADR reporting by community pharmacists between January to February 2017 (n=263), 35.3% (n=82) of community pharmacists reported at least one ADR to the TGA in the previous 12 months, even though 88.4% (n=205) of the pharmacists encountered an ADR in a patient, and 65.9% (n=153) documented ADRs as part of a clinical intervention at least once a month [28]. The documentation of opioid and penicillin ADR reports in hospital electronic health records showed that nurses and pharmacists were significantly less likely than doctors to omit the reaction description and that pharmacists were significantly more likely to enter the correct classification than doctors (53%, 95% CI 50.52-55.47; P<.001) [29,30].

Discussion

To the best of our knowledge, this is the first scoping review to integrate and synthesize the available published and scientific literature on ADR reporting within the Australian health care context. Thus, this study provides a broad overview of the Australian PV landscape and may highlight potential areas for innovation or quality improvement.

Consumers Participation in ADR Reporting

The results of our review indicates that consumer reporting is low, as reported in other studies [27]; despite this, consumers who are aware of reporting schemes may be willing to report. The studies showed that consumers were generally more likely to report ADRs to doctors (physicians) or pharmacists [27,28]. The findings are consistent with a recent study reporting that community pharmacists are usually the first point of contact regarding medication-related issues as the most frequently visited HCPs in Australia [10]. Introducing measures to facilitate ADR reporting for both consumer and patients and HCPs can be beneficial. A 2020 systematic review of interventions to improve ADR reporting also concluded that there was scope to include community pharmacies to improve ADR reporting [22]. These findings were also reported in other reviews [20,21]. Robertson and Newby [27] published in 2013 that only 10.14% of consumers (respondents) were aware of ADR reporting schemes. In 2020, Li et al [31] reported the findings of a black triangle scheme (ADR awareness) introduced by the TGA in

2018 to increase awareness and promote the reporting of ADRs by consumers and HCPs [31]. The effect of the black triangle scheme was only marginally successful at increasing ADR reports, that is, there was an improvement in the overall quality of ADR reports submitted but no meaningful increase in the quantity of reports [31]. The study concluded that additional strategies were required to enhance the overall PV system in Australia [28,31]. Considering that there has only been a marginal change in ADR reporting since 2013 [27], it suggests that there is opportunity for regulators to provide more awareness, such as education and further research. The provision of feedback to consumers about their ADR reports and involving consumers in the ADR management process, for example, the provision of ADR Warning cards, resulted in a high level of patient satisfaction and may have positively contributed to patient awareness [25]. In addition, feedback to health care providers on their submitted ADR reports may also encourage further reporting [28].

Health Care Provider Participation in ADR Reporting

Consumers who experienced a side effect reported the event to an HCP, most often a GP (physician) [27]. However, the review and analysis of all ADR reports submitted to the TGA highlighted a decline in GPs' contribution, from 28% of ADR reporting in 2003 to 4% in 2016 [26,27]. Therefore, understanding the barriers to and facilitators of ADR reporting among GPs in Australia may inform future interventions. Furthermore, in 2016, the TGA data also highlighted that hospital pharmacists and community pharmacists were a major source of ADR reporting, at a much higher rate than doctors (16% from pharmacists vs 4% from GPs) [26]. A Canadian study exploring why clinicians do not report ADRs posited that previous studies had focused predominantly on the knowledge and attitudes of HCPs and framed underreporting as a failure of individual clinicians without investigating workplace structures or practices that may have influenced reporting [18]. The discrepancies in reporting between GPs and pharmacists are vital and may warrant further investigation into organization and workplace structures. This is particularly important given our results in the documentation of opioid and penicillin ADR reports in a hospital electronic health records that showed that nurses and pharmacists were significantly less likely than doctors to omit the reaction description and that pharmacists were significantly more likely to enter the correct classification than doctors [29,30]. It is important to note that the study did not mention the reasons for reporting differences, leaving room for further investigations. Conversely, despite nurses being less likely to omit the reaction description, their perspective and reporting rate were not discussed and would benefit from further exploration. Nevertheless, although new technologies, for example, "electronic health records," present as an opportunity to facilitate ADR reporting [21], it has been noted that in practice, these electronic systems can cause unexpected errors, desensitize clinicians to alerts, and increase the documentation burden [19]. This is evident in our findings, where in June 2014, a pharmacy software vendor, GuildLink, created a web-based Adverse Events Recording module that integrated directly into the TGA ADR web service [28]. This allowed community pharmacists to report ADRs directly to the TGA from their professional service program instead of having to manually complete a separate ADR reporting form [28]. In the follow-up from the GuildLink intervention, the quantity of reports received by the TGA was nearly as high as that of the previous year (2013); however, despite the positive start, the numbers declined again in 2015 [28]. The factors that may have influenced a sustained adoption of the GuildLink system were not mentioned or discussed. As new digital technologies emerge and continue to transform health care management [32], exploring existing technology and their shortcomings, for example, GuildLink, and evaluating their health impact present areas of opportunity for improving health quality and patient safety.

Repeated calls for mandated ADR reporting for HCPs have been made, and as discussed above, patients are more likely to discuss or report issues with their medications to the HCPs who initially dispensed or prescribed them (GPs or pharmacists). The Consumers Health Forum in their 2015 submission argued for mandatory requirements for doctors and pharmacists to report ADRs [23,28]. However, the Royal Australasian College of Physicians also expressed the need for Australian physicians to receive payment for completing ADR reports [27]. Furthermore, one of the studies in our results suggested financial incentives for ADR reporting was also highly regarded as a measure to improve reporting by pharmacist [28]. Considering these points, none of the studies in our results explored or noted the impact of mandatory reporting or incentives, for example, financial, on ADR reporting. Furthermore, the finding of the review also showed that despite national and international guidelines for ADR reporting and management, there is no established gold standard systems (policy or guideline) at the individual health care facility level in Australia [26]. Therefore, there exists substantial interinstitutional variability with respect to the timing and nature of reporting ADRs [26]. It was also not possible to pinpoint the net effect of interinstitutional variability in ADR reporting to the TGA, which requires further investigation.

Strength and Limitation of the Review

The strength of this scoping review is that it is the first review to attempt an integration and synthesis of the available literature on ADR reporting, monitoring, and handling in the Australian health care context; the extent of participation; and ADR reporting systems. Notwithstanding the value of this research, some limitations must be acknowledged. This review was limited to papers published in English; it is possible that other potentially relevant literature in other languages were omitted. Although this review was performed using multiple major databases, searching other databases may have yielded other relevant published papers. A quality assessment of the studies included in the review was not undertaken; however, it was not relevant for the aim and not always necessary for scoping reviews [23,24]. There was limited data from the included studies in regard to the variabilities in participants' age, gender, or educational status. The majority of the studies were undertaken in the hospital setting and predominately focused on pharmacists and physicians; therefore, applying these results to the entire Australian health care system may require additional considerations, for example, the impact of age, gender, task, or work setting. Different states, regions, and countries may differ in their infrastructures, capacities, general workplace culture, medical education programs, and economic status, which limits the generalizability of the findings of this review.

Conclusion

The exploratory nature of the scoping review helped to integrate and synthesize the literature to give us a broad overview of the PV and ADR-reporting landscape in Australia. This review is beneficial for identifying research gaps and serves as a vital step to identify key areas for digital interventions and quality improvement in ADR reporting. It is also hoped that the results of this scoping review send a message to regulators (eg, the TGA), software vendors, or policy makers concerning the work that is needed to develop a robust and standardized PV system in Australia. This review did not find a generally accepted "gold standard" protocol or framework for ADR reporting among individual health care facilities, and there is substantial interinstitutional variability with respect to the timing and nature of ADR reporting in Australia.

Despite the marginal effects from previous interventions aiming to enhance ADR reporting, for example, ADR awareness (black triangle scheme) or digital health interventions (GuildLink), there is opportunity to improve patient safety in relation to ADRs. Further evidence-based research is needed to guide ADR interventions design and implementation. To support these interventions, knowledge of the barriers and enablers to ADR reporting among consumers, pharmacists, physicians, and nurses at a primary health care institutional level is warranted.

Abstract

Background: Vaccine safety surveillance is a core component of vaccine pharmacovigilance. In Canada, active, participant-centered vaccine surveillance is available for influenza vaccines and has been used for COVID-19 vaccines.

Objective: The objective of this study is to evaluate the effectiveness and feasibility of using a mobile app for reporting participant-centered seasonal influenza adverse events following immunization (AEFIs) compared to a web-based notification system.

Methods: Participants were randomized to influenza vaccine safety reporting via a mobile app or a web-based notification platform. All participants were invited to complete a user experience survey.

Results: Among the 2408 randomized participants, 1319 (54%) completed their safety survey 1 week after vaccination, with a higher completion rate among the web-based notification platform users (767/1196, 64%) than among mobile app users (552/1212, 45%; *P*<.001). Ease-of-use ratings were high for the web-based notification platform users (99% strongly agree or agree) and 88.8% of them strongly agreed or agreed that the system made reporting AEFIs easier. Web-based notification platform users supported the statement that a web-based notification-only approach would make it easier for public health professionals to detect vaccine safety signals (91.4%, agreed or strongly agreed).

Conclusions: Participants in this study were significantly more likely to respond to a web-based safety survey rather than within a mobile app. These results suggest that mobile apps present an additional barrier for use compared to the web-based notification–only approach.

Introduction

Vaccine safety surveillance is a core component of vaccination programs to monitor the safety of vaccines for health care professionals, policy makers, and the public. The implementation of a vaccine safety surveillance program increases the public confidence in various vaccines that are introduced [1]. Serious adverse events following immunization (AEFIs) are rare but do occur. For this reason, good-quality pharmacovigilance is necessary to detect AEFIs. Digital technology offers the potential to enhance and improve AEFI surveillance.

Vaccine pharmacovigilance in Canada currently involves passive and active surveillance systems that are designed to detect even very rare events in the population of vaccine recipients. However, passive surveillance suffers from underreporting and reporting biases (based on age, severity, and type of vaccine), while active surveillance occurs only for adverse events (AEs) in hospitalized children for specific conditions [2,3]. The detection of safety signals can be slow for either system and does not allow for the calculation of population-based incidence rates.

Participant-centered active vaccine reporting offers a potentially more economical and sustainable mechanism to conduct large-scale pharmacovigilance as it allows for rapid identification of AEFIs with minimal human resource needs. The Canadian National Vaccine Safety (CANVAS) network was established in 2009 to provide enhanced monitoring for pandemic and seasonal influenza vaccines using rapid, web-based active surveillance. CANVAS provides timely influenza vaccine safety information annually, via a web-based survey, collected from over 50,000 adults and parents across Canada. CANVAS includes an unvaccinated control group, which provides a robust approach for conducting rapid evaluations of vaccine safety.

The use of mobile health (mHealth) has allowed researchers, policy makers, and health care practitioners to reach individuals who are often less accessible, which, in turn, encompasses a broader and more representative sample of the population [4]. mHealth has not only increased accessibility but also provided low-cost health care solutions for various populations [5]. The COVID-19 pandemic and influenza outbreaks disproportionally harm individuals from communities that may be less accessible [6]. The need to reach broader populations is important in vaccine safety research to better improve postmarket surveillance and could potentially be aided through low-cost solutions via mHealth. However, this needs to be evaluated.

mHealth is a rapidly growing field, and the near ubiquity of smartphones presents a unique opportunity to incorporate digital technologies to address public health issues, such as monitoring AEFIs, and facilitate communication between individuals and public health officials. With increased mobile device and app usage, the potential exists to capture, transmit, and monitor postimmunization experiences rapidly using self-reporting and personal mobile devices. For example, Australia has successfully implemented participant-centered digital AEFI reporting using SMS text messaging technology [7]. CANImmunize is a digital immunization tracking solution that could serve as an acceptable platform for digital AEFI reporting [8,9].

In this study, we will evaluate the effectiveness and feasibility of using a mobile app for reporting participant-centered seasonal influenza AEFIs compared to a web-based notification platform.

Methods

Study Procedures

A 2-centered randomized controlled trial (RCT) was conducted to evaluate the use of safety reporting via a mobile app compared to safety reporting via web-based CANVAS notifications among individuals receiving the influenza vaccine from October 6 to November 29, 2020, during the seasonal influenza vaccine campaign in Ottawa, Ontario, and Vancouver, British Columbia, Canada.

Individuals were recruited at the time of receiving their influenza vaccine. Eligibility criteria included the ability to speak English or French, having an active email address and telephone number, and being immunized with the seasonal influenza vaccine.

Randomization

After study enrollment, participants were randomized to receive the web-based safety survey either through the mobile app or were emailed a link to the web-based survey using a 4-block randomization design.

Web-Based Notification Arm

All participants randomized to the web-based notification arm received the following web-based CANVAS notifications [10,11]. Briefly, participants received an email notifying them of their registration in the study. Eight days following their influenza vaccine, participants received an email with the survey link asking them to complete their web-based influenza vaccine safety survey. Participants received a reminder email on day 11 if they did not complete their survey. Further details on CANVAS surveillance and a description of the questionnaire can be found in previous studies [10,12,13].

Mobile App Arm

Participants randomized to the mobile app arm received an email asking them to download the app and activate their account. Users who did not activate their account after 48 hours received a reminder email. Participants who activated their accounts could spontaneously report an AE through the app and were also notified of the day 8 survey through the app.

Eight days following their vaccination, mobile app participants who activated their accounts received a push notification on their phone to complete their survey. A reminder push notice was sent out on day 11 to participants who had not yet competed the day 8 survey. On November 16, 2020 (midway through the recruitment period), additional email reminders in the mobile app arm were implemented on days 2, 4, and 6 to remind participants to register for the app. All participants received a day 8 email directing them to use their CANImmunize account to complete their influenza vaccine survey. Access to the survey link also was available in the email reminder.

Usability Survey

Following completion of the safety survey, all participants were sent a separate link via email to complete a user experience survey. Participants were asked about their history of participating in the flu vaccine safety survey and whether they previously used the CANImmunize app. Using a Likert scale, participants were asked questions on (1) perceived ease of use, (2) perceived usefulness, (3) their attitudes and intention of use toward the platform, and (4) questions pertaining to vaccine confidence and safety.

Statistical Analysis

The data were analyzed within the intention-to-treat arm to which participants were randomized. The data were summarized descriptively. Differences in response rates were compared using a chi-square test. AEFI incidence was compared between groups using a chi-square test and presented with 95% CIs. Response time between groups was assessed using a Student *t* test. A Mann-Whitney test with adjustments for multiple comparisons was used to compare useability responses among new and previous web-based notification platform users. Significance was accepted as *P*<.05.

Ethical Considerations

All participants provided informed electronic consent upon completion of the web-based survey for primary data collection as well as secondary analyses of research data. The Ottawa Health Science Network Research Ethics Board (20200591-01H) and the BC Children’s Hospital Research Ethics Board approved this study. This was a substudy under the CANVAS protocol (OHSN REB: 20100715-01H, BC: H10-02274). All participants’ personal data were anonymized to protect their privacy and confidentiality. Participants did not receive any monetary compensation for participating in this study.

Results

Overview

Between October 6 and November 29, 2020, a total of 2408 individuals agreed to participate in the RCT (Vancouver, n=1409; Ottawa, n=999). In total, 1196 participants were randomized to the CANVAS arm and 1212 to the CANImmunize arm (Figure 1).

Overall, 1319 (54%) RCT participants completed the web-based safety survey. Participant demographics are presented in Table 1. The completion rate was higher among web-based notification platform users (64%, n=767) than among mobile app users (45%, n=552; *P*<.001).

Of the 552 mobile app respondents, 15% (N=87) created a CANImmunize account and 4.3% (n=24) already had an account, 35 (6.3%) accessed the survey using the app, and the remaining participants (n=517, 93.6%) accessed the survey in the reminder email.

Of the users who created a new account, 100 (90% of registered users) registered for their account after November 16, 2020, compared to 10 before. Initiation of the reminder emails improved survey completion in the CANImmunize arm, with 73% (n=404) of mobile app survey completions occurring after the implementation of additional reminder emails.

Unknown	N/A	10 (5.2)	N/A

[a] Calculated on the basis of a total of 385 participants.

[b] Calculated on the basis of a total of 194 participants.

[c] Calculated on the basis of a total of 579 participants.

[d] N/A: not applicable.

Response Time

The mean response time for the day 8 survey was slightly longer for the mobile app group than for the web-based notification platform group (10.7, SD 3.9 days vs 10.1, SD 3.2 days, respectively; *P*=.001).

Spontaneous Reports

Spontaneous reports were available for mobile app users only. In total, 27 mobile app users accessed the spontaneous report survey, and 13 users submitted a spontaneous report, 1 of which was considered incomplete. The spontaneous reports were submitted on average 4.3 (SD 1.3, median 4) days after vacation. One of the 13 spontaneous reports was medically attended. Seven of the completed reports did not indicate any symptoms, suggesting that participants may have submitted their day 8 survey early or may have misunderstood the spontaneous report since they did not report any AEFIs despite the purpose of the survey being to gather AEFI information.

Event Reporting

Approximately 10% (n=134) of study participants reported experiencing a new or worsening health problem (78 web-based notification system users vs 56 mobile app users). In total, 43 of these participants (29 web-based notification system users vs 14 mobile app users) reported missing work or activities or consulting a medical professional (Table 2). No significant differences were observed in incidence rates between web-based and mobile app participants. The relative risk of developing or worsening of any health problem for the web-based notification arm relative to those in the mobile app arm was 1.002 (95% CI 0.7226-1.39). The relative risk of developing or worsening of any nonsevere health problem was 0.839 (95% CI 0.5702-1.2649). The relative risk of a health problem being severe enough to miss work or activities or a medical consultation was 1.491 (95% CI 0.7855-2.7619).

Table 2. Adverse event reporting rates among participants.

	Web-based notification system users, n (rate, 95% CI)	Mobile app users, n (rate, 95% CI)
Development or worsening of any health problem	78 (10.17, 8.12-12.53)	56 (10.14, 7.8-13.0)
Development or worsening of any nonsevere health problem	49 (6.39, 4.76-8.36)	42 (7.61, 5.5-10.1)
Adverse event severe enough to miss work or activities or a medical consultation	29 (3.78, 2.55-5.39)	14 (2.54, 1.4-4.2)

Usability and Perceived Usefulness

In total, 579 participants took the usability survey, with 194 mobile app and 385 web-based notification respondents, respectively. In total, 249 of those completing the usability survey had previously participated in the influenza vaccine safety survey (n=249, 43% of usability respondents) and 13% of usability respondents had used CANImmunize before (mobile app arm only, n=26).

Of the 35 mobile app users who completed the survey in the app, only 11 completed the useability survey; hence, we have only reported on the usability responses of the web-based notification platform users (Table 3). We conducted a sensitivity analysis among existing and new web platform users. There was no difference in responses between new and previous users of the web-based notification survey respondents (Multimedia Appendix 1).

Overall, 99% of web-based notification platform users agreed or strongly agreed that the platform was easy to use, and 88.8% of them thought that it made reporting AEFI easier.

When asked about perceived usefulness, 73.8% of web-based notification platform users agreed or strongly agreed that it will make vaccines safer, and 91.4% of them agreed or strongly agreed that it could make it easier for public health professionals to detect vaccine safety issues. The majority of participants (88.8%) agreed or strongly agreed that it made reporting a vaccine side effect easier, using this system was a good idea (93.2%), and that they would use it for additional vaccines (85.9%) or the COVID-19 vaccine (94.0%). Despite this, only 47.4% of web-based notification platform users who completed the usability survey reported that it increased their confidence in vaccine safety. Only 77.7% of users felt confident about data privacy and security.

Table 3. Perceived ease of use, usefulness, attitudes toward use, and intention to use among web-based notification survey users.

	Web-based notification survey (n=385)					
	Total respondents, n	Strongly disagree, n (%)	Disagree, n (%)	Neither agree nor disagree, n (%)	Agree, n (%)	Strongly agree, n (%)
Easy to use	380	1 (0.3)	0 (0)	2 (1.1)	61 (33.2)	316 (83.2)
Easy to open	382	1 (0.3)	0 (0)	2 (1.1)	75 (40.8)	304 (79.6)
Easy to access	377	0 (0)	0 (0)	2 (1.1)	72 (39.1)	303 (80.4)
This system will help make vaccines safer	382	2 (0.5)	3 (0.8)	95 (24.9)	132 (34.6)	150 (39.3)
This system increased my awareness of vaccine records	377	11 (2.9)	45 (11.9)	155 (41.1)	80 (21.2)	86 (22.8)
This system could make it easier for public health to detect safety issues with new vaccines	382	1 (0.3)	0 (0)	32 (8.4)	181 (47.4)	168 (44)
This system allows me to easily report a vaccine side effect (an adverse event) following immunization	376	5 (1.3)	3 (0.8)	34 (9.0)	150 (39.9)	184 (48.9)
Using this system to report vaccine side effects (adverse events following immunization) is a good idea	380	1 (0.3)	2 (0.5)	23 (6.1)	144 (37.9)	210 (55.3)
I feel confident about the privacy and security of my data in this system	381	1 (0.3)	3 (0.8)	81 (21.3)	152 (39.9)	144 (37.8)
If this was available for additional vaccines, I would use it	382	1 (0.3)-	1 (0.3)	52 (13.6)	142 (37.2)	186 (48.7)
I would use this system for a new COVID-19 vaccine	382	1 (0.3)	0 (0)	22 (5.8)	142 (37.2)	217 (56.8)
This system increased my confidence in the safety of vaccines	378	1 (0.3)	19 (5.0)	179 (47.4)	87 (23.0)	92 (24.3)
Getting vaccinated is a good way to protect myself and my family from disease	374	1 (0.3)	0 (0)	6 (1.6)	71 (19.0)	296 (79.1)
Vaccinating myself and my family is important for the health of others in my community	379	1 (0.3)	0 (0)	3 (0.8)	68 (17.9)	307 (81)
I am concerned about serious side effects of vaccines	381	32 (8.4)	94 (24.7)	80 (21.0)	106 (27.8)	69 (18.1)
New vaccines carry more risks than older vaccines	383	31 (8.1)	41 (10.7)	187 (48.8)	85 (22.2)	39 (10.2)

Discussion

Principal Findings

This study compared 2 digital reporting systems (a web-based notification platform vs a mobile app) for AEFI reporting during the 2020 seasonal influenza vaccination campaign. In total, 2408 individuals agreed to participate in the RCT. A total of 1196 participants were randomized to the CANVAS arm and 1212 to the CANImmunize arm (Figure 1). Overall, 1319 (54%) RCT participants completed the web-based safety survey. The completion rate was higher among web-based notification platform users (64%, n=767) than among mobile app users (45%, n=552). Ease of use was higher among web-based notification platform users. Our findings suggest that a web-based survey link is an acceptable approach for active, participant-centered AEFI reporting. We identified a number of concerns with mobile app reporting, which would need to be addressed to improve the acceptability and usability of app-based reporting.

To be successful, digital solutions must be easy to use, easy to access, and meet the needs of the users [14]. In this study, we saw lower rates of participant engagement in the mobile app arm and were unable to assess usability due to low participant responses. Participants were required to download the app and register their account. This added complexity and was likely a barrier to use.

Interestingly, the highest response rate in the mobile app group was observed among 30-39–year-old participants. This was possibly due to this demographic being having a higher level of technological literacy and comfort with mobile apps [15]. The lowest response rate among the mobile app users was observed among older adults aged >65 years. The low response rate among older adults may be due to less comfort with mobile apps or possibly barriers such as difficulty reading smaller font [16].

The lack of responses to the usability survey is also a potential concern as we were unable to assess exactly what needs to change to make mobile app reporting acceptable and user-friendly. The usability survey was provided as a separate email link after the safety survey was completed, and it may have been missed by users.

It is critical to make mHealth solutions accessible, and a barrier may be technological literacy or low perceived ease of use among some populations. It is important that mHealth apps are designed to be user-friendly for target demographics [17]. This is important in vaccine safety surveillance studies that need to capture data from a breadth of demographics.

Current literature suggests that the development of mHealth apps should follow 8 specific categories [17] with usability being one of the key categories. Usability refers to the app being adapted to the target population [17]. Making the app easy to use, with clear instructions, and the feedback of various community members who use the app is critical. Our finding—a lower response rate was observed among mobile app users than among the web-based notification platform users—implies that the mobile app may not have been optimally designed for usability for all of the target demographics. The app was possibly challenging to navigate or perceived to be so resulting in a lower response rate than that among users of the web-based notification system.

Enabling AEFI reporting from individuals who are already using a mobile app for another purpose would require less work for the user and may be a more successful approach. For example, 42% of Canadians report accessing websites, mobile apps, or other interactive web-based services to support or monitor their health [18]. Integrating use with these types of health monitoring apps would be an approach worth trialing. Indeed, since the completion of this study, the CANVAS-COVID safety survey has recruited control participants from among current CANImmunize users [19]. Other digital technologies have been used during the COVID-19 vaccine rollout. Social media was used to collect postmarket vaccine safety data [20-23], and the US Centers for Disease Control and Prevention created the V-safe After Vaccination Health Checker application, which allowed individuals to register and complete vaccine safety surveys after receiving their COVID-19 vaccine [23].

Based on the RCT conducted in this study, it was found that adding the extra step of using the mobile app introduced an additional barrier for participants who may have lower technological literacy. Future mHealth developments should include various participants from the target demographics in the development process to ensure usability.

Limitations

This study has several limitations. Mobile app users were required to register for a CANImmunize account for the study. Registration allowed for influenza vaccine data to be uploaded to the users' CANImmunize account; however, this additional step appeared to be a barrier to use as we saw low registration numbers. Study participants were randomized after study registration; hence, onsite personnel were not able to support participants randomized to the mobile app arm in activating their account, which may also have contributed to low account registration. However, this can be perceived as a strength as this provided more real-world effectiveness data of app usage as in a nonstudy setting, users would have to navigate this on their own without study staff assistance. The day 8 survey email served as a reminder to mobile app users to register their accounts if they had not yet done so, but it also provided a direct link to the web-based safety and usability surveys, which 94% of mobile app arm users who completed the survey chose to use, rather than registering for a mobile app account. As a result, we could not effectively evaluate user preference or experiences in the mobile app arm of the study. Another major limitation is that data about nonresponders were not collected, which could introduce risk for response bias, particularly since the response rate differed between the web-based notification arm (64%) and the mobile app arm (45%).

Conclusions

In summary, this study demonstrated high user acceptability with the web-based survey platform compared to that with a mobile app. Making AEFI reporting available to existing mobile app users may still be a viable initiative for participant-centered active reporting in Canada but would require further refinement.

Acknowledgments

We wish to thank the individuals who participated in this study. This project was supported by The Ottawa Hospital Academic Medical Organization (TOHAMO) and The Ottawa Hospital Foundation. The Canadian National Vaccine Safety Network as part of the Canadian Immunization Research Network is funded by a research grant from the Canadian Institutes of Health Research and the Public Health Agency of Canada (grant #151944; June 1, 2017, to December 31, 2022).

Conflicts of Interest

KW, KA, and CB were cofounders and shareholders of CANImmunize Inc, a corporation that provides consumer facing solutions to immunization information systems. KW has served on the Medicago Independent Data Monitoring Committee and is a member of the Moderna Global Safety Core Consultancy Group. All other authors have no conflicts of interest to disclose.

Editorial notice

This randomized study was only registered retrospectively due to delays caused by the COVID-19 pandemic. The editor granted an exception from ICMJE rules mandating prospective registration of randomized trials, because the risk of bias appears low. However, readers are advised to carefully assess the validity of any potential explicit or implicit claims related to primary outcomes or effectiveness, as retrospective registration does not prevent authors from changing their outcome measures retrospectively.

Abstract

Background: Opioid drug prescription (ODP) and opioid-related mortality (ORM) have increased in Spain. However, their relationship is complex, as ORM is registered without considering the type of opioid (legal or illegal).

Objective: This ecological study aimed to examine the correlation between ODP and ORM in Spain and discuss their usefulness as a surveillance tool.

Methods: This was an ecological descriptive study using retrospective annual data (2000-2019) from the Spanish general population. Data were collected from people of all ages. Information on ODP was obtained from the Spanish Medicines Agency in daily doses per 1000 inhabitants per day (DHD) for total ODP, total ODP excluding those with better safety protocols (codeine and tramadol), and each opioid drug separately. Rates of ORM (per 1,000,000 inhabitants) were calculated based on deaths registered (International Classification of Diseases, 10th Revision codes) as opioid poisoning by the National Statistics Institute, derived from the drug data recorded by medical examiners in death certificates. Opioid-related deaths were considered to be those that indicated opioid consumption (accidental, infringed, or self-inflicted) as the main cause of death: death due to accidental poisoning (X40-X44), intentional self-inflicted poisoning (X60-X64), drug-induced aggression (X85), and poisoning of undetermined intention (Y10-Y14). A descriptive analysis was carried out, and correlations between the annual rates of ORM and DHD of the prescribed opioid drugs globally, excluding medications of the least potential risk of overdose and lowest treatment tier, were analyzed using Pearson linear correlation coefficient. Their temporal evolution was analyzed using cross-correlations with 24 lags and the cross-correlation function. The analyses were carried out using Stata and StatGraphics Centurion 19.

Results: The rate of ORM (2000-2019) ranged between 14 and 23 deaths per 1,000,000 inhabitants, with a minimum in 2006 and an increasing trend starting in 2010. The ODP ranged between 1.51 to 19.94 DHD. The rates of ORM were directly correlated with the DHD of total ODP (r=0.597; P=.006), total ODP without codeine and tramadol (r=0.934; P<.001), and every prescribed opioid except buprenorphine (*P*=.47). In the time analysis, correlations between DHD and ORM were observed in the same year, although not statistically significant (all *P*≥.05).

Conclusions: There is a correlation between greater availability of prescribed opioid drugs and an increase in opioid-related deaths. The correlation between ODP and ORM may be a useful tool in monitoring legal opiates and possible disturbances in the illegal market. The role of tramadol (an easily prescribed opioid) is important in this correlation, as is that of fentanyl (the strongest opioid). Measures stronger than recommendations need to be taken to reduce off-label prescribing. This study shows that not only is opioid use directly related to the prescribing of opioid drugs above what is desirable but also an increase in deaths.

Introduction

The prescription of opioid drugs has grown enormously in Spain [1,2], with an increase of over 300% since 2001 [3,4]. This is not a local phenomenon. The same is occurring in many countries in Europe and around the world, resulting in a serious public health problem [5-7].

The increase in the opioid drug prescription (ODP) in Spain has been highlighted and registered in pharmaceutical surveillance systems [8], in addition to occasional investigations. This has resulted in recommendations to increase the precision of both prescription indications and duration of treatment [9,10], aligned with what is occurring in the international context [11]. The use of these medications has helped many people to manage their illnesses [9,11], especially those with chronic conditions and cancer [12]. However, the use of these medications is related to the potential appearance of adverse effects: the 2 most relevant are the development of an addiction to these drugs and death due to overdose [1,13].

The opioid crisis in North America is related to the medical prescription of these drugs. Both the number of people addicted to medically prescribed opioids and those addicted to other illegal opioids have increased dramatically in the last decade. The consequences for health, the loss of life years, and the economic costs are enormous [14-16].

The current data on the situation in Spain do not show a situation similar to that of North America [1,17]. The increase in ODP has not yet been accompanied by the phenomenon seen in other countries. However, concerns about the situation are important, and surveillance has been heightened in new profiles of addicted users in treatment as well as in the possible indirect indicators of an increase in consumption. This consumption has increased in an unequal way, based on different active ingredients and indications for use. There is an especially relevant increase in extrahospital use of tramadol and interhospital use of fentanyl [2,8,18], and at the same time, non-oncological use accounts for nearly 90% in certain cases [19].

Together with the registry of ODP, one of the most valuable indicators of the growth and type of use is the registry of deaths due to opioid overdose, also referred to as opioid-related mortality (ORM) [13,20]. This indicator reflects the number of deaths whose principal cause is overdose of any opioid and excludes the deaths due to other causes (such as terminal cancers) in which opioid treatment could exist [1,15,21]. The relationship between ODP and ORM is complex, as in Spain, they are recorded without differentiating between the type of opioid (legal or illegal). Therefore, determining the relationship between ODP and ORM can provide key information both about deaths due to prescribed opioid drugs and, in an indirect way, deaths due to illegal opioid consumption. The objective of this study was to examine the correlation between ODP and ORM in Spain from 2000 to 2019 and discuss their usefulness as a surveillance tool.

Methods

This was an ecological study using retrospective annual data (2000-2019) from the Spanish general population. Data were collected on people of all ages for ORM and ODP.

Data Source

To determine ORM, population data were collected from 2000 to 2019 through the Spanish National Statistics Institute [22], which produces a report of “statistics of deaths according to the cause of death derived from the drug data recorded by medical examiners in their death certificates” [23], following the criteria established by the World Health Organization (WHO) in the International Classification of Diseases, 10th Revision (ICD-10) [24]. This statistic provides information on mortality according to the cause of death. This is similar to methodology used in previous studies [1]. From these data, and according to the ICD-10 codes [24], we retrieved information on ORM. Opioid-related deaths were considered to be those that indicated opioid consumption (accidental, infringed, or self-inflicted) as the main cause of death: death due to accidental poisoning (X40-X44), intentional self-inflicted poisoning (X60-X64), drug-induced aggression (X85), and poisoning of undetermined intention (Y10-Y14). These codes excluded deaths due to opioid overdose in the contexts of compassionate sedation and euthanasia in terminal cases, given that in these cases, the codes were included in the disease codes. The complete list of codes is shown in Multimedia Appendix 1. These codes were used in ways that are similar to what has been carried out in prior publications [21], which also coincides with the codes for death related to the use of opioids as used in later publications [16,25,26]. These causes do not differentiate by the type of opioid, whether in the Spanish or international context. Some of the cited codes (X40, X60, and X85) do not fully correspond to the operational definitions that exist in the Spanish context. For each year (from 2000 to 2019), we report data on the number of ORM and ORM rates per 1,000,000 inhabitants (quotient between the number of opioid-related deaths and the total population).

The data on prescribed opioid drugs were obtained via the Spanish Agency of Medicines and Health Products (*Agencia Española de Medicamentos y Productos Sanitarios* [AEMPS]). All of the drugs require a medical prescription or special permissions to be sold in pharmacies or dispensed by health centers. The AEMPS receives state-level information on all of the prescriptions written for all drugs that contain opioids and separates them by active ingredient. In 2019, the complete list was made up of morphine, hydromorphone, oxycodone, oxycodone and naloxone, pethidine, fentanyl, dextropropoxyphene, pentazocine, buprenorphine, codeine and paracetamol, codeine and acetyl salicylic acid, codeine and ibuprofen, tramadol and paracetamol, tramadol and dexketoprofen, and tramadol and tapentadol. Prescribed opioid drugs were studied both globally and individually, which is explained later in this article. The measurement unit used was dose per 1000 inhabitants per day (DHD).

Statistical Analysis

Normal distribution was confirmed for the variables (ODP and ORM) using Shapiro-Wilk tests, and we observed that all of the variables followed a normal distribution (Multimedia Appendix 2). Subsequently, a description of the variables' evolution over time was carried out. We carried out an analysis of the correlation between the annual rates of ORM and the DHD of the prescribed opioid drugs globally, excluding medications of the least potential risk of overdose and lowest treatment tier [27] (codeine and tramadol), and separately, based on the frequency of their use or their growth over recent years from the initial descriptive analysis. The relationship between ORM and ODP was analyzed as follows: (1) total ODP, (2) total ODP excluding codeine, (3) total ODP excluding codeine and tramadol, (4) tramadol, (5) fentanyl, (6) tapentadol, (7) oxycodone (unifying presentations with and without naloxone), and (8) morphine. All correlations were calculated using Pearson linear correlation coefficient. Statistically significant differences were observed when $P<.05$.

Finally, an analysis of the evolution of each variable was carried out across time, using time series. The relationship between the total evolution of the mortality rate and the DHD of the rest of the drugs was analyzed via cross-correlations with 24 lags and the cross-correlation function. Using this method provides knowledge of the correlations of mortality over time t (in a determined year) and the DHD of each opioid drug in time $t-k$ (in annual spikes or intervals; in this case: 1 year prior, 2 years prior, etc). This could indicate a potential impact of the increase in a dose during year t on mortality in $t-k$ years (1 year later, 2 years later, etc), without necessarily demonstrating a causal relationship.

Time evolution was studied during the whole period of the data, for the periods 2000-2011 and 2012-2019, and for the periods 2000-2015 and 2016-2019. The fragmentation of these periods corresponded to changes in the trend in deaths observed in 2010 and the alert made by health authorities in 2016 about the increase in the use of these medications as well as a call for their rational use [28], respectively.

The analyses were carried out using the Stata statistical package (version 16.1; StataCorp LLC) and StatGraphics Centurion 19 (StatGraphics Technologies, Inc).

Ethics Approval

This study was a secondary analysis of data with no identifying information available to the researchers. It was approved by the institutional review board at the Hospital Clínico San Carlos (affiliated to Complutense University) on March 18, 2021 (approval 21/167-E).

Results

The temporal evolution of the rate of ORM from 2000 to 2019 ranged between 14 and 23 deaths per 1,000,000 inhabitants. Rates decreased progressively to a minimum in 2006, and after some fluctuations, there was a slight increase starting in 2010 that seemed to be stable over time (Figure 1).

In terms of the evolution of the DHD of the opioid drugs analyzed, we observed a continuous increase of more than 40% per year until 2006. Starting in 2006, this became more acute, especially in 2010 when the rate grew from 4.4 to 10 DHD, with a global increase from 2000 to 2019 of 1.51 to 19.83 DHD (12.6 times greater). The magnitude of tramadol stands out (prescribed alone or in conjunction with other nonopioid active ingredients); tramadol represents 63.7% of the total opioids prescribed, with an increase of 10% (of the total) since 2010. Codeine, however, declined from 17% of opioids in 2010 to 9% in 2019. Fentanyl accounted for 13% of prescribed opioids in 2019, followed by tapentadol (5%), buprenorphine (3.4%), and oxycodone (3%). Notable growth can be observed in all of these opioids. Fentanyl and tapentadol both grew by 1000% between 2000 and 2012, whereas oxycodone (first, without and, later, with naloxone) grew by 600% since 2011. The consumption of buprenorphine has been very stable over the past decade. Finally, morphine accounted for 1.3% of prescribed opioids, with an increase in consumption of 63% since 2010 (Figure 2).

Mortality rates for each year were directly correlated (the higher DHD of opioid drug, the higher the mortality rate) in all of the cases analyzed, except in the case of buprenorphine ($P=.47$). The strongest positive correlations were observed with global ODP without codeine ($r=0.902$; $P<.001$), global ODP ($r=0.597$; $P=.006$), global ODP without codeine or tramadol ($r=0.934$; $P<.001$), tapentadol ($r=0.873$; $P=.003$), and oxycodone ($r=0.835$; $P=.002$; Figure 3).

Figure 1. Evolution of opioid-related mortality per 1,000,000 inhabitants (2000-2019).

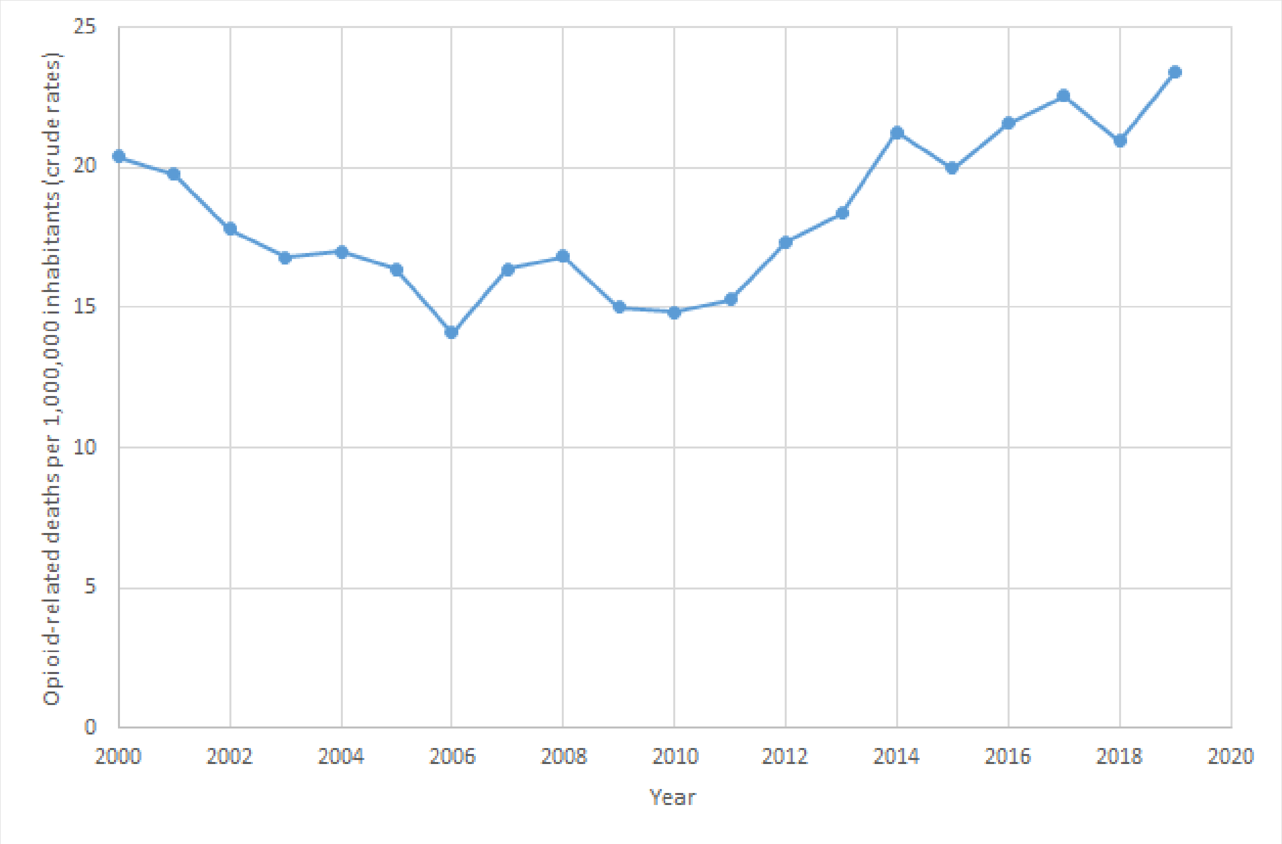

Figure 2. Opioid drug prescription evolution from 2000 to 2019 (unit: dose per 1000 inhabitants per day [DHD]).

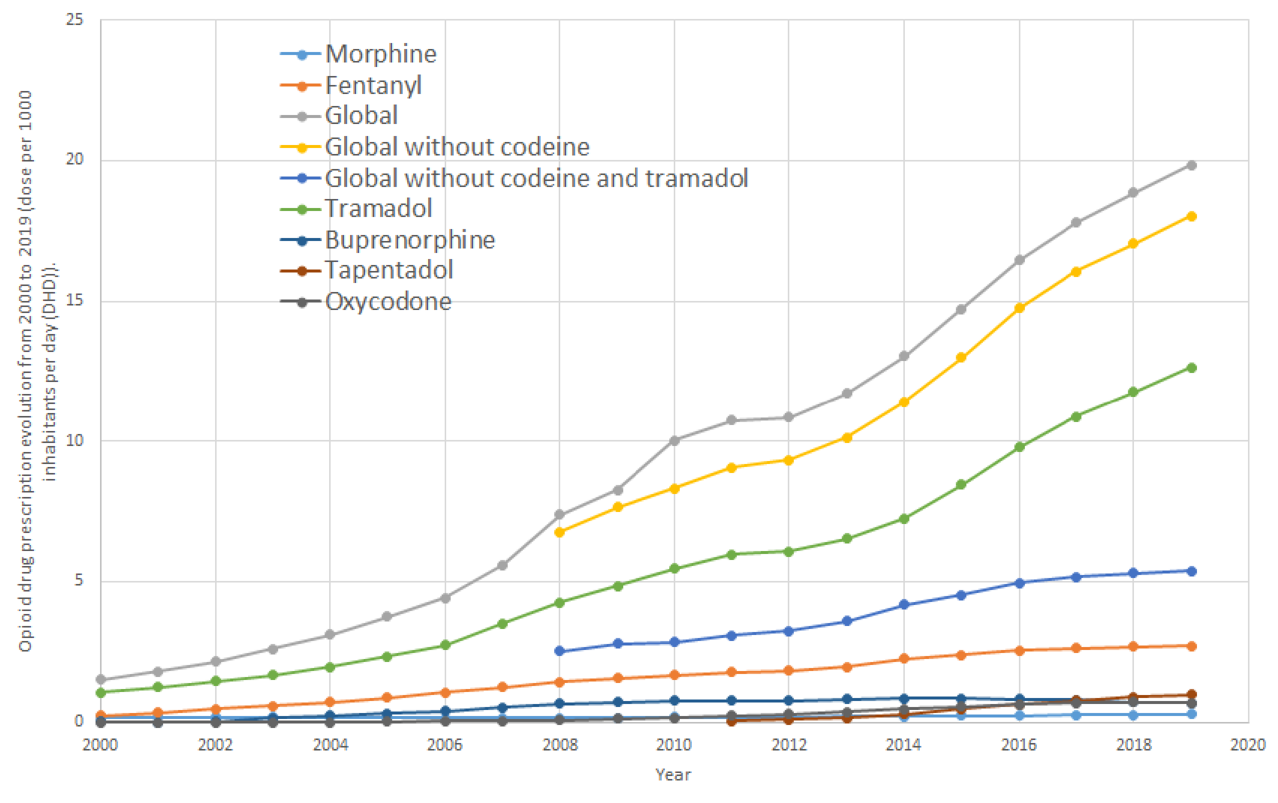

Figure 3. Correlation between opioid drug prescription (ODP; x-axis) and mortality rate per 1,000,000 inhabitants (y-axis).

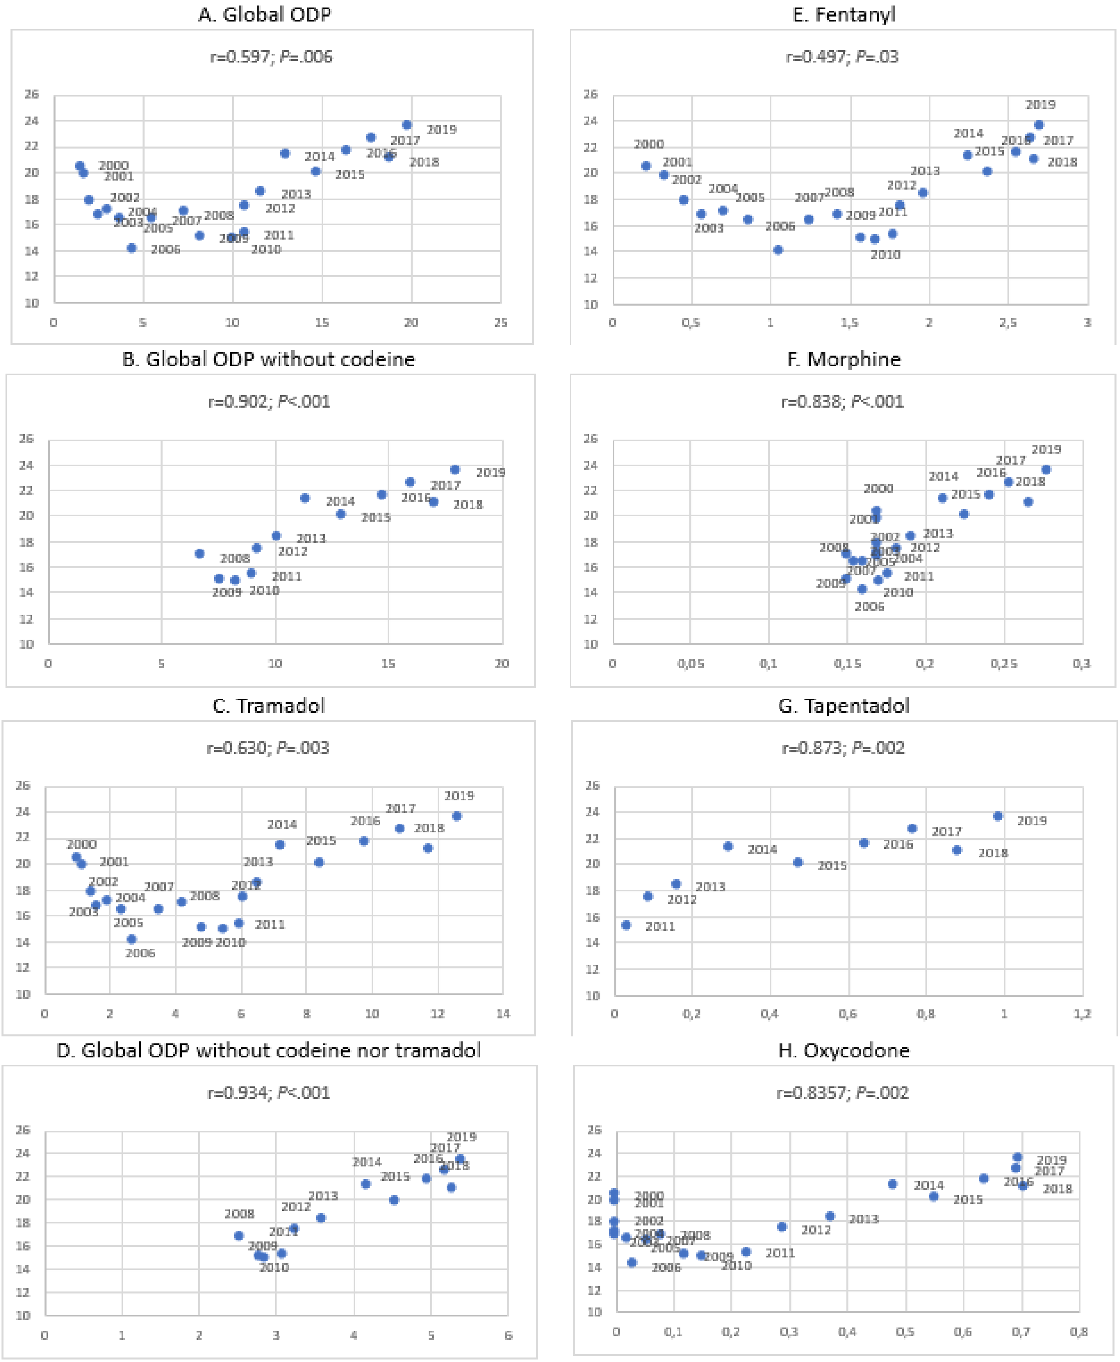
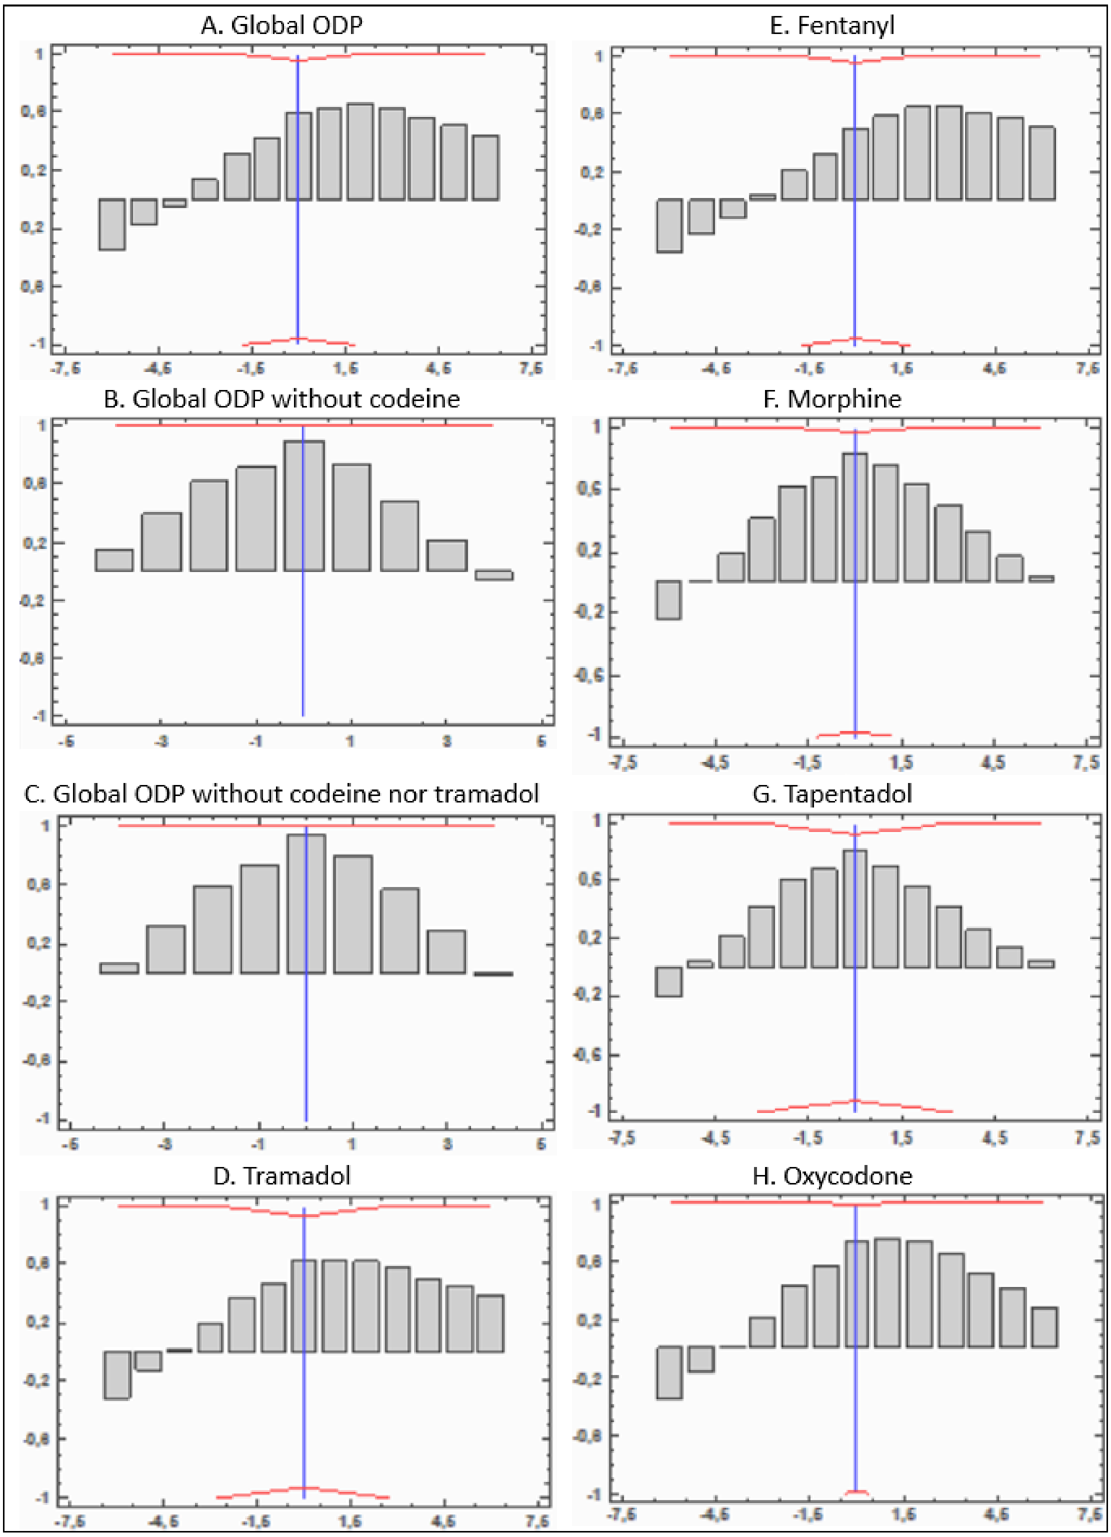


[Figure 4](#) shows the cross-correlations between mortality rates and the DHD of the different drugs analyzed. In considering all of these drugs, the figure shows a greater correlation between prescribed DHD in a year and the mortality rate 3 years later, reaching a maximum in the second year. However, after eliminating prescribed drugs with codeine and those with codeine and tramadol from the totals, the correlations with the mortality rate can be observed for the same year and not so much for the following years. The same situation occurred when exclusively considering morphine and tapentadol, where the greatest correlations were observed in the same year and in the 2 following years, with a gradual dilution of the correlation in successive years. This same relationship can also be observed with tramadol alone or in conjunction with another medicine. Fentanyl seems to have an impact on mortality over the medium term, in the second or third years, whereas buprenorphine has a long-term impact of between 4 and 6 years. Despite this pattern, these differences were not significant (all $P \geq .05$). The segmented analysis of the periods of 2000-2010 and 2011-2019 as well as 2000-2016 and 2017-2019 did not result in findings different from what is described here.

Figure 4. Cross-correlation between opioid-related mortality rates and opioid drug prescription (ODP). y-axis: correlation; x-axis: delay in years.



Discussion

This study confirms the enormous increase in the prescription of opioid drugs in the last 2 decades in Spain. This increase was driven especially by tramadol, but fentanyl, due to its potency and hospital use, also plays a very relevant role. It also points out a correlation between the increases in ODP and ORM.

Considering the fact that illicit opioid use has decreased or remained the same in the period from 2001 to 2019 [17,20], this could suggest that deaths related to prescribed opioid drugs have increased.

The increase in ODP has been highlighted in the past by other studies carried out in Spain that use different data sources [2-4]. This study includes a larger geographic region, Spain's national territory, in which medical indications are homogenous [28]. This suggests that the progression of ODP is evolving in a parallel way in different regions in Spain [4,17,18]. This increase corresponds with the situation in most other European countries [5].

Many of the causes of this enormous increase have been pointed out. The use of these drugs [11,12,28], as well as their target population, has increased (in large part due to the fact that the aging population experiences more disease and related pain [29]). However, both in Spain and in other countries where this phenomenon is taking place, prescriptions are increasing at a faster rate than these other factors [5,30,31]. More opioids are being prescribed and for longer terms than that recommended by treatment guidelines. This issue is beyond the scope of this study, but it is one in which the role of prescriptions, compared to other factors such as socioeconomic level or residing in rural versus urban areas [18], seems to be especially important given its potential as an area for improvement [32,33].

In addition to describing this general phenomenon, this study shows the correlation with ORM, which coincides with what has been shown to occur in other contexts [33]. In Spain, it appears that in the years included in this study, there has not been a proliferation in illegal consumption of prescribed opioid drugs or other opioids [17,20]. Therefore, it can be inferred that it is the prescribed opioid drugs and not illegal opioids that are provoking this increase in deaths. This suggestion should be taken with great prudence, but it corresponds with what has occurred in environments with greater problems related to illegal opioids [14]. With a lower proportion of illegal opioids, there is a greater correlation between prescriptions and opioid-related mortality. This study found the potential mortality from unstudied opioids to be minimal and the correlation between opioid medications and overdose deaths to be consistent with these occurrences. An absence of correlation might have indicated that illegal drugs were operating in the market. The results tell us that the increase in overdoses is related to an increase in opioid prescribing.

This fact reflects the situation up till 2019, but we should not forget that in the future, prescribed opioid drugs could spread to the illegal market, as has happened in other places [16,21,34]. Above all, precautions should be taken to detect such a situation if it were to occur [20]. The ORM-ODP correlation could be a useful indicator both separately and when harmonized with other indicators such as hospital admissions. In fact, from 2016 to 2019, hospital admissions related to poisoning, other consequences of external causes (S00-T88), and external causes of morbidity (V00-Y99) increased in Spain by 20% [35].

The existence of the ORM-ODP correlation may be as informative as its possible nonexistence in the future. The lack of a correlation could suggest that illegal opioids have increased [14] or that there has been an improvement in prescription practices. Furthermore, opioid-related deaths are an indicator of opioid consumption. It is the least desired adverse effect, but there is a proportionality between its frequency and consumption [20]. Therefore, the surveillance of ORM could provide information about possible variation in other parameters, such as addiction or other related comorbidities (associated infections, dual pathology, etc). Therefore, the surveillance of trends in ORM and ODP separately, as well as the correlations between them, could play an important role in the global monitoring of opioid consumption and its consequences.

In establishing preventive measures, it is useful to focus on certain active ingredients, in addition to prescribed opioid drugs in general, especially in the case of tramadol and fentanyl, in which we found an ORM-ODP correlation. These are 2 medications with different indications and safety profiles.

Tramadol accounts for not only the majority of prescriptions but its increase has also been constant and parallel to total ODP. It belongs to the group of second-tier analgesic opioids as defined by the WHO [27]. The indications of tramadol for non-oncological pain can possibly explain this increase, as suggested in other Spanish studies [18] and coinciding with the European and North American contexts [36]. It is unknown whether this increase corresponds to the increase in its target population. The indications for tramadol and the number of potential patients have increased [11,12]; however, studies of its misuse and misprescription are scarce and contradict each other [36-38]. This study did find a correlation between ORM and tramadol prescriptions; therefore, it is important to reinforce the correct use of tramadol among those who prescribe it [28], as well as to intensify surveillance. It is still the most prescribed opioid drug, where a simple prescription is all that is required [8]. It is much easier to prescribe than others.

In the third analgesic tier [27], fentanyl stands out due to its growth and the ORM-ODP correlation. It is the strongest opioid, specifically recommended for the treatment of irruptive oncological pain. It is also the opioid with the greatest potential number of overdoses, although this also depends on the posology [11,12,39]. This increase is in the context of the notable increase in the consumption of the strongest opioids [2-4,10]. This trend goes beyond the scope of this study. The number of prescriptions of opioids in the third tier increased by 9.6% between 2019 and 2020 [19]. What is surprising is that 89% is related to non-oncological indications [19]. Pain management is an essential component of medical care, but these data are worrisome [3]. Both the increase, as well as the possible adverse effects, have been highlighted in Spain by health authorities, who issued an alert in 2016 to restrain prescriptions to specific indications and the doses to the length of the disease [28]. This study did not find a change over time in the correlations prior to or after that date.

Of the opioid drugs studied, only buprenorphine was not correlated with ORM. It is possible that this could be due to the fact that this opioid is usually used as a substitute treatment for other opioids [40], with a stable number of users [20]. Data on the dispensation of buprenorphine did not differentiate between its use as an analgesic and as treatment for addiction, and as such, it is impossible to interpret these data.

In terms of the temporal patterns described, after eliminating the safest active ingredients from the totals (codeine and codeine with tramadol), the correlations with the mortality rate shifted and could be observed in the same year and less so in successive years. Individually, for morphine, tramadol, and tapentadol, the years with the greatest number of deaths coincided with the years with the greatest number of prescriptions of these drugs. Although these results are not statistically significant (probably because the time series analyzed is short and had few data points [19 data-year/opioid]), they could point to the fact that the ORM-ODP relationship is not mediated by all opioids. They should be studied individually, as they do not share the same indications, safety profiles, or prescription processes. Future studies should study in further depth the prescription of these drugs.

This study includes a number of limitations. Although the data collected correspond to precise definitions that use ICD-10 codes, the reliability of the determination and coding of the cause of death depends on each professional for each death and not on the data source itself. The codes selected are exclusively for deaths due to overdose. There are also specific codes for deaths provoked by opioids in euthanasia or compassionate sedation in the context of palliative care that we did not include. The deaths due to these other causes are not included in what we refer to as ORM. Even so, in some cases, it is possible to omit using the overdose code to avoid legal or administrative problems, especially in the case of accidents. Thus, the number of deaths could be understated. On the other hand, the data did not permit us to disaggregate by sex nor age, which could limit these conclusions. However, these data are acceptable in the international context, as the data source is used by the European Monitoring Centre for Drugs and Drug Addiction [41].

It is important to point out that the Spanish system exclusively includes the main cause of death, and not multiple causes. This differs from other information systems, such as the US system, in which several codes are collected. These codes can be cross-examined to refine the cases in which (1) opioid use has been registered and (2) a death associated with these substances has been recorded. This is the reason why we talk about opioid-related deaths rather than directly attributable causes of mortality in our paper.

This study suggests that at the population level, there is a correlation between greater availability of prescribed opioid drugs and an increase in opioid-related deaths. The correlation between ODP and ORM may be a useful tool in monitoring legal opiates but also possible disturbances in the illegal market. The role of tramadol (an easily prescribed opioid) is important in this correlation, as is that of fentanyl (the strongest opioid). Measures stronger than recommendations need to be taken to reduce off-label prescribing. This study shows that opioid use is not only directly related to the prescribing of opioid drugs above what is desirable but also an increase in deaths.

Acknowledgments

This study has been funded by Instituto de Salud Carlos III (ISCIII) through the project “PI19/00982” and cofunded by the European Union. The authors are grateful to the National Plan on Drugs and Spanish Agency of Medicines and Health Products (*Agencia Española de Medicamentos y Productos Sanitarios* [AEMPS], *Ministerio de Sanidad, España*) for their full support and Emily Felt for translation and suggestions.

Data Availability

The Spanish population data [42] and the data on opioid-related mortality [43] are publicly available at the Spanish National Statistics Institute website.

The data prescribed opioid drugs were obtained via the Spanish Agency of Medicines and Health Products (*Agencia Española de Medicamentos y Productos Sanitarios* [AEMPS]) [44].

Abstract

Background: The World Health Organization recently described sudden sensorineural hearing loss (SSNHL) as a possible adverse effect of COVID-19 vaccines. Recent discordant pharmacoepidemiologic studies invite robust clinical investigations of SSNHL after COVID-19 messenger RNA (mRNA) vaccines. This postmarketing surveillance study, overseen by French public health authorities, is the first to clinically document postvaccination SSNHL and examine the role of potential risk factors.

Objective: This nationwide study aimed to assess the relationship between SSNHL and exposure to mRNA COVID-19 vaccines and estimate the reporting rate (Rr) of SSNHL after mRNA vaccination per 1 million doses (primary outcome).

Methods: We performed a retrospective review of all suspected cases of SSNHL after mRNA COVID-19 vaccination spontaneously reported in France between January 2021 and February 2022 based on a comprehensive medical evaluation, including the evaluation of patient medical history, side and range of hearing loss, and hearing recovery outcomes after a minimum period of 3 months. The quantification of hearing loss and assessment of hearing recovery outcomes were performed according to a grading system modified from the Siegel criteria. A cutoff of 21 days was used for the delay onset of SSNHL. The primary outcome was estimated using the total number of doses of each vaccine administered during the study period in France as the denominator.

Results: From 400 extracted cases for tozinameran and elasomeran, 345 (86.3%) spontaneous reports were selected. After reviewing complementary data, 49.6% (171/345) of documented cases of SSNHL were identified. Of these, 83% (142/171) of SSNHL cases occurred after tozinameran vaccination: Rr=1.45/1,000,000 injections; no difference for the rank of injections; complete recovery in 22.5% (32/142) of cases; median delay onset before day 21=4 days (median age 51, IQR 13-83 years); and no effects of sex. A total of 16.9% (29/171) of SSNHL cases occurred after elasomeran vaccination: Rr=1.67/1,000,000 injections; rank effect in favor of the first injection (*P*=.03); complete recovery in 24% (7/29) of cases; median delay onset before day 21=8 days (median age 47, IQR 33-81 years); and no effects of sex. Autoimmune, cardiovascular, or audiovestibular risk factors were present in approximately 29.8% (51/171) of the cases. SSNHL was more often unilateral than bilateral for both mRNA vaccines (*P*<.001 for tozinameran; *P*<.003 for elasomeran). There were 13.5% (23/142) of cases of profound hearing loss, among which 74% (17/23) did not recover a serviceable ear. A positive rechallenge was documented for 8 cases.

Conclusions: SSNHL after COVID-19 mRNA vaccines are very rare adverse events that do not call into question the benefits of mRNA vaccines but deserve to be known given the potentially disabling impact of sudden deafness. Therefore, it is essential to properly characterize postinjection SSNHL, especially in the case of a positive rechallenge, to provide appropriate individualized recommendations.

Introduction

Background

SARS-CoV-2, the coronavirus responsible for COVID-19 disease, has spread rapidly, causing a global pandemic since early 2020. In late 2020, the first messenger RNA (mRNA)–based COVID-19 vaccine, Pfizer-BioNTech BNT162b2, Comirnaty (tozinameran), was authorized by the European Medicines Agency (EMA), followed by Moderna mRNA-1273, Spikevax (elasomeran). The monitoring of COVID-19 vaccines has been a major challenge in verifying their effectiveness in the general population and identifying any adverse drug reactions (ADRs) not yet observed in clinical trials. Postmarketing spontaneous pharmacovigilance systems provide a gold mine of data for drug safety research. Pharmacovigilance systems are designed to identify emerging signals using multiple data sources. Current pharmacovigilance is predominantly based on spontaneous reporting and mainly helpful in detecting type B effects (effects that are often allergic or idiosyncratic reactions; characteristically occur in only a minority of patients; are usually unrelated to dosage; and are serious, unexpected, and unpredictable) [1]. Signals may arise from one or multiple sources and may suggest a potentially new causal association or new aspect of a known risk of a drug. Indeed, because of the design of clinical trials, rare or delayed ADRs and those occurring in specific subpopulations could be identified only during postmarketing surveillance. Despite the use of many data sources to detect emerging signal, spontaneous reports continue to be the cornerstone of signal detection for most marketed drugs or vaccines, as they have been since the 1960s [2]. This challenge in COVID-19 vaccine surveillance seemed very important because of the large number of individuals (hundreds of thousands) exposed to these vaccines. In France, the National Agency for the Safety of Medicines and Health Products (*Agence Nationale de Sécurité du Médicament et des produits de santé* [ANSM]) is responsible for assessing the safety of vaccines through the continuous surveillance of all ADRs to quickly detect potential safety issues and take appropriate risk reduction measures. For the COVID-19 vaccination campaign, an enhanced surveillance system has been put in place [3]. If a safety signal was validated, the EMA Pharmacovigilance Risk Assessment Committee (PRAC) would make recommendations for any necessary changes to the product information or any further steps. For example, in May 2021, based on the cases reported in clinical trials and from vaccination campaigns, the EMA PRAC validated the potential signal about delayed injection site reaction for elasomeran and concluded that this information should be added to the product information of Spikevax [4]. Moreover, on October 28, 2022, the EMA PRAC recommended that heavy menstrual bleeding be added to the Summary of Product Characteristics of the mRNA vaccines (tozinameran and elasomeran) as a side effect of unknown frequency. This signal was supported by the ANSM's requested review of all spontaneous reports in European countries via EudraVigilance—the EMA's system for the management and analysis of information on suspected ADRs in the European Economic Area [5].

Sudden sensorineural hearing loss (SSNHL) is defined as a sensorineural hearing loss >30 dB over at least 3 consecutive audiometric frequencies occurring within <72 hours [6]. In cases where it occurs in the absence of reference audiometry, the diagnosis is made by comparing the hearing thresholds of the affected ear with those of the contralateral ear. SSNHL affects 5 to 20 individuals per 100,000 person-years [7,8], mainly those aged between 40 and 54 years [8,9]. Early detection and management of SSNHL are crucial to maximizing hearing recovery and the quality of life [10]. Although approximately 98% of SSNHL cases are unilateral [11], both their clinical presentation and prognosis vary greatly depending on the severity of the hearing loss [6], as well as the presence or absence of associated otoneurological manifestations such as tinnitus or balance disorders [6,11]. In most cases, there is no identifiable etiology, and SSNHL is classified as idiopathic [12]. The most likely pathophysiological mechanism for the development of idiopathic SSNHL is thought to be cochlear injury due to poor vascular perfusion or viral infection [13]. Disorders of the cochlear microcirculation due to altered plasma viscosity, platelet aggregability, red blood cell deformability, and endothelial dysfunction have been reported in patients with SSNHL [14,15].

According to the available literature, post–COVID-19 SSNHL is much less common than anosmia [16,17]. This may explain why post–COVID-19 SSNHL has been underdiagnosed by otolaryngologists compared with anosmia. However, several in-depth case studies have linked SSNHL cases to the COVID-19 outbreak [18-30]. The SARS-CoV-2 spike glycoprotein is known to have a particular tropism for human angiotensin-converting enzyme 2 receptors [31], which are expressed not only in the lung respiratory epithelium and the olfactory neuroepithelium but also in the vascular endothelium [32]. Accordingly, it was hypothesized that hearing loss in patients with COVID-19 might result from vascular endotheliitis with microthrombosis in the cochlea, auditory nerve, or hearing centers located in the temporal lobe [33]. Another mechanism advanced is the spread of viral meningitis from the subarachnoid space to the inner ear via the cochlear aqueduct, as supported by magnetic resonance imaging scans in clinical cases combining deafness and neurological symptoms [34]. A possible neurological manifestation of SARS-CoV-2 is the Guillain-Barré syndrome, which may induce auditory neuropathy [35]. Regardless of the pathophysiological mechanisms involved, it is interesting to note that increased high-frequency pure tone thresholds and reduced transient-evoked otoacoustic emissions, suggestive of cochlear outer hair cell damage, have been reported in asymptomatic patients who are COVID-19 positive [36].

SSNHL has recently emerged as a possible adverse effect of COVID-19 vaccines. Sporadic cases of unilateral SSNHL occurring shortly after the first or second administration of adenoviral vector– or mRNA-based vaccines have been recently reported, either isolated or in association with other cochleovestibular disorders (tinnitus, dizziness, and vertigo), in patients of both sexes with or without a history of audiovestibular, autoimmune, or cardiovascular diseases [37-40]. In February 2022, the World Health Organization (WHO) raised a signal detection about cases of SSNHL after COVID-19 vaccination, prompting the need for investigation. As of February 22, 2021, a total of 172 cases of hearing loss after COVID-19 vaccination (including 142 cases after tozinameran and 15 cases after elasomeran) were reported from 10 countries [41]. To date, 2 large-scale studies have investigated SSNHL after COVID-19 vaccine administration and reported conflicting results. One study, using data collected between December 2020 and July 2021 in the United States by the Centers for Disease Control and Prevention Vaccine Adverse Events Reporting System (a passive surveillance system), found no difference between the estimated incidence of SSNHL after COVID-19 vaccination with tozinameran, elasomeran, and ChAdOx1-S (0.6 to 28.0 cases per 100,000 person-years) and the historical incidence of SSNHL (11 to 77 cases per 100,000 person-years) [42,43]. By contrast, a retrospective cohort study conducted by the largest state-mandated health service organizations from Israel on data collected from December 2020 to May 2021 concluded that there is a proven, albeit small, risk (<1 per 100,000 vaccinated individuals) of SSNHL following immunization with tozinameran [44]. Recently, another retrospective cohort study performed on the Finish register–based countrywide data did not find a potential association between COVID-19 vaccinations and SSNHL. However, the results of these 3 studies were based on diagnosis codes in administrative databases, and the authors suggested the need for studies with more detailed clinical data with a more objective diagnosis of SSNHL [45]: none of these studies described the clinical characteristics of postvaccination SSNHL in terms of severity or duration or examined the facilitating role of potential risk factors, thereby prompting further research [46]. Moreover, the reliability of passive surveillance system databases when it comes to verifying SSNHL diagnostic criteria has been questioned [47]. To our knowledge, there is no large-scale, data-driven study investigating the cases of SSNHL after mRNA COVID-19 vaccine exposure identified using robust clinical measures of severity and recovery.

Objectives

After several spontaneous reports of postvaccination SSNHL to the pharmacovigilance system and requests from patients and physicians for documented data regarding the possibility of revaccination (dose 2 or 3) after a first event of post–mRNA vaccine SSNHL, a national population-based active surveillance study was conducted to perform a rigorous and objective analysis of spontaneously reported cases and assess this new potential signal.

Methods

Study Design and Settings

The French pharmacovigilance system was established at the end of the 1970s based on a decentralized network of Regional Pharmacovigilance Centers (RPVCs), with the mission of identifying, evaluating, and preventing adverse drug events after marketing authorization. The ANSM is a decisional authority and has mobilized the French network of 30 RPVCs to ensure the continuous monitoring and evaluation of ADRs of COVID-19 vaccines through the daily evaluation of spontaneous reports. Health care professionals or users can report potential ADRs following COVID-19 vaccines (similar to how they would following the administration of other drugs) directly to the RPVC or using a dedicated web portal [48]. Each report of a potential ADR is assessed through a careful clinical, chronological, semiological, and pharmacological analysis before being registered (anonymous registration) in a centralized French Pharmacovigilance Database (FPVDB). For this purpose, an intensive pharmacovigilance survey was set up, and 6 RPVC experts were appointed to prepare weekly pharmacovigilance reports for the first marketed vaccines (4 experts for tozinameran and 2 experts for elasomeran). In addition, a scientific monitoring committee was also set up, comprising ANSM staff members, pharmacovigilance experts in charge of the survey, and specialized medical experts (cardiologists; neurologists; ear, nose, and throat specialists; etc) for a collegial evaluation of the reports submitted daily [3]. In this study, we conducted a nationwide population-based surveillance study using this enhanced pharmacovigilance system to assess a potential signal for post–mRNA COVID-19 vaccine SSNHL.

Data Collection

We conducted a retrospective study to collect all ADRs recorded in the FPVDB occurring any time after mRNA COVID-19 vaccine administration from the beginning of the vaccination campaign (December 28, 2020) to February 2, 2022. Eligible SSNHL cases were selected using the Medical Dictionary for Regulatory Activity hierarchy, with preferred term selected from the narrow Standardized Medical Queries "Hearing impairment" [49]. The ANSM provided a line listing with all data related to ADR and the medical history generated by each RPVC. In addition, we requested medical records, audiometry examinations, magnetic resonance imaging, and all substantial examination results for each case. Two audiology experts analyzed all data according to the American Academy of Otolaryngology-Head and Neck Surgery Foundation guidelines [11]. The clinical analysis was performed on the basis of demographics (sex and age), risk factors (autoimmune, cardiovascular, or audiovestibular factors), the side of hearing loss (one or both ears affected), the presence of tinnitus or balance disorders, the degree of hearing loss (calculated by averaging hearing thresholds at 0.5, 1, 2, and 4 kHz) [50], the onset of SSNHL, and the rank of vaccination (first injection, second injection, or booster), with a particular focus on positive rechallenge cases. Following recent research on SSNHL [51,52], patients were categorized according to a grading system modified from the Siegel criteria [53]. This allowed both the quantification of hearing loss and assessment of hearing recovery outcomes using the same objective standards in all patients. The quantification of hearing loss included 5 grades covering all possible degrees of deafness: slight (grade 1), mild (grade 2), moderate to moderately severe (grade 3), severe (grade 4), and profound (grade 5). Recovery may be complete, partial, slight, or absent, or SSNHL may result in a nonserviceable ear (Tables 1 and 2).

Table 1. Modified Siegel criteria for hearing loss (HL) grades.

Level of HL	HL range (dB)
Grade 1	≤25
Grade 2	26-40
Grade 3	41-70
Grade 4	71-90
Grade 5	>90

Table 2. Modified Siegel criteria for hearing recovery outcomes.

Level of hearing recovery	Final hearing level (dB), gain (dB)
Complete recovery	≤25
Partial recovery	26-40, >15
Slight improvement	41-70, >15
No improvement	71-90, <15
Nonserviceable ear	>90

We classified the cases as medically or nonmedically documented. After a detailed review of complementary medical data, we excluded cases for which the attributable causes were different from vaccination or those that were nonevaluable because of missing data (nonmedically documented). Finally, the cases fulfilling the criteria of SSNHL were included and distinguished using a cutoff of 21 days. This cutoff value was recommended by the Safety Platform for Emergency Vaccines and the Brighton Collaboration guidelines for sensorineural hearing loss [54]. According to previous research on the auditory [43,44] or nonauditory [55] adverse events of mRNA vaccination, exposure could be defined as vaccination with an mRNA COVID-19 vaccine within the previous 21 days, and patients vaccinated beyond that date were considered unexposed. However, given the very limited number of large-scale studies available on the auditory adverse effects of mRNA COVID-19 vaccination, we also considered the spontaneous reporting of SSNHL after day 21 in the first instance.

A minimum of 3 months of follow-up was conducted (follow-up until August 1) for each SSNHL case to collect missing data and assess the potential hearing loss recovery.

Outcome Measure

Descriptive analysis was performed for the 2 mRNA COVID-19 vaccines (tozinameran and elasomeran) for all the items cited earlier. The primary outcome was the reporting rate (Rr) of SSNHL following mRNA COVID-19 vaccine administration per 1 million doses, which was calculated using the total number of mRNA COVID-19 vaccine doses administered over the study period as the denominator according to the month of administration. Since the beginning of the French vaccination campaign against COVID-19 to early February 2022, a total of 97,840,529 doses of tozinameran and 22,690,889 doses of elasomeran have been administered in France [56].

Statistical Analysis

Patient characteristics were expressed as count (percentage) for categorical variables and median (IQR) for quantitative variables according to the administered vaccine and for the whole cohort because of the few elasomeran cases. The Rr was expressed as cases per 1 million vaccine injections. The number of reported SSNHL cases and the number of vaccine injections were estimated by month during the study period. Finally, we performed a binomial test comparing a sample proportion with a hypothetical proportion to analyze the potential association of the Rr of SSNHL with sex, vaccination rank, and unilaterality or bilaterality of hearing loss (significance level: *P*<.05; R [version 4.2.1; R Foundation for Statistical Computing]).

Ethics Approval

This nationwide postmarketing surveillance study was conducted with the authorization of the *Commission nationale de l'informatique et des libertés* (CNIL; National Commission on Informatics and Liberty; n 2014-302). The authorization was granted specifically for the French pharmacovigilance spontaneous reporting database placed under the responsibility of the ANSM.

Results

During the study period, 400 cases of SSNHL after COVID-19 vaccine administration (n=340, 85% for tozinameran and n=60, 15% for elasomeran) were registered in the FPVDB. After case review, a total of 42.8% (171/400) of cases fulfilled the criteria of SSNHL (Figure 1). Hearing assessment was available either through an initial audiogram test (118/171, 69% of cases) or through an expert medical evaluation performed at the follow-up (53/171, 30.9% of cases).

Description of Post–Tozinameran Vaccine SSNHL Cases

A total of 323 cases of SSNHL after tozinameran vaccine administration were selected, of which 142 (43.9%) cases met the criteria for inclusion; 29 (8.9%) cases were consistent with otologic manifestations other than SSNHL, and 152 (47.1%) cases were not sufficiently documented to draw conclusions (Figure 1).

For these 142 cases, the delay onset was ≤21 days for 108 (76.1%) cases, with a median delay onset of 4 (range 2-9) days. Of these 142 cases, 84 (59.2%) were those of female patients. The median age was 51 (range 13-83) years, and 69% (98/142) of patients were aged 30 to 64 years. A total of 35.2% (50/142) of patients had a medical history, which was otoneurological in 11.9% (17/142) of cases. The vaccination rank was known for 88% (125/142) of cases, with the first injection involved in 42.3% (60/142) of cases. Steroids were administered orally in 47.2% (67/142) of cases. SSNHL was unilateral in 87.3% (124/142) of cases. The hearing loss grade ranged between 1 and 3 in 75.4% (107/142) of cases. Tinnitus was associated with SSNHL in 52.8% (75/142) of cases and vertigo in 28.9% (41/142) of cases. Complete recovery was observed in 22.5% (32/142) of cases, whereas no improvement was observed in 53.5% (76/142) of cases and nonserviceable ear in 8.5% (12/142) of cases (Tables 3 and 4).

Deafness was more often unilateral than bilateral (*P*<.001). No effect of sex or vaccination rank was observed. Case follow-up identified 3.5% (5/142) of cases of positive rechallenge (Table 5): four were those of female vaccine recipients and 1 was that of a male vaccine recipient (age range 32-72 years). SSNHL was unilateral in most cases, was of grades 2 (37/142, 26.1%) to 3 (46/142, 32.4%), occurred rapidly (<10 days) after the first and second doses in all cases, and completely resolved in 2.1% (3/142) of cases during the 3-month follow-up.

Description of Post–Elasomeran Vaccine SSNHL Cases

A total of 56 cases of SSNHL after elasomeran vaccine administration were selected, of which 29 (49%) cases met the inclusion criteria; 5 (8%) cases were consistent with otologic manifestations other than SSNHL, and 22 (37%) cases were not sufficiently documented to draw conclusions (Figure 1).

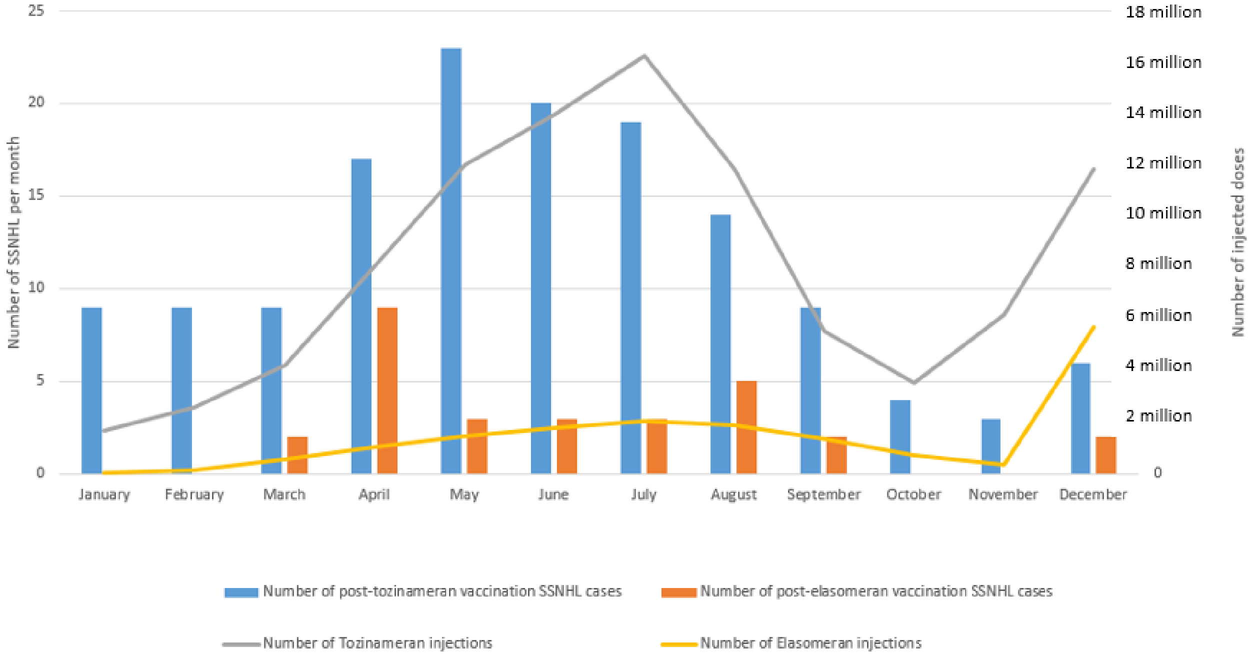
Among these 29 cases, the delay onset was ≤21 days for 26 (90%) cases, with a median delay onset of 8 (range 1-21) days, and 15 (52%) were those of female patients. The median age was 47 (range 33-81) years, and 72% (21/29) of patients were aged 30 to 64 years. A total of 31% (9/29) of patients had a medical history, which was otoneurological in 14% (4/29) of cases. The vaccination rank was known for 27 cases, with the first injection involved in 45% (13/29) of cases. Steroids were administered orally in 55% (16/29) of cases. SSNHL was unilateral in 76% (22/29) of cases. The hearing loss grade ranged from 1 to 3 in 66% (19/29) of cases. Tinnitus was associated with SSNHL in 34% (10/29) of cases and vertigo in 41% (12/29) of cases. Complete recovery was observed in 24% (7/29) of cases, whereas no improvement was observed in 38% (11/29) of cases and nonserviceable ear in 18% (5/29) of cases (Tables 3 and 4).

Deafness was more often unilateral than bilateral (*P*<.003). A rank effect was found in favor of the first dose (*P*<.03). No effects of sex or side of hearing loss were observed. Case follow-up identified 3 cases of positive rechallenge (Table 5): two (67%) were those of female vaccine recipients and 1 (3%) was that of a male vaccine recipient (age range 41-71 years). SSNHL was unilateral in most cases, was of grades 2 (5/29, 18%) to 3 (7/29, 24%), occurred rapidly (<10 days) after the first and second doses in 2 cases (in the third case, delay onset was >21 days, but with positive rechallenge with the booster), and completely resolved in 2 cases during the 3-month follow-up.

Rate of Spontaneous Reports

Figure 2 shows, by month, the number of spontaneous reports of SSNHL cases after tozinameran vaccine administration and after elasomeran vaccine administration, as well as the number of injections of each vaccine in 2021. The total Rr seemed similar for both vaccines and was estimated at 1.45/1,000,000 doses for tozinameran and 1.67/1,000,000 doses for elasomeran. During this period, a total of 86,993 and 20,265 spontaneous reports were registered for tozinameran and elasomeran, respectively, in the FPVDB, of which 22,619 (26%) and 3782 (18.66%) were serious cases, respectively. As a result, SSNHL cases accounted for 0.63% and 0.76% of the total serious adverse events recorded for tozinameran and elasomeran, respectively.

Figure 2. Reporting rate of sudden sensorineural hearing loss (SSNHL) cases for the 2 messenger RNA (mRNA) vaccines according to the month. Solid lines: the number of tozinameran (gray) and elasomeran (yellow) injections expressed in million doses (right y-axis) per month. Bar graph: the number of tozinameran-related (blue) and elasomeran-related (orange) SSNHL cases expressed in case number (left y-axis) per month.



Discussion

Principal Findings

The main objective of this nationwide postmarketing surveillance study was to conduct a continuous assessment of the safety of mRNA COVID-19 vaccines to generate potential safety signals related to serious and typical adverse effects and consider relevant measures that should be taken quickly [3]. Our results—based on all spontaneous reporting of mRNA vaccine–induced SSNHL registered in the FPVDB during >1 year, supported by intensive pharmacovigilance monitoring, and combined with administrative data on the doses of vaccines administered—suggested that the occurrence of SSNHL after mRNA COVID-19 vaccination could be defined as a very rare adverse effect, as it was estimated to be <2 per 1 million injections for both vaccines. The occurrence of SSNHL cases was found to parallel the number of injections of the most widely administered mRNA vaccine in France over the study period, with tozinameran accounting for 80% of the injections. This has not been verified for elasomeran injections, probably because of the smaller number of people exposed to this vaccine and the smaller number of SSNHL cases reported. The scarcity of this adverse effect supports the appropriateness of spontaneous reporting allowing a signal generation. Spontaneous reporting is particularly useful for identifying rare and idiosyncratic safety concerns. For example, 12 (57%) out of 21 drug withdrawals in France between 1998 and 2004 were solely based on spontaneous reports. Similarly, 8 (73%) out of 11 product withdrawals between 1999 and 2001 in the United Kingdom and the United States were based on early information from spontaneous reports. Some studies suggest that spontaneous reports are most useful for newly marketed products, specifically within 3 years after launch [2]. A larger investigation and disproportionality analysis of the spontaneous reporting of WHO database (Vigibase) could be useful to generate a signal. Moreover, a multicentric case-control study, methodologically appropriate to investigate rare events, might be of interest to conclude an association between mRNA COVID-19 vaccination and SSNHL, considering the different risk factors for SSNHL, as it has already been done for myocarditis or pericarditis [57,58]. That said, the Rr of mRNA COVID-19 vaccine–induced SSNHL cases remained below the estimated incidence of SSNHL cases in the general population (approximately 5 to 20 cases per 100,000 person-years in France). In addition, unlike cases of mRNA COVID-19 vaccine–induced myocarditis [58] and because of the lack of data, it should be difficult to compare the rate of SSNHL cases related to mRNA COVID-19 vaccine administration with that presumably related to COVID-19 infections.

Another contribution of this study is the first clinical description of SSNHL as an adverse effect of mRNA COVID-19 vaccination. Because strict diagnostic criteria were used, the risk of false-positive results when identifying SSNHL cases was reduced compared with previous research using passive surveillance system databases [47]. To name a few, conductive or posttraumatic hearing loss, vestibular neuritis, labyrinthitis, and fluctuating hearing loss related to a history of Ménière disease or acoustic neurinoma were excluded. Nevertheless, the clinical presentation of mRNA COVID-19 vaccine–induced SSNHL cases could include audiovestibular symptoms such as tinnitus, vertigo, or balance disorders associated with deafness. Although postvaccination hearing loss was most often found to be unilateral and of grades 1 to 3 (ie, slight to moderately severe hearing loss), there were also cases of bilateral and severe to profound hearing loss that may have required specific treatment in the absence of complete recovery for both vaccines studied. It is interesting to note that at the end of the follow-up period (minimal duration: 3 months), a complete recovery was achieved in less than one-quarter of the cases. Whereas SSNHL secondary to vaccination was found to be a very rare adverse event, it is of note that 10% of affected patients were diagnosed with a nonserviceable ear, which represents a potential indication for cochlear implantation. The rate of complete or partial recovery varied between 41% and 52% for hearing loss grades 1 to 3, whereas the rate of complete or partial recovery was 23% for grade 4 and only 9% for grade 5. This observation is in agreement with the evolution of SSNHL reported outside the vaccination context [51].

However, the rate of recovery could be greater because of missing feedback from patients who recovered completely. The most affected age group was intermediate (30-64 years), and the median age was approximately 50 years for both vaccines, which is consistent with the usual age of onset of idiopathic SSNHL [9,10]. Thus, there was no evidence for a more frequent occurrence of this adverse effect for the extreme age groups. Autoimmune, cardiovascular, audiological, or otoneurological risk factors were present in only one-third of the cases, definitively preventing the identification of a specific patient profile.

Furthermore, we should underline our findings related to the delay onset of SSNHL according to the vaccination rank. A rank effect was found only for elasomeran: the occurrence of SSNHL was higher after the first injection than after the second injection and the booster. In agreement with Safety Platform for Emergency Vaccines and Brighton Collaboration guidelines on postvaccinal SSNHL, as well as with previous data on audiological or cardiac adverse events with mRNA COVID-19 vaccines, we found that the median delay onset fell within the first 2 weeks after injection [42,43,54,57,58]. Wichova et al [39] also reported an average delay onset of 10.18 (SD 9) days, whereas the median (range) delay onset in the WHO report was 1 day (few hours to 19 days) [41].

Moreover, data supported a possible relationship between exposure to mRNA COVID-19 vaccines and the occurrence of SSNHL. Positive rechallenge cases were documented for 5 tozinameran and 3 elasomeran vaccinations, meaning that repeated exposure to a COVID-19 mRNA-based vaccine led to SSNHL for a minority of patients who had previously experienced the same adverse event. In a pharmacovigilance study, this result alone was sufficient to suggest a high probability of a causal relationship [59].

Since the beginning of the COVID-19 outbreak, the association between SARS-CoV-2 infection and the occurrence of SSNHL has been supported exclusively by cross-sectional studies conducted on limited case series [60]. Almost all reported cases were unilateral sudden deafness [26,28], which could be associated with disabling ipsilateral tinnitus [16,24] or vertigo with nystagmus beating toward the contralateral side [28]. Regardless of the clinical presentation, the estimation of the exact incidence of SSNHL attributable to COVID-19 infection may have been hampered by the difficulty in applying the same criteria for causal relationship across studies. These criteria could include, in addition to the certainty of viral infection by polymerase chain reaction test or the titration of specific antibodies, the temporal concordance between the infection and the onset of hearing loss; the presence of symptoms and signs consistent with concomitant labyrinthitis or neuritis; and, above all, the exclusion of any other reason that could be counted among the causes of SSNHL [61]. Recent updates have pointed out the need for the long-term documentation of audiovestibular symptoms in large cohorts of SARS-CoV-2–infected patients before conclusions can be drawn about their true incidence [62-64]. On the basis of the existing literature, SSNHL can be considered so far as a rare complication of COVID-19 infection [21,65,66].

Limitations

Our study has some limitations. An important step in assessing vaccine-related adverse events is to compare their rates in vaccinated and unvaccinated populations, as was done for myocarditis [58]. Because the studied adverse event is very rare, large population-based pharmacovigilance studies (Vigibase) or a case-control study appropriate for rare events is needed to further define the role of mRNA COVID-19 vaccination in the occurrence of SSNHL, as has been done for COVID-19 vaccines and menstrual cycle [67]. Herein, we conducted a "case series study," a well-known design in pharmacoepidemiology that differs from a cohort study or a case-control study. As such, our nationwide postmarketing surveillance did not include any control group, thus preventing the consideration of potentially important variables such as age or SSNHL time to onset. After drug marketing, case series are most useful for 2 related purposes: first, to quantify the incidence or rate of an adverse reaction and second, to detect any particular adverse effect not yet identified in clinical trials because of its scarcity [68]. Moreover, we cannot rule out the underreporting of ADRs, which may have biased the estimated rate of SSNHL. However, following the introduction of mRNA COVID-19 vaccines in France, a major effort has been made by the enhanced pharmacovigilance system to improve the reporting of any suspected ADR following the administration of these vaccines by health professionals or patients. By February 2022, approximately 80% of the French population had received the first 2 vaccine injections, and 52.6% had also received the booster [69]. The impressive number of reports of suspected ADRs (>80,000 between January 2021 and January 2022 in France) suggests that underreporting may have been very rare, particularly for potentially serious adverse events [3].

Other authors have retrospectively compared the incidence of SSNHL cases in the population exposed to mRNA COVID-19 vaccines with that in the general population using a population-based cohort and International Classification of Diseases, Ninth Revision, codes without any data on patients' medical history or risk factors [38,39]. In our clinical experience, this could lead to a selection of false-positive SSNHL cases. As previously done by Ouldali et al [70] for mRNA COVID-19 vaccine–induced pediatric inflammatory multisystem syndrome, we chose a restrictive method to select and describe medically confirmed SSNHL cases based on pharmacovigilance and complementary medical data, which is the added value of our survey. Nevertheless, the lack of available data for the general population precluded comparisons with historical incidence or incidence in the unvaccinated population. Another possible limitation is the underdiagnosis of SSNHL cases related to the COVID-19 outbreak due to the difficulties in accessing health care during the COVID-19 outbreak. However, disabling deafness remains a medical emergency and should lead to hospital admission.

Conclusions

This study identified very rare but severe cases of medically confirmed SSNHL after the administration of mRNA COVID-19 vaccines without calling into question the demonstrated benefit of vaccinating a large population in the context of rapid SARS-CoV-2 circulation. On the basis of our findings, particularly those related to the cases of positive rechallenge and grade-5 hearing loss, patients should undergo a comprehensive evaluation of any otologic manifestation occurring after COVID-19 vaccination. Early diagnosis of SSNHL is essential for positive outcomes. Each medical evaluation should be performed for 2 reasons: the prompt initiation of appropriate treatment to improve the prognosis of SSNHL and provision of expert counseling to patients regarding subsequent vaccine injections, given the evolution of SARS-CoV-2, its variants, and new adaptive vaccines. These data are new and of critical interest to patients, physicians, and regulatory policies to tailor public health messages and medical care.

Acknowledgments

The authors would like to acknowledge the support of French National Agency for the Safety of Medicines and Health Products (*Agence Nationale de Sécurité du Médicament et des produits de santé*).

The authors would like to thank all Regional Pharmacovigilance Centers (RPVCs) from the French Network of Regional Pharmacovigilance who generously provided their time for active surveillance and audiogram collection during this 1-year study: RPVCs Amiens, Angers, Bordeaux, Brest, Caen, Clermont-Ferrand, Dijon, Grenoble, Lille, Limoges, Nancy, Paris Hôpital Européen Georges-Pompidou, Paris Henri Mondor, Paris Fernand Widal, Paris Pitié Salpétrière, Paris Saint-Antoine, Paris Cochin-Port Royal, Poitiers, Reims, Rennes, and Rouen. The authors acknowledge the support of the Paris Hearing Institute from *Fondation pour l'Audition* (FPA IDA09) and are grateful to Hélène Boyer (*Direction de la Recherche en Santé*, *Hospices Civils de Lyon*, France) for carefully proofreading this manuscript. The authors acknowledge Samuel Tessier for statistical analysis.

The authors are grateful to all staff members of the French National Agency for the Safety of Medicines and Health Products (*Agence Nationale de Sécurité du Médicament et des produits de santé*) who interacted with them from the initiation to the completion of the study.

Data Availability

Data are available upon reasonable request to MBV-R and HB.

Authors' Contributions

HT-V, MBV-R, and HB contributed equally to this study. They had full access to all the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis. HT-V, MBV-R, and HB conceptualized and designed the study. All authors were involved in acquisition, analysis, and interpretation of the data. HT-V, MBV-R, MA, and HB drafted the manuscript. All authors critically revised the manuscript for important intellectual content. MBV-R and HB performed the statistical analysis. HT-V obtained the funding. AL, AM, JC, TP, AD, MD-P, and FP provided administrative, technical, or material support. HT-V, MBV-R, and HB supervised the study.

Conflicts of Interest

None declared.

Abstract

Background: The COVID-19 pandemic represents a global health crisis. The Shanghai municipal government in China implemented strict and comprehensive pandemic control strategies in the first half of 2022 to eliminate a wave of COVID-19 infection. The pandemic and the resulting government responses have led to abrupt changes to families' daily lives, including the mental health of children and adolescents.

Objective: The aim of this paper is to examine the impact of COVID-19 exposure and the stringent lockdown measures on the daily life and mental health of children and adolescents and to provide suggestions on maintaining their mental health when similar public health emergencies occur in the future.

Methods: In this cross-sectional study, an anonymous survey was distributed online in May 1-15, 2022, in Shanghai. Individuals were eligible to participate if they were currently the caregiver of a child or adolescent (aged 4-17 years). Outcomes were psychosocial functioning of children and adolescents, as reported by parents, using the Pediatric Symptom Checklist-17. COVID-19 exposure and life changes were also reported. Multivariate logistic regression was used to analyze risk factors for poor psychosocial functioning.

Results: In total, 2493 valid questionnaires were analyzed. The rate of positive scores on the global Pediatric Symptom Checklist-17 scale was 16.5% (n=411). Internalizing, attention, and externalizing problem subscale positivity rates were 17.3% (n=431), 10.9% (n=272), and 8.9% (n=221), respectively. Caregivers reported that 64.2% (n=1601) and 20.7% (n=516) of the children's interactions with friends or peers and parents deteriorated, respectively. Compared with male caregivers, female caregivers were less likely to report psychosocial problems in children and adolescents (adjusted odds ratio [aOR] 0.68; 95% CI 0.53-0.88). Older children and those with lower COVID-19 Exposure and Family Impact Scales scores were less likely to have psychological problems (aOR 1.15; 95% CI 1.10-1.21). Compared with children with screen times <1 hour per day for recreation, those using screens for >3 hours had higher odds of psychological distress (aOR 2.09; 95% CI 1.47-1.97). Children who spent 1-2 hours exercising and had better interactions with friends or peers and parents showed a trend toward lower odds of psychological problems. Children and adolescents with worse sleep compared with preclosure were more likely to have psychological problems.

Conclusions: The prevalence of psychosocial problems among children and adolescents is relatively high. Being young, having more COVID-19 exposure, and having more screen times (>3 h/day), less exercise time (<30 min), worse sleep, and deteriorated interactions with friends or peers and parents were risk factors for poor psychosocial functioning. It is necessary for governments, communities, schools, and families to take appropriate countermeasures to reduce the negative impact of the stringent control measures on caregivers' parenting and psychosocial functioning of children and adolescents.

KEYWORDS

COVID-19 exposure; psychosocial function; parenting; children and adolescents; China

Introduction

The COVID-19 pandemic represents a global health crisis. According to the latest data, as of June 7, 2022, there have been over 529 million confirmed cases of COVID-19 globally and over 6 million deaths [1]. Governments across the world have implemented several public health and social measures, such as mask wearing, school closures, international travel restrictions, and stay-at-home orders to prevent COVID-19 infection [1]. The unpredictability and uncertainty of the COVID-19 pandemic, the associated lockdowns and containment strategies, and the resulting economic disruption have led to abrupt and unpredictable changes to families' daily lives and could increase the risk of mental health problems [2]. Previous studies showed that shielding behavior in both clinically extremely vulnerable and non–clinically extremely vulnerable populations during the first wave of the 2020 COVID-19 pandemic was associated with worse mental and physical well-being, suggesting that the adoption of such behavior may have resulted in avoidable detriments to physical and mental health [3].

In late February 2022, a wave of intense COVID-19 infection appeared in Shanghai, China. According to the Shanghai Municipal Health Commission, as of May 4, 2022, 593,336 cases have been identified, including 538,450 asymptomatic carriers [4]. To limit the spread of and subsequently eliminate COVID-19, the Shanghai municipal government implemented strict and comprehensive pandemic control strategies from March to May, including mask wearing, school and business closures, restrictions on domestic movement, public transport closures, and stay-at-home orders. According to the Public Health and Social Measures Severity Index issued by the World Health Organization, Shanghai's policy was level 4 (of 5) in terms of severity [1]. The strict and comprehensive pandemic control strategies in Shanghai are designed to reduce the number of people infected and to allow for early diagnosis and appropriate treatment for severe COVID-19 cases [4]. Shanghai's significant and stringent efforts against Omicron are essential for China as a whole to exit the pandemic situation.

Studies showed that the global pandemic and the resulting government responses have led to abrupt and unpredictable changes to damage to human health and creating burdens for families, health care systems, and societies [5-7]. As members of society, children and adolescents will not escape the repercussions of COVID-19, and inevitably, some children and families will experience these social costs differently. Efforts to contain the spread of COVID-19 have involved sudden, and often mandatory, physical distancing, thus removing many regular sources of social connection. School closures and quarantine orders may have contributed to a considerable proportion of the harms experienced by children [8] through a reduction in social contact with peers and teachers [9]. Many children have been unable to play or socialize outside the home. Social connections with classmates and peers were reduced, and adolescents especially suffer from a lack of social stimuli [10].

The mental health of children and adolescents during the COVID-19 crisis has attracted great attention [11]. In a systematic review of 36 studies from 11 countries, school closures and social lockdown during the first COVID-19 wave were associated with adverse mental health symptoms and negative health behaviors among children and adolescents [12]. Between 18% and 60% of children and adolescents scored above risk thresholds for distress, particularly anxiety and depressive symptoms [12]. Significant anxiety rates of 10%-19% and depressive symptom rates of 17%-39% have been estimated during the first COVID-19 wave [12]. In a longitudinal study, earlier internalization of symptoms increased the risk of clinically relevant depressive symptoms [13]. Another study suggested that 1 in every 4 young people globally are experiencing symptoms of clinical depression, while 1 in 5 are experiencing symptoms of clinical anxiety [8]. Assessments should be performed, and risk factors should be found as soon as possible to prevent serious mental problems from developing.

Longitudinal analysis indicated that more stringent policies and intense pandemics are associated with worse mental health [14]. This study aimed to examine the impact of COVID-19 exposure and the stringent lockdown measures on the daily life change and mental health of children and adolescents and provide suggestions on maintaining their mental health when similar public health emergencies occur in the future, leading to stringent lockdowns.

Methods

Recruitment

From May 1, 2022, to May 15, 2022, we conducted a municipal-wide web-based questionnaire survey in Shanghai, China. Individuals were eligible to participate if they were currently the caregivers of a child or adolescent (aged 4 to 17 years). Data were collected through the Wenjuanxing online questionnaire platform, on which only a fully completed questionnaire can be uploaded. An invitation letter, detailing the research aim and providing a QR code automatically generated by Wenjuanxing, was issued on widely used social platforms. Snowball sampling method and convenient sampling method were used [15]. Any individual interested in the study could use the QR code and fill in the questionnaire. In addition, we have taken a number of questionnaire quality-control measures, including the following: respondent as caregiver, who should be older than 20 years old; respondents with Shanghai internet protocol addresses; each social account can only fill in the questionnaire once; and respondents who took less than 2 minutes to complete the questionnaire were excluded.

Ethical Considerations

This study was approved by the Ethics Committee of Xinhua Hospital Affiliated to Shanghai Jiaotong University School of Medicine (Approval Number: XHEC-C-2022-043). Appropriate ethical considerations were applied during all the stages of this study. Participation in the study was entirely voluntary. The survey questionnaire was distributed among respondents who provided their informed consent on the first page and clicking on the "agree" button after reading about the purpose of the survey. The questionnaire was anonymous to ensure the confidentiality and reliability of data.

Measures

Demographic Characteristics of Caregivers and Children

Caregivers were asked to report the following information: age, gender, education level, living area, and number of children aged <18 years. In addition, the caregivers were asked to report the child's age (4-18 years), gender, daily exposure time to screens for learning during school closures, daily exposure time to screens for recreation during school closures, amount of exercise per day during school closures, child's sleep time compared to preclosure, child's interactions with friends or peers compared to preclosure, child's interactions with parents compared to preclosure, and child's psychosocial symptoms.

COVID-19 Exposure and Family Impact Scales

The COVID-19 Exposure and Family Impact Scales (CEFIS) is a caregiver-report measure used to examine the degree to which families are exposed to potentially traumatic aspects of the COVID-19 pandemic, and the perceived impact on child, caregiver, and family functioning. It has been used to examine the impact of COVID-19 on various chronically ill pediatric populations [16,17], as well as on healthy children [18]. The CEFIS consists of the following three primary scales: Exposure, Impact, and Distress. Our study used the Exposure scale. The Exposure scale contains 25 "Yes/No" items that assess whether families have been exposed to COVID-19–related events such as lockdowns, school closures, changes in employment status, or the virus itself. When completing the CEFIS, residents are asked to think about the period from March 2022 to the present. "Yes" responses are summed to yield a total score, with higher scores indicating greater exposure to COVID-19 and related events.

Pediatric Symptom Checklist-17 Items

The Pediatric Symptom Checklist-17 (PSC-17) is one of the most frequently used general pediatric psychosocial screening instruments [19]. It is a caregiver-report measure of children's psychosocial functioning. Parents rate the frequency of a variety of symptoms in their child (0=*never*, 1=*sometimes*, and 2=*often*). A screen can be considered "positive" based on total or domain scores. Total scores can be used to categorize a child as "at risk" or "not at risk" based on established cutoff scores. A score of ≥15 corresponds to at-risk status. On the three PSC-17 subscales, scores of ≥5 is for internalizing and ≥7 for externalizing; scores of attention ≥7 indicate risk. The PSC-17 has 3 subscales that specifically assess internalizing, externalizing, and attention-related problems.

Statistical Analysis

Descriptive statistics were generated for respondent characteristics and CEFIS Exposure subscale scores. Caregiver and child age, as continuous variables, were presented as median with interquartile range, and were analyzed by the Wilcoxon rank sum test. Categorical variables are presented as numbers and percentages and were compared between poor psychosocial health (PSC-17 score ≥15) and good psychosocial health (PSC-17 score <15) groups using Pearson χ^2 test or Fisher exact test. *P* values for trends were calculated using mental health as a binary categorical variable—event=PSC-17 score ≥15 (1), nonevent=PSC-17 score <15 (0)—and Pearson $\chi2$ trend test. To further examine potential risk and protective factors for mental health, univariate and multivariate logistic regression were performed. All respondent characteristic variables were included and adjusted in the multivariate logistic regression; unadjusted odds ratios, adjusted odds ratios (aORs), and their 95% CIs were calculated. All analyses were performed with SAS 9.4 (SAS Institute, Inc) and R statistical software (version 3.6.3; R Development Core Team). Statistical significance was set at *P*<.05, and all tests were 2-tailed.

Results

Descriptive Analysis of Participants

A total of 2540 valid questionnaires were returned. Questionnaires completed in <180 seconds were excluded, and 2493 valid questionnaires were finally analyzed. In total, 38.31% (955/2493) of the participants were male (Table 1), and 73.20% (n=1825) had 1 child (aged <18 years). In total, 52.55% (n=1310/2493) of the children were boys, and their average age was 10.99 (SD 4.18) years. Interactions with friends or peers and parents reportedly deteriorated in 64.22% (n=1601/2493) and 20.70% (n=516/2493) of the children, respectively.

The mean CEFIS score was 11.5 (SD 2.49). The scores for individual CEFIS item are summarized in Figure 1.

Table 1. Participant demographic characteristics (N=2493).

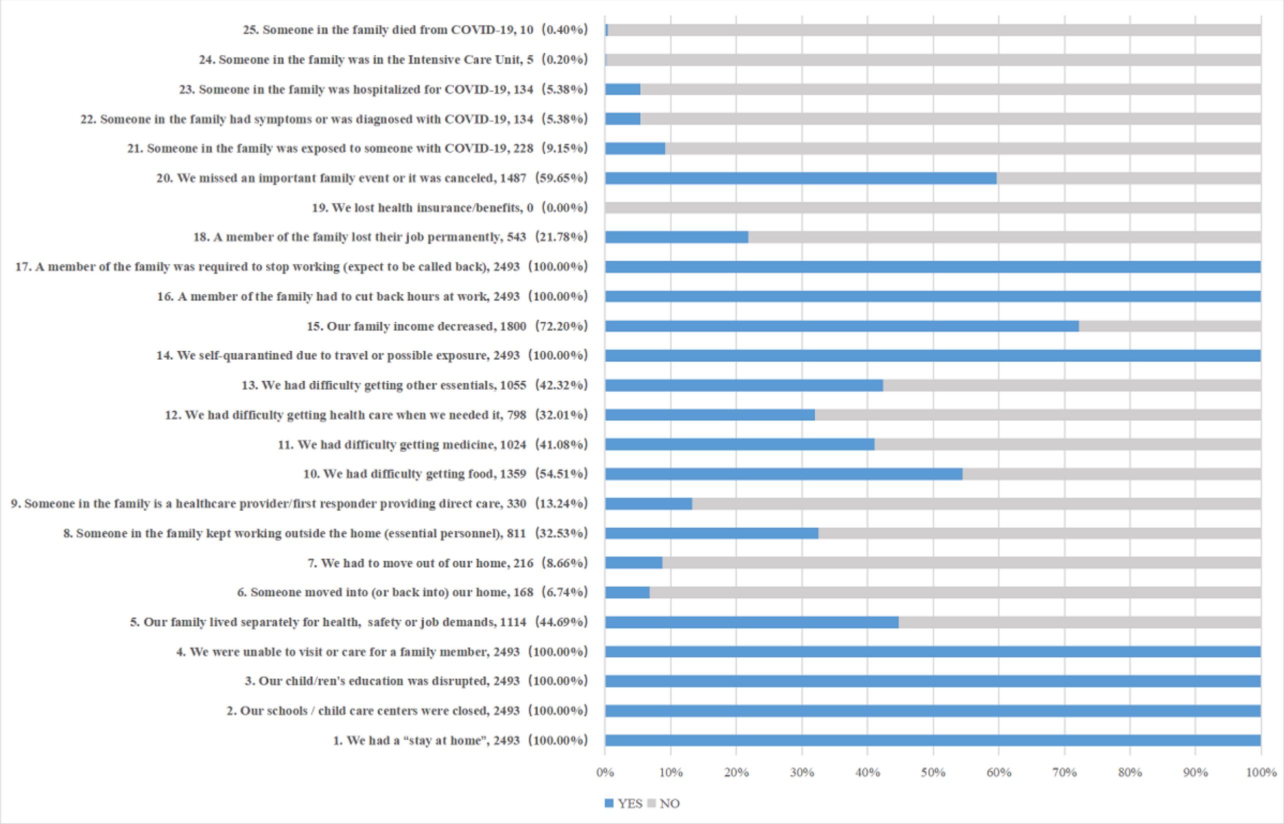
[d] CEFIS: COVID-19 Exposure and Family Impact Scales.

Figure 1. Individual COVID-19 Exposure and Family Impact Scales (CEFIS) item responses.



Bivariate Analysis of Psychosocial Functioning

As shown in Table 2, the proportion of positive screening scores on the global PSC-17 scale was 16.5% (411/2493). The internalizing, attention, and externalizing problem subscales had positive screening rates of 17.3% (431/2493), 10.9% (272/2493), and 8.9% (221/2493), respectively. Caregivers' gender, number of children (younger than 18 years old), CEFIS score, child age, child's length of daily exposure to screens for learning and recreation during closure, length of exercise per day, sleep, interaction with friends/peers and interaction with parents compared to pre-closure were significantly associated with psychosocial problems (Table 1).

Table 2. Caregiver reports of child mental health (N=2493).

Mental health	Positive screening scores, n (%)	Mean score (SD)
PSC-17[a] total problems	411 (16.5)	8.23 (6.72)
PSC-17 attention problems	272 (10.9)	3.43 (2.51)
PSC-17 internalizing problems	431 (17.3)	2.24 (2.29)
PSC-17 externalizing problems	221 (8.9)	2.55 (2.62)

[a] PSC-17: Pediatric Symptom Checklist-17 Items.

Logistic Regression Analysis

Multivariate logistic regression analysis showed that, compared with male caregivers, female caregivers were less likely to report psychosocial problems in children and adolescents (aOR 0.68; 95% CI 0.53-0.88). Older children and those with lower CEFIS scores were less likely to have psychological problems (aOR 1.15; 95% CI 1.10-1.21). Compared with children with screen times <1 hour per day for recreation, those using screens for >3 hours had higher odds of psychological distress (aOR 2.09; 95% CI 1.47-1.97). Compared with children who spent <0.5 hour exercising, those who spent 0.5-1 hour exercising had lower odds of psychological problems (aOR 0.70; 95% CI 0.52-0.94). Children who spent 1-2 hours exercising showed a trend toward lower odds of psychological problems. Children with worse sleep compared with preclosure and worse interactions with friends or peers and parents were more likely to have psychological problems (Table 3).

Table 3. Multivariate logistic regression analysis of characteristics associated with the mental health status of children and adolescents during the COVID-19–related school closures in Shanghai, China.

Discussion

Principal Findings

This study examined the impact of the COVID-19 crisis on a sample of children and adolescents in Shanghai during the lockdown in the first half of 2022. This was the first study to assess the mental health of children and adolescents using the PSC-17 in China. Nearly one-sixth (16.5%, 411/2493) of the children and adolescents were reported to be with psychosocial function problems by their caregivers, which was similar to the results of a US study [20]. In another study, 18% of urban school-age children (5-11 years old) were at risk according to the total PSC-17 score, while 18% were at risk according to the PSC-17 internalizing symptoms subscale score [19]. Given the mental health impact on children and adolescents of COVID-19 exposure, measures should be taken to help families and parents optimize child health and development [21].

Psychological problems of children and adolescents varied cross different gender of reporting caregivers. Female caregivers reported less psychosocial problems in their children. The results were similar to those by Dave et al [22] but in contrast to the findings from Hagerman [23]. Dave et al [22] reported higher scores for externalizing behaviors, such as conduct problems and hyperactivity, among children (according to their fathers). Because of the stay-at-home policy, many fathers spent more time with their children, were involved in looking after them, and were more sensitive to externalizing behaviors than mothers, who were often the primary caregivers. The results showed that older children had fewer psychological problems. A possible reason for this might be that younger children were more susceptible to the crisis situation [24]. Those caregivers who had more than one child (younger than 18 years old) reported more psychological problems of their children. The reason might be that large families with more children living in cramped conditions might be under additional stress, including parenting-related stress, abuse, violence against children [25], and an increased risk of COVID-19 infection [26]. Government and community efforts are needed that target those at-risk households.

COVID-19 exposure was a risk factor for psychological problems of children and adolescents. The results of our study indicated severe COVID-19 exposure in our sample and increased risks of psychological problems. To eliminate COVID-19, stringent measures were implemented in Shanghai. Transport restrictions resulted in inconvenience in everyday life. Schools were closed, and children's education was disrupted. Everyone, except essential workers, had to stay at home. Some families had difficulty obtaining essentials such as food, medicine, health care, and so on. Moreover, the shutdown had economic repercussions for many families, such as decreased income or unemployment. The infected families and those in which someone was serving as an essential worker outside the home had more difficulties with parenting and meeting the growth and developmental demands of their children. Government and community efforts are needed that target at-risk households. Children who are separated from their caregivers also require particular attention, including those infected with or suspected of being infected with COVID-19, those who are quarantined in local hospitals or medical observation centers, and those whose caregivers are infected with COVID-19 [27].

In this study, the rate of psychosocial problems increased with recreational screen time, consistent with other studies [28]. School closures and strict containment measures have led to more families relying on technology and digital solutions for their children's learning, entertainment, and connection to the outside world [28,29]. Many children and adolescents are spending more time online, allowing for social interactions in some cases but also increasing the risk of cyberbullying, cybercrime, privacy infringements, and screen fatigue [10,30,31]. It has been proved that cyberchondria partially mediated the relationships between perceived severity of the COVID-19 pandemic and depression, anxiety, and stress in China [32]. As screen time increased, so too did sedentary behavior [33], which was associated with poor behavioral conduct or prosocial behavior and reduced sleep duration [34,35]. Worse sleep was a risk factor for the development of psychosocial problems in our study. Therefore, for children and adolescents, the time spent being sedentary should be limited, particularly the amount of recreational screen time [36]. Mutually agreed rules, limits, and parental monitoring of screen time were perceived as likely to be effective [37]. Interactive games and exercises can serve as a supplement for filling the time previously spent on screen.

Children and adolescents who spent 1-2 hours exercising showed a trend toward lower odds of psychological problems, and exercise for less than 30 minutes per day had a high probability of psychosocial problems. Psychosocial problems were linked to lower levels of physical activity [38-40]. Greater levels of physical activity are associated with improved physical fitness, bone health, cognitive outcomes, and mental health (reduced symptoms of depression) and less adiposity [36]. The World Health Organization recommends that children and adolescents perform at least 60 minutes of moderate-to-vigorous–intensity (mostly aerobic) physical activity per day. Vigorous-intensity aerobic activities, as well as those that strengthen muscle and bone, should be performed on at least 3 days a week [36]. High-quality physical education and supportive environments can promote physical and health literacy for long-lasting, healthy, active lifestyles [41]. Special attention should be paid to long-duration exercise. Previous studies had showed exercise durations of >3 hours were associated with worse mental health than exercising for 45 minutes [42]. In this study, exercise durations of 30 minutes to 1 hour were shown to be better for the psychosocial function of children and adolescents. Moreover, excessive exercise might cause fatigue and worsen mental health of children and adolescents [43].

In total, 27.9% of the caregivers reported that their interactions with children improved, which was significantly associated with lower positive screening scores. The stay-at-home policy might promote stronger relationships of children and adolescents with their parents [25] and has shown to improve their mental health [44]. Previous studies have reported that parent-child activities and exercises together can improve interactions between caregivers and children and amplifies the beneficial effects of sleep on mental health [45]. For example, mindfulness-promoting exercises (ie, yoga and tai chi) could be performed indoors by parents and children together [42]. In total, 64.2% (1601/2493) of the children and adolescents reported worse relationships with friends and classmates, and these children and adolescents were more likely to have poor mental health. There is an urgent need to increase the social interactions of children and adolescents during lockdown. Communities could redesign neighborhoods to provide children with spaces to play together and enjoy interactions [10]. Studies have shown that digitalized social contact can mitigate the potentially harmful effects of physical distancing on young people [9]. Specifically, active use of social media, for example, engaging in direct communication (ie, messaging) or posting directly on another person’s social media profile, can increase well-being and help maintain personal relationships. Time-limited and active use of social media for contact with peers might be beneficial for the mental health of children and adolescents.

Limitations

This study had several limitations. First, its cross-sectional nature limits the ability to establish a causal relationship between risk factors and mental health. Furthermore, there were no preclosure PSC-17 data for Chinese children and adolescents, so we could not determine whether the psychosocial problems detected in the participants were intensified during COVID-19 exposure. Second, the data were collected online because of the COVID-19 pandemic, and caregivers whose lives were severely disrupted and had limited time online might have been less likely to finish the questionnaire. Third, data for the main variable of interest, psychosocial functioning, were obtained from caregivers of the children and adolescents, which may cause bias. When compared to self-report or direct observation of youth behaviors, caregiver report may not be as accurate.

Conclusions

In this cross-sectional study conducted during a wave of COVID-19 infection in Shanghai, in which stringent responses were implemented, we found that the prevalence of psychosocial problems among children and adolescents was relatively high. Daily life of the children and adolescents changed a lot, including screen time, exercise, sleep, and interaction with parents and peers. Younger children, more COVID-19 exposure, more recreational screen time, and worse sleep were risk factors for poor psychosocial functioning. In particular, exercise durations of 1-2 hours and better interactions with friends or peers and parents benefit the psychosocial function of children and adolescents. The findings suggest that it is necessary for governments, communities, schools, and families to take appropriate countermeasures to reduce the impact of the lockdown measures on daily life and its subsequent influence on mental health of children and adolescents, which can be provided as suggestions on maintaining the mental health when similar public health emergencies occur in the future, leading to the stringent lockdown. In addition, it will be necessary to conduct longitudinal studies to clarify whether psychosocial problems are reduced, maintained, or intensified over time, as well as to identify subgroups of young people most at risk.

Abstract

Background: The widespread use of vaccines against the novel coronavirus disease (COVID-19) has become one of the most effective means to establish a population immune barrier. Patients with cancer are vulnerable to COVID-19 infection, adverse events, and high mortality, and should be the focus of epidemic prevention and treatment. However, real-world data on the safety of vaccines for patients with breast cancer are still scarce.

Objective: This study aims to compare the safety of COVID-19 vaccines between patients vaccinated before or after being diagnosed with breast cancer.

Methods: Patients with breast cancer who sought medical advice from October 2021 to December 2021 were screened. Those who received COVID-19 vaccines were enrolled in this study to analyze the safety of the vaccines. The primary outcome was patient-reported adverse events (AEs). All events after vaccine injection were retrospectively documented from the patients.

Results: A total of 15,455 patients with breast cancer from 41 hospitals in 20 provinces in China were screened, and 5766 patients who received COVID-19 vaccines were enrolled. Of those enrolled, 45.1% (n=2599) of patients received vaccines before breast cancer diagnosis, 41.3% (n=2379) were vaccinated after diagnosis, and 13.6% (n=784) did not known the accurate date of vaccination or cancer diagnosis. Among the patients vaccinated after diagnosis, 85.4% (n=2032) were vaccinated 1 year after cancer diagnosis and 95.4% (n=2270) were vaccinated during early-stage cancer. Of all 5766 vaccinated patients, 93.9% (n=5415) received an inactivated vaccine, 3.7% (n=213) received a recombinant subunit vaccine, and 2.4% (n=138) received other vaccines, including adenovirus and mRNA vaccines. In the first injection of vaccines, 24.4% (n=10, 95% CI 11.2-37.5) of patients who received an adenovirus vaccine reported AEs, compared to only 12.5% (n=677, 95% CI 11.6-13.4) of those who received an inactivated vaccine. Patients with metastatic breast cancer reported the highest incidence of AEs (n=18, 16.5%, 95% CI 9.5-23.5). Following the second injection, patients who received an inactivated vaccine (n=464, 8.7%, 95% CI 8.0-9.5) and those who received a recombinant vaccine (n=25, 8.7%, 95% CI 5.5-12.0) reported the same incidence of AEs. No significant differences in patient-reported AEs were found between the healthy population and patients with breast cancer (16.4% vs 16.9%, respectively); the most common AEs were local pain (11.1% vs 9.1%, respectively), fatigue (5.5% vs 6.3%, respectively), and muscle soreness (2.3% vs 3.6%, respectively). The type of vaccine and time window of vaccination had little impact on patient-reported AEs.

Conclusions: Compared with patients vaccinated before breast cancer diagnosis, there were no significant differences in patient-reported AEs in the patients vaccinated after diagnosis. Thus, it is safe for patients with breast cancer, especially for those in the early stage, to receive COVID-19 vaccines.

KEYWORDS

breast cancer; COVID-19 vaccines; patients reported adverse events; healthy population; vaccine safety

Introduction

The outbreak of COVID-19 has had a huge impact on the lives and work of people worldwide [1-3]. Although several drugs have been authorized for emergency use by many countries [4,5], inaccessibility and strong demand have limited their widespread use during the pandemic. The establishment of a population immune barrier through mass vaccination with COVID-19 vaccines may be the one of the most effective means to end the pandemic at this moment [6]. However, for certain populations, safety concerns of vaccines may have negative impacts on widespread vaccination, thus weakening the process of herd immunity. In this process, vaccination of specific patients is an important part of epidemic prevention and control [7,8].

Cancers are the second leading cause of death worldwide, with high morbidity and mortality rates in the general population. In the setting of the SARS-CoV-2 pandemic, patients with cancer are at high risk of infection, and the safety of these patients after COVID-19 vaccination is an important consideration. Aberrant immune responses in the context of underlying cancer and the use of anticancer therapies may contribute to impaired immune responses and altered reactogenicity following immunization against SARS-CoV-2 [9,10]. Therefore, patients with tumors have had a high risk of infection, high incidence of serious events, and high mortality in the COVID-19 pandemic [11]. As a special group, there is still confusion on whether the safety of COVID-19 vaccines in such patients is the same as in healthy individuals because of their immunosuppression [12,13].

For patients with breast cancer, there has been a history of receiving vaccines for cancer treatment [14]. However, the COVID-19 vaccination rate remains low in China due to inadequate health education, the lack of vaccine safety data, and even some other social status influences rather than vaccine shortages [15-17]. The fear of delaying cancer therapy has surpassed the fear of COVID-19 infection [18]. To better understand why some patients with cancer are unwilling to receive vaccines and the safety profiles of those who have received vaccines, we conducted this real-world study, called CSCO BC NCP-02, from cancer centers across China [19]. Notably, we found that half of the patients in the study received COVID-19 vaccines before cancer diagnosis. This allowed us to compare the differences in adverse events (AEs) between patients who were vaccinated before or after breast cancer diagnosis, thus providing more data to encourage patients with breast cancer to be vaccinated with a COVID-19 vaccine. We aimed to describe the clinical features and AEs of patients with breast cancer and identify risk factors associated with AEs in these patients.

Methods

Sample and Data

This was a cross-sectional study initiated by the Chinese Society of Clinical Oncology breast cancer (CSCO BC) committee. The inclusion criteria were as follows: (1) patients who received at least 1 dose of a COVID-19 vaccine, (2) patients diagnosed as having invasive breast cancer, (3) inpatients who visited the participating hospital from November 2021 to December 2021, and (4) patients with more than 3 months of overall survival. The exclusion criteria were as follows: (1) patients with microinvasion of ductal carcinoma in situ breast cancer and (2) patients with a second primary tumors.

Different types of vaccines were recorded. Dosing regimens were as follows: 1 dose for adenovirus vectored vaccines, 2 doses for inactivated viral vaccines and mRNA vaccines, and 3 doses for recombinant vaccines.

Procedures

Inpatients with breast cancer who were vaccinated were asked to provide retrospective answers through self-reported questionnaires. For highly professional medical issues, physicians were asked to assist the patients to complete questionnaires. Differences for those who received vaccines before cancer diagnosis versus after cancer diagnosis were compared according to the time of cancer diagnosis and vaccination. Patients were recruited in hospitals by the CSCO BC committee. By adopting a competitive enrollment method, only hospitals that contributed more than 20 valid questionnaires by the cutoff date were included.

Through telephone follow-ups or questionnaire surveys, data including epidemiology, demography, clinical information, previous and current therapies, type of vaccines, and patient-reported AEs and their severity after vaccination were collected nationwide. Medical workers of participating hospitals were responsible for data collection, and at least 1 professional doctor from each hospital was responsible for data identification. To ensure the quality of the data, we reviewed all the data, and we retrieved missing data by answering questions. All the data were checked by 2 physicians.

Ethical Considerations

This study was registered (ChiCTR2200055509) and was approved by the ethics board of the Fifth Medical Center of the Chinese People's Liberation Army General Hospital (KY-2022-7-45-1). Oral informed consent was obtained from participants, and secondary analysis was allowed without additional consent. The study data were deidentified. No compensation was involved in this study.

Measures of Variables

The outcome was the safety of the COVID-19 vaccines in patients with breast cancer, which was mainly calculated by dividing the number of AEs by the total population. Another observed outcome was the incidence of AEs, which was calculated by dividing the number of patients with AEs by the total population. Patients were divided into 3 groups according to their time of vaccination and cancer diagnosis: vaccinated before cancer diagnosis, vaccinated after diagnosis, or unknown. AEs were analyzed according to the vaccination time and different doses of the vaccines.

Data Analysis Procedure

SPSS 21.0 (IBM) was used for data statistics. Pearson χ^2 was used for data analysis and a 2-way ANOVA was used to detect data differences. Frequency tables were analyzed using the χ^2 test or Fisher exact test. A multivariable logistic regression model was fitted to examine possible differences in AEs. Odds ratios (ORs) and 95% CIs were calculated with Mantel-Haenszel models. A 2-sided $\alpha<.05$ was considered statistically significant. GraphPad Prism v6.0 was used as the drawing software.

Results

A total of 15,455 patients from 41 hospitals in China were screened (Figure 1), and 5766 patients were eligible in this analysis, of which 45.1% (n=2599) were vaccinated before cancer diagnosis, 41. 2% (n=2379) were vaccinated after diagnosis, and 13.7% (n=788) lacked an accurate diagnosis time or vaccination time. The baseline characteristics of the patients are detailed in Table 1.

Among the patients vaccinated before breast cancer diagnosis, 57.9% (n=1505) were diagnosed with breast cancer 1-3 months after vaccination and 34.4% (n=963) were diagnosed 4-6 months after vaccination. Among the patients vaccinated after breast cancer diagnosis, 85.4% (n=2032) received the vaccine 1 year after cancer diagnosis (Figure 2).

Of all the patients, 93.9% (n=5415) received an inactivated vaccine, 3.7% (n=213) received a recombinant vaccine, and 2.4% (n=138) received other vaccines, including adenovirus and mRNA vaccines. Statistical analysis showed that more patient-reported AEs occurred following the first dose than following the second dose (Figure 3A). Following the first injection, 24.4% (n=10, 95% CI 11.2-37.5) of patients who received an adenovirus vaccine reported AEs compared to 12.5% (n=677, 95% CI 11.6-13.4) for those who received an inactivated vaccine. Following the second dose, patients who received an inactivated vaccine (n=464, 8.7%, 95% CI 8.0-9.5) or a recombinant vaccine (n=25, 8.7%, 95% CI 5.5-12.0) reported the same incidence of AEs (Figure S1 in Multimedia Appendix 1).

Considering the timing of vaccination, of the patients vaccinated before diagnosis, 13.1% (n=340, 95% CI 11.8-14.4) and 8.6% (n=219, 95% CI 7.5-9.7) reported AEs following their first and second injections, respectively (Figure 3B). The cohort included patients in the early stage and patients with metastatic breast cancer. In the early stage, 10.1% (n=227, 95% CI 8.9-11.4) of patients reported AEs following the second dose. Of the patients with metastatic breast cancer, 16.5% (n=18, 95% CI 9.5-23.5) reported AEs after the first dose and 9.3% (n=10, 95% CI 3.8-14.7) after the second dose.

Of all the patients included in this study, a total of 16.4% (n=427) and 16.9% (n=402) of patients vaccinated before or after cancer diagnosis, respectively, reported AEs (Table 2). The most common AEs were local pain (11.1% vs 9.1%, respectively), fatigue (5.5% vs 6.3%, respectively), and muscle soreness (2.3% vs 3.6%, respectively). Other reported AEs included local swelling, local induration, headache, fever, joint pain, and nausea, among others. The incidence of grade 3/4 AEs was relatively low. The highest incidence was for fever, which was reported by 0.4% (n=11) of patients vaccinated before diagnosis and 0.2% (n=5) of those vaccinated after diagnosis.

To identify the factors associated with AEs, a multivariate analysis was conducted (Table S1 in Multimedia Appendix 1). The type of vaccine (odds ratio [OR]=0.937, 95% CI 0.689-1.273) and the time window of vaccination (OR=0.919, 95% CI 0.785-1.077) had little impact on AEs. Patients with low educational degrees reported a lower incidence of AEs (OR=0.794, 95% CI 0.680-0.927) (Table S2 in Multimedia Appendix 1).

Discussion

Principal Findings

This was a real-world study to compare patient-reported AEs among patients vaccinated before or after breast cancer diagnosis. The results have several implications. First, most patients vaccinated after breast cancer diagnosis received their vaccines 1 year after diagnosis, indicating that most patients with early breast cancer received vaccines after chemotherapy due to the short therapeutic period. Second, the incidence of AEs in patients with early-stage breast cancer was lower than in those with metastatic breast cancer. When compared with patients vaccinated before diagnosis, the reported AEs from patients vaccinated after diagnosis was not increased. Third, patients reported a higher incidence of AEs following their first dose compared to following their second dose. The most common AEs were local pain and fatigue. The type of vaccine and time window of vaccination had little impact on AEs.

In this study, of those vaccinated before diagnosis, 90% were diagnosed with breast cancer within 6 months of vaccination. Ipsilateral axillary swelling was one of most frequently reported local reactions to the COVID-19 vaccine, occurring in 11.6% and 16% of recipients following the first and second dose, respectively [20,21]. The lymphadenopathy caused by vaccination may encourage them to seek specialist treatment, which was an important reason for the higher rate of positive lymph nodes on diagnosis in those patients [22]. For patients vaccinated after their diagnosis with breast cancer, most of them received a COVID-19 vaccine 1 year after their diagnosis. Due to the fact that 91.5% of these patients were in the early stage, this contributed to a large proportion of patients being vaccinated without any chemotherapy, which echoed the recommendations in the Chinese expert consensus [23] and mitigated the negative impact on the immune system from chemotherapy [24,25]. The promotion of the consensus does have potential benefits for elevating the rate of vaccination for patients with cancer [26].

In terms of different kinds of vaccines, the majority of patients in this study chose inactivated vaccines (eg, Beijing Biotech, Wuhan Biotech, and Sinovac). Compared with other types of vaccines [27,28], inactivated vaccines presented relatively good safety data in patients with breast cancer [29], although no significant result was shown in the multivariate analysis. We also found that there were significant differences in the incidence of AEs in patients with breast cancer at different stages. Compared with patients in the early stage, the incidence of AEs was higher in late-stage patients after the first dose of vaccine. For one thing, the overlap of the toxicity from the vaccine and cancer treatment in advanced breast cancer may increase the incidence of AEs [30,31]. For another, considering the complexity of antigens, the immune response may have been more aggressive, which can also lead to a significant increase in AEs [32].

The common AEs in this study included local pain, fatigue, muscle soreness, local swelling, local induration, headache, and fever. The incidence of AEs in this study was much lower than in a published randomized controlled study [33]. In our multivariable analysis, we found that the time window of vaccination and type of vaccine had little influence on AEs. Notably, patients with different education levels exhibited a significant difference in the incidence of AEs; patients with a low degree of education had a lower incidence of AEs. The limitation of real-world studies attributed to the lack of effective guidance during the investigation and incomplete data from case report forms may be one of the reasons [34]. To avoid declines and delays in cancer treatment after COVID-19 quarantine restrictions [35], patients might conceal some discomfort from their physicians. During cancer therapy, some AEs might be regarded as treatment-related AEs and ignored by patients and clinicians. In addition, patients with severe AEs might be transferred to a specialist hospital rather than a cancer hospital, which can also result in an underestimated incidence of AEs in this study.

As a retrospective real-word study, inevitable selection bias is another limitation. Over 90% of patients received an inactivated vaccine, so the safety data of other vaccines in patients with breast cancer might be premature. We also paid less attention to the efficacy of vaccines, and the originally planned follow-up of infections has also been terminated due to indiscriminative infection of COVID-19 after the end of quarantine restrictions in China since December 2022. Fortunately, we have collected blood samples from some of the patients to explore changes in antibody titers, which might be a remaining effective alternative indicator to evaluate the efficacy of vaccines [36,37]. Additionally, owing to the high possibility of selection bias and measurement bias, although no data support the notion that COVID-19 vaccination would induce breast cancer, much importance should be attached to this kind of population.

Conclusions

Despite the limitations, our retrospective study highlights the safety of COVID-19 vaccination in patients with breast cancer, and these patients are recommended to receive COVID-19 vaccines, just like healthy individuals. Much attention should be paid to the first injection of vaccines. While limited by retrospective data, more evidence from high quality, double-blind, randomized control trials are expected.

Abstract

Background: Wasting is an immediate, visible, and life-threatening form of undernutrition in children aged <5 years. Within a short time, wasting causes recurrent sickness, delayed physical and mental growth, impatience, poor feeding, and low body weight. The long-term consequences of wasting and undernutrition are stunting, inability to learn, poor health status, and poor work performance. Wasting remains a public health problem in Ethiopia. According to the World Health Organization, countries have to reduce undernutrition including child wasting to below 5% by 2025. Ethiopia is attempting to attain national and international targets of undernutrition while struggling with many problems.

Objective: This study aimed to identify the prevalence and associated factors of wasting to provide information for further renewing policy commitments.

Methods: We used community-based, cross-sectional data from the Ethiopian Mini Demographic and Health Survey. The survey was conducted in 9 regions and 2 city administrations. Two-stage cluster sampling was used to recruit study participants. In the first stage, enumerations areas were selected, and 28-35 households per enumeration area were selected in the second stage. Our analysis included 2016 women with children aged <5 years from the 2019 EMDHS data set. We dropped incomplete records and included all women who fulfilled the eligibility criteria. We used multilevel ordinal regression using Generalized Linear Latent and Mixed Models (GLLAMM) and predicted probability with log-likelihood ratio tests. Fulfilling the proportional odds model's assumption during the application of multilevel ordinary logistic regression was a cumbersome task. GLLAMM enabled us to perform the multilevel proportional odds model using an alternative method.

Results: In our analysis, wasting was 7.68% (95% CI 6.56%-8.93%). Around 26.82% of mothers never used antenatal care for their current child. Most mothers (52.2%) did not have formal education, and 86.8% did not have postnatal care for their children. Additionally, half (50.93%) of the mothers have ≥6 household members. Wasting was associated with feeding diverse foods (coefficient 4.90, 95% CI 4.90-4.98), female sex of the household head (–40.40, 95% CI –40.41 to –40.32), home delivery (–35.51, 95% CI –35.55 to –35.47), first (16.66, 95% CI, 16.60-16.72) and second (16.65, 95% CI 16.60-16.70) birth order, female child (–12.65, 95% CI –12.69 to –12.62), and household size of 1 to 3 (10.86, 95% CI 10.80-10.92).

Conclusions: According to the target set by World Health Organization for reducing undernutrition in children aged <5 years to below 5% by 2025, child wasting of 7.68% in Ethiopia should spark an immediate reaction from the government and stakeholders. Informed policy decisions, technology-based child-feeding education, and food self-sufficiency support could improve the current challenges. Additional effort is important to improve low maternal education, family planning, awareness of sex preferences, women empowerment, and maternal health services.

Introduction

Background

Child wasting is a key indicator used by the World Health Organization (WHO) to estimate the prevalence of childhood malnutrition. Child wasting refers to children who are too thin for their height because of recent rapid weight loss or failure to gain weight. A wasted child is one whose weight falls below 2 SDs of what is expected for the child's height. Moderately or severely wasted children are at a greater risk of death [1]. According to the United Nations Children's Fund (UNICEF), child wasting due to acute undernutrition piles additional life-costing health risks on children and usually arises as the result of maternal undernutrition, low birth weight, poor feeding and care practices, infection, food insecurity, and poverty [2].

The short-term consequences of undernutrition include frequent sickness, delayed physical and mental development, restlessness, poor feeding, and low body weight. In long run, it causes stunting, inability to learn, poor health status, and poor work performance [3-5]. Unfortunately, childhood undernutrition constraints are disproportionally large in low-income countries [6]. Despite this, evidence indicates that the international community is fragmented in regard to engaging against the problem [7]. Currently, the WHO developed a strategic plan outlining the urgent and accelerated action to end hunger and all forms of undernutrition by 2030 [8]. The status of the plan was not assessed at present. As part of this initiative, the government of Ethiopia is committed to ending wasting and stunting in children aged ≤2 years by 2030, through the effective coordination and collaboration of sectors, communities, and development partners [9]. According to the Ethiopian Growth and Transformation Plan II (GTP-II) evaluation, the rate of wasting was 9% in 2015 and 4.9% in 2020 [10]. However, the Ethiopian Health Sector Transformation Plan endorsed in the same year as GTP-II showed that wasting was 7% in 2020 and should be 5% by 2025 [11]. The discrepancy encourages further investigation.

Specific observations show that undernutrition largely occurs during the early time of childhood when higher energy is necessary for growth and development [6,12]. In other words, UNICEF, WHO, and World Bank all agree that a child who experiences wasting has a reduced immunity against various childhood infections and possibly result in death or poor mental and physical development later [13]. Nutritional inadequacy during the first 2 years is also prevalent in some Asian countries [14]; however, the severity of the problem is higher in African countries due to additional access and awareness constraints [15].

A study conducted in 35 low- and middle-income countries showed that the rate of wasting was still 12.9% in these countries [16]. Stunting, underweight, and wasting combined in sub-Saharan countries ranged from 12.14% in Benin to 0.58% in the Gambia [17]. Recently, children in many African countries still experience undernutrition [18]. Some of the prevalence are 18% in Niger, 15.5% in Burkina Faso, 12.7% in Mali, 11.1% in Comoros, 8.7% in Ethiopia, 6.2% in Namibia, 13% in Chad, and 10.5% in Sao Tomé and Príncipe [19]. It is 5.3% in Ghana [20] and 25.5% in Baka Pygmy [21]. Wasting is common in children aged <5 years and school-age children in Ethiopia. A new small-scale study in Ethiopia showed that 15.3 % of children aged 6-14 years are wasted [22], whereas another study also showed that 6.3% of children aged 6-12 years in the South Gondar Zone are wasted [23]. Another study showed that among children aged 6-59 months, the rate of wasting was 16.8% in Kersa [24], 18.2% in Dabat district [25], and 12.8 % North Wollo [26], showing that there is high wasting in various corners of the country.

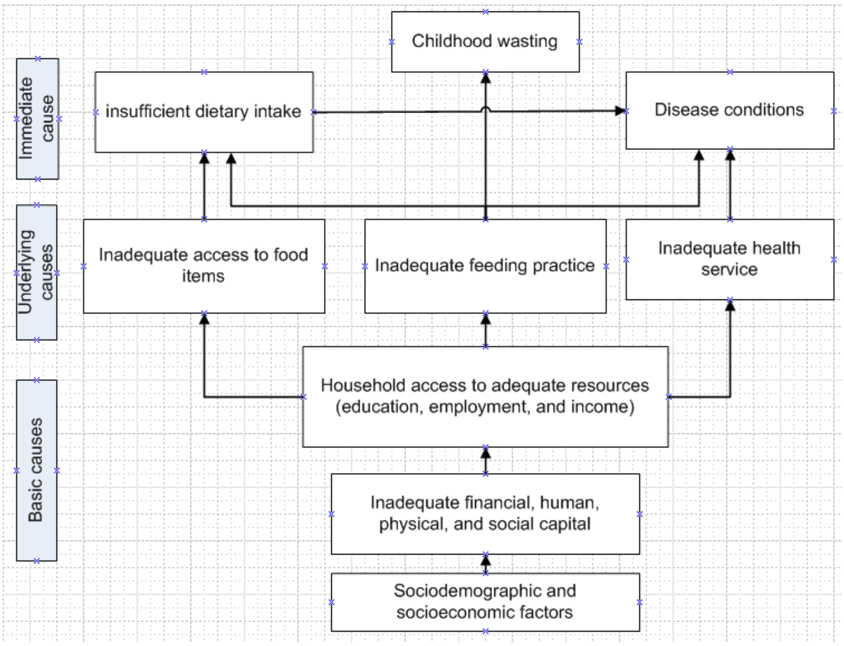
Recalling factors associated with wasting in low-income countries, one piece of evidence showed that child wasting was due to the quality of children's diet, low birth weight, maternal undernutrition, and poor complementary feeding [15]. In Ghana, wasting was associated with the wealth index of households, maternal educational status, and region of residence [27]. Another study in South Africa stated that wasting was associated with food insecurity and low awareness [28]. Household wealth, iron deficiency, recent diarrhea, and exclusive breastfeeding were the main associated factors of wasting in Somalia [29]. Generally, the age of the child, sex of the child, birth order, size of the child, education of the mother, wealth index of the family, working status of the mother, antenatal care, and postnatal care for that child are factors associated with wasting in the sub-Saharan region [17].

In Ethiopia, one study showed that wasting was significantly associated with the types of toilets and the sex of the household head [30]. In another study, wasting was associated with poor dietary diversity, late initiation of breastfeeding, absence of postnatal vitamin A supplementation, and maternal occupational status [25]. Child age, sex, dietary diversity score, husband or partner's educational level, and wealth index were associated with wasting in other studies [16,26,27,31-35]. According to the scaling-up management guideline, due to the climate liabilities and public health crises, Ethiopian children share a higher burden of wasting that needs undivided attention [36]. Despites this, relative to the WHO target for 2025, Ethiopia is struggling to reduce undernutrition of the targeted proportion [14]. Although wasting is an immediate, visible, and life-threatening form of undernutrition in children aged <5 years in peripheral and pastoralist areas in Ethiopia, studies usually do not focus on this undernutrition. Wasting is the first outcome of undernutrition, and early identification might help to control other undernutrition. It is challenging to comprehend wasting as a dichotomized variable because of its nature, which can be normal, moderate, or severe. Usually, studies dichotomize wasting as their main variable and this waste some information because of unnecessary merging. This has led to either over- or underestimation of wasting and not allowing appropriate policy decisions. Additionally, the inconsistent reports between GTP-II, Health Sector Transformation Plan, and some small scale studies mentioned above might show the existence of contextual gaps. The authors also believe that the unsuccessful previous efforts are because of the inability of identifying determinants in a country-representative sample that can show where to focus. Here, our main aim was to identify child wasting and its correlates using multilevel ordinary logistic regression to support policy direction.

Conceptual Framework

Figure 1 depicts a conceptual framework adapted from UNICEF's conceptual framework for determinants of child wasting. It summarizes the sequence in which the child wasting occurs [37].

Figure 1. A conceptual framework adapted from United Nations Children's Fund (UNICEF) determinants for childhood wasting.



Methods

Data Sources and Participants

We used the 2019 Ethiopian Mini Demographic and Health Survey (EMDHS) data for this analysis. This data were collected for the second EMDHS in 2019. In Ethiopia, there are 4 administrative levels (Ethiopia or federal, regions, zones, and woredas). The 9 regions are further divided into city administrations (Addis Ababa and Dire Dawa), agrarian regions (Tigray; Amhara; Oromia; Benishangul-Gumuz; Southern Nations, Nationalities, and People's Region; Gambela; and Harari), and pastoralists regions (Afar and Somali). We obtained data for 2016 eligible women with children aged <5 years from the 2019 EMDHS data set, downloaded from the MEASURE program web address, and extracted data elements necessary for this analysis. EMDHS 2019 used a sampling frame of all census enumeration areas (EAs) created for the 2019 Ethiopia Population and Housing Census (PHC) prepared by the Central Statistical Agency. There was a complete list of 149,093 EAs created for the 2019 PHC. An EA is a geographic area covering an average of 131 households. The sampling frame contained information about the EA location, type of residence (urban or rural), and an estimated number of residential houses focusing on key indicators for this survey. Each region was stratified into urban and rural areas, yielding 21 sampling strata. Samples of EAs were selected independently in each stratum in 2 stages. Finally, 305 EAs (93 in urban and 212 in rural areas) were selected with a probability proportional to EA size (based on the 2019 PHC frame) and with an independent selection in each sampling stratum. Either all women aged 15-49 years who were permanent residents of the selected households or visitors who slept the night before the survey were eligible for interview. The height and weight of children aged 0-59 months were collected, and women aged 15-49 years were interviewed using the Woman's Questionnaire [37].

Variables

The outcome variable of this study was wasting in children aged <5 years: if a child's weight for height is below 2 SDs from the expected weight-for-height median identified by the WHO for boys and girls [26]. In this study, we classified children as normal (when the weight-for-height *z* score is between –2 SDs to 2 SDs) [28]; moderate wasting (when the weight-for-height *z* score is between –3 SDs to –2 SDs); and severe wasting (when the weight-for-height *z* score is below –3 SDs), depending on the references from WHO 2006 guideline [38].

Independent Variables

We selected the following independent variables based on performance in previous evidence [17,23,25,26,30,32,33,39] and the availability of variables in the 2019 EMDHS data set. Age (mother and child), sex of the child, mother's educational status, head of household, wealth index, religion, residence, antenatal care, place of delivery, postnatal care, breastfeeding, anemia status of the mother, anemia status of the child, dietary diversity score, husband or partner's educational level, and birth order were independent variables.

Variable Definitions

Antenatal Care

Antenatal care visits were presented in groups of none, 1-3, or 4+. A mother may have no visits, 1-3 visits, or over 4 visits according to WHO.

Anemia Status of the Mother

The anemia state of the mother was defined as the percentage of women aged 15-49 years with mild, moderate, or severe anemia or with any anemia. It is the number of not pregnant women whose hemoglobin count is less than 12.0 grams per deciliter (g/dL) plus the number of pregnant women whose count is less than 11.0 g/dL.

Anemia Status of the Child

The anemia state of the child was defined as the percentage of children aged 6-59 months with mild, moderate, or severe anemia or with any anemia. This is when the hemoglobin count of a child is less than 11 grams per deciliter (g/dL).

Dietary Diversity Score

The dietary diversity score measured children aged <5 years who consumed a minimum of 5 of the 8 food groups (grains, roots and tubers, legumes and nuts, dairy products, meat [fish, poultry, and liver/organ meats], eggs, vitamin A–rich fruits and vegetables, other fruits and vegetables, and breast milk) in the past 24 hours.

Household Head

Households were the primary unit selected for interview in the Ethiopian Demographic and Health Survey (DHS). The definition of a household is a person or group of related or unrelated persons who live together in the same dwelling unit(s), who acknowledge one male or female adult as the head of the household, who share the same housekeeping arrangements, and who are considered a single unit.

Family Wealth Index

The questionnaire included queries concerning the household's ownership of several consumer items such as television and car; dwelling characteristics such as flooring material, type of drinking water source, toilet facilities; and other characteristics related to wealth status. Each household asset for which information was collected is assigned a weight or factor score generated through principal components analysis. The resulting asset scores were standardized about a standard normal distribution with a mean of 0 and an SD of 1. These standardized scores were then used to create the breakpoints that define wealth quintiles as lowest, second, middle, fourth, and highest [40].

Data Processing and Analysis

We used frequencies, weighted frequencies, means, SDs, and percentages or proportions to describe child wasting. Our data set contained many factors, so we checked multi-colinearity using the mean variance inflation factor (1.31), which was within an acceptable range. Before applying different models for analysis, we cleaned the data per the study criteria in Stata software (version 15.0; StataCorp) and weighted considering sampling weight, primary sampling unit, and strata before analyzing. Since wasting has normal, moderate, and severe categories, we applied multilevel ordinary logistic regression to fit the data. We conducted a bivariate analysis to identify candidate variables for multivariate analysis and selected variables with a *P* value <.20 [40,41] for the multivariable model. In current statistical analyses, studies conduct preanalysis filters to select variables for final models at a *P* value <.25 [42] and commonly at *P*<.20 [43]. We declared the final association at a *P* value of <.05. We presented the outputs of the model using coefficients and 95% CI.

Statistical Analysis—The Ordinal Logistic Regression Model

The data used in this analysis were hierarchical, which we could not analyze using binary logistic regression. Multilevel logistic regression was also not applicable since the response variable contained more than 2 categories. Therefore, we applied a special type of ordinal logistic regression (Generalized Linear Latent and Mixed Model [GLLAMM]) to account for the parallel planes and proportional odds assumptions. This model has been used to analyze clustered data [44]. We executed a mixed-effects ordinal logistic regression in a multilevel proportional odds model using GLLAMM. We used adaptive quadrature to estimate deviance and log-likelihood [45-47]. After fitting the full model, we also estimated posterior means and SDs of the latent variable. The marginal test gave us the expected response regarding the prior distribution of the latent variables so that we were able to look at the "marginal" or population-averaged effects of covariates [44,48].

Ethical Considerations and Consent to Participate

This study used secondary data from demographic and health survey data files. Initially, the authors formally requested access to the data sets from the MEASURE DHS team by completing the web-based request form [49]. Accordingly, permission to access the data and the letter of authorization were obtained from ICF International. Therefore, for this study, consent to participate is not applicable. We kept all data confidential, and no effort was made to identify households or individuals. The

Ethiopian Health Nutrition and Research Institute Review Board and the National Research Ethics Review Committee at the Ministry of Science and Technology of Ethiopia approved EMDHS 2019. The original informed consent allowed the free deidentified secondary analysis without additional consent. The authors also confirmed that all methods were carried out with relevant guidelines and regulations. The authors also ensured the study data were anonymous or deidentified for the confidentiality and privacy of the participants. According to the original consent, there was no compensation for this cross-sectional data acquisition.

Results

We analyzed the data of 2016 mothers with children aged <5 years and found an overall wasting of 7.68% (95% CI 6.56%-8.93%). Using weighted frequencies, we found that 1.86% of children were severely wasted and 5.79% were moderately wasted. Around half (48.68%) of the mothers of the children were in the age range of 25-34 years, where 26.82% of them did not have antenatal care for the current child. Over half (52.2%) of the mothers had no education, and 86.8% never had postnatal care for their current child. Half (50.93%) of the mothers had ≥6 household members. Additionally, 24.93% of mothers had a history of having 6 or more childbirths. More exceptionally, 36.6% of mothers gave birth to 2 children in the last 5 years. Many mothers (39.85%) did not use iron supplementation in the previous pregnancy. Additionally, 37.49% of mothers did not give their children solid or semisolid food yesterday, whereas 22.9% did not provide diverse food for their children (Table 1).

In the GLLAMM, variables such as giving diverse food to a child, sex of the child, total household members, sex of household head, wealth index, birth order, and maternal education were significantly associated with child wasting (all *P*<.001). Accordingly, a child fed diverse food had 4.90 times higher log odds of having normal body weight when other factors were kept constant (coefficient 4.90, 95% CI 4.90-4.98). If the sex of the household head was female, the log odds of having normal body weight was 40.40 times lower (–40.40, 95% CI –40.41 to –40.32), and when the child delivered at home, the log odds of having normal body weight was 35.51 times lower (–35.51, 95% CI –35.55 to –35.47). In other words, first and second birth-order children had higher log odds of falling into the normal body weight category (16.66, 95% CI 16.60-16.72; and 16.65, 95% CI 16.60-16.70, respectively). Families in the poor or middle-income category had 5.95 and 5.94 times lower log odds of having normal body weight (–5.95, 95% CI –6 to –5.90; and –5.94, 95% CI –6 to –5.88, respectively). The female sex of the child correlated with 12.65 times lower log odds of having normal body weight (–12.65, 95% CI –12.69 to –12.62) when all factors were constant. Children from smaller household sizes (1-3 and 4-5 members) had higher log odds of having the normal body weight (10.86, 95% CI 10.80-10.92; and 10.87, 95% CI10.91-10.92, respectively), and children whose mothers were educated (primary, secondary, and higher education) had higher log odds of having normal body weight (1.96, 95% CI 1.89-2.03; 1.99, 95% CI 1.92-2.04; and 1.99, 95% CI 1.90-2.10, respectively) (Table 2).

The equality between the nonproportional odds log-likelihood and postestimation log-likelihood shows that the assumptions hold for the model, and we applied the nonproportional model, although the proportional model almost performed similarly (Table 3).

Discussion

Principal Findings

From our analysis, the overall wasting among children aged <5 years was 7.68% (95% CI 6.56%-8.93%). This finding is consistent with the 7.4% and 9.5% wasting rates in Afghanistan and India, respectively [27]. The finding is less than the average wasting rate (12.14%) in sub-Saharan countries [17]. The rate was 18% in Niger, 15.5% in Burkina Faso, 12.7% in Mali, and 11.1% in Comoros [19]. It is less than other study findings in Ethiopia that show wasting was 15.3% in Northwest Ethiopia [22], 16.8% in Kersa [24], 18.2% in Dabat district [25], and 12.8 % in North Wollo [26]. The clear discrepancy might show that Ethiopia needs to work very hard to reach the less than 5% wasting target set by WHO for 2025 [14]. Additionally, 52.2% of the mothers did not have an education. This is also evidenced by the 60.25% of those with no educational attainment from country-level studies in 2019 [39]. From other evidence, 59.7% of mothers have no education in the country [50], and other studies have confirmed the same [33,51,52]. Education is repeatedly the factor behind the most underachievement in the country and needs further efforts. Nearly forty percent (39.85%) of mothers did not use iron supplementation during pregnancy, which is also consistent with a finding of 34.6% in Somali [29] but sufficiently different from prenatal iron use of 45.3% in a community-based study in the country [22]. Half (50.93%) of mothers have 6 or more children, which is greater than the finding of 30.8% from another study [53]. A poor wealth index of 44.47% is consistent with the finding of 44.2% in another study [54] that shows birth control and economically empowering mothers could be the crucial target for future improvement.

There are different factors associated with all underachievements. Children who were fed diverse foods by their mothers had higher log odds of normal body weight. The finding is consistent with the results in other studies in the country [26,51]. Ethiopia has diverse cultures, which are the base for various feeding styles; however, as things change over time, natural products are no longer available in sufficient volumes and mothers might need further health education [55,56]. Female household heads were associated with the poor body weight of their children aged <5 years. In Ethiopia, men lead the household and assume all responsibilities [57]. However, when the family is separated or divorced, finding food and feeding children lies with women [37]. This might result in the potential for the undernutrition of children [39,58]. Women are poor and undereducated and have low awareness in the country, which needs attention when household responsibility falls into their hands [37,58]. Home delivery is associated with poor feeding practices (wasting) in children aged <5 years, as was also observed in other studies [31,33]. The reason might be the exposure of mothers to health professionals' counseling, which could be useful for the future. However, mothers who gave birth in health institutions might be mothers who already know what to do. Therefore, careful intervention selection is necessary. Additionally, children with first or second birth order might get enough attention during development, as opposed to those born later. This information is also available from studies conducted in various parts of the country [20,39]. A planned and economically sized family is always important. It seems that those born with many children do not give equal attention to every child, which needs attention [50]. Consequently, wasting was largely experienced by large-family children. This is consistent with another study conducted in the country [31]. The essence of family planning to reduce the risk of big families and maintain already large families might be vital. Moreover, female children had higher log odds for moderate or severe wasting, which is also consistent with another study [33]. Thus, the problem of family planning and management might have reduced most of these feeding problems. In most studies in the country, maternal education is the most prevalent problem, which was also seen in this study [33,49,51,59-61]. Generally, the current problems could have been reduced by maternal education, family planning, avoidance of sex preference, and access to pregnant women's services. Despite all the essential findings of this study, there are also some possible limitations. Disproportion of sampling, missing data, and secondary nature of the data are some limitations. The authors approached the problem through multilevel analysis, weighting, dropping records with missing data, and considering the time of data collection in the discussion.

Conclusions

Considering the target set by WHO to reduce undernutrition in children aged <5 years to below 5% by 2025, the current 7.68% wasting rate in children aged <5 years is very high and should spark immediate commitment from the government. Additionally, improving low maternal education, supporting women to use family planning, creating awareness of sex preferences, empowering women economically, and renewing commitment to improving maternal health services and follow-ups during pregnancy might be inclusive activities that need further encouragement. It was suggested that revisiting policy with current technology-based child-feeding education and advocating food self-sufficiency in the country could improve the current challenges

Acknowledgments

The authors are grateful to MEASURE Demographic and Health Survey, ICF International for allowing us to use the 2019 Ethiopian Mini Demographic and Health Survey data.

The authors received no specific funding for this work.

Data Availability

The survey data set used in this analysis is third-party data from the Demographic and Health Survey (DHS) website (www.dhsprogram.com) and permission to access the data is granted only to the registered DHS data users.

Authors' Contributions

GG wrote the method section and analyzed the Ethiopian Mini Demographic and Health Survey data, whereas GG, SH, SS, FH, KG, BTS, and KK were equally involved in the conception of the study, interpreted the results, and drafted and critically revised the manuscript. All authors have read and approved the final version of the manuscript.

Abstract

Background: Cancer literacy is associated with several health-related behaviors and outcomes. However, there is still a lack of nationwide surveys for cancer literacy in China.

Objective: This study aims to evaluate cancer literacy in China, explore disparities, and provide scientific evidence for policy makers.

Methods: A cross-sectional survey was conducted in mainland China in 2021 using the multistage probability proportional to the size sampling method. Both the reliability and validity of the questionnaire were evaluated. The awareness levels were adjusted by sampling weights and nonrepresentativeness weights to match the actual population distributions. The Rao-Scott adjusted chi-square test was applied to test geographic, demographic, and socioeconomic disparities. A generalized linear model was used to explore potential factors.

Results: A total of 80,281 participants aged 15-74 years were finally enrolled from 21 provinces, with an overall response rate of 89.32%. The national rate of cancer literacy was 70.05% (95% CI 69.52%-70.58%). The rates were highest regarding knowledge of cancer management (74.96%, 95% CI 74.36%-75.56%) but were lowest regarding basic knowledge of cancer (66.77%, 95% CI 66.22%-67.33%). Cancer literacy was highest in East China (72.65%, 95% CI 71.82%-73.49%), Central China (71.73%, 95% CI 70.65%-72.81%), and North China (70.73%, 95% CI 68.68%-72.78%), followed by Northeast (65.38%, 95% CI 64.54%-66.22%) and South China (63.21%, 95% CI 61.84%-64.58%), whereas Southwest (59.00%, 95% CI 58.11%-59.89%) and Northwest China (57.09%, 95% CI 55.79%-58.38%) showed a need for improvement. Demographic and socioeconomic disparities were also observed. Urban dwellers, the Han ethnic group, and population with higher education level or household income were associated with prior knowledge. The questionnaire showed generally good internal and external reliability and validity.

Conclusions: It remains important for China to regularly monitor levels of cancer literacy, narrow disparities, and strengthen health education for dimensions with poor performance and for individuals with limited knowledge to move closer to the goal of Healthy China 2030.

KEYWORDS

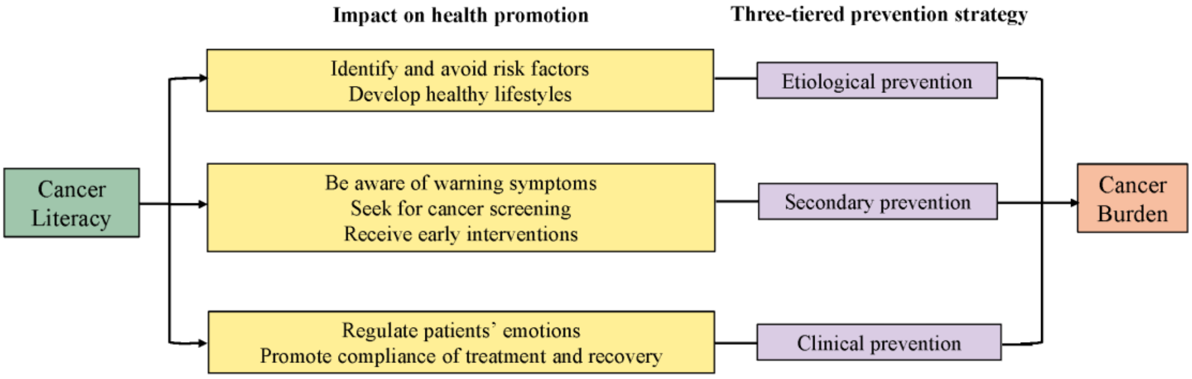
health literacy; cancer literacy; cross-sectional study; Healthy China Initiative; cancer control

Introduction

Cancer is a global issue that threatens public health, and 23.7% of new cancer cases and 30.2% deaths occurred in China in 2020 [1]. Meanwhile, regional and population disparities are evident in terms of the burden of cancer across China [2]. Cancer ranked the first and the third cause of death in urban and rural China in 2020, respectively, and more cancer-related resources, including qualified medical workers, high-level medical institutions, and health input, were allocated in East China [3]. Faced with this situation, the Chinese government has issued a series of documents [4-6] aiming to gradually promote comprehensive strategies to slow down the growth of cancer. Constant efforts have also been made to encourage health equity by increasing funds and enacting policies.

Policy makers in the United States have recognized the significance of health literacy, which may be a potential intervenable factor to reduce health disparities with decreased financial burdens on the health system [7,8]. Cancer literacy refers to all the knowledge a layperson needs to possess to understand the information and advice the health system has to offer with regard to preventing, diagnosing, and treating cancer [9]. Up to now, several studies have reported a consistent association between health literacy and some health-related behaviors or outcomes, including physical exercise, cancer screening, and mortality [8,10-12]. Therefore, the Chinese government has called for improvement in cancer literacy, with the aim of finally decreasing the burden of cancer on the basis of a 3-tiered prevention strategy (Figure 1) [13,14].

Figure 1. Cancer literacy might be associated with the burden of cancer through a 3-tiered prevention strategy.



Specifically, the Healthy China Initiative (2019-2030), the guiding principle for national health undertakings in China in the next decade, proposed phased targets for cancer literacy of 70% and 80% by 2022 and 2030, respectively [5]. The National Health Commission of China has formulated a series of the Three-year Action Plan for Cancer Prevention and Control, which repeatedly emphasized urgency and significance of improving cancer literacy [4,13]. As 1 of the 2 indicators for the assessment of government work in cancer control action in the Healthy China Initiative, the level of cancer literacy among the Chinese population needs to be evaluated to indicate the current status of progress in 2022 and to further promote the accomplishment of the next goal. However, there is still a lack of reliable measurement tools in China, and thus, national data on cancer literacy are not available. To fill this gap, the primary aim of this study was to evaluate the current level of cancer literacy in China using a well-developed questionnaire. The second aim was to assess disparities among regions and populations to provide references for health education.

Methods

Ethics Approval

This study protocol was approved by the ethics committee of the cancer hospital of the Chinese Academy of Medical Sciences (NCC-007739). We followed the Strengthening the Reporting of Observational Studies in Epidemiology reporting guideline [15].

Participants and Sample Size

A national cross-sectional survey was administered in 7 administrative divisions of mainland China using the multistage probability proportional to size sampling (PPS) method in 2021. Residents aged 15-74 years were selected, except for those registered in a collective residence. At least 2152 samples had to be included in each province to ensure their evaluations of cancer literacy (see details in Multimedia Appendix 1).

Sampling Method

The sampling process was divided into 6 stages in this national survey (Multimedia Appendix 1). Briefly, the primary sampling units of this study were provinces, and a total of 21 provinces were selected from 7 administrative units using the PPS method. The secondary sampling units (SSUs) were county-level administrative units, and the whole survey was conducted in urban and rural areas, which were classified according to the document issued by the Ministry of Civil Affairs. The PPS method was applied based on the *2020 China Statistical Yearbook* [14], and finally 3 streets or towns and 6 neighborhood or village committees were randomly selected in each SSU.

Simple random sampling was used to select households based on the electronic geographic listings of community households. One eligible family member was identified with the Kish grid method and selected to complete a questionnaire survey [16]. Participants were reached and reviewed by attempts tried per household.

Survey Tool

The tool applied in this study was designed by the National Cancer Center of China and contains a 3-level index framework constructed based on an extensive literature, public document, and expert opinions (Multimedia Appendix 2). The questionnaire consists of 13 true-or-false items, 13 single-choice items, and 11 multiple-choice items, and it covers 5 main dimensions: basic knowledge (9 scores, 24.3%), primary prevention (9 scores, 24.3%), early detection and treatment (10 scores, 27.0%), treatment (6 scores, 16.3%), and recovery of cancer (3 scores, 8.1%). Each item corresponds to the information recommended by the Chinese Health Commission after several rounds of deliberations, and all the items combined form a comprehensive assessment of individuals' cognition, attitude, skills, and behavior choices for cancer prevention and treatment [17]. In addition, basic information was also investigated, mainly age, sex, education level, ethnicity, family history of cancer, smoking status, annual income, and marital status.

Data Weighting and Calculation

For all items, 1 score was given for a complete correct answer, zero score was given for a wrong or partially correct answer, and the final score was defined as the sum of all the scores. Cancer literacy at the population level was calculated as the sum of the final scores of all respondents divided by the number of items to be answered. Meanwhile, the cancer literacy estimates were adjusted by the product of design weights and nonrepresentativeness weights, considering the inevitable inconsistencies of population distribution between the survey sample and the actual population (see details in Multimedia Appendix 1). SE values and the corresponding 95% CIs were also calculated.

Statistical Analysis

The completed questionnaires were included in the final analysis. Continuous variables are presented as the mean (SD) or median (IQR), and categorical variables are reported as counts and percentages. The internal and external reliability and validity of the questionnaire were evaluated. Item response theory (IRT) 2-parameter logistic analysis was used to evaluate the discrimination (*a* parameter) and difficulty (*b* parameter) of each item by dimension. The values of the Human Development Index (HDI), age-standardized incidence rates, and mortality rates for 7 administrative divisions were extracted to explore potential associations with cancer literacy [2,18]. The response rates were estimated based on both the unit nonresponse and the item nonresponse. R (version 4.1.0; R Foundation for Statistical Computing) and SAS (version 9.4; SAS Institute Inc) software were used to conduct data analysis. The Rao-Scott adjusted chi-square test was used to compare cancer literacy among subgroups, which is a modified chi-square test method for survey data by improving the performance in the goodness-of-fit problem and avoiding misleading results generated by clustering in the survey design [19,20]. When any assumptions of linear regression were violated (Linear relationship, Independence, Homoscedasticity, and Normality) [21], the levels of cancer literacy were grouped according to quartiles, and the multivariable logistic regression analysis was applied to explore the potential factors of cancer literacy, with adjustments of all the background variables except self-reported health status. A 2-sided $P<.05$ was considered statistically significant.

Results

Basic Characteristics

By December 31, 2021, a total of 80,281 questionnaires had been completed in mainland China, with an overall response rate of 89.32% (Table S1, Multimedia Appendix 3). The median age of all the participants was 46 (IQR 34-56) years, and the population with registered permanent residences in urban areas accounted for 51.24%, which was representative of Chinese citizens according to the Sixth Census in China. As shown in Table S2 (Multimedia Appendix 3), the survey sample overrepresented females (57.49%) and those with high levels of education (associate degree and above, 39.17%), whereas Western China (Southwest and Northwest, 14.58%) was underrepresented compared with the respective values of 21.19% from census data. Multistep adjustments of the above variables were carried out to ensure the representativeness of the main findings. Additionally, most participants were married (81.11%), never smokers (74.75%), and had no family history of cancer (68.50%). There were no logical errors in the collected questionnaires during random sampling checks, indicating good quality control of this survey.

Assessments of the Questionnaire

A panel composed of 26 experts in clinical medicine, preventive medicine, health economics, imaging diagnostics, and immunology assessed the difficulty and significance of the questionnaire framework, and the tool generally showed satisfactory content validity (Tables S3-S5, Multimedia Appendix 4). The cancer literacy rate of medical practitioners was different from that of nonmedical practitioners, that is, 80.15% (95% CI 76.08%-84.21%) and 69.83% (95% CI 69.29%-70.37%), respectively, suggesting reasonable external validity. The assessment of the internal consistency yielded an overall Cronbach coefficient of .92. The coefficient values of the 5 dimensions were 0.69, 0.79, 0.77, 0.76, and 0.59, respectively, and the former 4 dimensions were internally consistent on their own. Retest questionnaires were obtained 2 weeks later, and the correlation between the 2 rounds of testing was 0.75, indicating acceptable test-retest reliability. In addition, Table S6 (Multimedia Appendix 4) reports the IRT parameter estimates. Discrimination parameters for all the items ranged between 0.37 and 3.67, and the difficulty estimates were also in the reasonable range [22].

Overall Levels of Cancer Literacy

The national level of cancer literacy in China was 70.05% (95% CI 69.52%-70.58%). The awareness rates in terms of treatment and recovery of cancer were relatively high at 74.96% (95% CI 74.36%-75.56%) and 71.00% (95% CI 70.25%-71.76%), respectively, followed by the level of knowledge of primary prevention (70.81%, 95% CI 70.16%-71.46%). However, the corresponding levels of basic knowledge and early detection for cancer were below the target at 66.77% (95% CI 66.22%-67.33%) and 69.16% (95% CI 68.61%-69.71%), respectively. Detailed rates of cancer literacy in terms of more specific dimensions are shown in Table S7 (Multimedia Appendix 5). Levels of cancer literacy in terms of the early diagnosis of cancer, positive beliefs in cancer, and the physiological recovery were relatively low at 59.05% (95% CI 58.32%-59.79%), 63.35% (95% CI 62.72%-63.99%), and 66.13% (95% CI 65.16%-67.10%), respectively.

Disparities in Cancer Literacy Levels

There were distinct discrepancies among the geographical distributions of levels of cancer literacy (Figure 2). In general, the rates were highest in the population residing in East China (72.65%, 95% CI 71.82%-73.49%), Central China (71.73%, 95% CI 70.65%-72.81%), and North China (70.73%, 95% CI 68.68%-72.78%), followed by Northeast (65.38%, 95% CI 64.54%-66.22%) and South China (63.21%, 95% CI 61.84%-64.58%), and lowest in Southwest (59.00%, 95% CI 58.11%-59.89%) and Northwest China (57.09%, 95% CI 55.79%-58.38%). In general, the disease burden of cancer decreased with improvements in cancer literacy, and superior cancer literacy seems to be associated with a higher HDI value (Table S8, Multimedia Appendix 5).

Demographic and socioeconomic disparities in population distributions were also observed for cancer literacy within China (Table 1, Figure 3). Briefly, urban dwellers (vs rural dwellers, 71.25% vs 68.45%) and females (vs males, 70.73% vs 69.45%) had prior knowledge of cancer prevention and control. The rates also increased as the education level (*P*<.001) and annual household income (*P*<.001) increased. Although there was no significant trend in the rates of cancer literacy among age groups, individuals aged 35-54 years showed the highest overall and dimension-specific rates, and elderly individuals had better knowledge in terms of basic knowledge and early detection and treatment of cancer than those younger than 35 years. In addition, the levels of cancer literacy remained higher among people of the Han ethnic group (vs ethnic minorities, 70.43% vs 63.42%), married individuals (vs unmarried individuals, 70.38% vs 65.38%), never smokers (vs daily smokers, 70.58% vs 67.96%), and individuals with a family history of cancer (vs individuals without or with an unknown family history, 75.93% vs 69.45% or 64.34%). After multivariable adjustment, the above variables remained significantly associated with cancer literacy (Table 2).

Figure 2. Geographic disparities among provinces (A) and among administrative divisions (B) in terms of the rates of cancer literacy in China, 2021. The provinces included in each administrative division were determined following the government document of China, and all the provinces were allocated to 7 administrative divisions. AH, Anhui; BJ, Beijing; CQ, Chongqing; FJ, Fujian; GD, Guangdong; GS, Gansu; GX, Guangxi; GZ, Guizhou; HA, Henan; HB, Hubei; HE, Hebei; HI, Hainan; HK, Hong Kong; HL, Heilongjiang; HN, Hunan; JL, Jilin; JS, Jiangsu; JX, Jiangxi; LN, Liaoning; MO, Macao; NM, Inner Mongolia; NX, Ningxia; QH, Qinghai; SC, Sichuan; SD, Shandong; SH, Shanghai; SN, Shaanxi; SX, Shanxi; TJ, Tianjin; TW, Taiwan; XJ, Xinjiang; XZ, Tibet; YN, Yunnan; ZJ, Zhejiang.

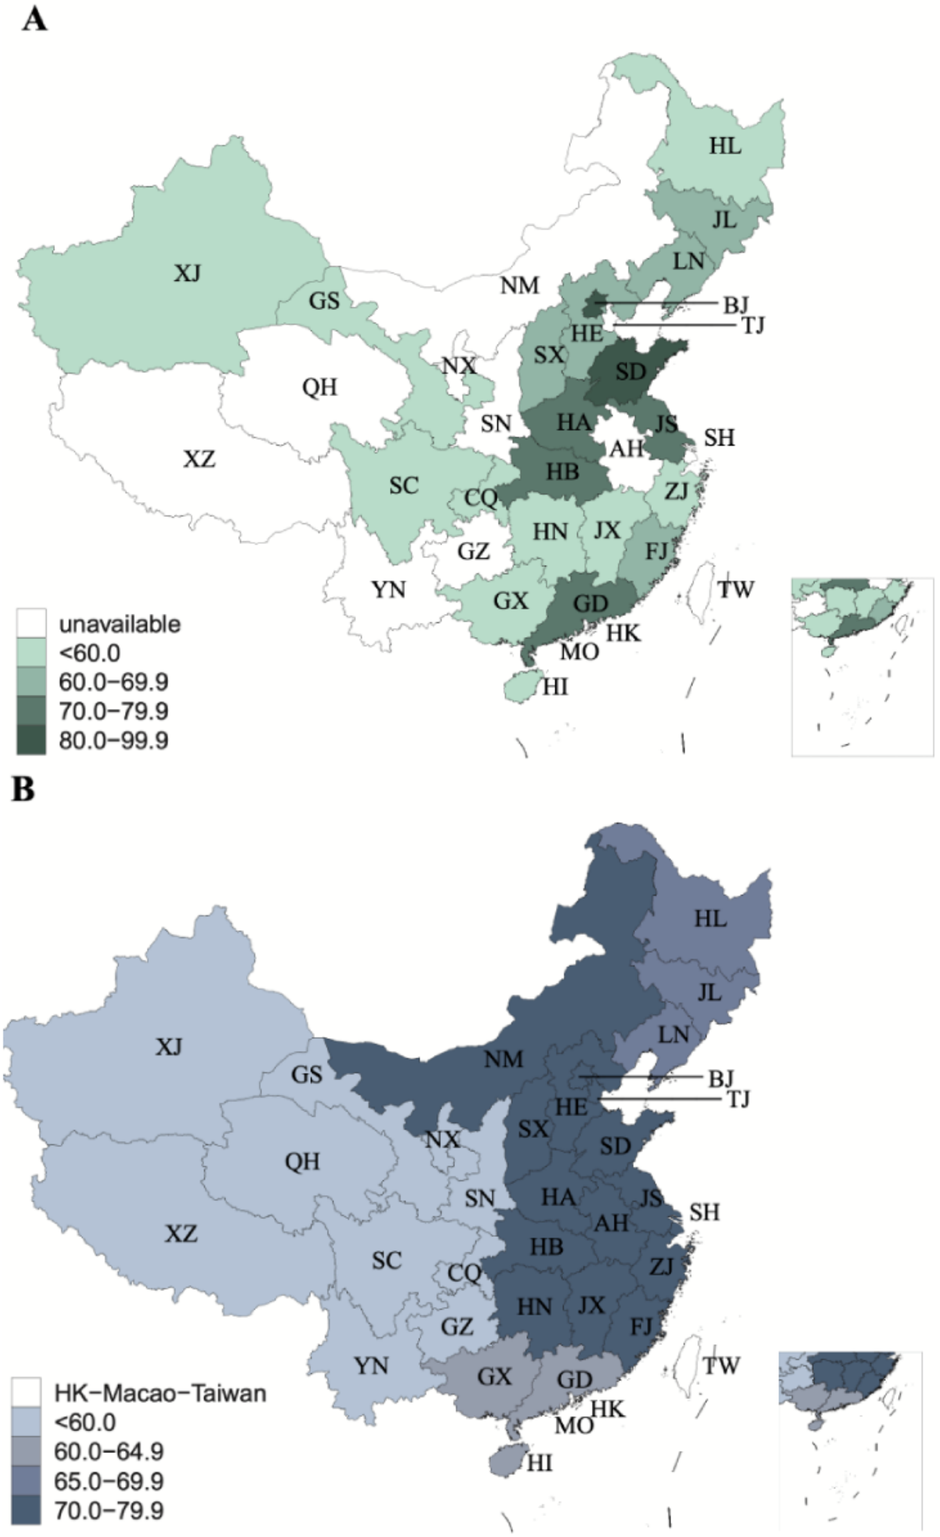


Table 1. The levels of cancer literacy by participant characteristics.

Characteristics	Sample size (n)	Cancer literacy, % (range)	*P* value
Sex			.02
Male	34,127	69.45 (68.72-70.19)	
Female	46,154	70.73 (69.96-71.51)

[a] The OR represents the odds ratio that higher levels of cancer literacy (level 2/level 3/level 4, compared with the reference level [level 1]) will occur given a particular exposure and the odds of the outcome occurring in the absence of that exposure.

[b] The rates were classified into 4 groups according to quartiles before the multivariate logistic regression analysis, which were level 1 (<59.46%, as the reference), level 2 (59.46%-81.08%), level 3 (81.08%-91.89%), and level 4 (>91.89%).

[c] Classified according to quartiles.

Discussion

Principal Results

To our knowledge, this is the first national survey to measure the level of cancer literacy through completely objective items, aiming to provide references for the Chinese government as an evaluation of former health education practices and a review of current strategies. In this work, the standardized rate of cancer literacy for the Chinese population has reached the target value proposed in Healthy China 2030 for 2022 ahead of schedule. However, from the perspective of knowledge dimensions, the corresponding rate of basic knowledge of cancer remained relatively low, and the grasp of information regarding early diagnosis and treatment also needed improvement. Furthermore, there were significant disparities in the distributions among regions and populations with different characteristics. Gender, household registration type, education level, smoking status, annual household income per capita, ethnicity, occupation, and family history of cancer were associated with cancer literacy.

Comparison With Prior Work

Before the development of the questionnaire, the published evaluation tools for cancer literacy were systematically searched and summarized (see Table S9 in Multimedia Appendix 6 [9,10,23-34] for details). In brief, there are several established tools, such as the measure of awareness and beliefs about cancer [23] and the Cancer Awareness Measure [24]. These questionnaires contain single- or multidimensional assessments of cancer understanding, attitude, and skills and have been adopted in local survey practices. The Chinese government proposed that the current task was to raise awareness of systematic knowledge of cancer prevention and control. Accordingly, we collected key information on cancer that the general population was expected to know through a systematic review and the Delphi method [35] and formed an item pool. Existing questionnaires did not completely cover the abovementioned core knowledge, and the corresponding Chinese versions were not available or have not been validated in the Chinese population. Although there have been 3 related surveys administered during government-funded cancer screening programs in China [26-28], 2 questionnaires were not considered comprehensive, and the other multidimensional tool was developed to assess attitudes instead of knowledge, which were not suitable for a national survey on the evaluation of cancer literacy. On the other hand, the questionnaire in this study has a clear theoretical framework, comprehensive coverage of information, and acceptable reliability and validity performance, and is closely connected to the current situation in China.

Disparities among levels of cancer literacy in each dimension reflected the achievements and shortcomings of health education at this stage in China. Awareness of cancer management was relatively high, possibly because the Chinese government encouraged strengthening the professional advantages of health workers, especially in popularizing science during clinical activities [13]. Furthermore, low requirements were set for this dimension considering its strong professionalism, which might explain the better performance than in another survey [12]. The corresponding rate of cancer prevention was also acceptable [12,36], given that it was one of the main subjects in health education that was closest to daily life and would not raise concern. In general, the awareness level of primary prevention in this survey was significantly higher than a survey conducted in rural China during 2007-2014 (mean score 56.1, SD 19.3) and a Switzerland survey in 2009 (mean score 54.9, SD 23.9) [12,26], while still lower than a similar level reported by a UK study [24]. In contrast, the lower awareness of basic knowledge of cancer in China provided lessons for other developing countries. Very high proportions of the participants showed positive beliefs toward cancer outcomes in a survey conducted in 6 high-HDI countries, especially in Norway, and the main barrier to symptomatic presentation was the busy schedule [37]. However, in Chinese culture, people tend to delay diagnosis or treatment because of social stigma, fear, familial obligations, and embarrassment [38-40]. Thus, it is essential to emphasize the importance of timely interventions and address common misunderstandings through interactive communication that may affect individual choices [41,42]. Meanwhile, paying more attention to exerting the patient effect can help to eliminate misconceptions of cancer through experience sharing. In addition, there was room for improvement in skills, mainly the identification of warning symptoms [40,41,43]. A population-based survey in the United States reported awareness of an average of 8.43 (in 11) cancer symptoms, with the rates of recognition on each symptom mostly over 76% [44]. Another survey in developed countries also reported better awareness of warning symptoms, ranging from 70.09% (7.71 in 11, Sweden) to 79.09% (8.70 in 11, Canada) [37]. There are currently 4 cancer screening programs targeting different regions and populations in China [45]. During community mobilization and the screening process, health education carried out by community health workers and clinicians respectively might contribute to this. It is believed that cancer screening will be familiar to a wider range of individuals with the expansion of programs and synchronous health education. Moreover, appropriate examples of the application of knowledge in practice are expected to contribute to cultivating comprehensive cancer literacy.

There were evident variations in the levels of cancer literacy among regions within China. Several prospective studies have shown potential associations between cancer literacy and HDI values or burden of cancer, while related evidence remains limited and the majority was cross-sectional studies. Specifically, low health literacy has been proven to be related to poorer use of health care services and higher mortality [8,27], which might exacerbate the disparities in health outcomes, taking into account the existing differences in cancer burdens and health resources among regions. Urban residents, individuals with higher income, or those who finished compulsory education tended to have higher levels of awareness, possibly due to the more myriad ways that they obtain professional information and their stronger ability to absorb information [40,46]. Therefore, health education efforts should be focused on regions with lower life expectancy, years of schooling, and per capita gross national income, especially Western China. Significant disparities were also observed among populations. Populations with a family history of cancer or those older than 55 years showed acceptable levels of awareness because they might be more willing to acquire knowledge and receive synchronous education during health care [43]. This provided additional evidence to counter the stereotype that elderly individuals are not well adapted to information technologies [47]. Hence, increasing the enthusiasm of actively seeking information may improve the efficiency of health education. Participants occupied in tertiary industry showed higher cancer literacy because of higher coverage of health workers. In addition, higher awareness rates were found among nonsmokers, which was consistent with previous findings [48]. The gap in rates between genders was not distinct, consistent with the results of a national survey on health literacy [49].

Strength and Limitations

In comparison with previous surveys focusing on single types of cancer (mainly colorectal cancer [40] and cervical cancer [43,50]) or specific populations (such as students [51], females [43,46], and elderly people [40]), this study was the first large-scale cross-sectional survey that covered almost 70% of provinces in mainland China and provided more comprehensive information. With the aim of assessing government work, this survey informs current disparities in cancer literacy in China and essential references for improvements in health education and promotion. However, there were also several limitations in this work. First, because of the limitation of data accessibility, only the distributions of the most important variables were adjusted. As it was impossible to fully consider all possible factors and approach the census population, the reported cancer literacy might be overestimated or underestimated in this study. Second, this was a cross-sectional survey, which can indicate correlations but cannot infer causality between awareness and other variables. Third, it was not appropriate to compare the overall cancer literacy with that reported in other surveys directly, considering the differences in the applied questionnaires and the main purposes. However, as the questionnaire was developed based on published articles, the items included in each dimension were consistent with the commonly recognized knowledge, and comparisons on some specific aspects can be made with caution.

Conclusions

In summary, the weighted cancer literacy for Chinese residents was 70.05% in this cross-sectional survey. The awareness level was highest in the dimension of cancer management but was lowest for basic knowledge of cancer and the knowledge of early diagnosis and treatment. There were significant geographic, demographic, and socioeconomic disparities regarding cancer literacy, which calls for urgent efforts to carry out targeted health education for individuals with a heavier disease burden, lower income, or limited education level, especially in Southwest and Northwest China. Policy makers should conduct regular surveys to grasp the most current situations, address weaknesses in knowledge, correct misunderstandings, and move toward the goal of Healthy China 2030.

Acknowledgments

We want to thank the health workers of 21 provinces in Mainland China, who conducted the face-to-face questionnaire survey and provided detailed data. We appreciate the following collaborators for their contributions to the development and evaluation of the applied questionnaire: Min Yang, Xin Wang, Xiaofeng Bi, Nan Bi, Fengwei Tan, Wei Tang, Zhijie Wang, Zhen Huang, Yi Fang, Chunguang Guo, Sujun Han, Li Xiao, Xia Wan, Xibin Sun, Hua Dong, Shaokai Zhang, Yuqin Liu, Yubei Huang, Xiaobin Hu, Li Liu, Yunyong Liu, Yonggang Qian, Xiaojie Sun, Minjie Wang, Ning Wang, Jinyi Zhou, Qingfeng Wei, Yunfeng Xi, Zhihua Yin, Yashen Zhang, and Weifang Zheng. We especially appreciate Yinghua Li from the Chinese Health Education Center for her kind and professional guidance on this survey. This work was primarily supported with grants from Sanming Project of Medicine in Shenzhen (SZSM201911015), the Non-profit Central Research Institute Fund of Chinese Academy of Medical Science (2019PT320027), and the Chinese Academy of Medical Sciences Innovation Fund for Medical Sciences (2021-I2M-1-033).

Data Availability

The study group welcomes potential collaboration to maximize the use of data. A data dictionary, a detailed study protocol, and the R programs can be reached by contacting the corresponding author of this paper. Due to Chinese legal restrictions and the current ethical approval for the study, data are not publicly available to share, but the research group can provide descriptive data in a table form. Requests can be made to WC or JH.

Authors' Contributions

WC and JH contributed equally as the corresponding authors. JH, WC, SH, JS, CX, NL, YY, and LZ contributed to the conception and design of the study. SH, HL, MC, and DS did the literature search and the construction of tables and figures. SH, FY, XY, and SZ verified the underlying data. SH, HL, MC, DS, CX, YY, LZ, JS, NL, XQY, WC, and JH contributed to data collection and quality control. SH, CX, LZ, JS, WC, and JH contributed to the administration and supervision. SH, WC, and JH drafted the paper. SH, HL, MC, DS, CX, JS, NL, XQY, WC, and JH interpreted the results. All authors contributed to data interpretation and rewriting the paper. All authors reviewed and approved the final version. All authors had full access to all the data and were responsible for the decision to submit the manuscript. The corresponding author had full access to all the data in the study and had responsibility for the decision to submit for publication.

Abstract

Background: Peritoneal dialysis (PD) care in mainland China has been progressing in the past 10 years.

Objective: To complement information from the dialysis registry, a large-scale nationwide survey was conducted to investigate the current infrastructure and management of PD care at hospitals of different tiers.

Methods: A web-based multiple-choice questionnaire was distributed through the National Center for Nephrology Medical Quality Management and Control to PD centers of secondary and tertiary hospitals in October 2020. The 2-part survey collected the information of PD centers and the clinical management of patients on PD. A total of 788 effective surveys from 746 hospitals were voluntarily returned, and data were extracted and analyzed.

Results: The effective survey data covered 101,537 patients on PD, with 95% (96,460/101,537) in the tertiary hospitals. The median number of patients per PD center was 60 (IQR 21-152); this number was 32 (IQR 8-65) and 70 (IQR 27-192) for secondary and tertiary hospitals, respectively. There was a discrepancy in the availability of designated physical areas for different functions of PD care between the secondary and tertiary hospitals. The proportion of tertiary hospitals with PD training (P=.01), storage (P=.09), and procedure area (P<.001) was higher compared to secondary hospitals. PD catheter placement was performed in 96% (608/631) of the PD centers in tertiary hospitals, which was significantly higher compared to 86% (99/115) in secondary hospitals (P<.001). Automated PD was available in 55% (347/631) of the tertiary hospitals, which was significantly higher than that in secondary hospitals (37/115, 32%) according to the survey (P<.001). The most commonly performed PD module was continuous ambulatory peritoneal dialysis (772/788, 98%), followed by intermittent peritoneal dialysis (543/788, 69%). The overall reported nocturnal intermittent peritoneal dialysis was 31% (244/788); it was 28% (220/788) for continuous cycling peritoneal dialysis and 15% (118/788) for tidal peritoneal dialysis. Comparisons between the secondary and tertiary hospitals revealed no significant differences in prophylactic antibiotic use for PD catheter placement and therapeutic use for peritonitis. The first peritoneal equilibrium test was conducted in 58% (454/788) of patients at 4-6 weeks after initiation of PD, and 91% (718/788) reported at least one peritoneal equilibrium test per year. Overall, 79% (570/722) and 65% (469/722) of PD centers performed assessment for dialysis adequacy and residual kidney function, respectively; and 87% (685/788) of patients on PD were followed every 1 to 3 months for laboratory and auxiliary examinations.

Conclusions: This national survey reflects the current status and disparities of PD center management in mainland China. The study results suggest that the PD care needs to be more conveniently accessible in secondary hospitals, and quality management and staff training in secondary hospitals are still in high demand.

KEYWORDS

renal replacement therapy; peritoneal dialysis; medical quality; tertiary hospital; secondary hospital; China

Introduction

It was not until the late 1990s that peritoneal dialysis (PD) started to grow rapidly in academic hospitals in large cities of mainland China [1]. Although those top PD centers gained significantly improved clinical outcomes in the late 2000s, the accumulated experiences were shared through published materials of standard operating procedure (SOP) for PD management [2] and through organized training materials [3] and courses from 2011 to 2012.

In China, the pyramid of the health care system is constructed by 3 tiers of hospitals and community convenient clinics. There were about 3000 tertiary hospitals and more than 10,000 secondary hospitals in China according to the 2020 China Health Care Development Statistics [4]. The tertiary hospitals are the top-level hospitals usually located in regional capitals, serving as teaching hospitals as well as medical care providers to manage complex and incurable diseases. The primary hospitals and clinics are often the service providers for long-term disease follow-up, general prescription renewal, and preventive care. Health care workers at tertiary hospitals and in large cities tended to have better exposure to up-to-date medical knowledge, clinical management concept, and more training opportunities for advanced procedures. More patients in end-stage kidney disease (ESKD) choose PD as their renal replacement therapy due to continuing increase in the prevalence and incidence of ESKD [5,6], average educational level of the patients, availability and accessibility of PD resources, and better policy support. In the recent 10 years, PD service is available not only in leading tertiary hospitals but also in secondary hospitals, which has raised a concern about the sufficient governance of PD care quality.

In mainland China, there has been a nationwide registry for dialysis—Chinese National Renal Data System (CNRDS) [7-9]—along with some independent provincial-level databases [10-12] that mostly record clinical and socioeconomic outcomes. Detailed facility infrastructure data, especially for PD centers, are not available in these databases. Although some data related to the concept and behavior of PD care providers (such as the common follow-up parameters, check-up schedule, and the use of medicine for comorbidities and peritonitis) are included in the dialysis registries, these data are largely not spontaneously reported. In addition, some of the information about the reasons that hindered PD as the choice for renal replacement therapy are not collected by the registries. Moreover, previously reported results from large-scale, real-world studies or analysis of registry data did not include information from the recent 2 years [12-14]. Thus, there is a strong need to have another way to collect real-world PD care data and elicit relevant information for better PD care in the future.

To complement a comprehensive picture of current PD practice in mainland China, a national survey was designed focusing on hospital infrastructure for PD as well as conceptual modalities and goals for management of patients on PD. By October 2020, the time when the questionnaires were distributed, data from CNRDS showed that there were about 1000 hospitals offering PD service, with only few in primary hospitals.

Methods

Participants

From September to October 2020, according to the information in the CNRDS, renal divisions from tertiary and secondary hospitals known to have or likely to have PD programs were invited to the web-based survey. Through the National Center for Health Care Quality Management in Nephrology Diseases, the invitation QR code and questionnaire instruction pack was first sent to each provincial Center for Health Care Quality Management in Nephrology Diseases and then distributed to physicians whose practice field was PD. Survey results were voluntarily submitted by participating centers and practitioners.

Survey Design

A multiple-choice type of questionnaire was designed and tested in a pilot group before being distributed to the target respondents. Detailed questions included in the survey are listed in Table 1. The questionnaire consisted of 2 parts. The first part collected the information of the hospital or PD center, including the location and health care level of the facility (secondary or tertiary), availability of nephrology and dialysis care resources, regulatory rules on PD, number of current patients on PD, and the types of PD performed.

The second part of the survey addressed practice concepts or the current situation of clinical management for patients on PD. The questions covered PD catheter placement and care; use of peritoneal equilibrium test (PET); regular follow-up schedule and items; as well as management of common complications, including peritonitis, anemia, and hypertension.

Table 1. Survey items listed in the questionnaire for peritoneal dialysis (PD).

Category	Item
Facility-related survey items	• Name and location of the hospital • Administrative ranking of the hospital (secondary hospital or tertiary hospital) • Number of current patients on PD • Types of PD performed in your center • Diseases treated with PD in your center • Common situations hindering you from choosing PD • Functional areas designated for PD • Does your center register patients on PD in the CNRDS[a] [15]? • Is PD catheter placement performed in your center? • Do you perform PD catheter implantation surgery?
Concept-related survey items	• Antibiotic medicine routinely given right after PD catheter placement • Maximal interval for change of external connecting tube • Do you prescribe or perform peritoneal equilibrium test (PET)? • Time to administer the first PET • Frequency of repeat PETs • Common follow-up interval for patients on PD • Laboratory tests and examinations administered for PD follow-up • Antibiotics for treatment of peritonitis • Common hemoglobin level of patients on PD in your center • Use of antihypertensive drugs, number of drugs, and estimated percentage of patients

[a] CNRD: Chinese National Renal Data System.

Statistical Analysis

Descriptive statistical analysis was performed to evaluate PD items in the survey, and median (IQR) or proportion (frequency) were reported for continuous or categorical variables, as appropriate. Comparisons by health care level of the facility were conducted using Pearson chi-square and Wilcoxon tests for categorical and continuous variables, respectively, along with figures. R (version 4.03; R Core Team) and GraphPad Prism (version 8.0; GraphPad Software Inc) were used for data analysis and figures.

Ethical Considerations

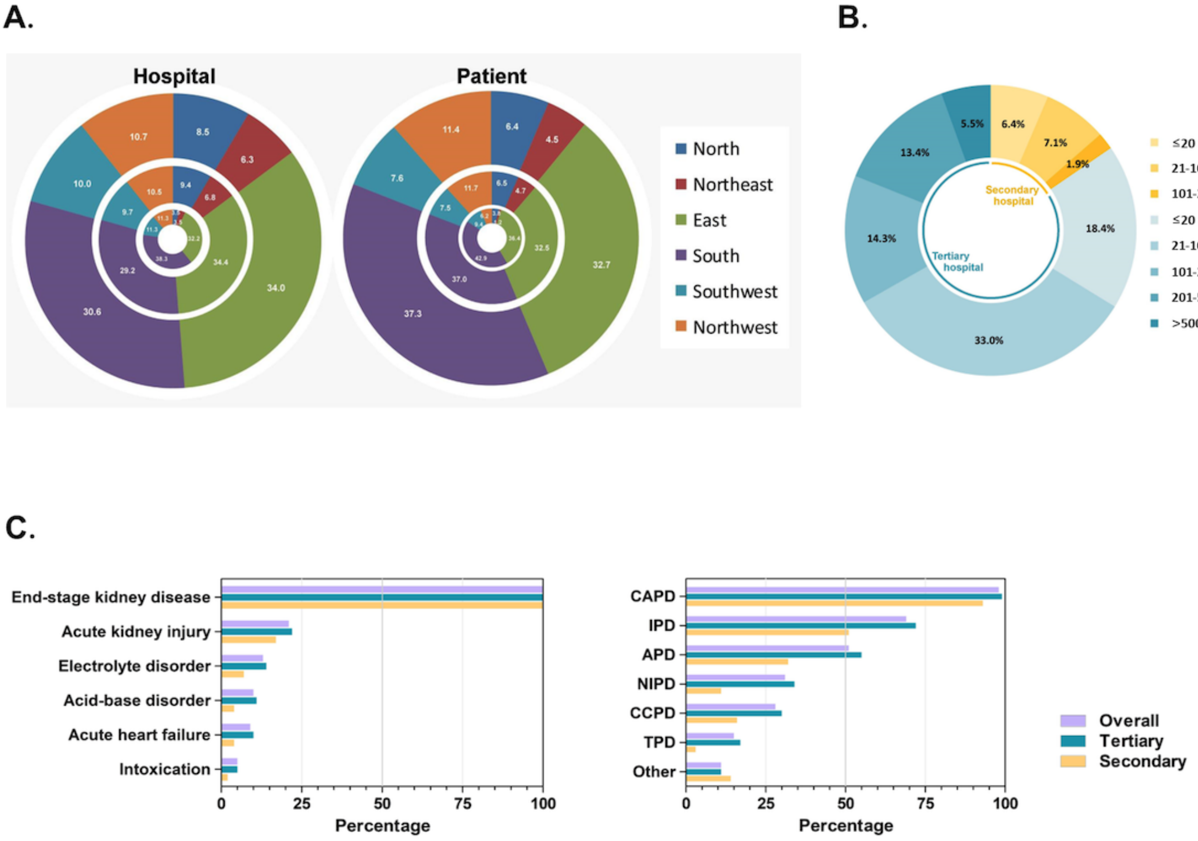
This work was carried out under the research program of National Health Care Quality Management in Nephrology Diseases of Chinese People's Liberation Army General Hospital. The research protocol was reviewed and exempted by the institutional review board of Chinese People's Liberation Army General Hospital. There was no collection of individual and identifiable patient data for the survey. The original informed consent from each participating hospital allows for secondary data analysis without additional consent. All questionnaires were voluntarily responded without compensation.

Results

Participating PD Centers and Patients

A total of 788 surveys from 746 hospitals located in all 31 provincial-level areas (ie, province, autonomous prefecture, or municipality directly under the central government) in mainland China were returned. These 746 centers covered 101,537 patients on PD, with 95% (96460/101,537) of them in the tertiary hospitals. Collected data were further grouped into 6 socioeconomic administrative areas (ie, North, Northeast, East, South, Southwest, and Northwest China); proportions of the hospitals and patients from each area are shown in Figure 1A. Overall, the median patient number per PD center was 60 (IQR 21-152), that is, 70 (IQR 26-192) for tertiary hospitals and 32 (IQR 8-65) for secondary hospitals (Figure 1B). There was no significant regional difference in the distribution of PD centers in terms of patient size. Among the 746 centers, 10 centers did not treat patients on PD, 6 (60%) of which were tertiary hospitals; however, among the 722 centers providing PD care, 611 (85%) were tertiary hospitals. All these indicate that tertiary hospitals are the primary provider of PD care in mainland China (*P*=.03).

Figure 1. Characteristics of hospitals and patients on peritoneal dialysis (PD) covered by the survey. (A) Proportions (%) of participated hospitals and patients in different regions of mainland China; inner ring: secondary hospitals; middle ring: tertiary hospitals; and outer ring: all hospitals. (B) Proportion of participated hospitals with different number of patients on peritoneal dialysis (PD). (C) Proportions of diseases treated with PD and the types of PD performed. APD: automated PD; CAPD: continuous ambulatory PD; CCPD: continuous cycling PD; IPD: intermittent PD; NIPD: nocturnal IPD; TPD: tidal PD.



Clinical Conditions Impacting PD Decision

Data from the 788 submitted surveys showed that besides chronic and acute renal failure, secondary hospitals tended to apply less PD compared to tertiary hospitals for acute congestive heart failure (*P*=.05), electrolyte (*P*=.03), acid-base disorders (*P*=.02), and drug intoxications (*P*=.10; Figure 1C). Between the secondary and tertiary hospitals, there was no significant difference in factors hindering PD decision when coming across clinical situations, such as extensive adhesion of the peritoneum (776/788, 98%), unrepaired hernia (721/788, 91%), and severe skin disease (671/788, 85%).

Treatment Module of PD

The most common PD type was continuous ambulatory peritoneal dialysis, which was reported by 98% (772/788) of the respondents. It was followed by intermittent peritoneal dialysis 69% (543/788). The overall reported nocturnal intermittent peritoneal dialysis, continuous cycling peritoneal dialysis, and tidal peritoneal dialysis were 31% (244/788), 28% (220/788), and 15% (118/788), respectively. Automated PD was available in 32% (37/115) of the secondary facilities and 55% (347/631) of the tertiary facilities by the end of October 2020 (Figure 1C). A combination of hemodialysis and PD was reported by 11 centers; daytime ambulatory PD was reported by 23 centers, and a combination of manual continuous ambulatory peritoneal dialysis and automated PD was reported by 1 center.

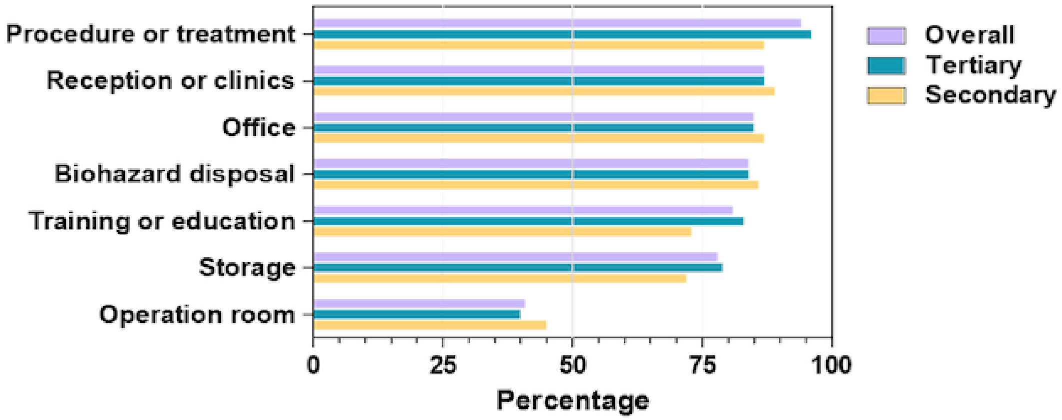
Management of PD Centers

Among the secondary centers, 17% (20/115) reported that there were no established management rules for the PD center, while this number was 7% (44/631) in tertiary hospitals (*P*=.002).

About 19% (22/115) of the secondary hospitals did not have specialized PD medical records for each patient, and this was 11% (69/631) in the tertiary hospitals (*P*=.01).

More than 80% of the centers reported separate functional areas designated for PD care, including areas for reception, procedure or treatment, biohazard disposal, and staff office (Figure 2), with no significant statistical difference between the secondary and tertiary hospitals. Compared to the secondary hospitals, tertiary centers were more likely to have designated areas for training or patient education (*P*=.01), storage (*P*=.09), and procedures (*P*<.001). Only 40% (289/722) of the PD centers had operation rooms exclusive for dialysis access, and there was no discernible difference between the secondary and tertiary centers.

Figure 2. Proportion of hospitals having functional areas designated for peritoneal dialysis use.



PD Catheter Implantation and Care

About 96% (608/631) of the participating tertiary hospitals performed implantation surgery for PD catheters, which involved 78% (515/662) of the survey participants; this was performed in 86% (99/115) of the secondary centers (vs tertiary centers; *P*<.001) and by 67% (85/126) of physicians in the secondary hospitals (vs tertiary hospitals; *P*=.01). Assessment and patient education were conducted before the implantation surgery in 100% of the 631 tertiary hospitals and 94% (108/115) in the secondary centers. Among the hospitals performing PD catheter implantation, 100% (746/746) provided preoperative assessment and patient education. Cephalosporin of the first or second generation was commonly used right after the surgery, accounting for 48.7% (384/788) of the antibiotics used. Other antibiotics included third or fourth-generation cephalosporin (72/788, 9.1%), quinolone (10/788, 1.3%), and aminoglycosides (4/788, 0.5%). About 40.4% (318/788) of the participants reported using antibiotics other than the ones mentioned above or not using them. There was no significant difference in postoperative antibiotic use between the tertiary and secondary hospitals.

There was a slight but significant difference in the frequency of replacing the external tube that connects to the PD catheter (*P*=.04). Among the secondary hospitals, 82% (94/115) changed the connecting tube every 6 months, and 15% (17/115) did so every 3 months; this was 90% (568/631) for every 6 months and 7% (44/631) for every 3 months in the tertiary hospitals. A few centers reported replacement frequency at every 9 months (about 2%) or every 12 months (<1%) from both secondary and tertiary hospitals.

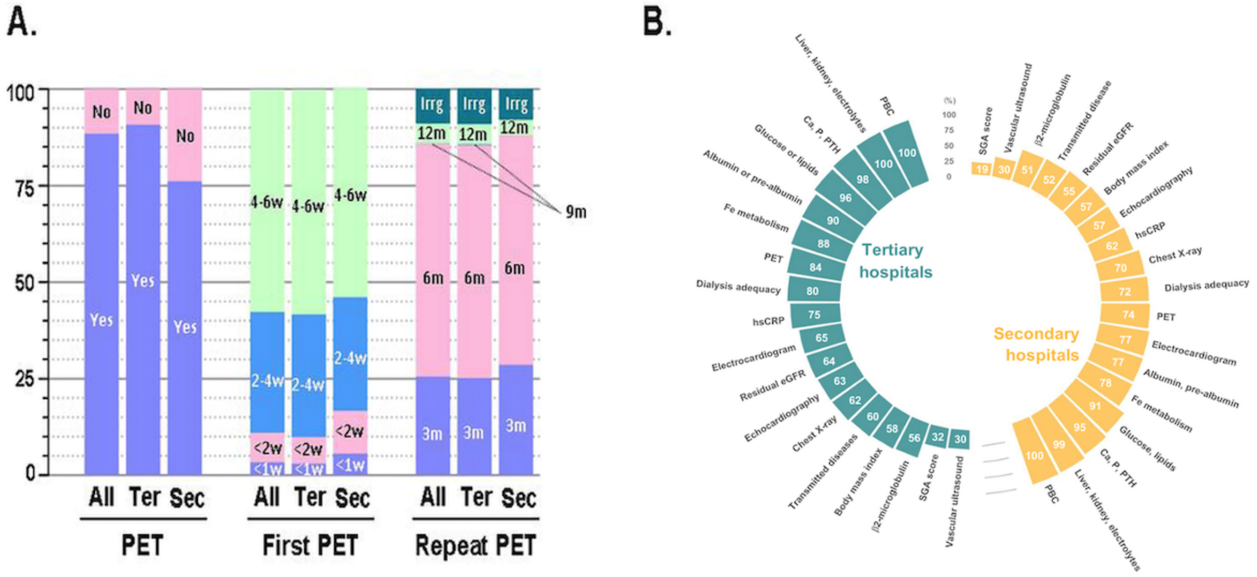
Management of PD Patient Follow-Up

The use of PET to assess the function of the peritoneum was reported in 91% (574/631) of the tertiary hospitals and 76% (87/115) of the secondary hospitals (*P*<.001; Figure 3A). Around 58% (454/788)of the first PETs were performed within 4-6 weeks after initiation of PD, and 31% (247/788) conducted the first PET between 2-4 weeks overall in tertiary and secondary hospitals. PET was repeated every 6 months in 60% (475/788) of the PD centers, and another 25%-29% (166/662 for tertiary hospitals and 36/126 for secondary hospitals) of the centers had repeat PET every 3 months (Figure 3A).

For PD long-term care, the most common follow-up interval was every month (385/788, 49%), followed by every 3 months (226/788, 29%), irregular (85/788, 11%), every 2 months (74/788, 9%), and every 6 months (18/788, 2%).

For the laboratory tests and imaging examinations, peripheral blood count was considered for each patient (788/788, 100%); blood biochemistry panel (ie, parameters for liver enzymes, kidney function, and electrolytes; 788/788, 100%); serum calcium, phosphate, intact parathyroid hormone (772/788, 98%); and glucose and lipid profiles (748/788, 95%) were routinely followed. Parameters for iron metabolism (*P*=.002), nutrition status (ie, albumin and pre-albumin; *P*<.001), and inflammation biomarker high-sensitive C-reactive protein (*P*=.003) were more likely to be followed up in the tertiary hospitals compared to the secondary hospitals (Figure 3B). Transmitted disease panel, BMI, serum β_2-macroglobulin, chest x-ray, electrocardiogram, and cardiovascular ultrasound were also checked in both tertiary and secondary centers, with checking rates ranging from 30% (236/788) to 67% (527/788). PET (*P*=.01), PD adequacy test (*P*=.06), and assessment for residual kidney function (*P*=.04) were administered more in tertiary hospitals than in secondary hospitals.

Figure 3. Follow-up Items for peritoneal dialysis. (A) Availability of peritoneal equilibrium test (PET) and the time it was performed (ter: tertiary hospital; sec: secondary hospital; w: week). (B) The follow-up items regularly applied in secondary and tertiary hospitals for patients on peritoneal dialysis. Ca: Calcium; eGFR: estimated glomerular filtration rate; Fe: Ferrum; hsCRP: high-sensitive C-reactive protein; P: Phosphorus; PBC: peripheral blood cell; PTH: parathyroid hormone; SGA: subjective global assessment.



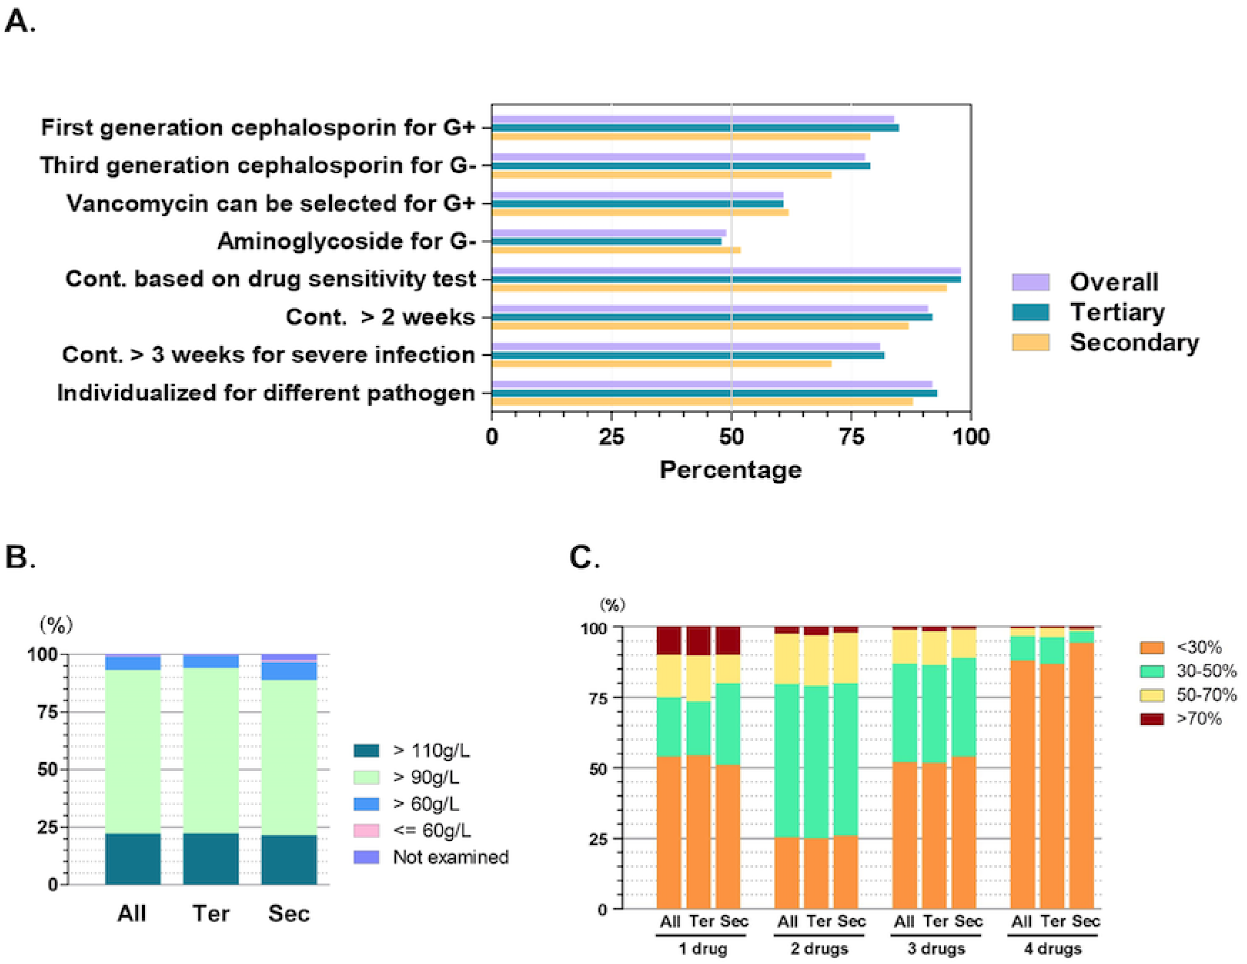
PD Complication Management

For infectious peritonitis, about 84% (659/788) of the participants chose first-generation cephalosporin for gram-positive bacteria, and 78% (612/788) chose third-generation cephalosporin for gram-negative pathogens (Figure 4A). Vancomycin was also commonly used for the treatment of gram-positive peritonitis, and aminoglycoside was used for gram-negative peritonitis. For severe infection, 29% (33/115) of the secondary hospitals did not continue antibiotic therapy longer than 3 weeks, compared to 18% (114/631) of the tertiary centers (*P*=.005). Awareness of applying drug sensitivity tests and individualized use of antibiotics was more than 92% (725/788) among the participants.

In the secondary hospitals, 89% (112/126) of the patients on PD had hemoglobin levels greater than 90 g/L, compared to 94% (623/662) of them in the tertiary centers (Figure 4B).

The majority of patients on PD took 1-3 antihypertensive drugs, with a total of 97% (764/788; 95% CI 95%-98%) of the respondents prescribing 1-3 drugs for more than 30% of the patients (Figure 4C). A combination of 2-3 antihypertensive medicines was more common than using a single drug (677/788, 86%, 95% CI 83%-88% vs 362/788, 46%, 95%CI 43%-50%; *P*<.001) or ≥4 drugs (vs 95/788, 12%, 95%CI 10%-14%; *P*<.001).

Figure 4. Complication management. (A) Antibiotic choice for peritonitis (G+: gram-positive; G–: gram-negative; Cont: continued). (B) Hemoglobin level in patients on peritoneal dialysis. (C) Number of antihypertensive drug used (ter: tertiary hospital; sec: secondary hospital).



Discussion

To our knowledge, this survey was the first nationwide study focusing on the current situation of PD management and PD practitioners' concepts and behavior in mainland China [1,12,14]. It covered about 80% of PD centers and nearly 90% of the estimated number of current patients on PD from all provincial-level areas, according to previously published registry data [9,13], as well as about 70% of PD centers and 80% of patients on PD, according to unpublished CNRDS 2021 data. The respondents who filled the survey were mostly physicians in charge of the PD centers or some chief nurses who were well knowledgeable about the PD center operations. The big number of the returned surveys and the personnel responding to the questionnaires suggested a faithful reflection of the real situations that may not be accurately captured or reported by the registries. The participating numbers of tertiary and secondary hospitals were about 20% and 1% of the total number of tertiary and secondary hospitals in mainland China, respectively, according to the 2020 China Health Care Development Statistics [4]. In this study, we reported that PD care was provided mostly by tertiary hospitals in mainland China, and about 5% of patients were managed by secondary hospitals. We found that tertiary hospitals had a more complete infrastructure of PD centers, performed more operations for PD catheter placement, treated more PD indication–related acute diseases, and conducted more assessments for peritoneal membrane characteristics and dialysis adequacy than the secondary hospitals. This study also showed that current concepts of the goals for long-term PD complication management were adequately adopted by health care providers (HCPs) in both tertiary and secondary hospitals, with a relatively similar compliance rate of the follow-up items.

Our study showed a couple of differences in PD care management between the secondary and tertiary hospitals. In the secondary hospitals, a lack of designated infrastructure for PD patient education was common, and the PD catheter placement procedure was significantly less performed. This discrepancy could be explained by the lack of clinical experience and human power as well as low financial incentive for PD catheter implantation. To overcome these barriers, it is necessary to implement a well-designed and feasible PD program for catheter implantation. Sufficient surgical training, a dedicated team and time, and protected reimbursement from payers would help to achieve this goal. Complex and more advanced PD treatment modules, such as cycler-facilitated nocturnal intermittent peritoneal dialysis or tidal peritoneal dialysis as well as a combination of hemodialysis and PD, were significantly less reported by secondary hospitals. We speculate that, along with the development of digital tools for PD patient management, more available web-based patient education resources, more use of PD cycler, and the shifting of reimbursement policy toward lower tiers of cities and health care facilities, more patients with incident dialysis will choose PD and more patients on PD will migrate to secondary and even primary health care centers for chronic PD management. In that regard, the proportion of patients on PD in rural and lower-tier facilities is expected to increase rapidly in the near future, which advocates strengthened implementation of standardized PD quality management and control at high priority.

Adequate patient follow-up scheme and good execution are necessities for quality PD care [16]. In China, a usual PD outpatient follow-up routine includes HCPs' tracking of the daily records of PD exchanges, measurement of blood pressure, prescriptions for examinations, and medication adjustment [17]. Our survey results showed that more than 85% of patients on PD were regularly followed every 1 to 3 months, and almost every patient was checked for anemia (low hemoglobin) and mineral bone markers (ie, calcium, phosphorus, and parathyroid hormone), which was similarly complied according to multiple international guidelines and recommendations [18-20]. These proportions were higher than that reported in China Kidney Disease Network 2016 Annual Data Report, which was around 90% [8]. The difference may be explained as follows: our survey covered wider regions and more patients on PD, whereas the China Kidney Disease Network Report used data sources from claim databases and included primary hospitals. Nonetheless, thanks to the continuous effort of improving health care accessibility and affordability from the government at all administrative levels, results from these 2 studies indicate that patients with ESKD are getting an adequate standard of care in mainland China.

In our survey, there were about 10% (10,150/101,537) of patients on PD whose hemoglobin level was below 90 g/L, the level at which rescue therapy for anemia should be considered [21]. These data were also similar to the data recently reported by the US Renal Data System [16]. Multiple guidelines recommend treating chronic kidney disease anemia to the hemoglobin level of 110-120 g/L [21,22] or around 110 g/L [18,19]. In our study, about 22% (175/788) of the respondents reported hemoglobin levels of their patients on PD as above 110 g/L, with no difference between the secondary and tertiary hospitals, indicating that further clinical effort may be needed to reduce the anemia burden in patients on PD. Multidrug therapy is usually required and recommended for the control of blood pressure in patients with chronic kidney disease worldwide [23-25]. In PD, antihypertensive treatment is dependent on not only the drug administration but also fluid volume control. Our study showed that 86% (87,321/101,537) of patients on PD took 2-3 antihypertensive medicines. Future studies on the relationships among blood pressure level; types of antihypertensive drugs; volume status; and other factors, such as retaining of residual kidney function, longevity of peritoneal membrane function, anemia treatment regimen, cardiovascular outcome, patient compliance, and health economics would provide guidance to improve PD outcomes as well as goal-directed value-based PD care [17,26].

Assessment for peritoneal membrane characteristics is helpful for appropriate PD prescription. International PD guidelines consistently recommended performing the first PET at 4-6 weeks after PD initiation and having it reevaluated every 6-12 months [27-30]. In our study, PET was not performed in 9% (57/631) of the tertiary hospitals and 24% (28/115) of the secondary hospitals. About 42% (334/788) of the first PETs was performed within 4 weeks after initiation of PD. Moreover, about 26% (202/788) of the respondents repeated PET every 3 months. All these indicate that Chinese HCPs use PET more frequently than those tests commonly recommended by different guidelines, suggesting that in-depth education about PET should be enhanced.

Infectious peritonitis or PD catheter–related infection is the major PD complication that affect long-term PD survival and require immediate empirical treatment with antibiotics and systemic long-term management [31,32]. In China, most participating hospitals implemented the same recommendations of the guideline of International Society for Peritoneal Dialysis [33] for the management of peritonitis in PD. Our survey revealed that 92% (726/788)of PD HCPs acknowledged the values of pathogen detections and drug sensitivity tests, continued antibiotic treatment for 2-3 weeks, and individualized antibiotic regimen for PD-related peritonitis [30,33]. For initial empirical therapy, 84% (659/788) of respondents chose first-generation cephalosporins for gram-negative pathogens, and 78% (612/788) chose third-generation cephalosporins for gram-negative pathogens. Besides the cephalosporins, vancomycin was also chosen for gram-positive pathogens by 61% (481/788) of the respondents and aminoglycoside for the gram-negative pathogens by 49% (386/788). These patterns of choice were in line with multiple guidelines or recommendations regarding PD-related peritonitis [29,30,33].

In our study, 95% (96,460/101,537) of the patients on PD were managed by tertiary hospitals, despite the fact that the number of secondary hospitals in China is about 5 times that of the tertiary hospitals. Although our survey covered a much larger PD patient population, it was likely that our data were skewed toward tertiary facilities. It is also possible that some transferring of patients on PD overlapped, and data were not completely aggregated for analysis in our study.

It is known that the quality of ESKD care is influenced by socioeconomic status and geographic regions [34]. Except for the number of responded hospitals and patients on PD, this study did not find significant regional differences in the answered items listed in the questionnaire. The dominance of patients in tertiary hospitals in this study might contribute to the diminished possible regional discrepancy because most of the tertiary hospitals similarly follow the SOP for PD, despite being from different regions. Due to the infrastructure inadequacy, there were still 13% (94/722) of the PD centers that did not have a dedicated PD reception area; 19% (137/722) had no PD training room, 22% (159/722) had no separated PD storage room, and only 41% (296/722) had their unique PD operation room. Furthermore, 9% (65/722) of PD centers had not established local SOP, and 12% (87/722) had no specific PD-related health records. These need to be improved in the future for sustainable growth of PD along with high-quality standards of care.

This study did not limit the qualification of participants from each hospital and used voluntary responses, and this could cause selection bias. In addition, disposing bias might be introduced during the process of aggregating data from the same facility. More studies on the relationship between PD clinical outcomes and hospital quality management can be more instructive for health care policy makers. Future studies addressing improved prognosis of patients on PD through strengthened measures will require longitudinal analyses using both registry and survey data.

In summary, this first national survey provided data reflecting the current status of PD center management in mainland China. It also collected HCPs' concepts for the routine practice of PD patient management. The discrepancy of PD care between the secondary and tertiary hospitals may guide future iteration of the SOP for PD and quality management, targeted HCP training for PD, as well as value-oriented patient education. To a broader extent, providing a better goal-oriented PD care would help to reduce the substantial health care costs and improve the quality of life of patients with ESKD.

Acknowledgments

The authors appreciated the efforts of all clinical practitioners who participated in this survey.

The authors would like to thank the contributions made by the study teams of the national center for health care quality management in kidney diseases: Wenhu Liu, Aili Jiang, Ying Li, Jinsheng Xu, Lihua Wang, Caili Wang, Hongli Lin, Li Yao, Lining Miao, Ping Luo, Jundong Jiao, Zhaohui Ni, Changying Xing, Jianghua Chen, Jianmei Zhou, Yi Yu, Jianxin Wan, Rong Wang, Aimin Zhong, Guohua Ding, Hong Liu, Wei Shi, Xiaomei Peng, Hong Li, Yani He, Li Wang, Yibin Yang, Zhu Zhou, Hongli Jiang, Jianqin Wang, Wenbo Hu, Menghua Chen, Jian Liu, Chen Lu, and Xiaoping Yang.

Abstract

Background: Depression escalating public health concern and the modest efficacy of currently available treatments have prompted efforts to identify modifiable risk factors associated with depression symptoms. Physical inactivity, poor nutrition, or other lifestyle behaviors are among the potentially modifiable risk factors most consistently linked with depression. Past evidence regarding the single effect of physical activity (PA) or dietary quality (DQ) on reducing the risk of depression symptoms has been well-documented. However, the association of the joint effect of PA and DQ on depression symptoms has never been investigated in a representative sample of adults.

Objective: This study investigates the association between PA and depression symptoms and between DQ and depression symptoms, and their combined effects on US adults.

Methods: Data were obtained from the National Health and Nutrition Examination Survey (NHANES) 2007 to 2018 cycles. The primary exposures were DQ and PA, measured using the Healthy Eating Index (HEI)-2015 and the metabolic equivalent (MET) minutes per week reported in questionnaires, respectively. Depression symptoms were defined as a 9-item Patient Health Questionnaire (PHQ-9) score of ≥10. We created 4 lifestyle categories: healthy diet and active individuals, unhealthy diet but active individuals, healthy diet but inactive individuals, and unhealthy diet and inactive individuals. Participants were considered to have a healthy diet if they fell within the 60th percentile of the HEI-2015 or to be active if they met the current guidelines for PA. A survey-multivariable logistic regression approach was used to model adjust the variables relevant to the associations, and an age-adjusted prevalence for depression symptoms was calculated following the NHANES guidelines.

Results: In total, 19,295 participants represented a weighted number of 932.5 million adults aged 20 to 80 years in the noninstitutionalized US population. The total age-adjusted prevalence of depression symptoms among all respondents was 7.08% (1507/19,295). Of the respondents, 81.97% (15,816/19,295) met the PA recommendation and 26.79% (5170/19,295) scored at or above the 60th percentile on the HEI-2015. Depression symptoms were inversely associated with a higher level of PA (adjusted odds ratio [AOR] 0.819, 95% CI 0.716-0.938) and healthy DQ (AOR 0.809, 95% CI 0.701-0.931), respectively. A healthy diet combined with recommended PA was associated with a significantly lower risk of depression symptoms (AOR 0.658, 95% CI 0.538-0.803) than those who consumed an unhealthy diet but were physically active (AOR 0.890, 95% CI 0.765-1.038) or consumed a healthy diet but were physically inactive (AOR 1.077, 95% CI 0.817-1.406).

Conclusions: Our findings indicate that people with a healthy diet and recommended PA have a lower risk of depression symptoms than those with an unhealthy diet and a low level of PA. A healthy dietary habit and regular PA are potential precautions against depression.

physical activity; dietary quality; depression symptom; adults; NHANES

Introduction

Depression, a major worldwide public health concern commonly characterized by low emotion, diminished interest, and decreased energy and attention, has been affecting nearly 7.2% to 9.2% of the US population, particularly adults, from 2015 to 2020 [1]. Depression will continue to affect individuals, the health care system, and the whole society if left unprevented [2]. The growing prevalence of depression poses an increasing demand for highly effective, preventative approaches. Some studies have reported potentially protective effects of dietary quality (DQ) or physical activity (PA) on depression symptoms, as well as the biological actions of nutrients or behavior, both within and beyond the context of healthy behavior [3,4]. Understanding PA and DQ is vital to intervene against depression symptom risks during adulthood, as dietary pattern, PA, and other behaviors are the major triggers determining the well-being of mental health [5].

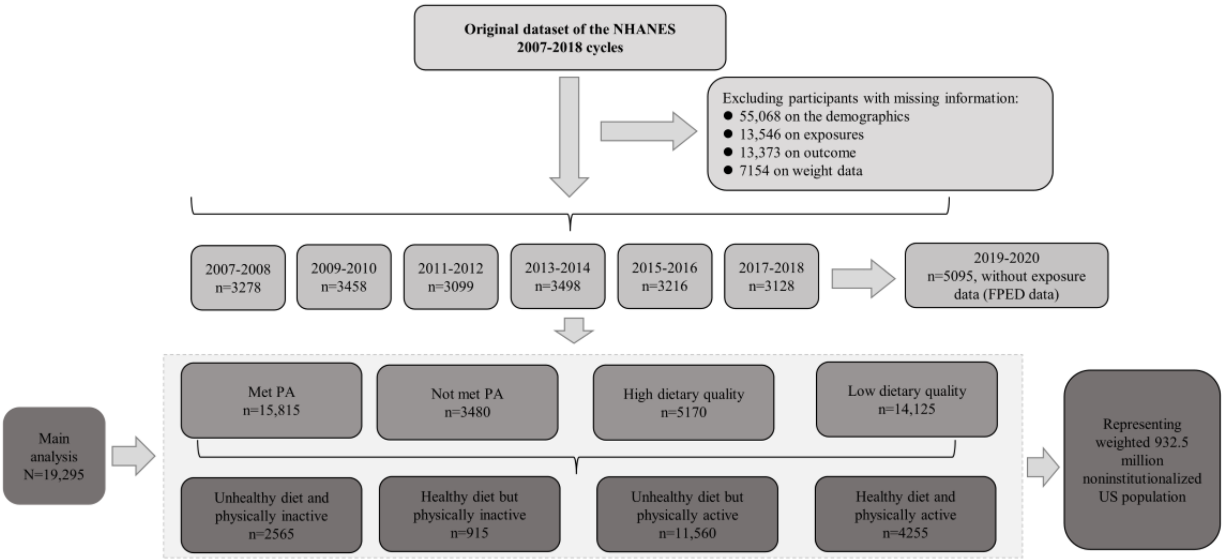
Nevertheless, robust evidence concerning the association between the single effect of DQ or PA and the prevalence of depression symptoms remains sparse and debated. For example, although PA was linked to a decreased risk of depression in several studies [6,7], these findings were not consistently replicated in another study [8]. Moreover, little is known about the combined influence of dietary behaviors and PA on depression symptoms in the US population. It can be argued that healthy diet and sufficient activity may be more effective than unhealthy diet and inactivity in promoting the mental health of adults. Nevertheless, empirical evidence for it is far from clear cut, and there exist limitations in prior related studies [9-14]. First, most previous studies simply examined isolated nutrients, such as energy intake and eating behavior, for depression symptoms, rather than the total DQ [9,10], which is a comprehensive representation of an individual's overall diet pattern. Second, the most important finding is that no studies so far have specifically targeted the association between DQ and PA and depression symptoms among the US population, except for some studies that investigated this exposure on other health indicators [11-13]. Furthermore, a few studies reported the trends for DQ with serial cross-sectional investigations using older data (updated to the year 2016) [14], but these findings need to be verified by more subsequent national data (National Health and Nutrition Examination Survey [NHANES] is updated to the 2020 cycle). Finally, as there might be no race-related information available in their studies, the impact of discrepancy on race or ethnicity on diets, which deserves more attention, was often neglected in previous studies. For example, Black people, commonly reported to have poor DQ, have the highest morbidity rates of diet-related diseases in comparison with other racial or ethnic groups in the United States [15,16]. Individual depression symptoms might be affected by lifestyle, depending on sex, age, and race, but no relevant study has examined the heterogeneity of populations. To compensate for these limitations, we sought to describe the prevalence of depression symptoms and its association with DQ and PA, considering age, race or ethnicity, sex, and sociodemographic status, among the US population using data from the continuous NHANES.

Methods

Study Design

The NHANES is an ongoing cross-sectional program conducted by the National Center for Health Statistics of the Centers for Disease Control and Prevention to investigate the public's general health-related behaviors, their socioeconomic and nutritional status, and the results of physical examinations. With a multistage, stratified probability sample selected from cities, blocks, households, and the number of people within households, the NHANES offers comprehensive data to represent the US civilian and noninstitutionalized population. The objectives, study design, and implementation of the NHANES have been introduced before [14]. The 24-hour dietary recall was administered in person by a trained interviewer using the United States Department of Agriculture automated multiple-pass method [17]. This study was conducted in accordance with the Declaration of Helsinki [18]. Flowchart of selection of NHANES participants can be found in Figure 1.

Figure 1. Flowchart of selection of National Health and Nutrition Examination Survey (NHANES) participants: unhealthy diet and physically inactive individuals (participants did not meet the US physical activity [PA] recommendation guideline and below the 60th percentile of the Healthy Eating Index [HEI]-2015 score), healthy diet but physically inactive individuals (participants did not meet the US PA recommendation guideline but at or above the 60th percentile of the HEI-2015 score), unhealthy diet but physically active individuals (participants met the US PA recommendation guideline but below the 60th percentile of the HEI-2015 score), healthy diet and physically active individuals (participants met the US PA recommendation guideline and at or above the 60th percentile of the HEI-2015 score). FPED: food patterns equivalents database.



Ethics Approval and Informed Consent

Written informed consent was obtained from all study participants, and the program was approved by the Ethics Review Board of the National Center for Health Statistics [19]. The NHANES data are free for public use and available on the web [20], so it was not necessary to obtain the agreement of the medical ethics committee board [21].

Assessment for DQ

With an interval of 3 to 10 days, two 24-hour recalls of all the food and drink consumed the day before the interview (midnight to midnight) were conducted. The Healthy Eating Index (HEI)-2015 is a comprehensive measurement of an individual's dietary pattern with overall and subcomponents scores, which adheres to the 2010 Dietary Guidelines for Americans [22]. The HEI-2015 contains 13 nutrient- and food-based components, which comprise 9 adequacy food components (total fruits, whole fruits, total vegetables, greens and beans, whole grains, dairy, total protein foods, seafood and plant proteins, and fatty acids) and 4 moderation components (refined grains, sodium, added sugars, and saturated fats). The total HEI-2015 score ranges from 0 to 100, with a higher score indicating greater overall DQ [22]. Participants whose average score of the 2 days was in or above the 60th percentile in the HEI were considered to have observed the dietary guidelines or consumed healthy foods [23].

Assessment for PA

Data were collected using the Global Physical Activity Questionnaire. Created by the World Health Organization (WHO), the Global Physical Activity Questionnaire was used to assess different domains of individuals' PA, such as leisure-time PA, occupation, and transportation PA [24,25]. In accordance with the WHO analysis guide, PA was converted to metabolic equivalent (MET) minutes of moderate to vigorous PA per week [24]. MET values vary with the type of exercise, and the NHANES offers the recommended MET values for each PA. PA was based on the MET values of type, frequency, and duration of activities per week, which was calculated using the following formula: PA (MET-min/wk) = MET × weekly frequency × duration of each PA [26]. PA=0 denotes participants who do not engage in any PA, else, it means that participants have constant or intermittent PA. The respondents were classified based on whether they met the American PA guideline (PA at moderate intensity should be done for 150 minutes [equivalent to 600 MET min/wk] a week or, at vigorous intensity, should be performed 75 min/wk for adults [27]).

Definitions of Lifestyle Groups for PA and DQ

According to previous studies [13,23], we created four lifestyle categories according to DQ and PA: (1) healthy diet and active individuals, (2) unhealthy diet but active individuals, (3) healthy diet but inactive individuals, and (4) unhealthy diet and inactive individuals. Participants were considered to have a healthy diet if they fell within the 60th percentile of the HEI or were active if they met the current guidelines for PA [13,27].

Outcome Measurements

The 9-item Patient Health Questionnaire (PHQ-9) is a brief self-report measure of depression symptoms in a primary care and research setting that has a well-established factor structure, reliability, and validity [28,29]. The range of scores for PHQ-9 is from 0 to 27, with higher scores reflecting greater severity, and a PHQ-9 score of ≥10 was recommended as the binary threshold to define the presence of depression symptoms, which has a sensitivity of 88% and a specificity of 88% for screening major depression symptoms [30].

Assessment of Covariates

According to prior research and clinical experts, potentially confounding and modifying variables were identified [31] as follow: age group (20-39, 40-59, or 60-80 years), sex (male or female), race or ethnicity (non-Hispanic White, non-Hispanic Black, Mexican American, Other races [including multiracial and other Hispanic]), the highest level of education achieved (less than 9th grade, 9th-11th grade [including 12th grade without diploma], high school graduate [general educational development or equivalent], college graduate or above, or some college or associate's degree), marital status (widowed or divorced or separated, never married, married or living with partner), poverty-to-income ratio (PIR; a family poverty index was used to estimate socioeconomic status, which is calculated by measuring the income thresholds of different types of households and updating them annually because of inflation, based on the Consumer Price Index. According to the commonly used cutoff levels for identifying eligibility for federal assistance, we classified these ratios as being either ≤100% or ≥100% of the poverty threshold, depending on whether they exceeded the poverty threshold), BMI (calculated based on the ratio of weight in kilograms to height in meters squared), smoking status (current, previous, or never), whether taking antidepressant or anxiolytic medications, sleep time (<7 h, 9 h, and >9 h), and sedentary behavior (SB; the amount of time spent sitting per day is considered SB, including sitting at a desk reading; playing cards; watching television or using a computer; sitting with friends; and traveling by car, bus, or train).

Statistical Analyses

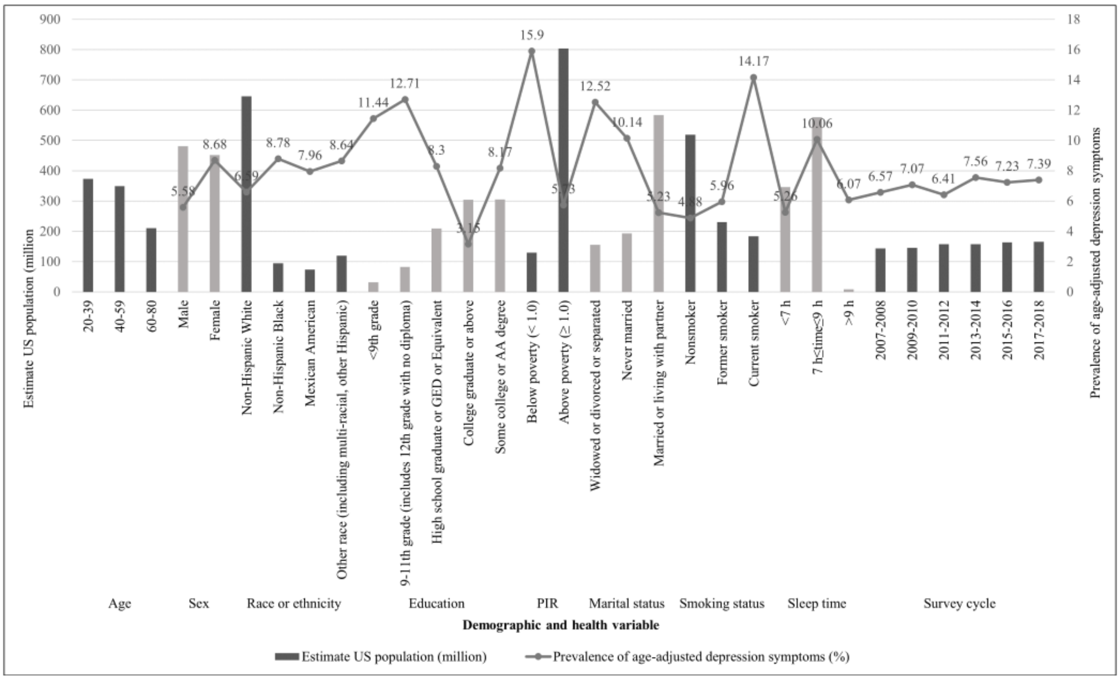
We used weighted samples and considered stratification and clustering in the design to generate nationally representative estimates that were applied to US residents [32]. The combined NHANES cycle and weights were constructed following the guidelines for continuous NHANES analyses [33]. Proportional outcome variables are presented as means (SD) with analysis of variance F and the proportional outcome variables as proportions (%) with analysis of the chi-square test to determine statistical significance by 4 groups. The estimates obtained from adjusted odds ratios (AORs) and corresponding 95% CIs were used to evaluate the associations between PA and DQ and depression symptoms. A survey-multivariable logistic regression approach was used to adjust the variables relevant to the associations. For each lifestyle group, the median values of health variables were treated as continuous variables in a multivariate linear regression model to estimate the trend between each lifestyle and depression symptom. We used 3 different models: a crude model; a model adjusted for age, sex, and race or ethnicity; and a model in which we additionally adjusted for age, sex, race or ethnicity, education, marital status, BMI, PIR, smoking status, sleep time, and SB. We also generated 3 indicators along with their 95% CI, namely, relative excess risk due to interaction (RERI), attributable proportion due to interaction (AP), and synergy index (SI), to estimate the interactive effect between PA and DQ [34,35]. The 95% CI of RERI and AP containing 0 indicates there is an additive interaction between the 2 exposures, and the greater the absolute value of RERI, the stronger the interaction between the 2 exposures (PA and DQ) [36]. For a 95% CI of SI, if it contains 1, it indicates that there exists an additive interaction between the 2 exposures (PA and DQ) simultaneously. An SI value greater than 1 indicates that the synergistic effect is enhanced when the factors were both exposures, while a value below 1 indicates that the effect of the 2 factors is weakened [36]. An age-adjusted prevalence for depression symptoms was calculated according to the NHANES guidelines [37]. To account for potential variability in the associations in terms of age, sex, and other demographic characteristics, exploratory subgroup analyses were performed with the interactions obtained, followed by sensitivity analyses after excluding individuals exposed to extreme PIR or individuals with extreme BMI values to identify the robustness of our findings. Moreover, alcohol use (former, never, and now), total energy, and whether taking antidepressant or anxiolytic medications were regarded as additional covariates to control their potential influence. The probability of the null hypothesis value (*P* value) below .05 was considered to reflect a statistically significant difference. All statistical analyses were conducted using R statistical programming language (X64 version 4.1.0; R Foundation for Statistical Computing).

Results

General Characteristics

Approximately, a weighted population of 932.5 million American residents was represented by 19,295 NHANES participants with valid data, and most of them were non-Hispanic White participants (645.6 million; Multimedia Appendix 1). Among the 19,295 respondents, 52.59% (n=10,147) were female, 44.76% (n=8637) were non-Hispanic White, 80.54% (n=15,541) had at least a high school education, and 20% (n=3859) lived in households with incomes below the federal poverty level. Overall, 81.97% (15,815/19,295) of the respondents met the PA recommendation, and 26.79% (5170/19,295) of participants scored at or above the 60th percentile on the HEI-2015. Moreover, participants with a healthy diet and regular exercise had an average HEI-2015 score of 69.32 (SD 0.19) and were active with 4476 (SD 105.15) MET minutes moderate to vigorous PA per week. In contrast, people who eat unhealthily and are inactive have an average score of 44.87 (SD 0.25) and only 316.90 (SD 4.24) minutes of moderate to vigorous PA per week. The age-adjusted prevalence of depression symptoms among respondents who did not meet the PA guidelines and had a low-quality diet was 9.51% (264/2565). In total, 4.19% (200/4255) of participants with depression symptoms in the group met the PA recommendations and had a higher DQ. The age-adjusted prevalence for another 2 groups was 7.54% (961/11,560; unhealthy diet but physically active) and 8% (82/915; healthy diet but physically inactive). We also found a relatively higher age-adjusted depression symptom prevalence in female (922/9148, 8.68%), low education participants (<9th grade: 152/1381, 11.44%; 9th-11th grade: 313/2373, 12.71%), and especially smokers (586/3982, 14.17%). Multimedia Appendix 1 and Figure 2 present the characteristics of the 19,295 US adults according to their lifestyles. The demographic characteristics and health variables of participants, both classified by depression symptom status and 6 survey cycles, are presented separately in Multimedia Appendices 2 and 3.

Figure 2. Prevalence of age-adjusted depression symptoms and estimate US population of different characteristics among US general adults, National Health and Nutrition Examination Survey 2007 to 2018. AA: Associate's Degree; GED: general educational development; PIR: poverty income ratio.



Association Between Single PA or DQ and Depression Symptoms

For the single effect of PA or DQ on depression symptoms, a statistically significant inverse relationship was found between the single PA effect and depression symptom prevalence in each model (*P*<.001; Figure 3). An inverse significant association was detected after controlling for multiple variables in the met PA guidelines group (AOR 0.817, 95% CI 0.714, 0.937; *P*=.003). Similarly, we noted a significant positive association between the single DQ effect and depression symptom prevalence: participants with a higher DQ had a lower risk of depression symptoms (AOR 0.827, 95% CI 0.716, 0.952; *P*=.009) compared with those with poor DQ (Figure 3).

Figure 3. Association between PA and dietary quality and their combined effect and prevalence of depression symptoms among 19,295 study participants. Significant results are in bold. Model 1: crude model, no covariates were adjusted; model 2: adjusted for age, sex, and race or ethnicity; model 3: adjusted for age, sex, race or ethnicity, education, marital status, BMI, poverty-to-income ratio (PIR), smoking status, sedentary behavior (SB), and sleep time. N/A: not applicable; OR: odds ratio; PA: physical activity.

Joint Association Between PA and DQ and Depression Symptoms

Regarding the joint effect of PA and DQ on depression symptoms, when comparing depression symptom prevalence between groups with different lifestyles, participants consuming a healthier diet and being more physically active had a lower risk ratio of depression symptoms of 0.670 (95% CI 0.548-0.819; *P*<.001). Participants who consumed a healthy diet but were physically inactive did not have a significantly lower risk of depression symptoms (AOR 1.076, 95% CI 0.816-1.407; *P*=.59), as well as those who consumed an unhealthy diet and were physically active (AOR 0.883, 95% CI 0.758-1.030; *P*=.13). The results regarding the additive interaction between the 2 exposures (PA and DQ) showed that the RERI and AP between PA and DQ were statistically significant (RERI=−0.052, 95% CI −2.149 to 2.044; AP=−0.078, 95% CI −3.333 to 3.177), which meant there is an additive interaction between the 2 exposures. A similar significant interactive effect of SI (SI=1.189, 95% CI 0.001-1170.880) was observed, which indicates the synergistic effect of PA and DQ is enhanced in our model (Figure 3).

Subgroup Analyses and Sensitivity Analyses

The main analysis of the lifestyle-depression symptom association based on demographic subgroups showed similar AORs within each group (Figure 4). The AORs remained significant for participants having a healthy diet and PA, who were male (AOR 0.572, 95% CI 0.404-0.806; *P*<.001), who were non-Hispanic Black (AOR 0.608, 95% CI 0.388-0.939; *P*<.05), or had a PIR above the average level (AOR 0.646, 95% CI 0.500-0.833; *P*<.001). In the sensitivity analyses for depression symptoms attributed to lifestyle exposures, after further adjusting for several potential indicators (alcohol users [former, never, and now], total energy, whether taking antidepressant or anxiolytic medications, and sleep time), the results remained similar in that DQ and PA were positively correlated with mental health (Multimedia Appendix 4).

Figure 4. Associations between exposure to different lifestyle groups and incidence of depression symptoms in stratified analyses. Significant results are in bold. The multivariable model was adjusted for age, sex, race or ethnicity, education, marital status, BMI, PIR, smoking status, SB, and sleep time. Discussion

Principal Findings

Comprising 19,295 participants with 6 waves (NHANES cycles: 2007-2018), the overall analysis indicated that lower depression symptom rates were seen in participants who either followed a healthier dietary pattern or were engaged in more PA and who both had better DQ and more PA. The association remained significant when other potential covariates were controlled for in sensitivity analyses.

The benefits of a healthy diet or PA alone for depression have been well-documented [3,38]. However, data from the latest Global Status Report on PA issued by the WHO in October 2022 showed that 27.5% of adults failed to meet the WHO's recommendation for PA that an adult should work out 150 to 300 minutes a week with moderate PA or 75 to 150 minutes a week at an aerobic intensity [27]. Consequently, among the 27.5% of adults with insufficient PA, 47% had health-related indicators of noncommunicable diseases caused by hypertension, and 43% had depression [39]. Similarly, our results also showed that 18.03% of US adult participants did not have adequate PA, as recommended by the WHO. The similarity of sample characteristics between our study and the global report makes our findings more reliable and increases their authenticity. In line with previous studies, our results showed that a single effect of PA or DQ was significantly associated with mental health [40,41]. This association is explained by the reaction of the endocannabinoid system to acute neuroendocrine stimulation and inflammation [42] and long-term brain adaptations, such as changes in neural architecture [43]. A Mendelian randomization study has investigated more than 100 potentially modifiable factors for their association with incident depression, but it only identified several modifiable risk factors for the prevention of depression, including PA-related domains and dietary [44]. PA showed a potential causal connection with depression in a large-scale genome-wide association study, which suggested more PA might help prevent depression [45].

Comparison With Prior Work

As noted earlier, there might exist a causal relationship between dietary habits and depression [44]. A comprehensive food-based diet pattern made up of multiple dietary components or food groupings, rather than single nutrients or foods, has become widespread and helps us understand health trajectories, as such dietary patterns can evaluate the interplay between nutrients and foods consumed simultaneously through a multidimensional approach with the impact of the overall diet considered [46,47]. Our findings revealed that a healthy diet was negatively associated with depression symptoms among adults by comparing their DQ. Recent studies using the same NHANES data to investigate the association between HEI and depression symptoms concluded that higher HEI scores significantly correlated with fewer depression symptoms [48]. For all age groups, a constantly optimized diet will probably offer substantial health gains, which are predicted to be larger with earlier optimization in diet [49]. The hypotheses for healthy dietary pattern are also applicable to the prevention of depression symptoms, probably because an inflammatory process can be inhibited by a high-quality diet that includes vegetables, fruits, whole grains, nuts, and legumes [50,51]. Several inflammatory markers, namely IL-1, IL-6, TNF-α, and hsCRP, have been found to be elevated in individuals with depression [52], and thus depression may be pathophysiologically underpinned by chronic inflammation. The researchers also found that people who closely followed the specific dietary patterns, such as the Dietary Approaches to Stop Hypertension (DASH) diet, Mediterranean diet, or Mediterranean-DASH Intervention for Neurodegenerative Delay diet—a newly developed one that incorporates elements from the Mediterranean and DASH diets, emphasizes plant-based food, and avoids animal-based food—tended to have lower depression risk [4,45,46]. Among the recommended diet for reducing depression risk are fruits, vegetables, legumes, wholegrain cereals, and nuts instead of unhealthy products such as fast foods, pastries, and soft drinks [53]. Despite the fact that existing evidence on DQ only discussed certain kinds of food, the healthy dietary pattern in our study is comprehensive enough to cover the aforementioned nutrients, whose potential positive impact on depression symptoms is worthy of prompt replication in larger populations [54]. As well-documented as either the single effect of diet or PA alone for preventing depression is, there are no relevant studies that have examined the effects of diet and PA as a whole on depression. PA and a reduction in certain "unhealthy" foods, such as fast foods and pastries, are widely recognized as independently protective against depression. However, these studies used self-reported PA measures and focused on a single nutrient or nutrient group rather than on the quality of the overall diet. Our study provides a new comprehensive diet pattern for depression prevention unlike previous findings focusing on single nutrients or food groups. A comprehensive DQ score captures not only individual intake levels but also higher-level interactions. Meanwhile, our results showed that PA exposure was also a recommended lifestyle. Specifically, this study emphasizes the importance of incorporating dietary behaviors into health behavior models when examining influence of PA on depression. On the basis of the most recent NHANES data (updated to the 2018 cycle) with 19,295 participants on behalf of approximately 932,548,888 US adults, the study measured health parameters for each of the 4 lifestyle groups to further demonstrate the joint benefits of adequate PA and healthy diet for depression symptoms among US adults. Furthermore, to enhance the robustness of our analyses, we have also considered a moderate number of potential confounders, such as SB, an important factor related to individual health that is independent of PA. On the basis of the findings of the integrated effect of PA and DQ on depression symptoms, we found that the risk of depression symptoms had reduced for participants who achieved the recommended PA level or consumed a healthy diet. However, when participants with different PA levels and DQ were classified into 4 lifestyle groups to examine the combined effect of PA and DQ, correlations of the 2 lifestyles (unhealthy diet but physically active and healthy diet but physically inactive) with depression symptoms (reported in Figure 3) were mild and moderate, respectively, without statistical significance. It showed that the combination of PA and DQ may be more effective than either factor alone in reducing depression symptoms. Hence, it may be hypothesized that regular PA and a healthy diet are both at work for the prevention of depression symptoms and neither can be omitted. In addition, our model has further demonstrated that there existed an additive interaction between PA and DQ, and the synergistic effect is enhanced on the improvement of depression symptoms when the recommended PA level and a healthy diet are simultaneously exposed. Such a synergistic effect may be linked to the Lifestyle Medicine (LM) preventive strategy, a multicomponent and multimodal therapeutic approach that combines nutrition, PA, and other behaviors management [55]. That the pathogenesis and progression of depression involve lifestyle determinants has been well established, although the effectiveness of these determinants in helping patients with depression is underappreciated in current first-line treatments [56]. The analysis of the integrated effect in our study agreed with the results of the meta-analysis that examined the effect of multicomponent LM interventions, which include PA, DQ, and smoking cessation, on relieving depression symptoms (nonclinical depression) among adults in comparison with the named control group [5]. This study deliberately excluded patients with clinical depression to examine the preventive effect of LM intervention on depression symptoms [5]. The results highlighted that patients with depression might benefit greatly from the LM intervention, whose potential effect in the prevention of depression symptoms may be valued by major clinical guidelines and mental health experts [57]. One meta-analysis analyzed 50 randomized controlled trials concerning LM intervention and revealed that the effect of multicomponent LM intervention on depression symptoms was greatly moderated by the number of lifestyle factors adopted [58], which was consistent with our main finding that the synergistic effect was enhanced when more lifestyle behaviors that are beneficial to depression symptoms have been involved in one's daily life. Considering that the multicomponent LM intervention could possibly be used in clinical practice of controlling depression, examining the preventative effect of this intervention on depression symptoms is therefore essential. LM may be a promising complementary treatment for depression symptoms. However, more research is needed to determine its effectiveness and applicability as an adjunct to existing first-line treatments and to understand the impact of LM interventions on different populations, such as adolescents and older adults [59]. On the basis of these findings, it is important to combine DQ and PA in national and community strategies for depression symptoms to obtain the optimal prevention effects.

Limitations

However, we acknowledge the possibility of limitations in our study that must be considered. First, PA was only measured by self-report, which is subject to recall and social desirability biases. Second, our cross-sectional study design made it difficult to establish causal links between diet and PA and depression. Nevertheless, evidence regarding the single effect of PA or a healthy diet on depression symptoms has been identified in previous Mendelian randomization studies [44,45], implying that reverse causation was less likely to occur in our study. Thus, high-quality prospective population-based studies should be conducted to verify this causal relationship. Third, as another common depression symptom population, children and adolescents are not included as they have not completed the relevant assessment concerning PA and depression symptoms. Thus, caution should be exercised when extrapolating this association in general adults to younger populations. Fourth, several potential risk factors, such as hypertension and diabetes mellitus, may also be the cause of the depression symptoms but are not considered as covariates in our study. Moreover, as our study focused on the PA pattern, we did not further explore the association between PA frequency, duration, and intensity and depression symptoms, and the dose-response relationship between them, which could be examined in a future study.

Conclusions

On the basis of the NHANES data from the 1999 to 2018 cycle, our study found that a higher level of PA incorporated with better DQ was inversely related to depression symptoms in a representative sample of the US population, which meant that participants experiencing the recommended PA level and consuming a healthy diet together enhance the synergistic effect on depression symptoms. Therefore, our findings help identify the elements of specific lifestyles that are effective for the prevention of depression symptoms and offer useful reference for decision makers to start relevant preventive programs and promote them to the public.

Abstract

Background: In some countries, including Japan—the leading country in terms of longevity, life expectancy has been increasing; meanwhile, healthy life years have not kept pace, necessitating an effective health policy to narrow the gap.

Objective: The aim of this study is to develop a prediction model for healthy life years without activity limitations and deploy the model in a health policy to prolong healthy life years.

Methods: The Comprehensive Survey of Living Conditions, a cross-sectional national survey of Japan, was conducted by the Japanese Ministry of Health, Labour and Welfare in 2013, 2016, and 2019. The data from 1,537,773 responders were used for modelling using machine learning. All participants were randomly split into training (n=1,383,995, 90%,) and test (n=153,778, 10%) subsets. Extreme gradient boosting classifier was implemented. Activity limitations were set as the target. Age, sex, and 40 types of diseases or injuries were included as features. Healthy life years without activity limitations were calculated by incorporating the predicted prevalence rate of activity limitations in a life table. For the wide utility of the model in individuals, we developed an application tool for the model.

Results: In the groups without (n=1,329,901) and with (n=207,872) activity limitations, the median age was 47 (IQR 30-64) and 69 (IQR 54-80) years, respectively (*P*<.001); female sex comprised 51.3% (n=681,794) in the group without activity limitations and 56.9% (n=118,339) in the group with activity limitations (*P*<.001). A total of 42 features were included in the feature set. Age had the highest impact on model accuracy, followed by depression or other mental diseases; back pain; bone fracture; other neurological disorders, pain, or paralysis; stroke, cerebral hemorrhage, or infarction; arthritis; Parkinson disease; dementia; and other injuries or burns. The model exhibited high performance with an area under the receiver operating characteristic curve of 0.846 (95% CI 0.842-0.849) with exact calibration for the average probability and fraction of positives. The prediction results were consistent with the observed values of healthy life years for both sexes in each year (range of difference between predictive and observed values: −0.89 to 0.16 in male and 0.61 to 1.23 in female respondents). We applied the prediction model to a regional health policy to prolong healthy life years by adjusting the representative predictors to a target prevalence rate. Additionally, we presented the health condition without activity limitations index, followed by the application development for individual health promotion.

Conclusions: The prediction model will enable national or regional governments to establish an effective health promotion policy for risk prevention at the population and individual levels to prolong healthy life years. Further investigation is needed to validate the model’s adaptability to various ethnicities and, in particular, to countries where the population exhibits a short life span.

Introduction

Global public health, secure social systems, and advances in medical practice have contributed to the extension of life expectancy and healthy life years (referred to as the healthy life expectancy) of humans worldwide. With the growing recognition of the importance of taking into account the state of being alive or quality of life, "healthy life years" has come to be focused on as an integrated health indicator that combines not only mortality data but also data on the state of being alive. Healthy life years are not merely defined as life without disability or illness but include a holistic life of well-being. Although life expectancy has been increasing, healthy life years have not yet been kept pace, necessitating an effective health policy to narrow the gap [1,2].

There have been several measures to estimate healthy life years, which are used to evaluate national or regional health status. The World Health Organization has used the health-adjusted life expectancy, a measure of healthy life years based on a specialized health survey producing disability weight on various diseases, injuries, and sequelae [3-5]. In some countries, including Japan—the leading country in terms of longevity, a national survey is conducted to investigate healthy life years using a questionnaire for the presence of activity limitations.

To date, some determinants of healthy life years and the relevant activity limitations have been identified. Typical risk factors, such as obesity, hypertension, hyperglycemia, smoking, and excessive alcohol consumption, are negatively associated with a healthy life [6,7]. Physical activity and exercise [8-11] as well as a diverse healthy diet [12,13] are expected to prolong healthy life years. In addition to fatal diseases, several nonfatal conditions, such as mental health disorders, musculoskeletal problems, and ophthalmic diseases, are also crucial determinants of activity limitations [10,14,15].

Despite the increasing interest in a healthy life for public health campaign and individual health awareness, a prediction model of healthy life years with integrated features has not been reported. In this study, we sought to develop a prediction model for healthy life years without activity limitations using machine learning and to deploy the model to a health policy in prolonging healthy life years at the population and individual levels.

Methods

Data Description

The Comprehensive Survey of Living Conditions, a cross-sectional national survey, is conducted every 3 years by the Japanese Ministry of Health, Labour and Welfare to investigate the fundamental aspects of the nation's livelihood, such as health, medical care, welfare, pension, and income [16]. In health questionnaire of the Comprehensive Survey of Living Conditions, subjective symptoms, health problems in daily life, disease or injury under treatment, subjective health assessment, worries and stress, mental state, and receiving rate of health check-ups are surveyed. The response rate in 2019 was 72.5% according to the Japanese Ministry of Health, Labour and Welfare. Among the data in 2013, 2016, and 2019, data from 1,537,773 responders were used for the analysis. The activity limitations of responders were evaluated using responses to the questions, "Do you have any health problem which limits your daily activity?" Respondents who answered "yes" were categorized as the "activity limitations" group, and those who answered "no" were categorized into the "no activity limitation" group. Activity limitations, age, sex, and the 40 types of diseases or injuries under treatment were included in the analysis.

Model Description

The activity limitations, which were classified as binary, were set as model target; the "activity limitations" group was classified as 1, and the "no activity limitation" group as 0. Age, sex, and the 40 types of diseases or injuries under treatment were included as features. We implemented the extreme gradient boosting (XGB) classifier—a widely used supervised tree-based model, which uses labeled data sets to train a model [17-19]—for the binary classification of activity limitations using the scikit-learn 1.1.1 package [20] in Python 3.10.4. Using the "*train_test_split*" function, we randomly split the data set into training (n=1,383,995, 90%) and test (n=153,778, 10%) subsets [21,22]. We selected the best feature set using the recursive feature elimination function in the training data set, with the XGB classifier as an estimator. To determine the best hyperparameter values providing the highest model performance, we used *the GridSearchCV* function for training subset with the five-fold cross validation. A total of 480 XGB models were compared using different combinations of hyperparameters. Consequently, we selected a model with hyperparameters (n_estimators=200, max_depth=9, eta=0.1, min_child_weight=2, max_delta_step=5, and subsample=0.5) yielding the highest area under the receiver operating characteristic curve (AUROC). Finally, the model performance was evaluated for the test subsets.

The impact of the features on the model accuracy was estimated by permutation importance, which is defined as difference of error when a feature value is randomly shuffled, assigning 1.0 to the highest impact. The SHapley Additive exPlanations (SHAP) value, which explains a feature contribution on model output in each sample, was used to evaluate the effect of features on the model output [23]. We calculated the area under the curve and log loss, a measure of how close predictive probability is to observed value, as the model accuracy metrics for the XGB classifier, random forest, and logistic regression. Other metrics were calculated based on the confusion matrix. We used *calibration_curve* function for the model calibration between predictive probability and fraction of positives, dividing samples into 10 bins according to predictive probability. Cost-benefit was calculated to determine the optimal cut-off of prediction by the sum of true positive and true negative as 0, false positive as +1, and false negative as −1 in the confusion matrix. Healthy life years without activity limitations of female respondents in Kyoto Prefecture were predicted using the prediction model with the original and target prevalence rates of the representative diseases, which are much higher than the mean prevalence rates in the whole country. Random sampling was performed for populations with each disease to achieve target prevalence rate. The web-based application tool for the model was developed on a web application platform based on the programming code [24].

Statistical Analysis

General descriptive statistics were performed in R (version 4.2.0; R Core Team) [25]. Categorical values are represented as numbers (along with percentages), and numerical values are represented as medians (IQRs). The chi-square test was used for categorical values, and the Mann-Whitney *U* test was used for continuous values with a nonparametric distribution. *P*<.01 was considered statistically significant. The health condition without activity limitation (HCAL) index was calculated by subtracting the percentage of predictive probability for activity limitations from 100. Curve fitting was performed using third-order polynomial regression. Healthy life years without activity limitation were calculated using Sullivan's method, which is widely used to calculate life expectancy based on age-stratified mortality rate and life table, incorporating the prevalence rate of activity limitations to a life table in Japan [26,27].

Ethical Considerations

The study was approved by the ethics committee of Kyoto Prefectural University of Medicine (approval number ERB-C-2496). This study conformed to the principles outlined in the Declaration of Helsinki. Since this study used only existing national survey data, opt-out decline was adopted for participants on the university website instead of informed consent. The study data are anonymous. There was no compensation for participants.

Results

Participant Characteristics

The characteristics of participants (N=1,537,773) are described and stratified according to the presence of activity limitations (Table 1). In the groups without (n=1,329,901) and with activity limitations (n=207,872), the median age was 47 (IQR 30-64) and 69 (IQR 54-80) years, respectively (*P*<.001), and female sex comprised 51.3% (n=681,79) of the participants in the group without activity limitations (vs n=118,339, 56.9%; *P*<.001). Diseases under treatment, except for infertility, were also significantly different between the two groups (depression or other mental disease: n=13,727, 1% vs n=15,347, 7.4%; dementia: n=2420, 0.2% vs n=8667, 4.2%; stroke, cerebral hemorrhage, or infarction: n=8452, 0.6% vs n=10,818, 5.2%; angina or myocardial infarction: n=16,467, 1.2% vs n=13,043, 6.3%; rheumatoid arthritis: n=5153, 0.4% vs n=6239, 3%; arthritis: n=15,682, 1.2% vs n=19,753, 9.5%; back pain: n=42,856, 3.2% vs n=37,980, 18.3%; kidney disease: n=7415, 0.6% vs n=7866, 3.8%; malignant neoplasm or cancer: n=7594, 0.6% vs n=6249, 3%). All participants (N=1,537,773) were randomly split into training (n=1,383,995, 90%) and test (n=153,778, 10%) subsets with similar characteristics (Table S1 in Multimedia Appendix 1).

Table 1. Characteristics of participants stratified by presence of activity limitations.

Characteristics	All (N=1,537,773)	Without activity limitation (n=1,329,901)	With activity limitation (n=207,872)	*P* value

Model Performance Evaluation

To create the model feature set, the AUROC was compared for each feature number. A total of 42 features were included in the feature set because they had the highest AUROC (Figure S1 in Multimedia Appendix 1). The feature impact estimated by permutation importance showed that age had the highest impact on model accuracy, followed by depression or other mental diseases; back pain; bone fracture; other neurological disorders, pain, or paralysis; stroke, cerebral hemorrhage, or infarction; arthritis; Parkinson disease; dementia; and other injuries or burns (Figure 1).

The accuracy metrics were compared for some learners. We selected the XGB classifier as a learner because it exhibited a high AUORC and low log loss compared with random forest and logistic regression (Table S2 in Multimedia Appendix 1). The model performance was evaluated by depicting the receiver operating characteristic curve, and the AUROC was 0.846 (95% CI 0.842-0.849; Figure 2A). The calibration plot exhibited exact calibration for the average probability and fraction of positives (Figure 2B). We set the cut-off of 0.31 according to the lowest absolute value of the mean cost-benefit (Figure 2C). The prediction results were consistent with the observed values of healthy life years for both sexes in each year (range of difference between predictive and observed value: −0.89 to 0.16 in male and 0.61 to 1.23 in female respondents; Figure 2D). Thus, the developed model exhibited a markedly high performance in predicting healthy life years without activity limitations.

Figure 1. Feature impact estimated by permutation importance. Permutation importance was calculated for features using test data.

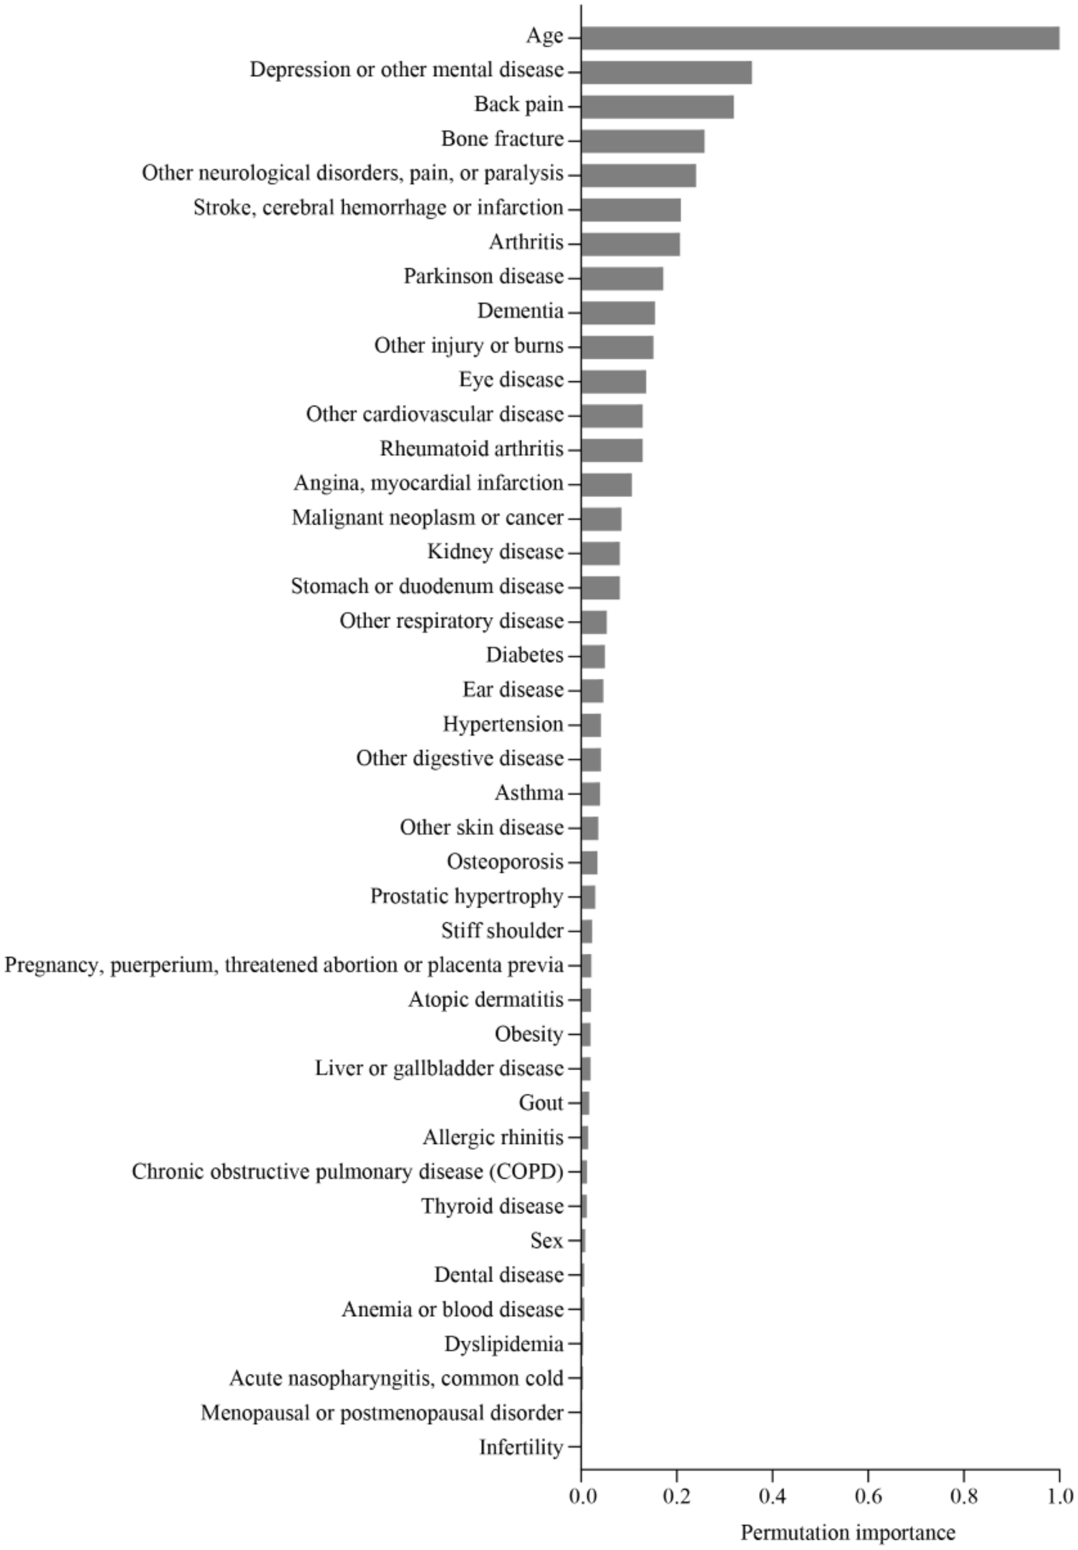

Figure 2. Evaluation of model performance. (A) Receiver operating characteristic curve for the model. Area under the receiver operating characteristic curve was 0.846 (95% CI 0.842-0.849). (B) Calibration plot for the model; samples were divided into 10 bins according to probability. (C) Mean cost-benefit curve. (D) Predictive and observed value of healthy life years for male and female respondents in each year.

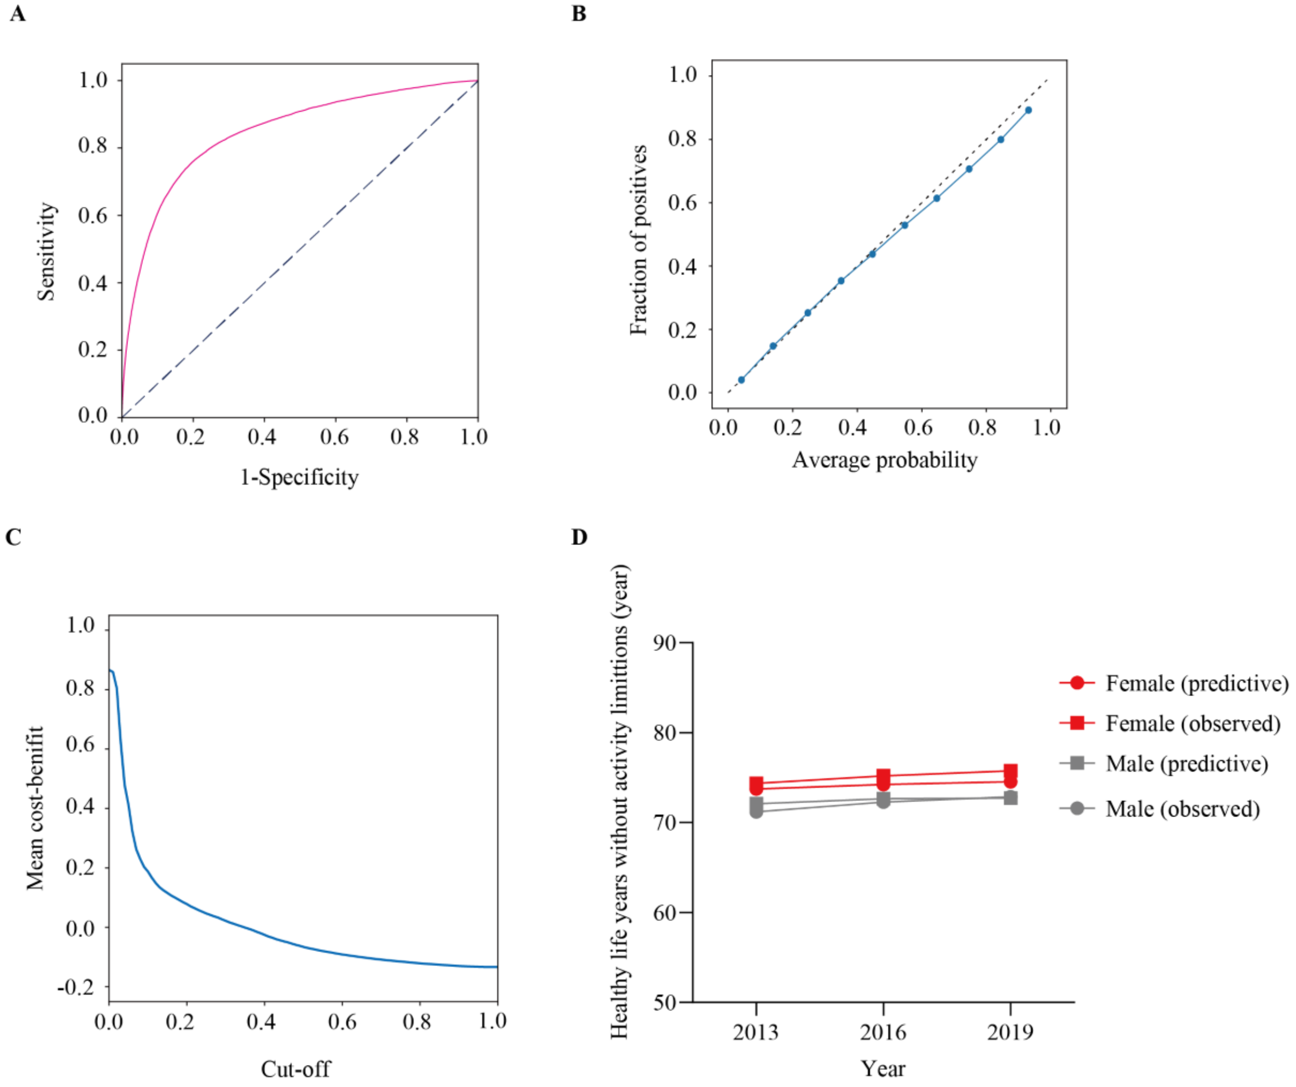

Model Application for Population and Individual Health

For model application at the population level, we used the prediction model for a regional health policy regarding healthy life years (Table S3 in Multimedia Appendix 1). Healthy life years without activity limitations of females in Kyoto prefecture in Japan were predicted using the prediction model with the original and target prevalence rates of representative predictors, such as depression or other mental diseases, back pain, and stiff shoulder. As a result, healthy life years without activity limitations were simulated to be prolonged from 73.25 in the original to 73.81 in the target, a difference of 0.56. Herein, we demonstrate the use of a prediction model for a regional health policy to prolong healthy life years at the population level.

To enhance the interpretability of the feature effect on the model output, the SHAP value is displayed for each feature (Figure 3). This shows that age has the greatest effect on model output. HCAL index was decreased by aging (Figure 4). For the wide utility of the model in individuals, we developed a web-based application tool to display the HCAL index (Figure S2 in Multimedia Appendix 1).

Figure 3. Feature effect on model output. SHapley Additive exPlanations (SHAP) value was calculated for features using test data.

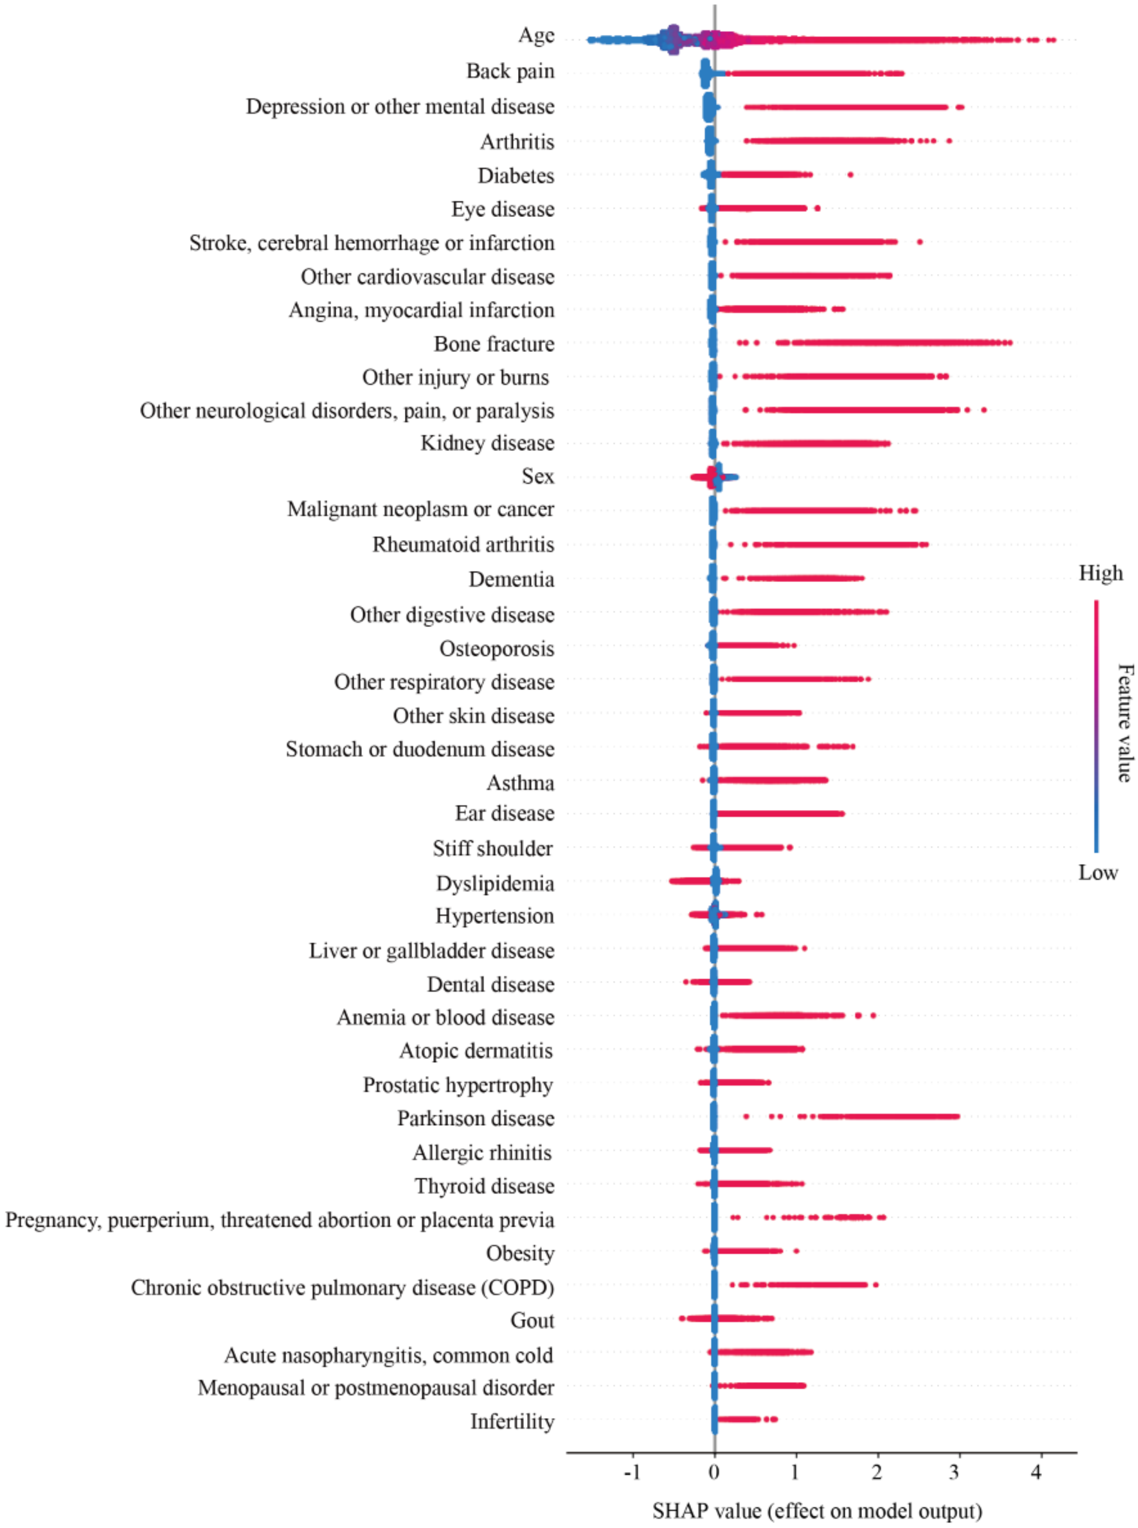

Figure 4. Health condition without activity limitation (HCAL) per age. The HCAL index indicates subtraction of the percentage of predictive probability from 100. Curve fitting was done using third-order polynomial regression. Error bar indicates 95% CI. Each dot represents mean HCAL index per age.

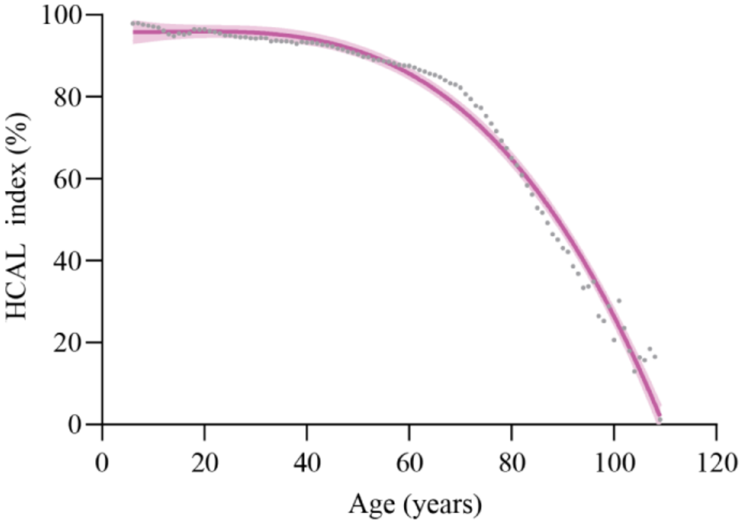

Discussion

Principal Findings

In this study, we developed a prediction model for healthy life years without activity limitations using machine learning by analyzing a cross-sectional national survey. The model exhibited markedly high performance with a high AUROC and subtle differences between the observed and predicted values of healthy life years without activity limitations. We applied the prediction model to a regional health policy to prolong healthy life years by adjusting the representative predictors to a target prevalence rate. Additionally, we presented the HCAL index, followed by the application development, for individual health promotion.

We estimated the feature impact on model accuracy by permutation importance and the effect on model output by the SHAP value. The impact of features on model accuracy showed that age had the highest impact, followed by depression or other mental disease; back pain; bone fracture; other neurological disorders, pain, or paralysis; stroke, cerebral hemorrhage, or infarction; arthritis; Parkinson disease; dementia; other injuries or burns. Interestingly, the high-impact features included several nonfatal conditions, such as mental disorders, musculoskeletal problems, and neurological diseases. Our findings were consistent with previous reports that suggest mental health disorders and musculoskeletal problems are crucial predictive factors for activity limitations [10,15]. Of mental disorders, schizophrenia and major depression have heavy disability weight according to the Global Burden of Disease Study [3]. A study using data from the Global Burden of Disease Study found no association between health output and common health system per prefecture in Japan [28]. These findings indicate that healthy life years without activity limitations largely rely on mental, musculoskeletal, or neurological causes rather than other typical lifestyle-related factors.

We leveraged machine learning to predict healthy life years without activity limitations. The presence of activity limitations assessed by a subjective questionnaire was used for the model target; nonetheless, healthy life years could be predicted accurately with the objective 42 features using machine learning. Machine learning facilitated model deployment by application development at the population and individual levels. Natural language processing has been applied to calculate the health-adjusted life expectancy using electronic medical records [29]. Machine learning combined with natural language processing for electronic medical records will provide a solution for global health issues regarding healthy life years.

We demonstrated the model application for population and individual health. Healthy life years without activity limitations of females in Kyoto prefecture were simulated using the prediction model with the original and target prevalence rates of representative predictors. Thus, the model could be used to present effective ways to prolong healthy life years for a regional health policy. Moreover, the application tool was developed using the model for wide utility in individual health promotion. The tool can be used in several situations, such as health check, patient education, and outpatient clinics. Our model was developed with machine learning and can be used for prediction of population-level healthy life years as well as individual health conditions, increasing its feasibility compared with other measures for healthy life years.

Limitations

This study had certain limitations, as it was based on a survey that included subjective data, and only data from Japan were used. Further investigation is needed to validate the model's adaptability to various ethnicities and, in particular, countries where the population has a short life span. For complexity of machine learning to explain and interpret, we used permutation importance and SHAP values for feature impact.

Conclusions

In conclusion, we developed a prediction model for healthy life years without activity limitations, using machine learning. The prediction model will enable the national or regional government to establish an effective health promotion policy for risk prevention at the population and individual levels to prolong healthy life years. It would be interesting to investigate the model's applicability to other countries and ethnicities.

Abstract

Background: Multimorbidity causes substantial disease and economic burdens on individuals and the health care system.

Objective: This study aimed to explore the disease burden of multimorbidity and the potential correlations among chronic noncommunicable diseases (NCDs) in a rural population in Henan, China.

Methods: A cross-sectional analysis was performed using the baseline survey of the Henan Rural Cohort Study. Multimorbidity was defined as the simultaneous occurrence of at least two NCDs in a participant. This study examined the multimorbidity pattern of 6 NCDs, including hypertension, dyslipidemia, type 2 diabetes mellitus, coronary heart disease, stroke, and hyperuricemia.

Results: From July 2015 to September 2017, a total of 38,807 participants (aged 18-79 years; 15,354 men and 23,453 women) were included in this study. The overall population prevalence of multimorbidity was 28.1% (10,899/38,807), and the multimorbidity of hypertension and dyslipidemia was the most common (8.1%, 3153/38,807). Aging, higher BMI, and unfavorable lifestyles were significantly associated with a higher risk of multimorbidity (multinomial logistic regression, all $P<.05$). The analysis of the mean age at diagnosis suggested a cascade of interrelated NCDs and their accumulation over time. Compared with participants without 2 conditional NCDs, participants with 1 conditional NCD would have higher odds of another NCD (1.2-2.5; all $P<.05$), and those with 2 conditional NCDs would elevate the odds of the third NCD to 1.4-3.5 (binary logistic regression, all $P<.05$).

Conclusions: Our findings indicate a plausible tendency for the coexistence and accumulation of NCDs in a rural population in Henan, China. Early prevention of multimorbidity is essential to reduce the NCD burden in the rural population.

KEYWORDS

multimorbidity; prevalence; associating factors; noncommunicable disease accumulation; NCD accumulation; public health

Introduction

Multimorbidity is the coexistence of multiple disease conditions over time. Many of these conditions shared similar age-associated structural, physiologic, and biological changes in predispose patients with multimorbidity, resulting in compound risks and adversities [1-4]. The occurrence of multimorbidity is often a powerful predictor of poor health outcomes in the future. Recent studies have demonstrated that people with multimorbidity were at significantly increased risks of depression, disability, and premature death. The physiological interaction between multiple disease conditions increases the difficulty of treating individual conditions [5]. Multimorbidity often leads to a substantial financial burden on individuals, families, and the health care system [6-10].

In China, this prevalence ranged from 6.4% to 76.5%, as reported in 2015 [11]. Previous studies have reported that aging, physical inactivity, and higher BMI were contributors to noncommunicable diseases (NCDs) and their multimorbidity [12]. However, as the study population and the targeted NCDs varied, the prevalence and associating factors of multimorbidity also substantially varied across different studies [11-13]. Further, in China, most studies have focused on older adults and were conducted among the community-dwelling population [14,15], whereas research on multimorbidity in rural adults remains limited. With an aging population and high levels of risk factors, multimorbidity is becoming a public health issue in China. However, understanding the trend and characteristics of the coexistence and accumulation of NCDs is limited.

The United States has emphasized the importance of timely diagnosis of multiple NCDs to support the development of effective clinical guidelines for multimorbidity [16]. In addition, previous studies found that NCDs can mutually interact with each other [17-22]. However, to our knowledge, the study of the accumulation of NCDs based on the temporal sequence of NCD onset was limited. A better understanding of the accumulation of NCDs can help explore complex interactions between NCDs and develop interventions for managing multimorbidity to diminish the public health burden.

Our study aimed to explore the disease burden of multimorbidity and determine the pattern of NCD accumulation among rural adults in Henan, China. We recruited 39,259 participants aged 18-79 years in Henan province for this study.

Methods

Study Population

The baseline survey of the Henan Rural Cohort Study enrolled a total of 39,259 participants aged from 18 to 79 years between July 2015 and September 2017 in the counties of Yuzhou, Xinxiang, Tongxu, Yima, and Suiping in Henan Province by using the stratified cluster sampling method. Detail description of the cohort had been previously published [23]. In this study, participants were excluded if they (1) had cancer or renal failure (n=350; for abnormal metabolism [protein, glucose, and lipid]) [24,25] or (2) did not have complete NCD information on hypertension, dyslipidemia, type 2 diabetes mellitus (T2DM), coronary heart disease (CHD), stroke, or hyperuricemia (n=102). Ultimately, 38,807 participants were included in this study (see the study flowchart about the data process in Multimedia Appendix 1).

Ethics Approval

This study was approved by the Zhengzhou University Life Science Ethics Committee (ethics approval 2015 MEC [S128]). Informed consent was signed by all participants.

Data Collection and Measurements

Information was collected through face-to-face interviews using a standardized questionnaire. Demographic characteristics included age (18-44, 45-59, and ≥60 years, according to the classification provided by the World Health Organization [WHO] [26]), gender, educational level (elementary school or below, junior high school, and senior high school or above), marital status (married or cohabiting and living alone), and average monthly individual income (<500 RMB [<US $72.4], 500-1000 RMB [US $72.4-144.8], and ≥1000 RMB [≥US $144.8], according to the average monthly income of Chinese rural populations [27]). Lifestyle factors included smoking status (never, former, and current), drinking status (never, former, and current), and physical activity (low, moderate, and high) [28]. Dietary status included vegetable and fruit intake (low [<500 g/day] and high [≥500 g/day]), salt diet (low and high according to dietary flavor habits), and fat diet (low [<75 g/day] and high [≥75 g/day] according to an average taking of meat from livestock and poultry). Family history of hypertension, dyslipidemia, diabetes, CHD, stroke, and gout were also recorded.

BMI was calculated as weight in kilograms divided by height in meters squared, and further categorized as underweight (<18.5 kg/m^2), normal (18.5-23.9 kg/m^2), overweight (24.0-27.9 kg/m^2), and obesity (≥28.0 kg/m^2) [29]. Systolic blood pressure and diastolic blood pressure were obtained by using an electronic sphygmomanometer (HEM-770afuzzy, Omron). Venous blood samples were obtained from individuals after at least eight hours of overnight fasting. Total cholesterol, triglyceride, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, fasting blood glucose, and serum uric acid (SUA) level were measured by a chemistry analyzer (Cobas C501, Roche Diagnostics GmbH).

Definitions of NCDs and Multimorbidity

In light of the lack of a standard approach to measure multimorbidity, the selection of morbidities to be included is inevitably subjective and relies on the previous studies. We have selected 6 NCDs—hypertension, dyslipidemia, T2DM, CHD, stroke, and hyperuricemia—that have been reported to be the core diseases in multimorbidity studies [30,31]. These 6 NCDs have been defined in our original survey for the cohort [23]. The definition of hypertension was average systolic blood pressure ≥140 mm Hg, diastolic blood pressure ≥90 mm Hg, or self-reported hypertension diagnosed by a physician and receiving antihypertensive therapy within the past 2 weeks [32]. Dyslipidemia was defined as one of the following conditions: elevated total cholesterol level (≥6.2 mmol/L); elevated low-density lipoprotein cholesterol (≥4.1 mmol/L); low high-density lipoprotein cholesterol (<1.0 mmol/L); elevated triglyceride (≥2.3 mmol/L); or self-reported dyslipidemia diagnosed by a physician and the use of anti-dyslipidemia medications in the past 2 weeks [33]. T2DM was defined as fasting blood glucose ≥7.0 mmol/L or self-reported T2DM diagnosed by a physician and the use of antidiabetic medications in the past 2 weeks [33]. CHD and stroke were defined as self-reports of a previous diagnosis by specialist physicians according to criteria recommended by the WHO [34,35]. The definition of hyperuricemia was SUA >7.0 mg/dL (417.0 μmol/L) in men and SUA >6.0 mg/dL (357.0 μmol/L) in women. Multimorbidity was defined as the simultaneous occurrence of at least two NCDs in a single patient [36-39].

Statistical Analysis

The participants were divided into healthy individuals, individuals living with 1 NCD, those with multimorbidities of 2 NCDs, and those with multimorbidities of ≥3 NCDs. Continuous variables were expressed as mean (SD), and ANOVA was used for statistical analysis. Categorical variables were presented as counts and percentages, and the chi-square test was used for statistical analysis.

The prevalence of multimorbidity was assessed for each characteristic group, and we quantified the number of events for each NCD separately and visualized all observed combinations of NCDs with an intersection diagram. Multinomial logistic regression analysis was used to analyze the relationship between demographic factors, lifestyle, BMI, or family history of NCDs and 1 NCD or multimorbidity. When one factor was analyzed, all other factors were adjusted as covariance.

Based on the mean age at diagnosis, the temporal order of NCDs was determined, and binary logistic regression was used to explore the associations between NCD pairs. An NCD with an earlier onset was regarded as a predictor of an NCD with a later onset [40]. Following the cascade of NCD onset, binary logistic regression was used to assess the combined association of 2 conditional NCDs with a third, later NCD by creating a new combined variable with 4 groups of both conditional NCDs, in which the combined group without both conditional NCDs served as the reference. Demographic characteristics, lifestyle factors, dietary status, BMI, and family history of NCDs were adjusted in the regression models. In addition, in the regression of assessing the combined association, when 3 of the conditions were analyzed, the others were adjusted.

Results from the logistic regression models were presented as odds ratio (OR) with a 95% CI. The level of statistical significance was set at *P*<.05. Statistical analysis was conducted using SPSS (version 21.0; IBM Corp) and R (version 4.0.4; R Foundation for Statistical Computing).

Our study was implemented according to the Strengthening of the Reporting of Observational Studies in Epidemiology (STROBE) guidelines [41] (see the study STROBE checklist for cross-sectional studies in Multimedia Appendix 2).

Results

Characteristics of Study Participants

Table 1 showed the characteristics of the participants of the baseline survey from July 2015 to September 2017. The mean age was 55.6 (SD 12.2) years among the 38,807 participants. Across the NCD groups, age, gender, educational level, average monthly individual income, marital status, physical activity, smoking status, drinking status, high-salt diet, high vegetable and fruit intake, high-fat diet, and BMI were all significantly different (ANOVA and chi-square test, all *P* values were <.001, except high-salt diet [*P*=.008]). Compared with the healthy individuals, participant groups with 1, 2, or 3 or more NCDs were more likely to be older and women and have lower education and income, higher BMI, poorer marital status, a higher-salt diet, and lower physical activity level (ANOVA and chi-square test, all *P*<.001). They were also less likely to have a high-fat diet and adequate fruit and vegetable intake than healthy individuals (chi-square test, all *P*<.001).

[a] NCD: noncommunicable disease.

Prevalence of NCDs and Their Multimorbidities

Among all participants, 33.5% (12,990/38,807) were living with 1 NCD, among which dyslipidemia was the most common (5858/38,807, 15.1%). In contrast, 18.8% (7285/38,807) of participants were living with 2 NCDs, and the most frequent cluster of NCDs was dyslipidemia and hypertension (3153/38,807, 8.1%). Moreover, 9.3% (3614/38,807) of participants were living with 3 or more NCDs, and the cluster of dyslipidemia, hypertension, and hyperuricemia (818/38,807, 2.1%) was the most common in participants (Figure 1 and Table 2).

Overall, the prevalence of multimorbidity (2 or ≥3 NCDs) was 28.1% (10,899/38,807), and it was significantly higher in participants who were aged over 60 years (1330/3982, 36%), men (4621/15,354, 30.1%), educated in elementary school or below (5585/17,366, 32.2%), living alone (1330/3982, 33.4%), had low physical activity (4286/12,544, 34.2%), and obese (3280/6878, 47.7%; chi-square test, all *P*<.001; Table 2).

Figure 1. NCDs multimorbidity. The left panel displayed bars for each NCD separately that quantify the total number of events per disease, and the line chart showed the cumulative prevalence of NCDs. CHD: coronary heart disease; DYS: dyslipidemia; HTN: hypertension; HUA: hyperuricemia; NCDs: noncommunicable diseases; T2DM: type 2 diabetes mellitus.

[a] CHD: coronary heart disease.

Associating Factors of Multimorbidity

Overall, participants with older age (all *P*<.001), those who are living alone (*P*<.001 and *P*=.007), those who are overweight and obese (all *P*<.001), former drinkers (all *P*<.001), current drinkers (*P*=.006 and *P*=.047), and those with a history of family hypertension and diabetes (all *P*<.001) were at a significantly higher risk of multimorbidity (2 or ≥3 NCDs, respectively; multinomial logistic regression). Although women (all *P*<.001) and participants with moderate and high physical activity (all *P*<.001), high-fat diet (*P*=.004 and *P*=.008), and who are underweight (all *P*<.001) were less likely to report multimorbidity (2 or ≥3 NCDs, respectively), individuals who currently smoke were less likely to report multimorbidity (≥3 NCDs; multinomial logistic regression, *P*<.001; Table 3).

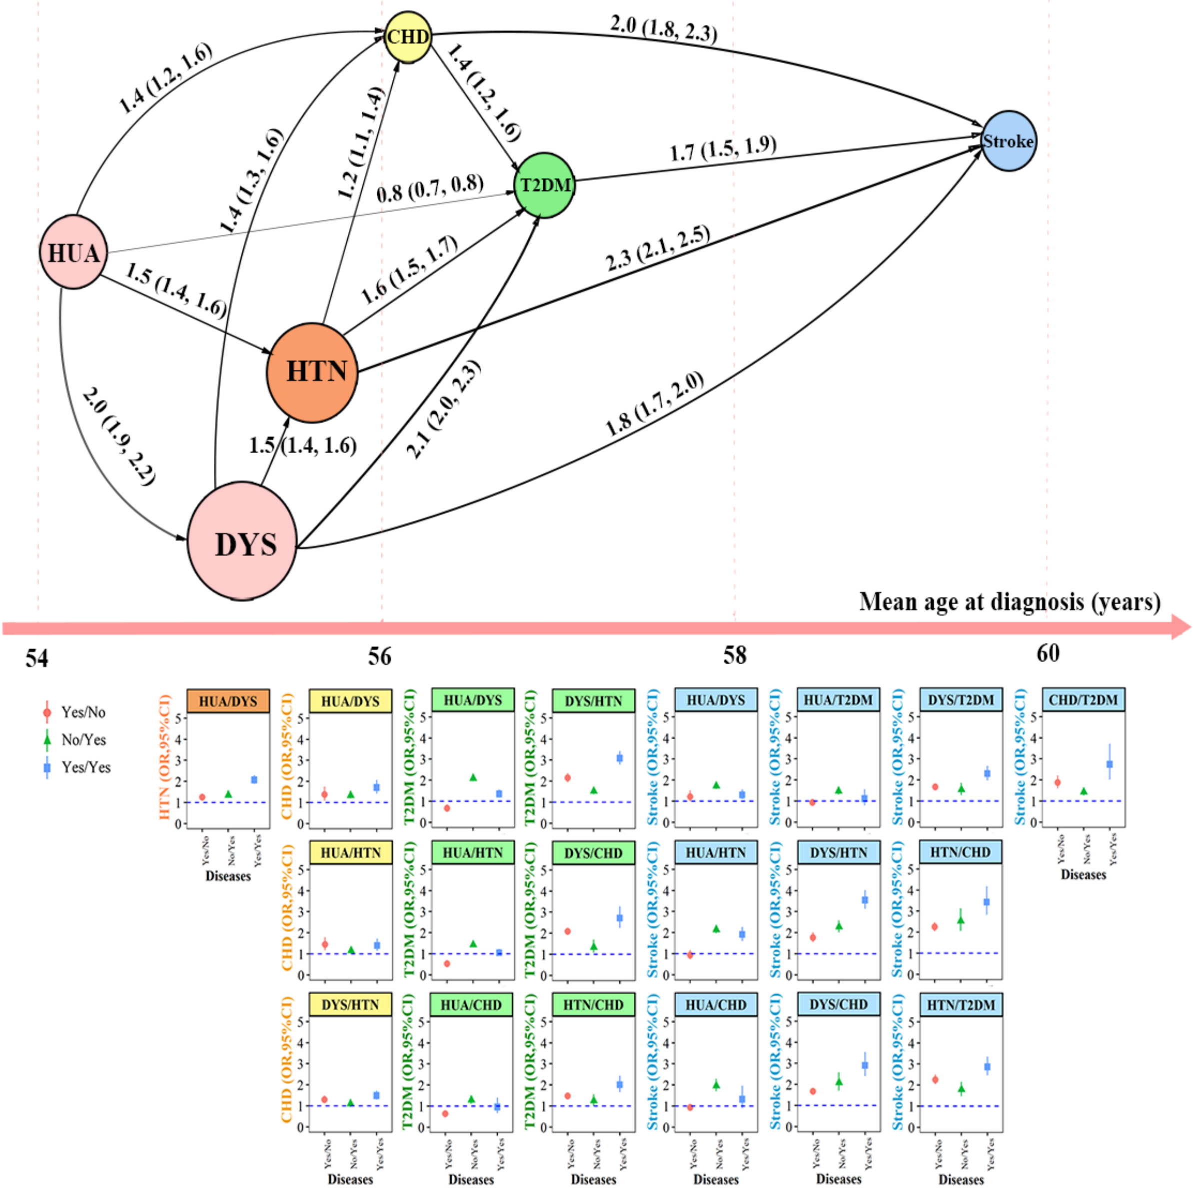
[a]OR: odds ratio.

[b]CHD: coronary heart disease.

Age Gaps Between NCDs

A cascade of NCDs was depicted by the mean age of participants at diagnosis. Among the study participants, 10.2% (3973/38,807) were diagnosed with hyperuricemia at a mean age of 54.0 years, followed by dyslipidemia (14,569/38,807, 37.5% at 55.1 years), hypertension (12,692/38,807, 32.7% at 55.4 years), CHD (1708/38,807, 4.4% at 56.1 years), T2DM (3664/38,807, 9.4% at 56.7 years), and stroke (2613/38,807, 6.7% at 59.1 years). In addition, we observed additional connections between NCD pairs (Figure 2 and Multimedia Appendix 3).

Figure 2. Age gaps between NCDs and the accumulation of NCDs in individuals based on mean age at diagnosis. NCDs along the x-axis were in order of increasing mean age at diagnosis. The number of the connected edge reflected the OR (95% CI) of the NCD pairs. The forest plot displayed the independent and combined effects of NCDs. The dots and lines exhibited OR and 95% CI, respectively. The model reference was "no/no," which meant without 2 conditional NCDs; "yes/no" meant having the first NCD of the 2 conditional NCDs, "no/yes" meant having the second NCD, and "yes/yes" meant having both conditional NCDs. CHD: coronary heart disease; DYS: dyslipidemia; HTN: hypertension; HUA: hyperuricemia; NCD: noncommunicable disease; OR: odds ratio; STR: stroke; T2DM: type 2 diabetes mellitus.



Impact of Multimorbidity on Hypertension Occurrence

Compared with individuals without 2 conditional NCDs, individuals with 1 conditional NCD (hyperuricemia or dyslipidemia) would have significantly higher odds of hypertension (1.3-1.4, logistic regression; both *P*<.001). Individuals with 2 conditional NCDs (hyperuricemia and dyslipidemia) would further elevate their odds of hypertension to 2.1 (*P*<.001; Figure 2 and Multimedia Appendix 4).

Impact of Multimorbidity on CHD Occurrence

Compared with individuals without 2 conditional NCDs, individuals with one of the conditional NCDs (hyperuricemia, dyslipidemia, or hypertension) would have significantly higher odds of CHD (1.2-1.5; the combination of hyperuricemia without dyslipidemia: *P*=.008; the combination of no hyperuricemia but dyslipidemia: *P*<.001; the combination of hyperuricemia without hypertension: *P*=.001; and the combination of no hyperuricemia but hypertension: *P*=.02). Individuals with 2 conditional NCDs (hyperuricemia and dyslipidemia combination: *P*<.001; or hyperuricemia and hypertension combination: *P*=.002) would further elevate their odds of CHD to 1.4-1.7 (Figure 2 and Multimedia Appendix 4).

Impact of Multimorbidity on T2DM Occurrence

Compared with individuals without 2 conditional NCDs, individuals with 1 conditional NCDs (dyslipidemia, hypertension, or CHD) would have a significantly higher odd of T2DM (1.3-2.2; all *P* values were <.001 except the combination of no dyslipidemia but CHD [*P*=.01]), and individuals with these 2 conditional NCDs (dyslipidemia and hypertension combination or dyslipidemia and CHD combination) would further elevate their odds of T2DM to 2.7-3.1 (all *P*<.001; Figure 2 and Multimedia Appendix 4).

Impact of Multimorbidity on Stroke Occurrence

Compared with individuals without 2 conditional NCDs, individuals with one of the conditional NCDs (dyslipidemia, hypertension, CHD, or T2DM) would have significantly higher odds of stroke (1.4-2.5; all *P*<.001). Individuals with these 2 conditional NCDs (6 NCD combinations) would further elevate their odds of a stroke to 2.3-3.5 (all *P*<.001; Figure 2 and Multimedia Appendix 4).

Discussion

Principal Findings

Our findings indicated a strong tendency for the coexistence and accumulation of NCDs in a rural population in Henan, China. The prevalence of multimorbidity was 28.1% (10,899/38,807) and increased with age, unfavorable lifestyles, and a higher BMI among Henan rural adults. The multimorbidity of dyslipidemia and hypertension was the most prevalent in study participants of all age groups. In addition, the onset of NCDs was associated, and a later NCD is often predictable by 1 or more preceding NCDs. The tendency of NCD accumulation indicates that compared with participants without conditional NCDs, participants with 1 existing NCD are more likely to develop a second NCD, whereas participants with 2 NCDs have an even greater likelihood to develop a third NCD.

Our study finding demonstrated a lower multimorbidity prevalence than previous studies [14]. A younger age, existing recall and reporting biases, and a fewer number of NCDs included may have contributed to the lower prevalence observed in our study. Further, consistent with previous studies [2,42,43], the prevalence of multimorbidity increases with age, and approximately one-third of older adults aged 60-79 years develop multimorbidity. Nevertheless, multimorbidity in the young and middle-aged population should not be neglected, given the increasing trend of risk factors in the young and middle-aged population [13,44]. Multimorbidity research and preventive strategies should not focus on older adults only but should instead recognize its importance throughout the whole life cycle.

Our study found that unfavorable lifestyles and a higher BMI were associated with a higher risk of multimorbidity. Our finding is supported by evidence in other settings. A multinational cohort study found that a prediagnostic healthy lifestyle, such as a healthy diet, lower BMI, and higher physical activity, could reduce the risk of multimorbidity [45]. A pooled study from 16 cohort studies demonstrates that a high BMI significantly contributes to the risk of cardiometabolic multimorbidity [46]. Further, a systematic review identifies that physical activity may improve immunity and reduce systemic inflammation and thereby ameliorate multimorbidity [47]. Overall, many modifiable risk factors associated with multimorbidity, including drinking, overweight and obesity, and physical inactivity, could be targets of behavioral prevention and interventions. Differing from previous studies [48-50], our study found that a high-fat diet, current smoking status, and being underweight may reduce the risk of multimorbidity. Given our study is a cross-sectional study with certain biases, the power to explain the causative effects of risk factors on diseases is limited. Further investigation is necessary to confirm this particular finding. Our findings support the WHO’s recommendation to implement evidence-based strategies to reduce poor use of alcohol, encourage physical activity, and maintain a healthy weight.

Our study suggested a tendency for NCD accumulation among the participants. The clustering of dyslipidemia and hypertension was the most prevalent multimorbidity observed in our study, consistent with previous studies [30,51]. A Japanese study further describes hypertension as the most common comorbidity among individuals with dyslipidemia [52]. In addition, the temporal sequence reflects the order of NCDs onset and suggests a potential causal association between the occurrence of these NCDs and the development of other comorbidities [40]. The accumulation of NCDs reflects that participants who lived with 1 conditional NCD are more likely to develop a second NCD, whereas individuals with 2 conditional NCDs are more likely to develop a third NCD than otherwise. Similar results have also been reported in a large-series prospective study: participants with the multimorbidity of T2DM and hypertension have a higher risk of CHD or stroke than participants with hypertension or T2DM [53]. This observation might be partly explained by obesity and the variations of metabolites that have accumulating side effects on health over time [54,55]. Kivimaki et al [54] found that obesity-related disease predicted or was predicted by 1 or more other obesity-related diseases, leading to the accumulation of NCDs. A study of 11,000 participants to examine metabolic pathways associated with 27 NCDs shows that two-thirds of metabolites are associated with more than 1 NCD. In addition, 420 metabolites shared between multimorbidity have been found, revealing several key common pathways in NCDs [55]. Our study suggests that taking reasonable health management and therapies of early NCDs can reduce the incidence or slow down the progression of multimorbidities effectively and ultimately improve the quality of life of the population [56,57].

Our findings have important implications for research and public health policy for multimorbidity. This study indicates that multimorbidity is an important health concern in rural Henan. In light of the WHO Sustainable Development Goals for preventing and controlling NCDs [58], existing health care needs to be improved to cope with the burden of multimorbidity. First, the prevalence of multimorbidity is higher in those older than 45 years. A life cycle approach to multimorbidity and to the challenges it poses to public health is vitally important [59]. Second, there is a clear need to increase the awareness of the importance of a healthy lifestyle in the rural population in Henan. Measures of propagating publicity and education on relevant health knowledge, improving health literacy, and changing unfavorable lifestyles should be implemented. Third, disease-specific guidelines are insufficient to effectively manage patients with multimorbidity, and new detailed guidelines for multimorbidity need to be developed [6]. Given the tendency of the coexistence and accumulation of NCDs, preventing multimorbidity will become difficult if the NCDs are treated separately. Integrated strategies for multimorbidity should be developed, such as monitoring at the individual level with electronic health records and increasing the screening management of high-risk populations.

Limitations

This study has several limitations. First, the causal relationship between NCDs may not be reliable on account of the data being from the baseline survey of a prospective cohort study in Henan Province. Therefore, prospective studies are needed to confirm the results of this study. Second, we define hypertension, dyslipidemia, hyperuricemia, and T2DM by self-report with laboratory measurements, whereas CHD and stroke are defined only by self-report, which might underestimate their prevalence. Finally, although several potential confounders are controlled, there may be other unknown confounders affecting the results of this study.

Conclusions

In conclusion, our study indicates that multimorbidity is an important health issue in rural Henan. Older age, unfavorable lifestyles, and a higher BMI are associated with a higher risk of multimorbidity. In addition, our findings highlight a plausible explanation for the coexistence and accumulation of NCDs. Care for multimorbidity is complex, and concerted efforts and early interventions to prevent the occurrence of multimorbidity are essential to improve health in the rural population in Henan, China.

Abstract

Background: Cambodia has seen an increase in the prevalence of type 2 diabetes (T2D) over the last 10 years. Three main care initiatives for T2D are being scaled up in the public health care system across the country: *hospital-based care*, *health center–based care*, and *community-based care*. To date, no empirical study has systematically assessed the performance of these care initiatives across the T2D care continuum in Cambodia.

Objective: This study aimed to assess the performance of the 3 care initiatives—individually or in coexistence—and determine the factors associated with the failure to diagnose T2D in Cambodia.

Methods: We used a cascade-of-care framework to assess the T2D care continuum. The cascades were generated using primary data from a cross-sectional population-based survey conducted in 2020 with 5072 individuals aged ≥40 years. The survey was conducted in 5 operational districts (ODs) selected based on the availability of the care initiatives. Multiple logistic regression analysis was used to identify the factors associated with the failure to diagnose T2D. The significance level of $P<.05$ was used as a cutoff point.

Results: Of the 5072 individuals, 560 (11.04%) met the definition of a T2D diagnosis (fasting blood glucose level ≥126 mg/dL and glycated hemoglobin level ≥6.5%). Using the 560 individuals as the fixed denominator, the cascade displayed substantial drops at the testing and control stages. Only 63% (353/560) of the participants had ever tested their blood glucose level in the last 3 years, and only 10.7% (60/560) achieved blood glucose level control with the cutoff point of glycated hemoglobin level <8%. The OD hosting the coexistence of care displayed the worst cascade across all bars, whereas the OD with hospital-based care had the best cascade among the 5 ODs. Being aged 40 to 49 years, male, and in the poorest category of the wealth quintile were factors associated with the undiagnosed status.

Conclusions: The unmet needs for T2D care in Cambodia were large, particularly in the testing and control stages, indicating the need to substantially improve early detection and management of T2D in the country. Rapid scale-up of T2D care components at public health facilities to increase the chances of the population with T2D of being tested, diagnosed, retained in care, and treated, as well as of achieving blood glucose level control, is vital in the health system. Specific population groups susceptible to being undiagnosed should be especially targeted for screening through active community outreach activities. Future research should incorporate digital health interventions to evaluate the effectiveness of the T2D care initiatives longitudinally with more diverse population groups from various settings based on routine data vital for integrated care.

Introduction

Background

In 2021, globally, 1 in 10 adults aged 20 to 79 years was living with type 2 diabetes (T2D) [1]. Similar to other countries in the Western Pacific region—the World Health Organization (WHO) region with the highest number of adults living with T2D (206 million) [1]—Cambodia has been severely affected by the T2D epidemic. In 2016, the prevalence rate of T2D in this lower–middle-income country was 9.6% among adults aged 18 to 69 years, signifying a significant increase compared with the prevalence rate in 2010 (2.9% among adults aged 25-64 years) [2]. As a response to the increased burden of chronic conditions, including T2D, across the globe, the WHO adopted the innovative care for chronic conditions (ICCC) framework as a road map for countries, regardless of income level, to transform their health systems toward better care for chronic conditions [3].

The incurable nature of T2D, along with its chronicity and silent progression, requires the condition to be diagnosed as early as possible and managed properly and promptly on a regular basis by patients, caregivers, and health care professionals to prevent or delay complications [3]. Care for T2D relies not only on medical interventions provided by health care professionals but also on high-quality and continuous self-management [4]. A systematic review shows that the quality of T2D care in low- and middle-income countries (LMICs) in Asia and the Middle East has been reported to be limited, with the care goals recommended in the evidence-based guidelines not being met [5]. The WHO promotes the adoption of integrated care for disease management in the health system as outlined in the ICCC framework [3], which is evidence based in improving blood glucose level control [6,7], to fill the gaps.

Likewise, care for T2D in Cambodia has been limited among the population at risk and people living with T2D. Many adults (more than two-thirds of the population) have never had their blood glucose level tested, and more than half of those living with T2D are not receiving treatment [2].

Cambodia’s health system is pluralistic—both public providers and private providers (including nonprofit organizations) provide care for T2D in the country. The ministry of health is in charge of the public health providers, which are organized on a district health system model and guided by the primary health care approach [8]. In this model, an operational district (OD) usually comprises a referral hospital providing secondary care and 10 to 25 health centers providing primary care with support from community health workers. The public providers mainly cover health prevention activities by providing primary health care for people with infectious diseases (such as HIV infection and AIDS, tuberculosis, and malaria) and focusing on maternal and child health, leaving care for chronic conditions, including T2D, to be provided mainly by private providers [9]. A self-reported survey on availability of T2D services at primary care facilities indicated that only approximately 1 in 5 health centers reported providing T2D services [10].

To improve the availability of integrated care for T2D, three main care initiatives for T2D are currently being scaled up across the 103 ODs in Cambodia [11]: (1) *hospital-based care*, (2) *health center–based care*, and (3) *community-based care*. In 2019, the ministry of health approved a national standard operating procedure for the management of T2D and hypertension in primary care in an attempt to integrate these 3 care initiatives for the T2D and hypertension care continuum in which health centers provide continuity and coordination across the care levels in the OD [11]. This standard operating procedure was adapted from the WHO package of essential noncommunicable disease interventions (WHO PEN) [12]—we refer to health centers implementing the standard operating procedure as the WHO PEN health centers.

Hospital-based care is standard care at the referral hospitals that provide ambulatory care for serious or complicated T2D cases. In 2018, with support from the ministry of health, 29 of the 117 referral hospitals provided exclusive care for T2D and hypertension at separate noncommunicable disease (NCD) clinics [13]. Health center–based care is implemented at the WHO PEN health centers. They are allowed to take care of mild or stable T2D cases without complications, with the diagnosis confirmed and treatment initiated at the referral hospital. In early 2020, only 86 of the 1221 health centers had implemented the WHO PEN program [13]. Community-based care is implemented through peer educator networks run by a Cambodian nongovernmental organization called MoPoTsyo. The networks offer (1) self-management support to patients through peer educators who have been diagnosed with T2D themselves, (2) laboratory tests, (3) physician consultations, and (4) low-cost medicines through a revolving drug fund program [14]. Each peer educator is responsible for a health center’s catchment area, with populations ranging from 10,000 to 20,000 [8]. By 2019, MoPoTsyo had 255 peer educators trained to serve >40,000 patients [14]. Detailed descriptions of the 3 care initiatives have been provided in a study protocol [15].

The coexistence of the 3 care initiatives—combining hospital-, health center–, and community-based care components—in an OD could potentially produce the ideal context for integrated care as described in the ICCC framework [3]. However, for the care initiatives to be integrated and thus for these 3 care initiatives to strengthen each other, necessary information has to be shared, and resources have to be coordinated in an effective and efficient manner [16].

To our knowledge, no empirical study has assessed the performance of the aforementioned 3 care initiatives—either individually or in coexistence—across the T2D care continuum in Cambodia. We used the test-treat-retain cascade of care as adapted from the HIV program to assess the T2D care continuum [17]. This method allowed us to document how many patients were lost along the care continuum with regard to testing, diagnosis, retention in care, receiving treatment, and achieving good control of their health condition. In other LMICs, limited existing studies have pooled secondary data from cross-sectional surveys to generate countrywide cascades of care [18-20] as an approach to assess health system performance to meet the T2D care continuum goals. A systematic assessment of the performance of the different care initiatives—either individually or in coexistence—currently being scaled up in Cambodia is not yet available.

Objectives

This study aimed to address the research gap by assessing the performance of the aforementioned care initiatives either individually or in coexistence with the cascade-of-care framework using primary data from a population-based survey and determining the factors associated with the undiagnosed status of T2D among the population.

Methods

Study Design

The study was part of a population-based survey conducted in 2020. It was a cross-sectional study involving 5072 individuals aged ≥40 years [15]. A detailed explanation of the study design was included in the study protocol [15].

Study Setting

Five ODs were purposively selected to assess the performance of the aforementioned care initiatives—individually or in coexistence. OD Samrong in Oddar Meanchey province provided hospital-based care at the NCD clinic of the referral hospital—the only public provider for T2D care in the OD at the time of the study. People with T2D visited the physician for a medical consultation (prescriptions and medicines were provided) on a monthly appointment basis. The second selected OD was OD Pearaing in Prey Veng province. This OD began implementing health center–based care in 2015. Assigned staff at the WHO PEN health centers receive training to perform screening, provide follow-up care for mild and stable T2D cases, and offer health education and counseling on healthy behavior as part of cardiovascular disease risk factors management [11]. By structural design, the NCD clinic at the referral hospital is required to support the WHO PEN health centers. In this OD, at the time of the study, 8 of the 9 health centers were WHO PEN health centers (high coverage). The third selected OD was OD Sotr Nikum in Siem Reap province. This OD has been historically and substantially influenced by financial aid from various development partners and nongovernmental organizations. At the time of the study, 5 of the 25 health centers in the OD were WHO PEN health centers (low coverage), supported by a chronic disease clinic that provided treatment and care to both people with T2D and hypertension and those with HIV infection [21]—the clinic was essentially the NCD clinic of the referral hospital. Therefore, we consider this OD the host of health center–based care (with context). The fourth selected OD was OD Kong Pisey in Kampong Speu province. In this OD, the peer educator network provided community-based care. At the time of the study, none of the public providers in this OD formally offered care for people with T2D. MoPoTsyo made arrangements with the referral hospital to provide physician consultations for people with T2D in the network once a week. The fifth selected OD was OD Daunkeo in Takeo province—the only OD found to host all 3 care initiatives together across the 103 ODs in Cambodia. At the time of the study, hospital-based care in this OD was provided at the NCD clinic of the referral hospital, whereas 8 of the 15 WHO PEN health centers in this OD provided health center–based care. The peer educator network provided community-based care, but the network had already been handed over to the OD health authorities for governance. Table 1 summarizes the study settings.

Table 1. Selected provinces and operational districts (ODs) with different types of care initiatives.

Name of OD	Province	Existing care provision	Care initiative
Samrong	Oddar Meanchey	NCD[a] clinic at referral hospital	Hospital-based care
Pearaing	Prey Veng	NCD clinic+WHO PEN[b] (high coverage)	Health center–based care
Sotr Nikum	Siem Reap	NCD clinic+WHO PEN (low coverage)	Health center–based care with context
Kong Pisey	Kampong Speu	Peer educator network	Community-based care
Daunkeo	Takeo	NCD clinic+WHO PEN+peer educator network	Coexistence of care

[a] NCD: noncommunicable disease.

[b] WHO PEN: World Health Organization package of essential noncommunicable disease interventions.

Study Participants and Recruitment

The target study participants were adults aged ≥40 years. This age group was targeted for T2D screening according to the national standard operating procedure [11]. The recruitment was processed via a 3-level procedure. First, within each OD, a list of villages affected by the care initiative was drawn up, and 44 villages were randomly selected. Second, 24 eligible households (ie, those containing at least 1 household member aged ≥40 years) were randomly selected from a list of all eligible households in the selected villages. Within the selected households, potential participants had to be (1) usual members of the household either staying in the house the night before the interview or not being absent for >6 months, (2) physically and mentally capable of answering questions, and (3) well-informed regarding the consent procedure for participation in the study. In the third step, 1 household member meeting the aforementioned eligibility criteria from each randomly selected household was randomly recruited into the study. Each selected participant was interviewed based on a preset questionnaire and their anthropometric measurements (blood pressure, body weight, height, and waist and hip circumferences) and biochemical measurements (fasting blood glucose [FBG] level, glycated hemoglobin [HbA$_{1c}$] level, and creatinine level) taken. Data were digitally collected using the KoboToolbox system developed by the Harvard Humanitarian Initiative [22].

Measures and Analytical Strategy

Primary Outcome of Interest

The main outcome of interest in this study was the cascade of care consisting of six bars: (1) the *prevalence* bar, (2) the *ever tested or screened* bar, (3) the *ever diagnosed* bar, (4) the *in care* bar, (5) the *in treatment* bar, and (6) the *under control* bar. A fixed denominator approach was used for constructing the cascades of care to identify the leakages between the stages of the care continuum [23]. Table 2 shows the definitions of each bar and describes the sources of the data extracted for analysis.

Table 2. Definitions of the cascade bars for type 2 diabetes (T2D).

Bars of the cascade of care for T2D and definitions	Source of data extracted for analysis
Prevalence of the target population living with T2D	
Participants having biochemical measurement of FBG[a] (capillary plasma value) level ≥126 mg/dL (7 mmol/L) and HbA$_{1c}$[b] level ≥6.5% [18,24,25]	• Measurement of FBG level • Measurement of HbA$_{1c}$ level
Participants reporting the use of drugs for T2D, irrespective of their biomarker values	• Response to the question, *Have you ever been told by a physician or other health worker that you have T2D?*
Number of people in the target population with T2D ever tested for T2D	
Patients classified as living with T2D having had FBG level tested in the last 3 years	• Response to the question, *Have you ever had your blood glucose level tested in the last 3 years?*
Number of those tested ever diagnosed for T2D	
Tested patients with T2D reporting ever being told by a physician or other health worker that they have T2D	• Response to the question, *Have you ever been told by a physician or other health worker that you have T2D?*
Number of those diagnosed in care	
Patients diagnosed with T2D reporting receiving treatment or care for their conditions at least once in the past 12 months	• Response to the question, *Did you get treatment or care for your T2D condition in the past 12 months?*
Number of those in care receiving treatment	

Patients with T2D in care reporting using drugs for T2D or insulin in the past 2 weeks	• Response to the question, *Are you currently receiving any of the following treatments for your T2D condition prescribed by a physician or other health care worker?*
	  • *Insulin*
	  • *Drugs (medication) that you have taken in the past 2 weeks*

Patients with T2D in care reporting following advice to lose weight, stop smoking, perform physical exercise, and be on a special prescribed diet	• Response to the question, *Are you currently receiving all of the following advice for your T2D condition prescribed by a physician or other health care worker?*
	  • *Special prescribed diet*
	  • *Advice to lose weight*
	  • *Advice to stop smoking*
	  • *Advice to start or perform more physical exercise*

Number of those receiving treatment with T2D under control	
Patients with T2D in treatment having HbA$_{1c}$ level <8% [18]	• Measurement of HbA$_{1c}$ level for known T2D

[a] FBG: fasting blood glucose.

[b] HbA$_{1c}$: glycated hemoglobin.

Secondary Outcomes of Interest

The secondary outcomes of interest were the factors associated with the undiagnosed status of participants living with T2D. We defined *person with undiagnosed status* as a person having biochemical measurements of FBG level ≥126 mg/dL and HbA_{1c} level ≥6.5% in our study but never being told by a physician or other health worker that they had T2D.

Explanatory Variables

The explanatory variables for this analysis included demographic characteristics, socioeconomic status, and the care initiatives (either individually or in coexistence). The demographic characteristics consisted of (1) age in years (40-49, 50-59, or ≥60); (2) sex (male or female); (3) educational attainment (none, primary school, secondary school, or higher); and (4) socioeconomic status (poorest, poor, medium, rich, or richest), which was measured using a household wealth index. To obtain the household wealth index, each household was interviewed using a 20-item questionnaire adapted from the 2014 Cambodia Demographic Health Survey [26]. This tool has been validated and widely used to classify household socioeconomic class [27]. Finally, the care initiative settings included (1) hospital-based care, (2) health center-based care, (3) health center-based care with context, (4) community-based care, and (5) the coexistence of the 3 care initiatives.

Statistical Analysis

We produced bar charts of the T2D cascades of care in accordance with the definitions provided in Table 2. We used bivariate analyses to compare the proportion of participants living with T2D without a diagnosis by participant characteristics. Subsequently, a multiple logistic regression analysis was used to identify the factors associated with the undiagnosed status. As we had only a limited number of explanatory variables in the bivariate analysis, we included all these variables in our initial multiple logistic regression analysis, regardless of the significance level. We additionally used a backward elimination method. Variables with the highest *P* value were eliminated from the model one by one. We retained all variables with a significance level of *P*<.05 in the final model. The statistical software Stata (version 14.2; StataCorp LLC) was used to perform the statistical analyses [28].

Ethics Approval

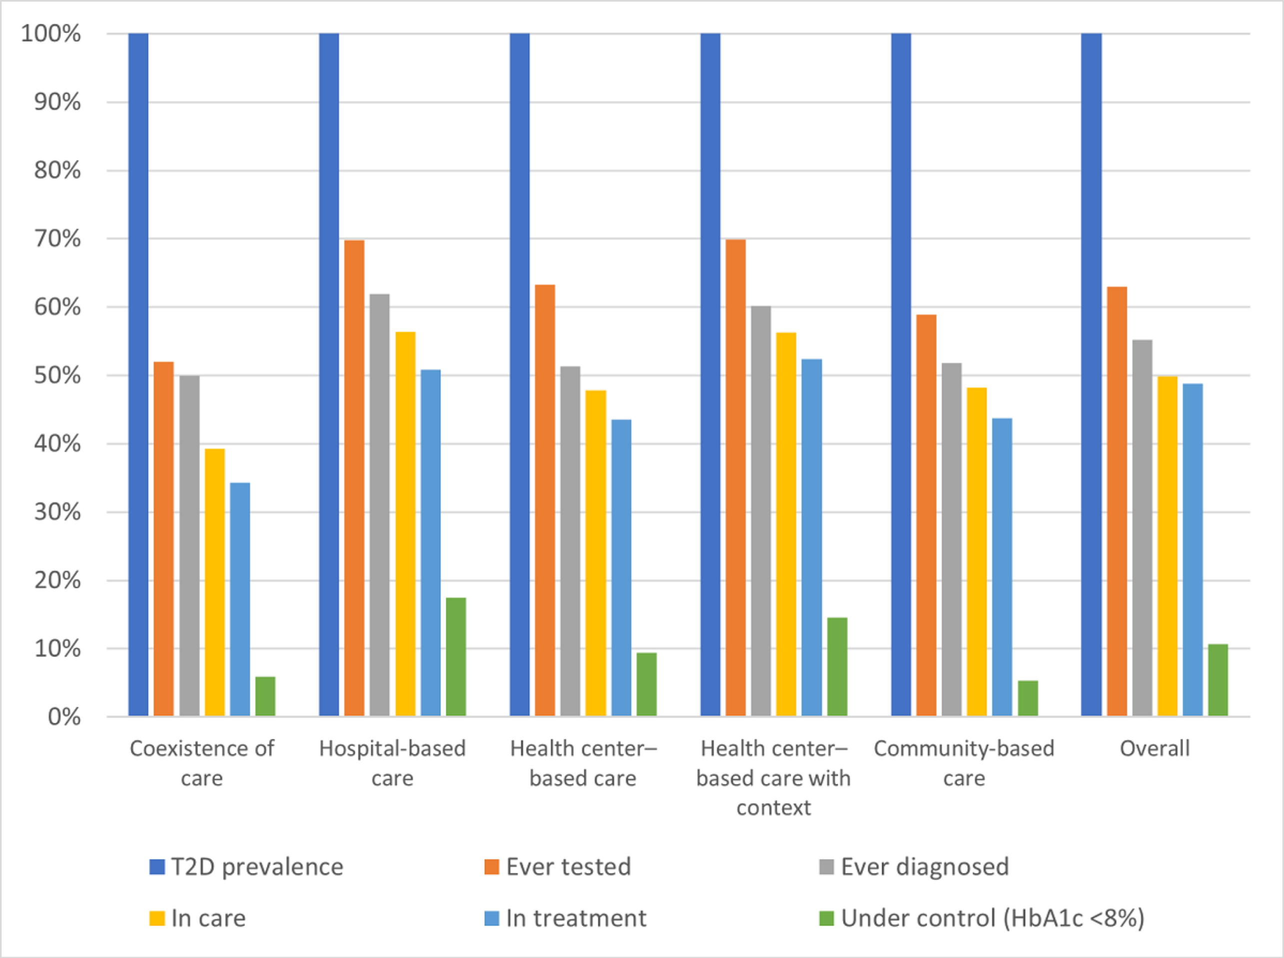
This study was approved by the National Ethics Committee for Health Research in Cambodia (NECHR; 105 NECHR) and by the institutional review board of the Institute of Tropical Medicine (Antwerp, Belgium; 1323/19). The study has also been registered as part of the Scale-up Integrated Care for Diabetes and Hypertension (SCUBY) project protocol at the ISRCTN Registry (ISRCTN41932064).

Results

Cascade of Care

Of the 5072 individuals participating in this study, 614 (12.11%) had raised blood glucose level (FBG level ≥126 mg/dL), and 560 (11.04%) met the definition of having T2D (Multimedia Appendix 1). Using the 560 individuals as the fixed denominator, we observed that 2 bars—*ever tested* and *under control*—had a substantial drop. Of the 560 individuals with T2D, only 353 (63%) had ever undergone a blood glucose level test in the last 3 years, 309 (55.2%) had ever been diagnosed as having T2D, 279 (49.8%) had received care in the past 12 months, and 273 (48.8%) had received insulin or antidiabetic medication in the past 2 weeks. In addition, only 130 (47.6%) of the 273 treated participants also received advice regarding a prescribed diet, weight loss, smoking cessation, and physical exercise. Only 10.7% (60/560) achieved blood glucose level control with the cutoff point of HbA_{1c} level <8% (Multimedia Appendix 1). Figure 1 shows the comparison of the cascades of care by setting with the overall cascade of care.

Figure 1. Type 2 diabetes (T2D) cascades of care by setting in 2020 in Cambodia. HbA_{1c}: glycated hemoglobin.



Participant Characteristics

As can be seen in Table 3, the majority of our study participants with T2D were those aged ≥50 years (476/560, 85%), female (418/560, 74.6%), and with low educational level (primary school level or lower: 490/560, 87.5%). Of the 560 participants living with T2D, 251 (44.8%) were undiagnosed. In this bivariate analysis, we observed that age (*P*<.001) and sex (*P*=.03) were associated with the undiagnosed status of participants living with T2D.

Table 3. Characteristics of the diagnosed and undiagnosed type 2 diabetes cases in 2020 in Cambodia.

Characteristics	Overall (N=560), n (%)	Diagnosed cases (n=309), n (%)	Undiagnosed cases (n=251), n (%)	*P* value

Community-based care	112 (20)	58 (18.8)	54 (21.5)	
Health center–based care	117 (20.9)	60 (19.4)	57 (22.7)	
Health center–based care with context	103 (18.4)	62 (20.1)	41 (16.3)	
Hospital-based care	126 (22.5)	78 (25.2)	48 (19.2)	

[a] Italicization indicates values that met the significance threshold (*P*<.05).

In the multiple logistic regression analysis (Table 4), being aged 40 to 49 years was associated with higher odds of not receiving the T2D diagnosis (adjusted odds ratio [AOR] 3.2, 95% CI 1.9-5.5; *P*<.001) compared with those aged ≥60 years. Male participants with T2D displayed higher odds of not being diagnosed (AOR 1.7, 95% CI 1.1-2.5; *P*<.001) than female participants living with T2D.

We also observed that being in the poorest category of the wealth quintile was associated with having higher odds of not being diagnosed with T2D (AOR 2.3, 95% CI 1.3-4.2; *P*=.005) than those in the richest category. Finally, the care initiative setting was also associated with the undiagnosed status of participants with T2D. Compared with those in the hospital-based care setting, higher odds of not being diagnosed were observed in the coexistence of care setting (AOR 1.9, 95% CI 1.1-3.3; *P*=.03), community-based care setting (AOR 1.9, 95% CI 1.1-3.3; *P*=.02), and health center–based care setting (AOR 2.1, 95% CI 1.2-3.6; *P*=.01).

It was observed that among the 309 participants diagnosed with T2D, 177 (57.3%) were diagnosed by a private provider, 121 (39.2%) by a public provider, and 11 (3.6%) by others. Table 5 compares public providers with private providers in each setting in terms of the proportion of participants with diagnosed T2D status and that of those with T2D control status. No statistical significance was observed.

HbA_{1c} level <8%	3 (5.7)	3 (5.7)	
HbA_{1c} level ≥8%	25 (47.1)	22 (41.5)	
Health center–based care (n=55)			.20
HbA_{1c} level <8%	1 (1.8)	10 (18.2)	
HbA_{1c} level ≥8%	12 (21.8)	32 (58.2)	
Health center–based care with context (n=57)			.23
HbA_{1c} level <8%	8 (14)	7 (12.3)	
HbA_{1c} level ≥8%	15 (26.3)	27 (47.4)	
Hospital-based care (n=67)			.19
HbA_{1c} level <8%	11 (16.4)	11 (16.4)	
HbA_{1c} level ≥8%	15 (22.4)	30 (44.8)	

[a] The category of *other provider* was removed from the analysis owing to its small proportion, which made the statistical test unreliable.

[b] HbA_{1c}: glycated hemoglobin.

Discussion

Principal Findings

This study used primary data from a cross-sectional survey to generate the cascade of care for the T2D care continuum in 5 purposively selected ODs in Cambodia. Overall, the cascade displayed substantial drops at the testing stage (207/560, 37%, loss from the *prevalence* bar) and at the control stage (213/560, 38%, loss from the *in treatment* bar), indicating that all selected settings, regardless of the care initiatives present, have limited capacity to detect people with T2D and control the condition (blood glucose level control) in those with T2D despite being in receipt of treatment. The findings were consistent with the T2D cascade analyses in other LMICs that displayed significant losses at the testing stage (also 37%) [18]. However, the drop between the treatment stage and the control stage observed in this study was much larger than that in the studies in other LMICs—only 15% in other LMICs compared with 38% (213/560) in this study [18]. With the cutoff point of HbA_{1c} level <8%, the proportion of those with T2D under control was 23% in other LMICs [18]; in this study, 10.7% (60/560) were considered as having achieved blood glucose level control. This is an exceptionally low rate, indicating that T2D in Cambodia is not being treated properly and adequately.

We disaggregated the cascades of care by study setting to observe the influence of the care initiatives. Unexpectedly, the coexistence of care setting displayed the worst cascade across all bars, whereas the hospital-based care setting had the best cascade among the 5 settings. This discovery was unexpectedly contradictory to the ICCC theoretical framework [3], calling into question the assumption underlying the ICCC framework that the combined care initiatives of health care organization and community represent an ideal context for integrated care for T2D and thereby would reduce leakages in the cascade. This suggests that the presence of health care infrastructure is not directly translated into improved care performance [29]. Implementation fidelity that focuses on the process of care implementation has to be taken into account [30]. Working mechanisms such as integrated care management across care levels and actors, the use of shared disease registries, and coordinated resources for self-management support and community education have to be in place for the coexistence of care to represent the ideal ICCC framework [3,16]. An investigation of the actual implementation of the care initiatives in these ODs was conducted in another study (Te V et al, unpublished data, July 2022). The investigation found that the 3 care initiatives were not implemented in an integrated way as intended in the written guideline [11] but in isolation, with limited interaction among them. The working mechanisms that facilitate integrated care for T2D in terms of shared necessary information and coordinated resources [16] were not observed. There was no proper system for following up patients for the continuity of care. The referral system among the communities, health centers, and referral hospitals was dysfunctional. The peer educator network in the OD with coexistence of care was not functioning optimally. The network had been handed over to the OD health authorities for governance, and technical or financial support from MoPoTsyo disappeared, rendering the network dysfunctional.

It should be noted that the care initiatives were not solely responsible for the provision of care for T2D in the selected ODs. On the basis of the same survey data, we found that, in general, health care use occurred dominantly in the private sector (78% among those seeking care in the 3 months preceding the survey), and referral hospitals were the common public health care facilities used by those with T2D and hypertension [31]. Therefore, our findings may not be fully attributed to the care initiatives. In the community-based care setting of OD Kong Pisey, only 12% (7/58) of the study participants were people living with T2D who were connected to the peer educator network, and only 4% (2/51) were connected to the peer educator network in the coexistence of care setting of OD Daunkeo. This may potentially undermine the effectiveness of community-based care. In a study based on MoPoTyso’s routine data, 43% of the people in the network achieved the median HbA_{1c} level of 7.1% [32]. In the hospital-based care setting of OD Samrong, only 5% (4/78) of the participants were seeking T2D care or treatment at the NCD clinic of the referral hospital in the 3 months preceding the survey, whereas at WHO PEN health centers in the health center–based care setting of OD Pearaing with high WHO PEN coverage, 3% (2/60) of the participants were identified seeking care for T2D.

Further statistical analysis, although not statistically significant, found that in all settings, except for the coexistence of care, private providers—who could not be fully incorporated into our study design owing to a lack of trustworthy information system in this sector—played a dominant role in diagnosing people with T2D. This suggests that the coexistence of care would increase the role of public health providers in the care continuum. In another study based on the same survey data, we found that the proportion of people with T2D seeking care at public health care facilities was higher than that of those with only hypertension or no condition [31]. This increased use of public health care facilities was also associated with a reduction in health care expenditure among patients, especially those in the poorest category of the wealth quintile who benefit from Health Equity Fund membership [31]. In a health system–level study, financial constraints have been found to be one of the main barriers to the T2D care continuum [6].

In this study, we found that 11.04% (560/5072) of the participants aged ≥40 years were identified as having T2D—of whom almost half (251/560, 44.8%) had not been diagnosed. This is a high prevalence rate because the overall prevalence rate of undiagnosed T2D in other LMICs has been reported to be 4.8% [18]. Predictors of being undiagnosed were being aged 40 to 49 years, being male, or falling in the poorest category of the wealth quintile. This suggests that more testing efforts are needed from the health system to reach people at risk for T2D, especially those from the aforementioned groups. A systematic review found that targeted screening was more cost-effective than universal screening [33]. A more convenient implementation arrangement for immediate diagnosis after testing should be put in place so that avoidable loss between these stages can be further minimized. In the national standard operating procedure [11], the WHO PEN health center staff are only allowed to perform the screening, whereas the diagnosis needs to be confirmed by the physician at the NCD clinic of the referral hospital. If the people who have been screened cannot have access to the diagnosis procedure at the referral hospital for some reason, the chances of not receiving prompt care or treatment increase. This requires strong coordination between the health centers and the NCD clinics, which has to be robust and supportive.

Limitations

First, despite using the primary data collected intentionally for the construction of the cascades of care, the sample size was not large enough to yield a sufficiently large number of patients with T2D who had achieved T2D control to enable us to assess the determinants of this particular bar. Second, the care initiatives, either individually or in coexistence, were not exclusively responsible for the provision of T2D care in each OD, thereby resulting in a weak connection between the presence of care initiatives and the cascade of care results of each study setting. We used the OD as a proxy variable to measure the effect of the care initiative, which in fact could mask a number of potential confounding contextual factors such as the dominant use of private services. In addition, in the Cambodian health system, the population is not confined to a particular public health facility in the catchment area. People can shop around freely, which means that patients may use services outside the catchment area of the facility. Third, the cross-sectional design did not allow us to determine the causal pathways leading to diabetes care outcomes, and the use of self-reported data in related sections could have produced biased results. A longitudinal study design with the collection of routine cohort data would enable us to address the limitations and evaluate the effectiveness of the different T2D care initiatives over time. This can be supported by digital health interventions. Systematic reviews have demonstrated the effectiveness of telemedicine via smartphone functions to provide self-care education, facilitate self-monitoring, produce the required treatment reminders, and collect feedback for health care professionals, which facilitates informed treatment recommendations [34,35]. In Cambodia, a study assessing the potential use of a wearable health monitor in the prevention and control of NCDs revealed that this health technology had the potential to support activities related to health promotion, patient follow-up and monitoring, and surveys of NCD risk factors, with positive user experiences and high levels of acceptance [36,37]. A digital health intervention that was tried among the MoPoTsyo networks produced valuable knowledge on pathways to address barriers to successful adoption in the Cambodian context [38].

Conclusions

This study provided an updated estimate of T2D prevalence among people aged ≥40 years (approximately 1 in 10 people) in Cambodia. The findings revealed that the unmet need for T2D care was large, particularly in the testing and control stages, indicating the need to substantially improve early detection and management of T2D in Cambodia. With almost half of the study participants with T2D undiagnosed (251/560, 44.8%) and thus unaware of their condition, early detection of people with T2D is an important first step that the health system needs to achieve to improve the T2D care continuum. We recommend rapid scale-up of T2D care components at public health facilities to increase the chances of the population with T2D of being tested, diagnosed, retained in care, and treated, as well as of achieving blood glucose control. At the same time, raising awareness and encouraging testing among the population at risk through a broad public health campaign should be one of the priorities. With advanced technology, a social media campaign has the potential to reach large parts of the population at low cost. Public health care use can reduce financial constraints among the population, particularly among those in the poorest category of the wealth quintile. We also recommend that within the context of resource constraints, specific groups considered susceptible (being male, being aged 40-49 years, or falling in the poorest category of the wealth quintile) should be especially targeted for testing through active community outreach activities because these groups are more likely to be unaware of their T2D condition. Adding care during off-hours for chronic conditions, including T2D, at public health facilities could increase access to care for male patients who are employed or busy during working hours. Future research should focus on evaluating the effectiveness of the different T2D care initiatives longitudinally with more diverse population groups from various settings. Given that digital health interventions have the potential to improve the prevention and control of NCDs while, at the same time, collecting longitudinal routine data vital for integrated care, feasibility and effectiveness studies of digital health interventions, such as telemedicine and mobile health, should be prioritized as a promising means to enable improvements along the T2D care continuum in Cambodia.

Acknowledgments

The authors would like to kindly acknowledge the Belgian government for funding this work through the VLIR-UOS project (KH2019TEA481A102) and the Fourth Funding Agreement Program of the Belgian Directorate-General for Development Cooperation and Humanitarian Aid and the Institute of Tropical Medicine (Antwerp). This study is part of the Scale-up Integrated Care for Diabetes and Hypertension (SCUBY) project, which received funding from the European Union's Horizon 2020 research and innovation program under grant agreement No 825432.

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

All authors took part in conceptualizing the study design. VT and SC prepared the original draft. PI, JVO, VB, WVD, and EW provided feedback on the drafts. All authors read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Health advocates and the media often use the rankings of the leading causes of death (CODs) to draw attention to health issues with relatively high mortality burdens in a population. The National Center for Health Statistics (NCHS) publishes “Deaths: leading causes” annually. The ranking list used by the NCHS and statistical offices in several countries includes broad categories such as cancer, heart disease, and accidents. However, the list used by the World Health Organization (WHO) subdivides broad categories (17 for cancer, 8 for heart disease, and 6 for accidents) and classifies Alzheimer disease and related dementias and hypertensive diseases more comprehensively compared to the NCHS list. Regarding the data visualization of the rankings of leading CODs, the bar chart is the most commonly used graph; nevertheless, bar charts may not effectively reveal the changes in the rankings over time.

Objective: The aim of this study is to use a dashboard with bump charts to visualize the changes in the rankings of the leading CODs in the United States by sex and age from 1999 to 2021, according to 2 lists (NCHS vs WHO).

Methods: Data on the number of deaths in each category from each list for each year were obtained from the Wide-ranging Online Data for Epidemiologic Research system, maintained by the Center for Disease Control and Prevention. Rankings were based on the absolute number of deaths. The dashboard enables users to filter by list (NCHS or WHO) and demographic characteristics (sex and age) and highlight a particular COD.

Results: Several CODs that were only on the WHO list, including brain, breast, colon, hematopoietic, lung, pancreas, prostate, and uterus cancer (all classified as cancer on the NCHS list); unintentional transport injury; poisoning; drowning; and falls (all classified as accidents on the NCHS list), were among the 10 leading CODs in several sex and age subgroups. In contrast, several CODs that appeared among the 10 leading CODs according to the NCHS list, such as pneumonia, kidney disease, cirrhosis, and sepsis, were excluded from the 10 leading CODs if the WHO list was used. The rank of Alzheimer disease and related dementias and hypertensive diseases according to the WHO list was higher than their ranks according to the NCHS list. A marked increase in the ranking of unintentional poisoning among men aged 45-64 years was noted from 2008 to 2021.

Conclusions: A dashboard with bump charts can be used to improve the visualization of the changes in the rankings of leading CODs according to the WHO and NCHS lists as well as demographic characteristics; the visualization can help users make informed decisions regarding the most appropriate ranking list for their needs.

Introduction

Vital statistics can be used to monitor the vital signs of a nation [1]. Health advocates and the media often use the rankings of the leading causes of death (CODs) to draw attention to major health issues with relatively high mortality burdens in a population. The National Center for Health Statistics (NCHS) publishes “Deaths: leading causes” annually [2]. However, the ranking list used by the NCHS and statistical offices in several countries includes broad categories such as cancer, heart disease, and accidents [3-7]. The International Classification of Diseases and Health Related Problem Tenth Revision (ICD-10) has 89 subcategories in the broad cancer category, 41 subcategories in the broad heart disease category, and more than 100 subcategories in the broad accidents category [8]. Different subcategories within a broad category may have different levels of preventability, and therefore, may require different prevention strategies. For example, the 2019 version of the Organisation for Economic Co-operation and Development/Eurostat list of preventable and treatable CODs includes only 16 out of 89 cancer sites [9]. Stakeholders in public health policy require more specific and actionable information to help them set priorities.

To address the limitations of using broad categories for ranking, the World Health Organization (WHO) proposed a list in which cancer was divided into 17 cancer sites, heart disease into 8 specific forms of heart disease, and accidents into 6 unintentional injuries. Furthermore, more comprehensive COD categories are defined in the WHO list. For example, in the WHO list, the Alzheimer disease and related dementias (ADRD) category has ICD-10 codes F01 (vascular dementia), F03 (unspecified dementia), and G30 (Alzheimer disease), whereas in the NCHS list, ICD-10 code G30 is the only code available to classify ADRD-related mortality. In the WHO list, the hypertensive diseases category includes ICD-10 codes I10 (essential [primary] hypertension), I11 (hypertensive heart disease), I12 (hypertensive renal disease), I13 (hypertensive heart and renal disease), and I15 (secondary hypertension); however, in the NCHS list, ICD-10 codes I10, I12, and I15 are composed as one rankable category (essential hypertension and hypertensive renal disease) and I11 as well as I13 are included in the broad heart disease category. The WHO list has been routinely used to present the leading CODs by the WHO, the United Kingdom, Australia, and Italy [10-13]. However, the ranking profiles of leading CODs in the United States according to the WHO list remain unexplored.

Regarding the data visualization of the rankings of the leading CODs, the bar chart is the most commonly used chart [10-12,14]. However, it is difficult to reveal the changes in the rankings over time through bar charts. For example, the stacked bar chart by year was used by the UK Office for National Statistics; nevertheless, it was difficult to detect the changes in the ranking of a particular COD across years [11]. Bump charts have been recommended to represent the changes in the position of a given number of competing entities over a fixed duration [15]. Accordingly, in this study, we sought to design a dashboard with bump charts to visualize the changes in the rankings of the leading CODs in the Unites States by sex and age from 1999 to 2021 according to 2 lists (NCHS vs WHO).

Methods

The data on the number of deaths in each category were obtained from the Wide-ranging Online Data for Epidemiologic Research system maintained by the Center for Disease Control and Prevention for the period from 1999 to 2021 [16]. The NCHS list had 52 categories, and the WHO list had 65 categories. The name and ICD-10 codes of each category in the WHO list mapped to the NCHS list are presented in Table S1 in Multimedia Appendix 1. We followed the method used by the NCHS to determine the rank of each category. The NCHS determines the rank of each category on the basis of the number of deaths in each category.

We used Tableau to create a dashboard with a bump chart that can be filtered by list and demographic characteristics (ie, sex and age), which allows the viewers to select the dimension in which they are interested [15]. In the bump chart, each COD has a specific color, and the abbreviated name of each COD category appears in each circle. When the cursor points to a circle in the bump chart, a tooltip appears and indicates the number of deaths for that category, the proportion of total deaths that category accounts for, and the full name of the category. We also designed a filter to highlight the particular COD.

Ethical Considerations

This study used publicly available mortality data. All data used in this study were anonymized. This study was approved by the Institutional Review Board of National Cheng Kung University Hospital (B-EX-112-016) and the requirement of informed consent was waived by the abovementioned ethics committee.

Results

According to the NCHS list, the first and second leading CODs for both sexes of all ages were heart disease and cancer throughout the 23-year study period (Figure 1B). However, according to the WHO list, the first and second leading CODs were ischemic heart disease (IHD) and cerebrovascular disease from 1999 to 2002, IHD and lung cancer from 2003 to 2007, IHD and ADRD from 2008 to 2019, IHD and COVID-19 in 2020, and COVID-19 and IHD in 2021 (Figure 1A). In the WHO list, IHD and heart failure were each identified in the 10 leading CODs, whereas in the NCHS list, these 2 conditions were both classified as heart diseases and are not distinguished. Likewise, lung cancer and hematopoietic cancer were among the 10 leading CODs in the WHO list but were not distinguished in the NCHS list because in the NCHS list they were both classified into the broader cancer category (Figure 1A).

The 10 leading CODs for men of all ages according to the WHO and NCHS lists are presented in Figure 2. We noted an abrupt increase in the rank of unintentional poisoning according to the WHO list, from ninth in 2019 to seventh in 2020 and third in 2021 (Figure 2A). In contrast, the accidents category was the third leading COD from 2001 to 2019 and the fourth leading COD in 2020 and 2021 (Figure 2B). Several CODs such as cirrhosis, kidney disease, and pneumonia, which appeared among the 10 leading CODs according to the NCHS list (Figure 2B), were squeezed out from the 10 leading CODs if the WHO list was used.

The rankings of leading CODs among women of all ages in the WHO and NCHS lists are compared in Figure 3. According to the WHO list, ADRD ranked first from 2014 to 2020 and third in 2021 (Figure 3A). However, the Alzheimer disease category used in the NCHS list ranked fifth from 2002 to 2018, fourth from 2019 to 2020, and fifth in 2021 (Figure 3B). According to the WHO list, hypertensive diseases persistently increased in ranking, from eighth in 2009-2014 to seventh in 2015-2020, and to sixth in 2021 (Figure 3A). However, the category “hypertension” used in the NCHS list did not appear in the 10 leading CODs during the study period, except in 2019 and 2021, when it was ranked tenth (Figure 3B). By contrast, several CODs including pneumonia, kidney disease, and sepsis that appeared among the 10 leading CODs according to the NCHS list did not appear among the 10 leading CODs if the WHO list was used.

Figure 4 contrasts the rankings of the 10 leading CODs among men aged 45-64 years according to the WHO list with and without using a highlight filter. For example, by selecting unintentional poisoning in the highlight filter, we can better visualize the marked increase in the rankings of unintentional poisoning (Figure 4B).

Figure 1. Ranking of the 10 leading causes of death for both sexes of all ages in the United States according to (A) the World Health Organization (WHO) list and (B) the National Center for Health Statistics (NHCS) list. This dashboard is accessible [17]. Figure 4. Ranking of 10 leading causes of death for men aged 45-64 years in the United States according to the World Health Organization (WHO) list (A) without using and (B) with using the highlight filter. This dashboard is accessible [17]. Cirr: chronic liver disease and cirrhosis; ColC: colon cancer; CLRD: chronic lower respiratory disease; CO19: COVID-19; CVD: cerebrovascular disease (stroke); DM: diabetes mellitus; HemC: hematopoietic cancer; Hypt: hypertensive diseases; IHD: ischemic heart disease; LunC: lung cancer; Pois: unintentional poisoning; Suic: suicide; Tran: transportation accidents.

Discussion

Principal Findings

The findings of this study indicate that profiles of the rankings of the 10 leading CODs differ depending on which list is used. Several CODs were among the 10 leading CODs in several sex and age subgroups when the WHO list was used, including brain, breast, colon, hematopoietic, lung, pancreas, prostate, and uterus cancer (all classified as cancer on the NCHS list); unintentional transport injuries; poisoning; drowning; and falls (which were all classified as accidents on the NCHS list). ADRD and hypertensive diseases, which have more comprehensive definitions in the WHO list, were ranked higher in the WHO list than similar categories in the NCHS list. By contrast, some CODs that appeared among the 10 leading CODs according to the NCHS list, such as cirrhosis, kidney disease, sepsis, and pneumonia, were squeezed out of the 10 leading CODs according to the WHO list. Through the use of a dashboard with bump charts, users can select a list, stratify the data by age and sex, and use a highlight filter to visualize the changes in the rankings of a particular COD across years.

The main reason for the differences between the lists in the COD rankings was the number of categories used to rank CODs. The NCHS list had 52 categories, and the WHO list had 65 categories (Table S1 in Multimedia Appendix 1). Selecting which list to use involves a trade-off. Some new specific CODs that existed in the 10 leading CODs according to the WHO list could not be revealed if the NCHS list was used. On the contrary, some CODs that appeared in the 10 leading CODs according to the NCHS would be squeezed out if the WHO list were used. The use of a more comprehensive definition for ADRD and hypertensive diseases might sacrifice the specificity, meaning that some individuals with ADRD diagnosis might be false positives. To obtain the most comprehensive information for health policy decision-making, we recommend using both lists.

Several studies have examined the changes in the rankings of the leading CODs in the United States [18-20]. Because the categories in the NCHS list are relatively broad, prominent changes cannot be detected, except for accidents, which increased in rank from fifth in 2011 to third in 2018 [19]. The pattern of changes in the leading CODs in the United States according to the WHO list differed from that in Japan, Korea, and Taiwan [7]. According to the WHO list, the leading COD from 1999 to 2020 in the United States was IHD, whereas in Japan, Korea, and Taiwan, the leading COD in most of the years during this period was stroke [7].

Strengths and Limitations

This study has several strengths. First, this study was the first to use the WHO list to illustrate changes in the ranking of the leading CODs in the United States. Using the WHO list enabled us to detect several drastic increases in the ranks of some leading CODs, which could not be revealed according to the NCHS list. The second strength of this study was the use of bump charts, which aid in visualizing the changes in rankings of specific CODs in a ladder-like manner. The third strength was the creation of a dashboard, which enables viewers to select the specific demographic group they wish to examine using either the NCHS or the WHO list (or another list can be added) and highlight the changes of a particular COD.

However, several limitations should be considered when interpreting the findings of this study. First, the changes in the relative position of each rank on the bump charts did not correspond to the extent of the changes in the proportions of total deaths accounted for by each category. For example, ADRD increased in ranking between 2013 and 2020 (from second to first) but accounted for fewer proportion of deaths in 2020 than it did in 2013 (10.9% vs 12.1%, respectively). Therefore, an increase (or decrease) in ranking does not indicate an increase (or decrease) in either burden or risk. Second, although the WHO list uses more specific categories compared to the NCHS list, several categories are still relatively broad. For example, unintentional poisoning comprises ten 3-digit ICD-10 codes (X40-X49) that each correspond to a different drug or chemical. Third, both ranking lists are limited in terms of detail and are not comprehensive, meaning that not all deaths can be categorized and ranked. The increase in the number of deaths in some emergent diseases within the residual category could not be detected using rankings of leading CODs.

Conclusions

The rankings of the leading CODs constitute a highly popular health statistic used to convey relative mortality burdens and are widely used by media and health advocates. A dashboard with bump charts can be used to improve visualizing the changes in the rankings of the leading CODs according to the WHO and NCHS lists as well as the demographic characteristics; it can also help users make informed decisions regarding the most appropriate ranking list for their needs.

Acknowledgments

The authors would like to thank Ms Pai-Huan Lin for the data analysis. This study was funded by the Ministry of Science and Technology, Taiwan (grant 111-2314-B-006-030). The funders had no role in the design of the study, collection and analysis of data, decision to publish, or preparation of the manuscript.

Data Availability

The data that support the findings of this study are publicly available [17].

Authors' Contributions

SYT and THL conceived the study design. YCC, YWC, and IK participated in the collection and analysis of data. SYT and THL drafted the manuscript. All authors contributed to the interpretation of the data and critically revised the manuscript. All authors read and approved the final manuscript.

Abstract

Background: The world is undergoing an unprecedented wave of urbanization. However, the effect of rapid urbanization during the early or middle stages of urbanization on seasonal influenza transmission remains unknown. Since about 70% of the world population live in low-income countries, exploring the impact of urbanization on influenza transmission in urbanized countries is significant for global infection prediction and prevention.

Objective: The aim of this study was to explore the effect of rapid urbanization on influenza transmission in China.

Methods: We performed spatiotemporal analyses of province-level influenza surveillance data collected in Mainland China from April 1, 2010, to March 31, 2017. An agent-based model based on hourly human contact–related behaviors was built to simulate the influenza transmission dynamics and to explore the potential mechanism of the impact of urbanization on influenza transmission.

Results: We observed persistent differences in the influenza epidemic attack rates among the provinces of Mainland China across the 7-year study period, and the attack rate in the winter waves exhibited a U-shaped relationship with the urbanization rates, with a turning point at 50%-60% urbanization across Mainland China. Rapid Chinese urbanization has led to increases in the urban population density and percentage of the workforce but decreases in household size and the percentage of student population. The net effect of increased influenza transmission in the community and workplaces but decreased transmission in households and schools yielded the observed U-shaped relationship.

Conclusions: Our results highlight the complicated effects of urbanization on the seasonal influenza epidemic in China. As the current urbanization rate in China is approximately 59%, further urbanization with no relevant interventions suggests a worrisome increasing future trend in the influenza epidemic attack rate.

Introduction

The influenza virus is mainly spread within close ranges rather than over long distances [1,2]. The distance from an influenza-infected individual may significantly affect the potential of influenza transmission. Social distancing is a well-recognized nonpharmaceutical intervention that could reduce the transmission of viruses from infected to susceptible individuals because of the increased physical distance between these individuals or reduced frequency of congregation in socially dense community settings such as schools or workplaces [3]. Urbanization is a complex phenomenon that is associated with population density in an urban area. In this study, urbanization rate, defined as the percentage of population living in an urban area, was used to characterize the urbanization process. Urbanization can worsen an epidemic through a variety of mechanisms [4]. Studies on low-income nations have clearly documented the association between epidemic severity and the combination of high-density living conditions, extreme poverty, and poor sanitation [5]. With respect to communicable diseases such as influenza, which is mainly spread within close ranges [1,2], the population concentrations in an urban area can lead to more rapid proliferation of infectious diseases [6]. Urbanization affects the seasonal epidemic transmission in highly urbanized countries [4,7]. In the United States with an urbanization rate of 83% in 2021 [8], cities in urban areas with higher population densities had a higher influenza transmission potential [7]. In Australia with an urbanization rate of 88% in 2021 [8], the peak influenza infection rate and peak prevalence increased steadily as the urban population density increased [4]. However, the impact of urbanization on the influenza epidemic in urban countries such as China with urbanization rates at 63% and India with urbanization rates at 35% in 2021, where about 70% of the population live, is less well-understood. In addition, in highly urbanized countries, urban living has been the norm in the last century. Therefore, the direct effects of further increases in the urban population density on the potential seasonal influenza epidemic might be less obvious [4]. In this study, attack rate, defined as the cumulative incidence rates of seasonal influenza during the study period, was used to characterize the seasonal influenza activities. Since urbanization will continue in urban countries in the near future, understanding the impact of urbanization on influenza transmission is essential for precise influenza prediction and prevention and for building a healthy society.

As a low-income country, China has experienced an unprecedented wave of rapid urbanization, as reported by the rapid increase in the urbanization rate from 17.9% in 1978 to 58.5% in 2017 [9]. The urbanization rate also varies significantly between provinces in China, thereby providing a unique opportunity to study the impact of urbanization on the influenza epidemic at different levels of urbanization within a single health care system. In China, urbanization has led not only to a rapid increase in the urban population density but also to a sharp decrease in the household size [10]. As households, schools (workplaces), and communities have been identified as the primary contexts of influenza transmission [11,12], the impact of urbanization on seasonal influenza in China may be complicated.

Dynamic models such as the susceptible-infected-recovered models have been developed to understand the dynamics of influenza transmission [7]. However, these models do not study the dynamics of influenza transmission at the individual level [13]. In highly urbanized countries, urban living has been the norm in the last century; thus, the susceptible-infected-recovered model could be used to study the impact of urbanization on influenza transmission [7]. However, the impact of urbanization on the influenza epidemic in urbanizing countries is complicated. In this study, to characterize the complicated impact of urbanization on human contact behaviors and population age structures in China, we used an agent-based model in which each individual or group of people was defined as an agent. The agent-based model based on human contact behavior has been used previously to model infectious disease transmission [11,14,15]. We also used similar models previously to successfully simulate influenza transmission in China [12,16].

In this study, we aimed to explore the effects of urbanization on seasonal influenza epidemic intensities in urban Mainland China (except Hong Kong, Macao, and Taiwan) according to the spatiotemporal analyses and modelling study of influenza surveillance data collected in Mainland China from 2010 to 2017.

Methods

Data Sources

We used weekly reports of influenza surveillance data from the Chinese National Influenza Center. The study data set was based on the number of specimens tested at 554 sentinel hospitals located in the urban areas of 31 provinces of Mainland China (including autonomous regions and municipalities). After excluding Tibet from the analysis due to the incompleteness of data, 30 provinces were evaluated. Although the surveillance data collection began in 2004, we focused on the period from April 1, 2010, to March 31, 2017, as the surveillance network was improved and expanded after the 2009 influenza A/H1N1 pandemic [17]. Shu et al [18] provide additional details about the Chinese influenza surveillance system. The data set of the influenza surveillance system in China included the number of visits at each hospital, number of cases of influenza-like illness (ILI), number of specimens tested, and number of laboratory-confirmed cases of influenza A (H1N1, H3N2, and pdmH1) and B (Yamagata and Victoria). ILI cases were identified based on a standard case definition: body temperature >38 °C, either cough or sore throat, and the absence of an alternative diagnosis. Several indicators were defined to characterize influenza activity in China. First, the ILI rate was defined as the number of ILI cases divided by the number of visits. Second, the influenza viral positive rate was defined as the number of laboratory-confirmed influenza cases divided by the number of specimens tested. In accordance with earlier studies [18-20], in this study, we defined a proxy for the weekly incidence rate (henceforth, incidence rate) of influenza, which is the multiplication of the ILI rate and the influenza viral positive rate. The incidence rate more precisely represents the incidence of influenza infection.

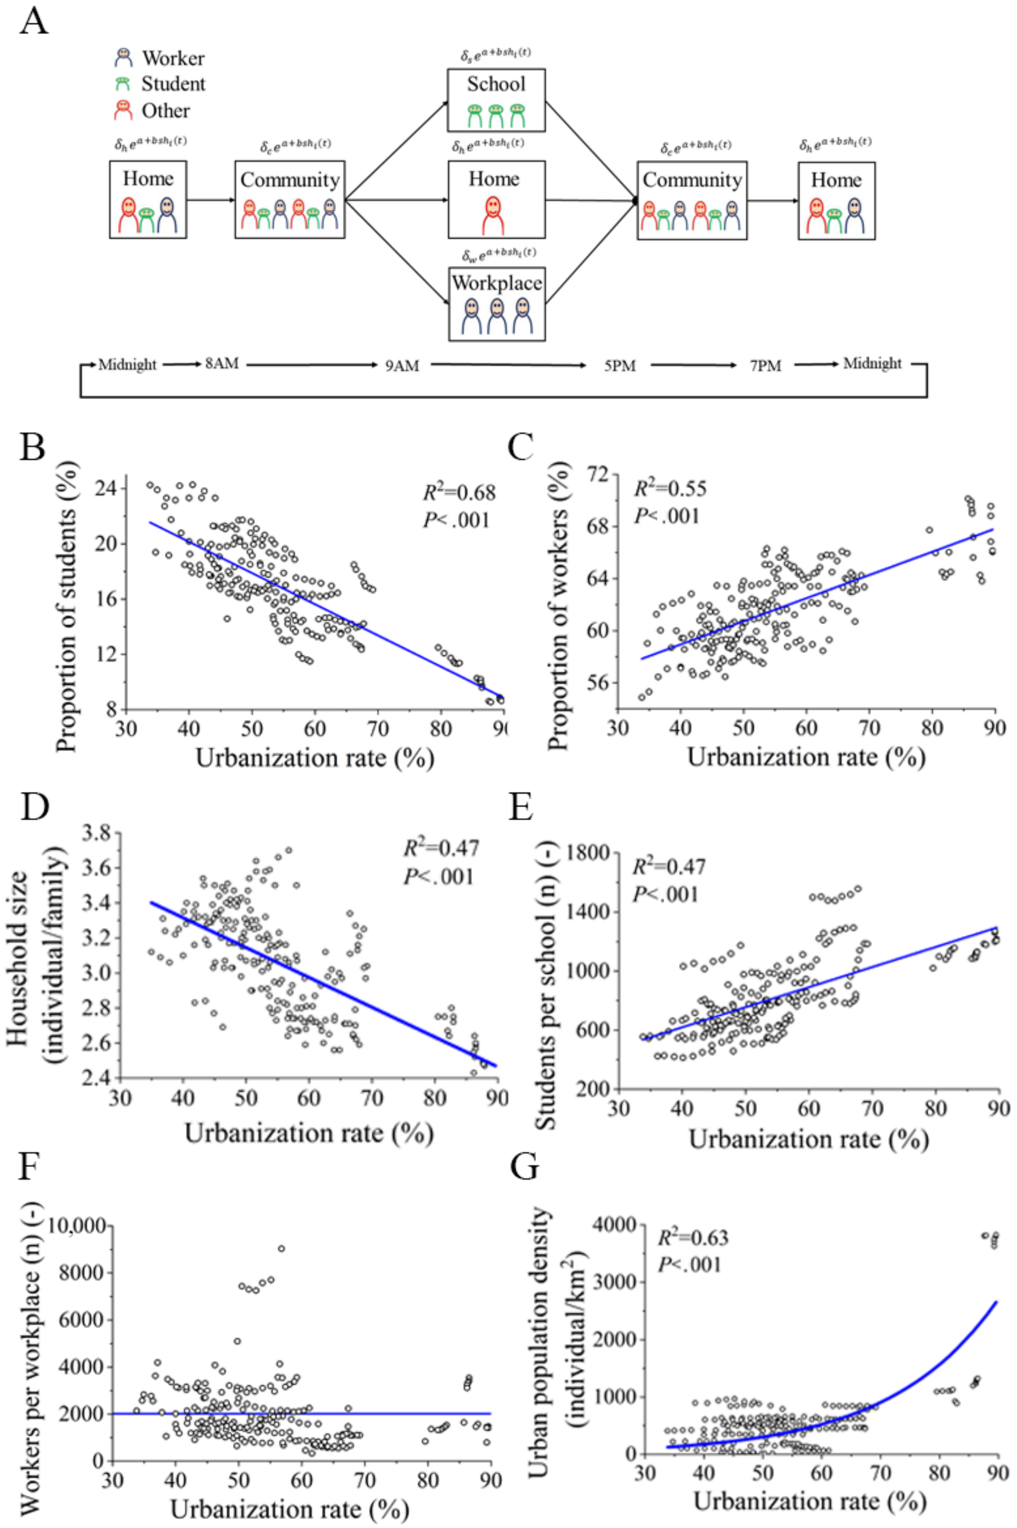
The influenza epidemic in Northern China intensifies in winter-spring months, while that in Southern China shows a semiannual cyclic pattern with clear peaks in both summer and winter [21,22]. We therefore defined an epidemiological annual cycle as the period from April 1 to March 31 of the following year [21], and we divided the annual cycle into summer months and winter-spring months, which included calendar weeks 14-39 (26 weeks in total) and weeks 40-13 of the following year (26 or 27 weeks in total), respectively [21]. The attack rate of the winter-spring or summer influenza epidemic in each province is defined as the cumulative weekly incidence rates during the half-year time (25 weeks in total): 12 weeks within the peak weeks since the median duration of an influenza epidemic wave is 15.6-22.5 weeks [21]. Province-level data on urbanization, urban areas, populations, household and school sizes, and number of students, schools, and factories from year 2010 to year 2016 were obtained from the China Statistical Yearbook [9], China City Statistical Yearbook [23], and National Bureau of Statistics of China [24].

Modelling

We used an agent-based model to simulate the influenza transmission dynamics in provinces with different urbanization rates. Our simulation strategy is similar to that reported previously in the literature [11]. Similar models have been used to simulate influenza transmission in Beijing [25] and Hong Kong [16]. In this study, we simplified the model and considered 4 types of indoor spaces: homes, schools, workplaces, and communities (ie, public spaces). These 4 types of indoor spaces are known as the primary contexts of influenza transmission [11,12]. Populations were divided into 3 groups: workers, students, and others.

Figure 1A presents the assumed typical daily movements of 3 groups of people. Although real human movement patterns are much more complicated, we considered the simulated movement pattern to represent a general daily schedule. The time step in the simulation was set to 1 hour. For each case, the simulation was performed with 100 replications to account for randomness in the status of each individual (infectious, susceptible/removed). Differences in human movement behaviors between weekdays and weekends were not considered. The percentage of students decreased significantly with urbanization (Figure 1B). The number of workers (N_W) was estimated based on the number of people aged between 18 and 60 years ($N_{18\text{-}60}$), the number of students in universities (N_{SU}), and the unemployment rate (R_u) as $N_W = (N_{18\text{-}60} - N_{SU}) * (1 - R_u)$. The percentage of workers increased significantly with urbanization (Figure 1C). The remaining populations were classified as others. Influenza transmission is affected by the number of students, workers, and others, as well as by the distributions of these populations in each indoor space. The province-level distribution of household sizes at different urbanization levels is shown in Figure 1D. Notably, the school size increased with urbanization (Figure 1E). As we did not observe a significant linear relationship between urbanization and the number of workers per workplace (Figure 1F), we adopted a mean value of 2020 workers per workplace at all urbanization levels. With urbanization, the urban population density increased exponentially (Figure 1G), and it is reasonable to believe that population contact in the community would also increase.

Figure 1. Individual routines and population distribution data in Mainland China between 2010 and 2016. (A) Flowchart of individual hourly routines. (B) Changes in the proportion of students with increasing urbanization. (C) Changes in the proportion of the workforce with increasing urbanization. (D) Changes in the household size with increasing urbanization. (E) Changes in the school size distribution with increasing urbanization. (F) Changes in the workplace size distribution with increasing urbanization. (G) Changes in the urban population density with increasing urbanization rates.



Here, we defined *Ii* as 1 if individual *i* were infectious and 0 otherwise. The force of infection per hour experienced by individual *i* by 1 infected person in a home, community, school, and workplace was then calculated as $I_k\delta_h e^{a+bshi(t)}$, $I_k\delta_c e^{a+bshi(t)}$, $I_k\delta_s e^{a+bshi(t)}$, and $I_k\delta_w e^{a+bshi(t)}$, respectively, where n_{hi} is the household size of individual *I*; n_{ci} is the mean number of people in the community that individual *i* would contact per hour, which was assumed to be in proportion to the urban population density [25]; n_{si} (n_{wi}) is the mean number of individuals that individual *i* would contact in school (workplace) per hour if he/she were a student (worker), which was assumed to be constant in different provinces and n_{si}=9, n_{wi}=4 [26]; and *a* and *b* are parameters used to adjust the impact of specific humidity, *sh*(t), at time t on influenza transmission. For this study, *a*=0.788 and *b*=–180 [27], while δ_h, δ_c, δ_s, and δ_w indicate the influenza transmission coefficients in a home, community, school, and workplace, respectively. We assumed that $\delta_h:\delta_c:\delta_s:\delta_w = 6:1:12:6$ [11], as children are known to have high clinical attack rates of influenza [28,29]. The absolute influenza transmission coefficients in homes, communities, schools, and workplaces (δ_h, δ_c, δ_s, and δ_w, respectively) are always unknown, and these are mainly determined by the antigenic evolution of the influenza virus and thus vary across years [7]. Therefore, we relied on our model approach to back-calculate the transmission coefficients. For each year, we selected the surveillance data in 1 province and used the least squares method to determine the influenza transmission coefficient parameter value in that year. Then, we used the back-calculated transmission coefficients to simulate the influenza transmission in other provinces and compared them with surveillance data to test our model. The simulation duration of influenza transmission was set to 8 months from November 1, 2013, to June 30, 2014. The time step was set to 1 hour. Each simulation under different settings was conducted 100 times to improve the reliability of the results. The latent and infectious periods were set to 2 and 4 days [30], respectively.

There were 2 types of settings in our simulation. When we simulated infection spread in different provinces, the real parameters from each province were used. When we simulated infection spread at different urbanization levels, the ideal parameters obtained by data fitting based on real parameters from all provinces were used. In this setting, Beijing climate data were used to eliminate the impact of climate differences. The detailed model structure and parameter estimation are shown in Multimedia Appendix 1 [11,12,27,30-34].

Spatial Analysis of the Influenza Surveillance Data by Province

The spread of influenza is influenced by climate [35]. As China is a climatologically diverse country, we cannot directly compare the province-level intensities of the influenza epidemic. To minimize the influence of climate on the analysis, we attempted to compare the epidemic attack rates in provinces with similar climates by using the following 2 methods. First, we analyzed the attack rates of the influenza epidemic in 15 provinces in Northern China that are situated in the temperate climate zone. Second, there is no significant latitude gradient with respect to province-level urbanization in China. Therefore, we classified the provinces according to the urbanization rate. The province urbanization rates ranged from 33.8% to 89.6%, and therefore, we classified the provinces according to the following urbanization rate ranges: <40%, 40%-50%, 50%-60%, 60%-70%, and >70%. The urbanization within each range was defined as the mean urbanization level of the provinces within this range. The influenza epidemic attack rate was also defined as the mean attack rate in the provinces within each urbanization range. Using year 2013 as an example, the provinces within different urbanization ranges are shown in Figure S2 of Multimedia Appendix 1. The mean latitudes of the provinces with urbanization levels <50%, 50%-60%, 60%-70%, and >70% were 31.8, 35.7, 30.4, and 36.8 °N, respectively; the variance in the latitude was narrow within each urbanization range. Therefore, the influence of climate could be minimized. Last, binomial fitting was used to quantify the observed U-shaped relationships between the province-level influenza epidemic attack rates and urbanization rates by the following equation: $y = ax^2+bx+c$, where y represents the influenza epidemic attack and x represents the urbanization rate. The least squares method was used to estimate the unknown parameters a, b, and c. The turning point of the urbanization rate was $-b/2a$.

Ethical Considerations

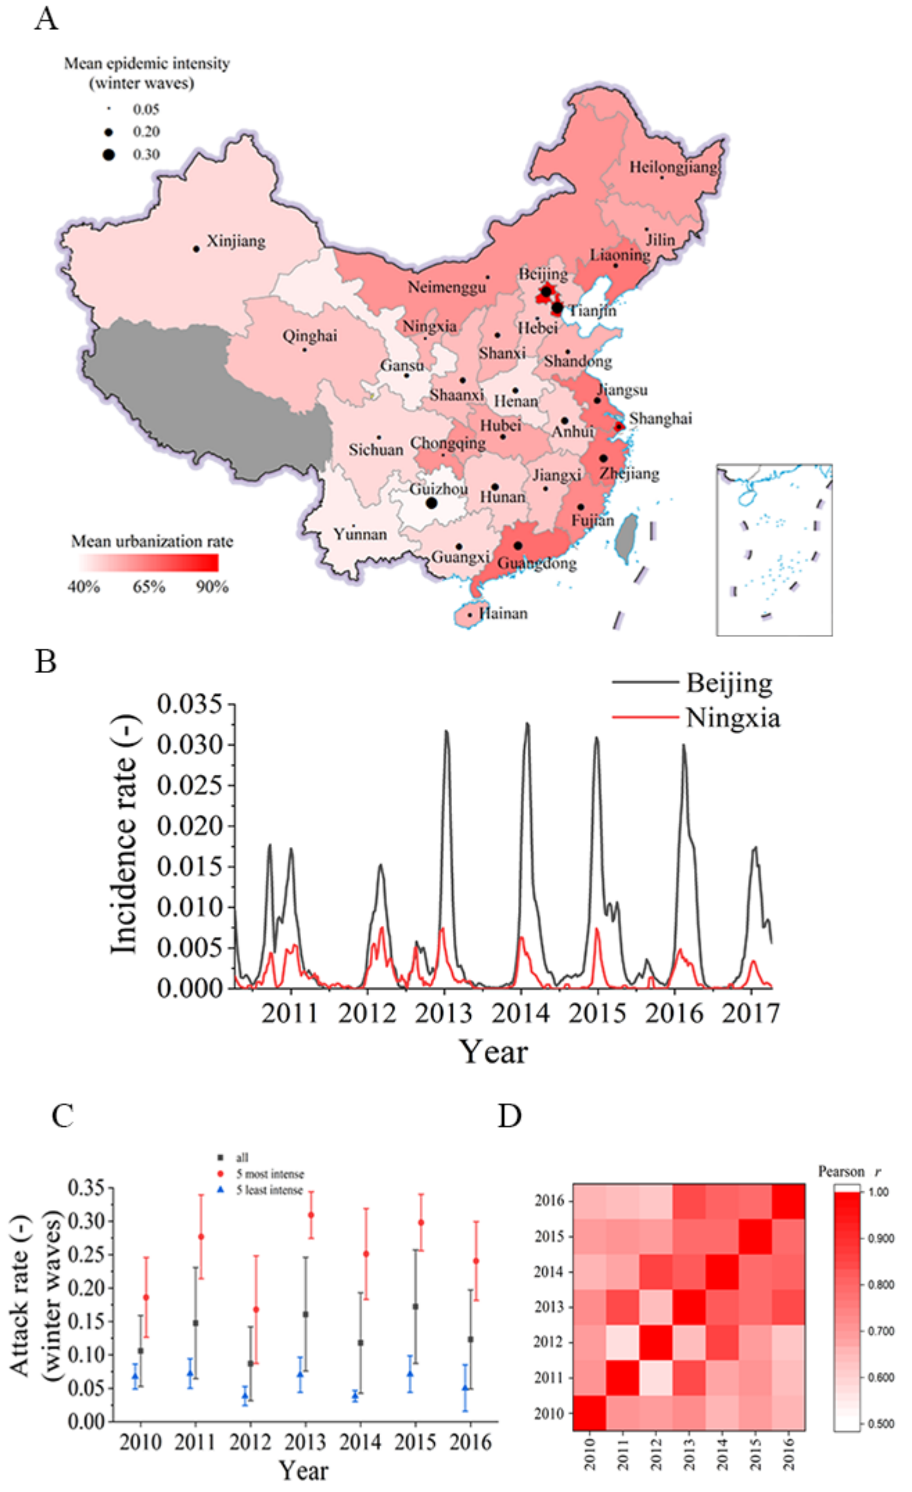
Data in this study are from public database, ie, Chinese National Influenza Centre [36]. We did not make any interventions in the study.

Results

Spatiotemporal Analysis of the Influenza Surveillance Data

During the study period between 2010 and 2016, differences in the mean epidemic attack rate followed a geographic pattern, with the highest intensive epidemic detected in both the most and least urban regions of Beijing (mean urbanization, 86%) and Guizhou (mean urbanization, 39%), respectively. The lowest epidemic attack rate was observed in moderate urban regions such as Ningxia (mean urbanization, 53%) and Chongqing (mean urbanization, 58%; Figure 2A). In addition, the differences persisted over time, that is, some provinces had consistently more intense epidemic than others year after year. The influenza incidence rates in Beijing were always higher than those in Ningxia (Figure 2B). For these 5 provinces with the most or least intense epidemic, the mean epidemic attack rates followed a similar trend over time as the mean epidemic attack rates in all 30 provinces (Figure 2C). The Pearson correlation coefficients of the epidemic attack rates in the 30 provinces between any 2 epidemiological years were higher than 0.5 (Figure 2D), indicating that the differences in the epidemic attack rates among provinces persisted over time. There was no significant linear relationship between the urbanization rate and influenza surveillance intensity (*P*=.64) (Figure S3 of Multimedia Appendix 1).

Figure 2. Systematic differences in the seasonal influenza epidemic attack rates in the winter-spring waves across provinces in Mainland China according to surveillance data between 2010 and 2016. (A) Mean influenza epidemic attack rates (black circles) and urbanization rates (colored bars) in 30 Chinese provinces; grey areas indicate a lack of data. (B) Time-series influenza incidence rates in Beijing and Ningxia provinces. (C) Influenza epidemic attack rates in 5 provinces with the most or least intense epidemic and in all provinces across epidemiological years, where error lines represent 95% CIs. (D) Pearson correlation coefficients of the epidemic attack rates in 30 provinces between epidemiological years.



Modelling Study

We hypothesize that these patterns of epidemic attack rates are due to urbanization. The categorization of the provinces by urbanization rates revealed that the correlation between the influenza epidemic attack rate and urbanization rate yielded a U-shaped curve throughout the study period, with a turning point at about 55% urbanization (Figure 3A). From our binomial-fitter curves, we also found U-shaped relationships between province-level influenza epidemic attack rates and urbanization rates in 15 provinces in Northern China, and we consistently observed the lowest attack rates in provinces with urbanization rates of 50%-60% (Figure 3B and Table 1). The agent-based model that we built in this study also revealed U-shaped relationships between province-level influenza epidemic attack rates and urbanization rates (red line in Figure 3B). The sensitivity analyses of the key parameters in the agent-based model are shown in Figure S4 of Multimedia Appendix 1.

Figure 3. Determination of a U-shaped relationship between the influenza epidemic attack rates and urbanization rate in China. Data are presented by (A) clustering of 30 provinces by the urbanization rate and (B) province-level data in 15 provinces in Northern China. The curves are the binomial fitting of the data in 2010-2016. The red line indicates the agent-based model simulation results, and the error bars indicate the 95% CIs of the 100 replications.

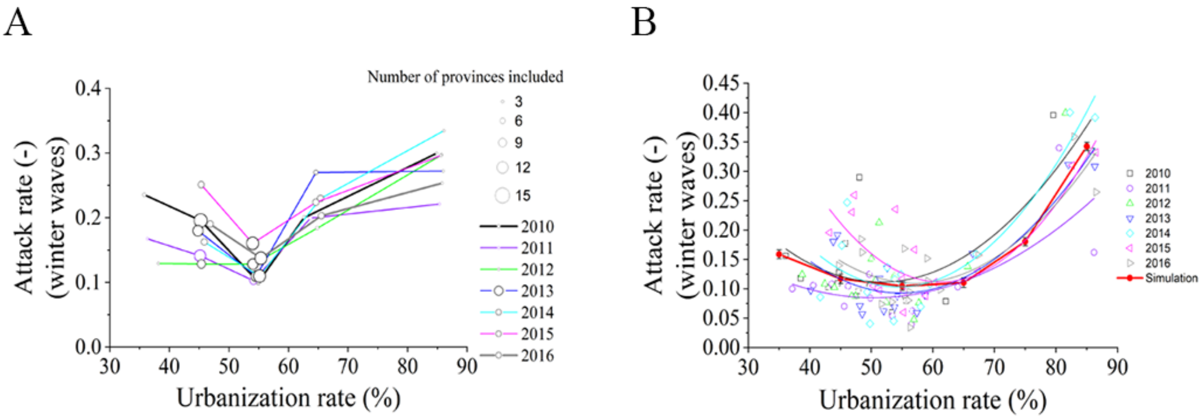


Table 1. Binomial fitting of the province-level epidemic attack rates in the 15 provinces in Northern China.

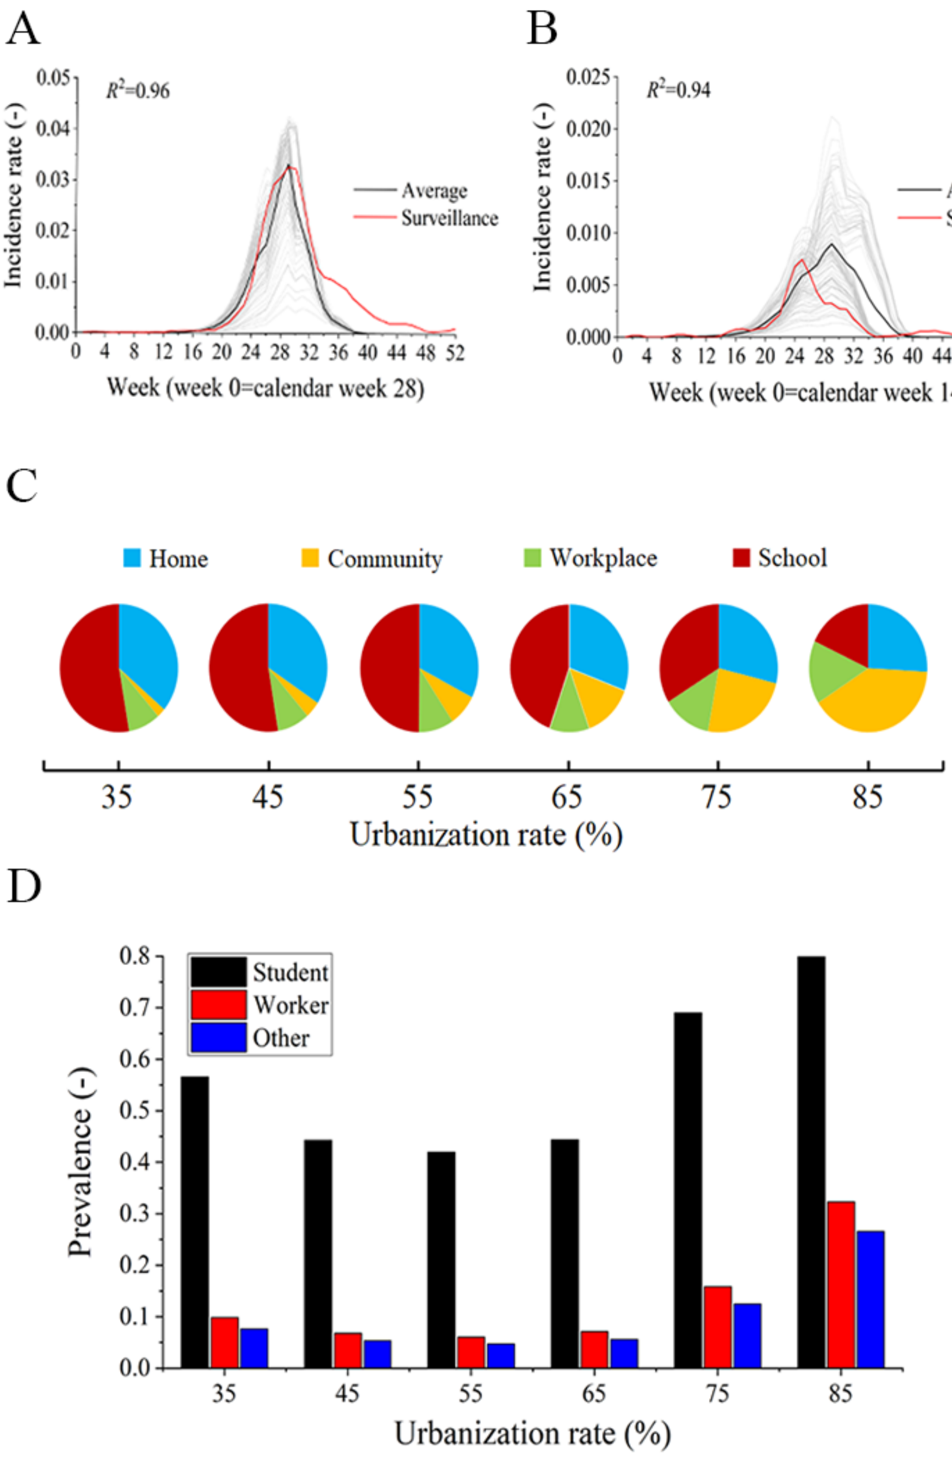
Epidemiological year	R^2	*P* value	Urbanization rate turning point (%)
2010	0.61	.004	52
2011	0.51	.01	50
2012	0.76	<.001	50
2013	0.77	<.001	55
2014	0.79	<.001	55
2015	0.67	.001	61
2016	0.68	.001	57

Next, we simulated the influenza transmission to quantify the U-shaped relationship observed in Figure 3. As demonstrated using 2013 as an example, we selected surveillance data from Beijing for back-calculation of the unknown transmission coefficients (Figure 4A, R^2=0.96). The back-calculated transmission coefficients and our model simulated the influenza transmission dynamics in Jilin well (Figure 4B, R^2=0.94), demonstrating that the models could be used to simulate influenza transmission in China. Next, we used the model to simulate influenza transmission in provinces with different urbanization rates. The model also yielded a U-shaped association between the urbanization rate and influenza epidemic attack rate (Figure 3B), with a turning point at 55% urbanization.

Figure 4. Simulated influenza epidemic in provinces with different urbanization rates. Simulated incidence rates in (A) Beijing and (B) Jilin. (C) Simulated contributions of each setting to influenza transmission according to the urbanization rate. (D) Influenza prevalence among students, workers, and others according to the urbanization rate.



Taking the simulation in Beijing and Jilin as an example, the agent-based model built in this study well-fitted the influenza surveillance data (Figure 4A and 4B). Thus, using the agent-based model built in this study, we simulated the contributions of different locations and people in influenza transmission with different urbanization rates. Figure 4C presents the percentage contributions of the 4 studied locations with different urbanization rates to influenza transmission. As the urbanization rate increased from 35% to 85%, the contributions of each location to influenza transmission increased from 2.7% to 41.8%: the contribution of workplaces increased from 8.3% to 13.4%, but that of homes decreased from 38.9% to 27.4% and that of schools decreased from 50.2% to 17.4%. Given the relatively frequent number of contacts and the high infection risk per contact in schools, our simulation results demonstrate that students face a much higher infection risk than workers (relative risk 5.4, SD 1.7) and others (relative risk 6.8, SD 2.2; Figure 4D).

Discussion

To the best our knowledge, this study is the first to explore the effect of urbanization on the attack rate of the seasonal influenza epidemic in a country experiencing an unprecedented rapid rate of urbanization. This study was made possible by the availability of census data and influenza surveillance data. Our analyses revealed a U-shaped relationship between the urbanization rate and influenza attack rate, with a turning point at around 55% urbanization rate. We used an agent-based mathematical model based on hourly human contact behaviors to explore the 2 main primary mechanisms responsible for the observed trend. We found that an increase in the urban population density (Figure 1G) increased the number of close contacts between people in communities and thus enhanced the transmission of influenza in public areas. Further, decreases in household sizes (Figure 1D) and percentages of students (Figure 1B) reduced the rates of influenza transmission in homes and schools, respectively. The net effects of these 2 mechanisms provide a simple but reasonable explanation for the observed U-shaped trend in the influenza epidemic attack rate over the 7-year study period. Further confirmation of this U-shaped trend would have significant implications for the influenza epidemic in China. In addition, although this study analyzes the influenza data in China, the methods may also be applicable in other urbanizing countries and for other respiratory infections such as COVID-19, measles, and Middle East respiratory syndrome because indoor environments such as households, schools (workplaces), and communities have always been identified as the primary context of infection transmission [37,38].

The epidemic attack rate is an important parameter for the development of medical surge capacities and public health systems, including primary care facilities. This is particularly important for influenza, as a vaccine specific for a new pandemic virus might not be widely available for up to 6 months based on the current vaccine production technology [3]. Previous studies have proposed that socioeconomic factors may affect both the influenza epidemic and pandemic [4,7,39]. Our study also demonstrates regional differences in the intensity of the influenza epidemic across China, which suggest that seasonal influenza interventions should vary among provinces. We found that the most intense influenza epidemic occurred in the most and least urbanized provinces, suggesting that increased attention should be directed to influenza control in the latter provinces, which are also economically underdeveloped. Previous analyses of the history of infectious diseases and human populations have suggested that the host population density is a critical determinant of the establishment and persistent endemicity of a pathogen in a population. Accordingly, urban aggregations play an important role in maintaining infectious disease endemics [40]. As people have become increasingly concentrated in urban areas, and particularly in large cities, influenza viruses could potentially be spread more easily nowadays. Moreover, large cities always serve as hubs in intercity travel networks, which are linked by high-speed rail in China. These hubs could also influence the spread of the influenza epidemic among cities. These potential trends associated with urbanization pose a challenge to future influenza interventions.

There are at least 2 policy implications to build healthy cities in the aspect of infection control. The first is that influenza vaccine recommendations in China should speed up since vaccine coverage is only approximately 2% in China [41], especially in provinces with urbanization rates greater than 60%. In this study, we found a U-shaped relationship between the influenza epidemic attack rate and urbanization rate, with a turning point between 50% and 60% urbanization. In China, the recent urbanization rate is approximately 60%, and a large number of provinces are currently at the turning point in the U-shaped trend curve. As further urbanization is expected, the trajectory of the influenza epidemic intensity in those provinces in the near future would be worrisome if no interventions were made because of the nonlinear increase in the strain placed on the medical infrastructure [4]. The second is that nonpharmaceutical interventions implemented to control the influenza epidemic and even pandemic should vary by province since this study demonstrates regional differences in the intensity of the influenza epidemic across China. This study shows that in low urbanized regions, influenza transmission mainly occurs in the schools, while in highly urbanized regions, influenza transmission mainly occurs in the community. These findings are well supported by the observed decreasing effectiveness of school closure with increasing urbanization in China [42]. Thus, in highly urbanized regions, ventilation and surface cleaning/disinfection in public places may be effective, while in low urbanized regions, school closures should be recommended.

Parameters in the simulation determined the infectious disease transmission (eg, attack rate). Some parameters such as the time schedule of workers and students and number of students per class were obtained from the literature or real statistical data. However, other parameters such as the daily numbers of the contacted students in each class and the number of workers in each office were estimated and assumed. We adjusted these parameters to minimize the difference between the simulation results and the real infection spread. Moreover, we performed a sensitivity analysis for 10 parameters to show how these parameters influence the infection spread (Figure S4 of Multimedia Appendix 1).

This study suggests a number of limitations and possibilities for future research. First, our model did not consider differences in the medical service levels. Highly urbanized areas have access to better medical services, which would enable a more rapid cure of infectious cases and better control of the influenza epidemic. However, approximately 90% of the seasonal influenza cases remain unreported [43], and infectious cases are mostly transmissible during the incubation period and during 2-3 days with clinical symptoms. Therefore, the medical service level would have a very limited impact on the influenza epidemic. Second, our model did not consider differences in the influenza vaccine coverage because this rate has increased only gradually to approximately 2% of the Chinese population over the past 15 years [41]. This low influenza vaccination rate would have a very limited influence on an epidemic. Third, the results of this study cannot be generalized to rural areas since there is a lack of rural-related data. Fourth, this study assumes that all types of agents (eg, worker, student) have a constant time schedule and all offices and classrooms in a province have the same setting. Therefore, the random scenarios, which could be referred to as a dynamic network, were ignored. Finally, higher resolution analyses of the influenza epidemic, such as those conducted at a city level, would provide more accurate information, as cities are the principal locations of influenza transmission between humans [7]. However, our relatively coarse data set did not allow us to evaluate the influenza patterns at the city or hospital level, even though the surveillance data from 4 of the 30 studied provinces were based on single cities (Beijing, Tianjin, Chongqing, and Shanghai).

In conclusion, we found a U-shaped relationship between the influenza attack rates and urbanization rate in provinces of the urbanizing mainland China, with a turning point between 50% and 60% urbanization. This finding is different from that reported in other studies in urbanized countries. Our study poses the potential challenges of the expected further urbanization process in China on population health and health infrastructure. Further, our results will be critical for precise influenza prediction and prevention.

Abstract

Background: The increase in tobacco/conventional cigarette (CC) and electronic cigarette (EC) usage among Chinese youth has become a growing public health concern. This is the first large-scale study to compare the impact of CC and EC usage on risk for nonsuicidal self-injury (NSSI) and suicidality in cis-heterosexual and sexual and gender minority (SGM) youth populations in China.

Objective: This study examines the CC and EC risks for NSSI and suicidality among Chinese youth and compares the extent to which SGM and cis-heterosexual youth's risks for NSSI and suicidality are influenced by their CC and EC usage and dependence.

Methods: A total of 89,342 Chinese participants completed a cross-sectional self-report survey in 2021. Sociodemographic information, sexual orientations, gender identities, CC and EC usage, CC and EC dependence, and risks for suicidality and NSSI were assessed. The Mann-Whitney *U* test and chi-square test were performed for nonnormally distributed continuous variables and categorical variables, respectively. The multivariable linear regression model was used to examine both the influence of CC and EC usage and CC and EC dependence on NSSI and suicidality as well as the interaction effects of CC and EC usage and CC and EC dependence on NSSI and suicidality by group.

Results: The prevalence of CC usage ($P<.001$) and dependence ($P<.001$) among SGM participants was lower than that among their cis-heterosexual counterparts. However, the prevalence of EC usage ($P=.03$) and EC dependence ($P<.001$) among SGM participants was higher than that among their cis-heterosexual counterparts. The multivariable linear regression model showed that CC dependence and EC dependence had a unique effect on NSSI and suicidality (CCs: B=0.02, $P<.001$; B=0.09, $P<.001$; ECs: B=0.05, $P<.001$; B=0.14, $P<.001$, respectively). The interaction effects of (1) CC usage and group type on NSSI and suicidality (B=0.34, $P<.001$; B=0.24, $P=.03$, respectively) and dual usage and group type on NSSI and suicidality (B=0.54, $P<.001$; B=0.84, $P<.001$, respectively) were significant, (2) CC dependence and group type on NSSI were significant (B=0.07, *P*<.001), and (3) EC dependence and group type on NSSI and suicidality were significant (B=0.04, *P*<.001; B=0.09, *P*<.001, respectively). No significant interaction effect was observed between EC usage and group type on NSSI and suicidality (B=0.15, *P*=.12; B=0.33, *P*=.32, respectively) and between CC dependence and group type on suicidality (B=–0.01, *P*=.72).

Conclusions: Our study shows evidence of intergroup differences in NSSI and suicidality risks between SGM and cis-heterosexual youth related to CC and EC usage. These findings contribute to the growing literature on CC and EC in cis-heterosexual and SGM populations. Concerted efforts are necessary at a societal level to curb the aggressive marketing strategies of the EC industry and media coverage and to maximize the impact of educational campaigns on EC prevention and intervention among the youth population.

Introduction

Electronic cigarettes or e-cigarettes (ECs) are battery-based vaping devices simulating tobacco/conventional cigarette (CC) smoking by aerosolizing artificially manufactured liquid solutions containing nicotine for users' inhalation [1]. The association between the usage of CCs and suicidality is well-established, with previous studies showing that regular usage of CCs is associated with an increased risk of suicidality (ie, suicidal ideation, plan, and attempt) [2-4]. Several studies have reported the neurotoxicity of CC usage on adolescents' brain structure, increasing the risk of oxidative stress–related neurological disorders while promoting emotional dysregulation [4-6]. Subsequently, the emotional dysregulation brought about by CC usage could further aggravate individuals' pre-existing mental health conditions (eg, depressive thinking featured by hopelessness and worthlessness). Combined with relevant social factors (eg, isolation), the complex interplay between CC usage and mental health risks may heighten the risk of suicidality among CC users [4-6].

Similar to CC usage, EC usage can impose not only physical risks (ie, nicotine dependence, cardiovascular injury, respiratory system damage, and noncancer pulmonary disease) but also mental health threats, including but not limited to depression, anxiety, and nonsuicidal self-injury (NSSI) [5,6]. In addition, recent studies suggest that nicotine usage, including CC and EC usage, has a bivariate relationship with NSSI, underscoring the potential relationship between NSSI and both CC and EC usage [7,8]. Nevertheless, although findings from the abovementioned studies have shown the impact of CC and EC usage on youth NSSI and suicidality, their differences in chemical composition, method of consumption, and sociocultural perceptions are drastically different from each other. First, regarding the chemical composition, compared to tobacco in CC, EC is featured with a liquid containing both nicotine and flavoring, with a high percentage of it being glycerol or propylene glycerol [9]. Second, concerning the method of consumption, compared to the lighting process of CC, EC often uses a power button to activate an atomizer to generate an aerosol from its liquid, which simulates smoke from CC and requires no fire and burning, thereby making its usage more prevalent in places where CC is banned [9,10]. Third, with regard to sociocultural perceptions, EC has been marketed as less harmful than CC in the Chinese market, with relatively limited regulations on the minimum age to purchase compared to CC [10]. Due to the abovementioned differences, EC and CC may influence youth NSSI and suicidality differently.

Findings from past research postulate that college students' high susceptibility to mental health risks, exemplified in forms of anxiety, depression, and stress, when facing concerns resulting from sudden environmental changes (ie, moving from one's hometown to another city), social isolation, social alienation, worries of financial independence, high academic performance expectations, and learning style change corresponds to their high risk of suicidality [11,12]. Previous research argues that college students often begin to explore their gender and sexual identity in their college lives, during which the disparity between cis-heterosexual and sexual and gender minority (SGM) youth in suicidality may surface [13,14]. The 2016 National Health Interview Survey showed that 20.5% of sexual minority young adults smoke CCs, which is much higher than that reported among their heterosexual counterparts (ie, 15.3%) [15]. The prevalence of CC usage in the transgender and gender-diverse population is also higher than that in their cisgender counterparts [15,16]. Similarly, recent studies have also found that the prevalence of EC usage in the SGM population is higher than that in their cis-heterosexual counterpart [17-20]. Specifically, there is burgeoning evidence from previous studies that suggest SGM youth's current usage (SGM: 9.4%; cis-hetero: 4.9%), lifetime usage (SGM: 25.1%; cis-hetero: 14.3%), and past 30-day usage of ECs (SGM: 28.5%; cis-hetero: 23.4%) are all higher than those among cis-heterosexual youth, indicating this group's vulnerability toward EC usage [18-20].

Such a disparity in EC and CC usage between SGM and cis-heterosexual youth could be potentially explained by the minority stress model. Minority stressors, including but not limited to heterosexist discrimination, social rejection, social isolation, and homo/bi/transphobic harassment, could further worsen the stigmatization of SGM youth's identities while inducing higher stress levels among them, contributing to their increased risk of substance usage [21]. Furthermore, besides the minority stress experienced by SGM youth, the tobacco industry has further exploited their vulnerability since they have historically been targeting SGM youth as a major consumer crowd and pushed forward relevant campaigns such as the Project Subculture Urban Marketing for gay individuals in San Francisco [22]. Nevertheless, to date, no study has examined the relationship between the usage of CCs and ECs on college students' NSSI and suicidality while investigating potential intergroup differences existing between cis-heterosexual and SGM youth, leaving a critical gap in the literature. Most of the current CC and EC research [4-22] examining the increasing risks of youth for NSSI and suicidality focused on studying CC and EC usage separately and did not further investigate the different extents to which the SGM and cis-heterosexual youth's risks for NSSI and suicidality were affected by CC and EC usage, ignoring the potentially existing intergroup differences. Our cross-sectional study aims to fill this gap by investigating the effects of CC and EC on NSSI and suicidality and the difference in the effects between SGM and cis-heterosexual youth. This study's hypotheses postulate that (1) cigarette usage (including CC and EC usage) and cigarette dependence (including CC and EC dependence) have a unique and positive impact on both NSSI and suicidality, (2) cigarette usage has a more pronounced impact on NSSI and suicidality among SGM youth than on NSSI and suicidality among their cis-heterosexual peers, and (3) cigarette dependence has a more severe impact on NSSI and suicidality among SGM youth than on NSSI and suicidality among their cis-heterosexual peers.

Methods

Participant Recruitment

University students from 63 universities and colleges in the Jilin province, China, were invited to participate in a cross-sectional web-based self-report survey. Recruitment was performed via universities' and colleges' staff teachers and targeted WeChat groups (similar to WhatsApp groups). Students who were interested in participation entered the secure and anonymous questionnaire through the QR code mentioned in the study poster that was distributed by school staff teachers. Students were first asked to thoroughly read the study description, and those who selected the commensurate button and continued to answer the questionnaire were deemed as consented to this study. Individuals who successfully completed this questionnaire were offered the opportunity to join a cash prize lottery by accessing a separate link. The description of the cash prize lottery was listed on the front page of the web-based survey, and the amount was carefully calibrated to strike a balance between being sufficient to encourage participation and minimize dropout without being excessively large to create an undue influence on participants' behavior or reporting. Respondents' data were collected between October 26 and November 18, 2021, via Credamo [23].

For statistical quality control of this study, we excluded respondents who (1) were younger than 15 years (ie, below the lowest threshold of the regular age range of college or university students in China), (2) failed 2 or more of the 4 attention check questions (ie, this question is an attention check question. There are many colors of the sky, which can be green, blue, red and black, but, for this question, please choose "green" for your answer) that were designed to assess whether survey respondents were focused during their responding process, and (3) showed presence of logical contradictions or inconsistencies within responses (eg, male participants choosing "male" for sexual preference while choosing "heterosexual" for sexual orientation), omission of answers (eg, leaving blanks in their answers instead of choosing options such as "none of the above" or "prefer not to say"), or their answers showed evidence of patterned or nondiscriminatory responses (eg, consistently choosing the first option across multiple questions). The final sample consisted of 89,342 participants, among which 8853 were SGM respondents and 80,489 were cis-heterosexual respondents.

Study Measures

Gender Identity

Participants' sociodemographic information, including age, ethnicity (Han ethnicity or non-Han ethnicity), educational background (undergraduate, master, or doctoral students), residence areas prior to university/college enrollment (urban or rural), only-child status, and annual family income, was collected. This study's 3 gender identity assessment questions were based on the GenIUSS published report from the Williams Institute, University of California, Los Angeles [24]. First, participants were asked, "What was your sex assigned at birth? (gender specified at birth or the one listed on your original birth certificate)" with options being male and female. Second, participants were asked, "What is your gender identity? (your personal thoughts and understanding of your own gender)" with options being cisgender, transgender, nonbinary/gender nonconforming/agender/others, unsure, and cannot understand the question. Third, participants were asked, "If you can only choose from 1 option below, which gender option best describes you?" with options being male, female, transgender male (female-to-male or longing to become male), transgender female (male-to-female or longing to become female), genderqueer/nonbinary/gender nonconforming, cross-dresser, unsure, and not listed (please write down your answer in the blank). The third question served the function of discerning self-identified transgender male and female participants in our sample, including male-to-female, female-to-male, and participants who desired to live their lives as the opposite sex. Written answers from participants who chose "not listed (please write down your answer in the blank)" were manually inspected and reviewed by 2 research assistants who then recoded those participants' gender identities after reaching a consensus in thorough discussions. Due to the sociocultural unfamiliarity with the gender identity glossary, a validity check was performed for the first and third questions. Transgender and gender nonconforming participants, including transgender males, transgender females, and participants who were genderqueer/nonbinary/gender nonconforming, who answered consistently across all 3 questions were included in the analyses.

Sexual Orientation

This study's 3 sexual orientation assessment questions were also based on the SMART published report from the Williams Institute, University of California, Los Angeles [25]. First, participants were asked, "Which one of the following best describes your sexual orientation?" with choices being asexual (not sexually attracted to others or have low interest in sexual activity), homosexual, heterosexual, bisexual (can be romantically and sexually attracted to both males and females), pansexual (can be romantically and sexually attracted to anyone, regardless of their sex or gender identity), and not listed. Participants were then asked to answer the second and third questions, "What kind of person are you sexually attracted to?" and "What kind of person are you romantically attracted to?" with the same set of choices ranging from male, female, both male and female, any gender (including transgender, genderqueer, and nonbinary), unsure, and not listed (please write down your answer in the blank). For participants who chose "not listed" for the first question, 2 aforementioned research assistants manually inspected their written answers, confirmed their answers' consistency by comparing their answers to the second and third questions, and eventually recoded their sexual orientations after reaching consensus in thorough discussions. Participants who sexually identified as homosexual, bisexual, and pansexual were included in the final analyses. Upon coding completion, all participants in this study were successfully labeled as SGM and cis-heterosexual.

CC and EC Usage

We employed 2 screening questions to assess participants' CC and EC usage. Participants were asked to answer the first question, "Do you currently have smoking habits?" with options including yes and no. Those who chose yes continued to answer the remaining questions related to CC and EC usage, while others directly skipped to the next section of the questionnaire. Those who chose yes were then asked the second question, "Do you usually smoke e-cigarettes or conventional cigarettes?" with options including e-cigarettes, conventional cigarettes, and both. First, those who chose conventional cigarettes were then assessed by answering the 6-item validated Chinese version of the Fagerström Test of Nicotine Dependence (FTND) [26,27]. Their scores, ranging from 0 to 10, were calculated by summing up their responses, with higher scores indicating higher levels of nicotine dependence. Scores from 0 to 2 demonstrate very low dependence; scores from 3 to 4 demonstrate low dependence; scores at 5 demonstrate medium dependence; scores from 6 to 7 demonstrate high dependence; and scores from 8 to 10 demonstrate very high dependence. The validated Chinese version has been used in previous research for similar purposes, demonstrating good internal consistency and validity [28,29]. Second, for those who chose ECs, we revised the validated Chinese version of the FTND to measure their EC dependence. Although the revised scale also contains 6 items, we expanded the measurement ranges of both the first and fourth items by adding 2 additional options for each item, increasing the score range from 0-10 to 0-14. Nevertheless, participants still scored on a response scale, with a higher score indicating a higher level of EC dependence. Third, those who chose "Both" were asked to answer both sets of questions. For those who did not answer the corresponding part of the questionnaire, scores were set to 0. In this study, the reliability values of FTND (ω=0.83) and e-FTND (ω=0.80) were acceptable.

Suicidality

The Suicidal Behaviors Questionnaire-Revised (SBQ-R) was designed to measure individuals' suicide-related behaviors from 4 different dimensions, that is, individuals' history of suicide attempt(s), individuals' frequency of suicidal ideation, individuals' suicide threats, and individuals' future suicide attempts likelihood [30]. The validated Chinese version of the SBQ-R contains 4 items, with the total score ranging from 3 to 18 and higher scores indicating higher levels of suicidality [31]. A total score of 7 or higher was considered a high suicide risk, while a total score below 7 was considered a moderate or low suicide risk. In this study, the ω of SBQ-R was 0.81.

NSSI Analysis

Two items adapted based on the Clinician-Rated Severity of Nonsuicidal Self-Injury were used in this study [32]. The first item asked participants whether they have ever engaged in NSSI, with options including "Yes. I engaged in NSSI more than one year ago," "Yes, I engaged in NSSI within the past year," and "no." The second item asked how many days during the past year did participants engage in NSSI, with options including none, 1 to 4 days, 5 to 7 days, 8 to 11 days, and 12 days or more. We combined these 2 items as 1 item for participants to answer, with options ranging from "None," "I engaged in NSSI more than one year ago," "I have had NSSI 1 to 4 days in the past year," "I have had NSSI 5 to 7 days in the past year," "I have had NSSI 8 to 11 days in the past year," to "I have had NSSI 12 days or more in the past year," with participants' scores ranging from 0 (none) to 6 (12 days or more in the past year). Since NSSI for 5 or more days in the past year was the clinically recommended cutoff, as suggested by the American Psychiatric Association [32], participants in this study were classified into 3 groups (ie, group with no NSSI history, group with less than 5 days of NSSI within the past year, and group with more than 5 days of NSSI within the past year) for further analyses.

Data Analysis

First, we performed a descriptive analysis of the sociodemographic variables of the SGM and the cis-heterosexual groups. The Mann-Whitney *U* test and chi-square test were performed for nonnormally distributed continuous variables (eg, scores of CC dependence, EC dependence, NSSI, suicidality) and categorical variables (eg, classifications of cigarette usage, NSSI, and suicidality), respectively. Our primary analyses using the multivariable linear regression model involved examinations of both the influence of CC usage and EC usage on NSSI and suicidality and the interaction effects of CC usage and EC usage on NSSI and suicidality by group (ie, SGM and cis-heterosexual). Both models were controlled for other sociodemographic variables. Results were reported at 95% CIs and were only considered significant when *P* values were less than .05. For variables with a small number of missing values (eg, age, education background), we used mean substitution to input the missing data. We used ω as the measure of the tools' reliability index [33]. All statistical analyses were performed using SPSS (version 28, IBM Corp).

Ethics Approval

This cross-sectional survey received approval from the ethics committee at Jilin University (approval 2021-9-29). Informed consent for primary data collection and secondary data analyses from participants was automatically collected from students who selected the commensurate button and continued to answer the questionnaire. The privacy and confidentiality of the participants in this study were protected during data collection and analysis through anonymization and deidentification. None of the personally identifiable information was collected, and all data were stored in a personal computer in the laboratory with password protection. As mentioned earlier, compensation for participants in the study was provided with a link on the postsurvey completion page to the cash reward lottery, with the amount being meticulously calculated to be rewarding while not generating potential bias.

Results

Table 1 summarizes the sociodemographic characteristics of the participants by group type (ie, SGM or cis-heterosexual). Cigarette usage prevalence was different between SGM participants and cis-heterosexual participants (χ^2_3[N=89,342]=149.8; *P*<.001). Specifically, the proportion of SGM participants (454/8853, 5.1%) who only used CC was lower than that of their cis-heterosexual counterparts (7161/80,489, 8.9%; *P*<.05); the proportion of SGM participants (53/8853, 0.6%) who only used EC was higher than that of their cis-heterosexual counterpart (348/80,489, 0.4%; *P*<.05). Moreover, the proportion of SGM participants who used CCs was lower than that of their cis-heterosexual counterpart (873/8853, 9.9% vs 10,685/80,489, 13.3%; χ^2_1[N=89,342]=82.5; *P*<.001, respectively). In contrast, the proportion of SGM participants who used ECs was higher than that of their cis-heterosexual counterpart (472/8853, 5.3% vs 3872/80,489, 4.8%, χ^2_1[N=89,342]=4.7; *P*=.03, respectively).

Table 2 summarizes the intergroup differences between SGM and cis-heterosexual individuals in this study. The CC dependence score of the SGM group was lower than that of their cis-heterosexual counterpart (*z*=–9.25, *P*<.001). Furthermore, the SGM participants had lower dependence levels on CCs than the cis-heterosexual participants (χ^2_4[N=89,432]=37.6; *P*<.001). However, compared to the cis-heterosexual group, the SGM group scored higher in EC dependence, suicidality, and NSSI (*z*=3.20, *P*=.001; *z*=69.91, *P*<.001; *z*=54.32, *P*<.001, respectively). At the same time, the SGM group had higher suicide risk and individuals with more NSSI compared to the cis-heterosexual group (χ^2_1[N=89,432]=4507.5; *P*<.001; χ^2_2[N=89,432]=3070.9; *P*<.001, respectively). In addition, we analyzed the intergroup difference between the SGM and the cis-heterosexual groups in the revised 6-item scale measuring EC usage. As shown in Table S1 of Multimedia Appendix 1, results from the chi-square test analysis highlighted that compared with the cis-heterosexual group, the SGM group showed a greater degree of EC dependence on each item of the revised scale.

Table 3 summarizes the effects of cigarette usage and cigarette dependence on NSSI. When only cigarette usage was included in the model (model 1), CC usage, EC usage, and dual usage were associated with increased risks of NSSI when compared to no usage (B=0.12, *P*<.001; B=0.24, *P*<.001; B=0.29, *P*<.001, respectively). However, when cigarette usage and cigarette dependence were both included in the model (model 3), EC usage was not associated with increased risks of NSSI when compared to no usage (B=0.05, *P*=.13). Regardless of whether cigarette dependence was included alone (model 2) or in conjunction with cigarette usage (model 3), EC dependence and CC dependence were associated with increased risks of NSSI (CCs: B=0.04, *P*<.001; B=0.02, *P*<.001; ECs: B=0.06, *P*<.001; B=0.05, *P*<.001, respectively).

[b] N/A: not applicable.

Besides, the multivariable linear regression models showed that cigarette usage has a unique effect on NSSI and suicidality (Table 5). Specifically, the results demonstrated that CC usage, EC usage, and dual usage increased risks for both NSSI and suicidality when compared to no usage (CC: B=0.09, *P*<.001; B=0.22, *P*<.001; EC: B=0.20, *P*<.001; B=0.64, *P*<.001; dual usage: B=0.22, *P*<.001; B=0.68, *P*<.001, respectively). The results also showed that SGM participants had increased risks of NSSI and suicidality when compared to cisgender heterosexual participants (B=0.35, *P*<.001; B=1.94, *P*<.001, respectively). Table 5 underscores the significant interactions of (1) CC usage and group type on NSSI and suicidality (B=0.34, *P*<.001; B=0.24, *P*=.03, respectively) and (2) dual usage and group type on NSSI and suicidality (B=0.54, *P*<.001; B=0.84, *P*<.001, respectively). No significant interaction effect was observed between EC and group type on NSSI and suicidality (B=0.15, *P*=.12; B=0.33, *P*=.32, respectively).

Table 5. Interaction effects of cigarette usage with group models.[a]

Variables	Nonsuicidal self-injury		Suicidality	
	B (95% CI)	*P* value	B (95% CI)	*P* value
Main effects				
Cigarette usage				
No	1 (Reference)	Reference	1 (Reference)	Reference

[b] Group (0=cis-heterosexual participants; 1=sexual and gender minority participants).

In addition, the multivariable linear regression models showed that CC dependence and EC dependence have a unique effect on NSSI and suicidality (Table 6). Specifically, the results demonstrated that participants' CC and EC dependence simultaneously increased risks for both NSSI and suicidality (CCs: B=0.03, *P*<.001; B=0.12, *P*<.001; ECs: B=0.04, *P*<.001; B=0.13, *P*<.001, respectively). The results also showed that SGM participants had higher levels of NSSI and suicidality when compared to the cisgender heterosexual participants (B=0.38, *P*<.001; B=1.97, *P*<.001, respectively). Table 6 underscores the significant interactions of (1) CC dependence and group type (ie, SGM or cis-heterosexual) on NSSI (B=0.07, *P*<.001) and (2) EC dependence and group type on NSSI and suicidality (B=0.04, *P*<.001; B=0.09, *P*<.001, respectively). No significant interaction effect between CC dependence and group type on suicidality was found (B=–0.01, *P*=.72).

Table 6. Interaction effects of cigarette dependence with group models.[a]

Variables	Nonsuicidal self-injury		Suicidality

Discussion

Principal Findings

To our knowledge, this is the first study examining the usage of different cigarette types (ie, CCs and ECs) and their relationship with NSSI and suicidality while investigating intergroup differences between Chinese cis-heterosexual and SGM youth by using data from a large-scale cross-sectional survey. We found that CC usage and dependence were more prevalent among cis-heterosexual individuals, whereas EC usage and dependence were more prevalent among SGM individuals. We found that only CC usage or EC usage increased individuals' risks for both NSSI and suicidality; in particular, dual usage increased these risks. We also found that CC dependence and EC dependence could simultaneously impact individuals' risks for NSSI and suicidality independently, and the impacts of each could overlay with the usage of CCs and ECs.

Our findings shed light on the existing intergroup differences in susceptibility to NSSI and suicidality risks. Although CC usage, EC usage, and dual usage increased an individual's risk of NSSI and suicidality compared with no usage, we found that only CC usage and dual usage increased the risks of NSSI and suicidality in the SGM population compared to those in the cis-heterosexual population. These results are supported by previous research [34-42]. SGM youth are susceptible to the disproportionately high risk of CC usage due to societal, peer, and community influence, which are the major risk factors for NSSI and suicidality. Such societal, peer, and community influences could also be applied to EC usage with its increasing advertisements on social media, and EC usage could be a significant risk factor for mental health risks. Furthermore, recent studies [34-43] underline the fact that there is a significant overlap between CC and EC users in the SGM population, supporting our finding that individuals with dual usage have the highest risks of NSSI and suicidality compared to individuals with no usage of CC and EC.

We found that both CC dependence and EC dependence increased an individual's risk of NSSI and suicidality. Specifically, we found that both CC and EC dependence increased the risks of NSSI in the SGM population compared to that in the cis-heterosexual population. However, only EC dependence increased the risk of suicidality in the SGM population compared to that in the cis-heterosexual population. Although only a relatively limited amount of research has focused on investigating EC dependence, findings showed that youth with EC usage could experience dependence symptoms (ie, higher usage frequency compared to CC) unique to ECs, creating more barriers to EC cessation [43]. Considering that SGM youth could be more influenced by EC due to societal, peer, and community influence and EC has been deemed as the major risk factor for SGM population's mental health, we believe our findings on EC dependence and its impact on SGM youth could be valuable for further research. Thus, our findings add to the emerging breadth of evidence emphasizing the imminent risks posed by CC and EC usage and dependence among youth.

The existing intergroup difference between SGM and cis-heterosexual college students in NSSI and suicidality risks resulting from CC and EC usage and dependence can be explained by SGM individuals' less stable mental health and their vulnerability toward CC usage and EC dependence. First, findings from US and international studies have consistently underlined the continuing worsening situation of SGM youth's mental health [34-37]. Such a disparity arises from a wide range of structural vulnerabilities such as unavoidable systemic discrimination and prejudice in education, employment, and health care opportunities [38,39]. Further, these structural vulnerabilities stem from the imbalanced hierarchical social power structure that is responsible for generating and widening the mental health gap between SGM and cis-heterosexual individuals while limiting SGM individuals' accessibility to determinants of health, leaving the SGM population defenseless against risky behaviors such as substance use [39-45].

As previously mentioned, a number of explanations have been proposed in past research, including being impacted by the marketing target of the tobacco industry on the media scale, community norms on a group scale, and minority stressors on a personal scale. First, it is well-established that SGM youth are at disproportionately high risk of CC usage [41,42]. Past research also suggests that the SGM population has been the major marketing target of the tobacco industry, resulting in increased difficulties for SGM youth to resist CC usage when such behavior is normalized by the public media [44]. With the increase in EC usage, recent research underlines that the same aggressive marketing strategy has also been employed by the EC industry and public media. To be more precise, studies indicate that SGM youth were more likely to report being exposed to, searching for, sharing, or being shared with EC–related content on the news or social media platforms compared to their non-SGM peers [46-50]. Second, from a community standpoint, past research has pointed out that the community context could be an influential factor in SGM youth's smoking behavior [47-50]. Under the influence of increasing exposure to EC-related content among the SGM population, it becomes reasonable to assume that, in social situations with SGM peers (ie, one of the potential triggers for EC usage and combined CC and EC usage), SGM youth would become more susceptible to the rising trend of EC usage among their peers [48]. Third, on a personal scale, as mentioned earlier, the minority stress model underscores that unique stressors experienced by the SGM population, including but not limited to discrimination and internalized homo/bi/transphobia, could result in higher stress levels among this stigmatized group [40-45]. Such stress could then contribute to the thought pattern of EC usage being a way for individuals to express or assert their gender identity or to rebel against traditional gender norms [40-45]. Due to all the aforementioned reasons, concerted efforts need to be made on a societal level in terms of educating SGM youth about the misconceptions, safety concerns, and, most importantly, adverse mental health outcomes such as increased risks for NSSI and suicidality that could be potentially induced by EC usage.

From a broader perspective, the rise of EC usage among Chinese youth has become a public health concern in recent years. Unlike the easy accessibility of the adverse effects of CC usage from various reliable sources, youth often receive inaccurate information about EC usage, resulting in a higher likelihood of maintaining their positive perception of ECs. Under the massive impact created by extensive marketing campaigns, ECs have been promoted as less harmful than CCs and, therefore, have rapidly gained popularity among the younger generation [45]. Compared to the downhill journey of CC usage among Chinese youth (ie, a significant reduction from 12.9% in 2014 to 3.9% in 2019), the rise in EC usage (ie, from 1.2% in 2014 to 2.7% in 2019) reveals that smoking among youth is still a major public health concern in China, many of whom are not fully aware of the physical and mental health risks induced by EC usage [46]. Although camouflaged by the utility for smoking cessation, nonsecondhand smoke exposure, and easy accessibility, ECs' negative impact on youth's physical and psychological well-being cannot be ignored. Considering EC's relationship with NSSI and suicidality, efforts to prevent youth from EC addiction must be made on a societal level [50].

It is worth noting that Chinese government officials and policy makers have promulgated the *Law on Youth Protection* and published the *Notice of the "Guarding Youth" Special Action Plan for Youth Protection from Tobacco Abuse* in 2021 while further strengthening the supervision of EC products, regulating the market order, and standardizing industrial governance by putting into effect the Measures for the Administration of Electronic Cigarettes as of May 1, 2022 [50]. The implementation of these measures has prohibited youth younger than 18 years from purchasing EC products, which could correspondingly reduce their NSSI and suicidality risks. Nevertheless, to prevent the situation from further worsening, future efforts are still required from a societal level to regulate the aggressive marketing of the EC industry and to expand the media and school coverage of educational campaigns in formats such as nonprofit advertisements, school lectures, and short videos on social media platforms on EC usage prevention and its adverse mental health effects on youth.

Limitations

The findings from this study must be considered in light of a few limitations. First, findings from this study are limited to Chinese SGM college students and, thus, may not be generalizable to SGM youth of other cultural backgrounds or who reside in other countries. Nevertheless, our findings provide crucial insights into the disparity between SGM and cis-heterosexual youth with regard to EC usage, propelling future studies to further investigate the extent and nature of such disparity. Second, although the effect size found in this study was relatively small, our large sample size indicates that such an effect was still stable on a large population scale. Specifically, the impact of cigarette usage and dependence on suicidality and NSSI in SGM youth is more pronounced than that on their cis-heterosexual peers, highlighting the need from a public health standpoint to pay more attention to the impact of EC and CC on suicidality and NSSI among the SGM population. Third, due to the cross-sectional nature of this study, only associations were examined. Longitudinal data are required to investigate these associations over time. Fourth, the sex assigned at birth of the SGM participants in this study was mostly female (6531/8853, 73.8%), which could potentially incur sampling bias and limit the study findings' generalizability.

Conclusions and Implications

Overall, our findings have crucial implications for understanding the disparity of NSSI and suicidality risks between SGM and cis-heterosexual youth. First, this study contributes to the growing body of literature highlighting the mental health risks induced by CC usage and EC usage, emphasizing that SGM youth are more susceptible to EC usage. Second, since the sample in this study consisted of Chinese college students, these results could suggest that relevant school policies (eg, CC-free and EC-free campus policies that prohibit EC usage in school public areas and dormitories) and other school-level activities (eg, informative workshops directed by student health centers on EC usage, SGM susceptibility to EC usage, and its physical and mental health risks) could be enacted and hosted to address the health disparity among SGM students. Feedback surveys could be distributed for those policies and school-level interventions to ensure that these interventions attenuate SGM students' needs rather than perpetuate and exacerbate SGM stereotypical views. Third, findings from this study could inform governmental officials and policy makers on the vulnerability of SGM youth to EC usage. For instance, policy makers could further develop comprehensive EC control policies that are similar to the *Notice of the "Guarding Youth" Special Action Plan for Youth Protection from the Tobacco Abuse* in 2021 but with an emphasis on reducing EC usage and content exposure among SGM youth. Overall, our study provides clear guidance for influential parties to develop effective strategies to resolve the rising imminent public health concern of EC usage among SGM youth.

Acknowledgments

We would like to thank and appreciate all the college students in the Jilin province, China, who participated in this study, for taking the effort to participate in the survey, and be willing to share their information; the Vanke School of Public Health at Tsinghua University for the support; and all the research assistants and students at the Youth Mental Health Lab for their dedication.

Authors' Contributions

SX and RC contributed equally as co-corresponding authors. Yinzhe W, SX, and RC contributed to study conception and study design. SX performed data collection. Yinzhe W and YZ conducted data analysis. XZ, YF, and Yinzhe W interpreted the data. Yinzhe W, XZ, Yuanyuan W, YZ, SX, and RC contributed to paper writing and revision.

Conflicts of Interest

None declared.

Abstract

Background: China is facing a rapidly expanding aging population. Insights into the health status of older adults are of great significance for health resource allocation and health care provision to this population.

Objective: With the goal of providing a comprehensive understanding of the health status of older adults and to inform potential interventions, we investigated the level of disability and identified risk factors associated with disability among the older population (aged ≥60 years) living in China.

Methods: A total of 8467 older adults living in the Chinese city of Shenzhen were enrolled in this cross-sectional study. We used a multidimensional ability assessment survey, which assessed their activities of daily living (ADL; including eating, bathing, grooming, dressing, defecation control, urination control, using a toilet unaided, transfer, flat-ground walking, stair activity), mental status (including cognitive function, aggressive behavior, depression symptoms), sensory and communication (including consciousness level, vision, hearing, communication), and social participation (including living, working, time/space orientation, distinguish persons, social communication) abilities. The impact of demographic risk factors on ability levels was analyzed using ordinal logistic regression. The correlations between the four dimensions of ability mentioned above were analyzed using Spearman correlation analysis.

Results: A total of 7766 participants were effectively assessed. The participants' average age was 70.64 (SD 8.46) years comprising 56.53% females. The overall ability level was classified as mildly, moderately, and severely impaired for 27.57% (n=2141), 2.83% (n=220), and 4.28% (n=332) of the 7766 participants, respectively. With increasing age, the proportion of impaired participants increased from 17.62% (365/2071) in the age group 60-64 years to 91.3% (253/277) in the age group above 90 years (*P*<.001), corresponding to an approximate 10% rise for every 5-year age increment. The odds of having more severe overall ability impairment in females was 1.15 times that in males (odds ratio [OR] 1.15, 95% CI 1.04-1.28). Participants who were divorced or widowed had a higher risk of more severe overall ability impairment than those currently married (OR 1.98, 95% CI 1.68-2.33). Participants living with nonrelatives had an increased risk of more severe overall ability impairment than those living alone (OR 2.38, 95% CI 1.46-3.91). Higher education level was a protective factor of overall ability impairment (college degree or above: OR 0.32, 95% CI 0.24-0.42). The four dimensions of ability assessed were significantly correlated; a low score for ADL was significantly correlated with poorer mental status, sensory and communication, and social participation (all *P*<.001).

Conclusions: The proportion of disability among Chinese older adults increases with age, being female, having lower education levels, being divorced or widowed, and living with nonrelatives. Impairment in ADL ability is significantly correlated with poor mental status, social participation, and sensory and communication abilities. A holistic approach to improving the health of the older population is recommended in China.

older adults; ability assessment; activities of daily living; mental status; sensory and communication; social participation

Introduction

Population aging is accelerating worldwide due to declining birth rates, economic development, and improved medical and health services that extend human life longevity [1]. It is estimated that the world's population aged 60 years and over will rise by 56% from 901 million to 1.4 billion during 2015-2030 [2]. In China, an estimated 176 million individuals were aged 65 years or above in 2019, accounting for 12.6% of the Chinese population. This indicates that China has entered a fast track of population aging [3]. By 2050, the older population aged 65 years or above in China is expected to reach 330 million, accounting for more than 20% of the world's older population [4]. Notably, China is currently in a stage of rapid development and the necessary resources required to address the aging population, including financial, material, and human resources, have not been fully prepared [5]. The rapidly aging population has brought substantial challenges to China's health care system, in particular with respect to the allocation of limited health resources and pension services required to secure a healthy life in older age [6].

Aging is accompanied by multiple chronic diseases such as hypertension, diabetes, cardiovascular diseases, and dementia. These conditions are often due to chronic, low-grade inflammation; macromolecular and organelle dysfunction; stem cell and progenitor changes; and cellular senescence [7,8]. According to the Fourth National Health Data Survey in China, the prevalence of chronic diseases was 64.5% in people aged above 65 years [9]. Moreover, mental health has also become a prevalent issue among the older Chinese population. Li et al [10] reported a depression prevalence of 11.6% among community-dwelling older adults and of 18.1% among older hospital inpatients in China. Physical and mental disabilities are known to have a profound impact on the quality of life experienced by older adults. This may be attributed to the challenges faced by this population in creating wealth due to their disabilities, which often place them in a lower socioeconomic profile rendering them highly susceptible to social isolation [11]. China has the largest population of disabled older adults in the world [12]: approximately 41 million older people were considered disabled and semidisabled in 2015, accounting for approximately 18.3% of people aged above 60 years in the country [13]. This number is expected to increase to 62 million in 2030 and to 98 million in 2050 [14]. In this context, to improve the quality of life of older people, it is important to adopt personalized multicomponent prevention and intervention measures to improve or maintain their overall abilities [15]. Hence, multidimensional ability assessments for older adults would provide the necessary evidence to inform prevention and intervention strategies.

To date, numerous studies have been conducted to assess the multidimensional abilities of older adults in developed countries with comprehensive assessment tools used in community settings, such as the Resident Assessment Instrument for Home Care and the EASYcare instrument, which have been widely used to evaluate physical functioning, including activities of daily living (ADL), mental functioning, and social functioning [16,17]. In comparison, there have been limited studies related to multidimensional ability assessment in the older population in China. Previous studies on ability assessment in older adults mainly focused on the ability to fulfill ADL [18,19]. Yet, as mentioned, a more comprehensive approach that assesses various aspects, including physical, mental, and social function, among the older population would provide more holistic insights into this population's overall health status [20-24]. In addition, previous studies in China have reported that the overall ability of the older population was largely related to their sex, education, and living condition; however, the findings were not consistent across different settings [25,26].

In this study, we investigated a large group of older adults in the Chinese city of Shenzhen. We aimed to comprehensively assess the older population's overall ability across multiple dimensions, including ADL, mental status, sensory and communication, and social participation. We further explored the potential demographic factors associated with the impairment of overall ability and the correlation between the four dimensions of ability. The study findings will provide evidence to inform interventions, health policy, and health resources allocation for the older population in a Chinese setting.

Methods

Setting

The study was conducted across two districts (57 community centers) in the city of Shenzhen, China. The rollout of the survey and data collection was coordinated by a community-based nursing home privately founded in 2016. The nursing home provides aged care, nursing services, rehabilitation training, and mass health education for older adults living in the community. The nursing home has employed a smart information cloud platform that can generate an electronic version of the questionnaire used to assess the overall ability of the older population. The information system enabled a sanity check on the input information and reported errors if the input information is inappropriate, providing a certain accuracy guarantee for the data. Data were securely backed up and stored on the cloud platform.

Study Design

A cross-sectional study design was used and the study was conducted according to STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines (see Multimedia Appendix 1). From April 2017 to December 2019, a total of 8467 older adults aged ≥60 years and owning a local household registration were recruited through the nursing home mentioned above. The nursing home's catchment area covers a total of 57 local communities and 8467 older adults. Of the 8467 recruited older adults, 7965 completed assessments that were ultimately collected, excluding those who were absent at the time of the assessment or chose not to participate. During the assessment, the participants were routinely asked to provide demographic information and complete a standardized ability assessment survey. The survey was conducted using the "Ability Assessment for Older Adults" questionnaire, which is the standardized questionnaire published by the Ministry of Civil Affairs of the People's Republic of China. This questionnaire was jointly drafted by members of the China Social Welfare Association, School of Nursing of Peking University, China Medical Women's Association, and other units regarding the existing tools for the ability assessment of older adults in China and abroad [27]. A team of 30-50 staff members from the nursing home was trained to conduct face-to-face interviews to administer the survey. After they explained the purpose and significance of the survey, the participants provided informed consent. For the participants who were unable to complete the survey independently due to physical or cognitive disabilities, family members or primary caregivers answered the survey on their behalf. The collected data were then entered into the smart information cloud platform to inform the future provision of services. In this study, we retrospectively examined the information provided by the participants at enrollment.

Inclusion and Exclusion Criteria

The inclusion criteria for participants were as follows: (1) aged 60 years or older, (2) have a local household registration and have lived there for more than 6 months, (3) willing to participate in the survey for ability assessment, and (4) completed the demographic information collection form and the overall ability assessment questionnaire. Note that criteria 1-3 were utilized for selecting participants during the field survey, whereas the fourth criterion was employed during the data analysis phase.

Participants were excluded if there was missing information on the (1) variable "accidents over the last 30 days" in the demographic information collection form, (2) ADL assessment part of the overall ability assessment questionnaire, (3) mental status assessment part of the overall ability assessment questionnaire, (4) sensory and communication assessment part of the overall ability assessment questionnaire, and (5) social participation assessment part of the overall ability assessment questionnaire. All five criteria were used for excluding participants during the data analysis phase.

Ethics Approval

Ethics approval was obtained from the Biomedical Ethics Committee of the Medical Department of Xi'an Jiaotong University (Human Ethics Approval Number 2020-10). The data collection process was carried out using a deidentified approach to ensure the confidentiality of the study participants. During the study period, participants were offered certain services, including meal delivery and room cleaning, by the nursing home mentioned above, without any form of compensation. Prior to participation in the study, all participants provided their oral informed consent, in line with established ethical guidelines and regulatory requirements governing human research studies. This crucial step ensured that participants were fully informed of the study's objectives, procedures, and potential risks, and made an informed decision to voluntarily participate in the study.

Data Collection

We collected demographic and ability assessment data from the information service platform. To fulfill one of our research objectives, we selected demographic variables that were commonly collected from all study participants and had been previously shown to contribute to the ability level of older adults [25,26]. Ultimately, we selected five variables (age, sex, education, marital status, and living situation) as the demographic variables of interest for this analysis.

The participants' overall ability assessment consisted of four main dimensions. First, the ADL assessment included 10 daily activity items (eating, bathing, grooming, dressing, defecation control, urination control, using a toilet unaided, transfer, flat-ground walking, stair activity) and had a total score of 100 points (see Multimedia Appendix 2 for details). The score was graded according to four levels (100 points, unimpaired; 65-95 points, mildly impaired; 45-60 points, moderately impaired; ≤40 points, severely impaired). Second, the mental status assessment included three items (cognitive function, aggressive behavior, depression symptoms) with 6 points in total, which were divided into four levels (0 points, unimpaired; 1 point, mildly impaired; 2-3 points, moderately impaired; 4-6 points, severely impaired). Third, the sensory and communication assessment included four items (consciousness level, vision, hearing, and communication). The assessment results were classified according to certain conditions and were divided into four levels (unimpaired, mildly impaired, moderately impaired, and severely impaired). Fourth, the social participation assessment included five items (living ability, working ability, time/space orientation, distinguish persons, social communication ability) with a total score of 20 points divided into four levels (0-2 points, unimpaired; 3-7 points, mildly impaired; 8-13 points, moderately impaired; 14-20 points, severely impaired).

The classification of the overall ability level was predetermined by the survey according to the standard of the Chinese Ministry of Civil Affairs [27]. In brief, if all ADL, mental status, and sensory and communication dimensions were classified as "unimpaired" and only social participation was classified as "unimpaired" or "mildly impaired," then the overall ability result was classified as "unimpaired." The overall ability level was defined as "mildly impaired" if it satisfied one of the following: (1) the result of ADL was "unimpaired" but at least one of mental status or sensory and communication was classified as "mildly impaired" or above or the social participation was classified as "moderately impaired"; (2) the ADL was classified as "mildly impaired" but at least one of the other three dimensions was classified as "unimpaired" or "mildly impaired." The overall ability was classified as "moderately impaired" if it satisfied one of the following: (1) the result of ADL was "mildly impaired" but the other three dimensions were all classified as "moderately impaired" or at least one dimension was classified as "severely impaired"; (2) the result of ADL was "moderately impaired" and one or two of the other three dimensions were classified as "mildly impaired" or "moderately impaired." The overall ability was defined as "severely impaired" if it satisfied one of the following: (1) the result of ADL was "severely impaired," (2) the results of four dimensions were all "moderately impaired," and (3) the result of ADL was "moderately impaired" and at least one of the other three dimensions was classified as "severely impaired." Notably, participants with cognitive impairment/dementia or mental illness would raise the original level by one level. Participants with two or more falls, choking, suicide, and missing in the past 30 days would raise the original level by one level. Participants in a coma would be assessed as "severely impaired."

Statistical Analysis

Data management and statistical analysis were completed using Microsoft Excel 2016 and R 4.1.1; statistical significance was set at *P*<.05. Continuous variables are described by mean and SD, whereas categorical variables are described by frequency (n) and percentage (%). Data between different groups were compared with the χ^2 or Fisher test for categorical data and then the proportion test was used for posthoc multiple comparisons; *P* values were adjusted using Bonferroni correction. Ordinal logistic regression was used to analyze the association between demographic characteristics and the severity of the overall ability impairment. In this model, the assessment results of the overall ability of participants were used as the dependent variable and the demographic variables that exhibited statistical significance based on the χ^2 or Fisher test were used as independent variables. The η coefficient, SE, and *t* value were estimated to determine the statistical significance of each independent variable in the model. Associations between the severity of the overall ability impairment and demographic characteristics were also assessed by odds ratios and corresponding 95% CIs. The correlation between the various assessment items was analyzed using Spearman correlation analysis.

Results

Demographic Characteristics

According to the inclusion and exclusion criteria, 7766 participants out of 8467 individuals were selected for the analysis (Figure 1). Among the 7766 participants, the average age was 70.64 (SD 8.46) years, ranging from 60 to 109 years (Table 1). There were 3376 (43.47%) males and 4390 (56.53%) females. Among the 7766 participants, 45.58% (n=3540) had primary or junior high school education levels and 13.67% (n=1062) were divorced or widowed. Most participants (3745/7766, 48.22%) were living with their children before enrollment.

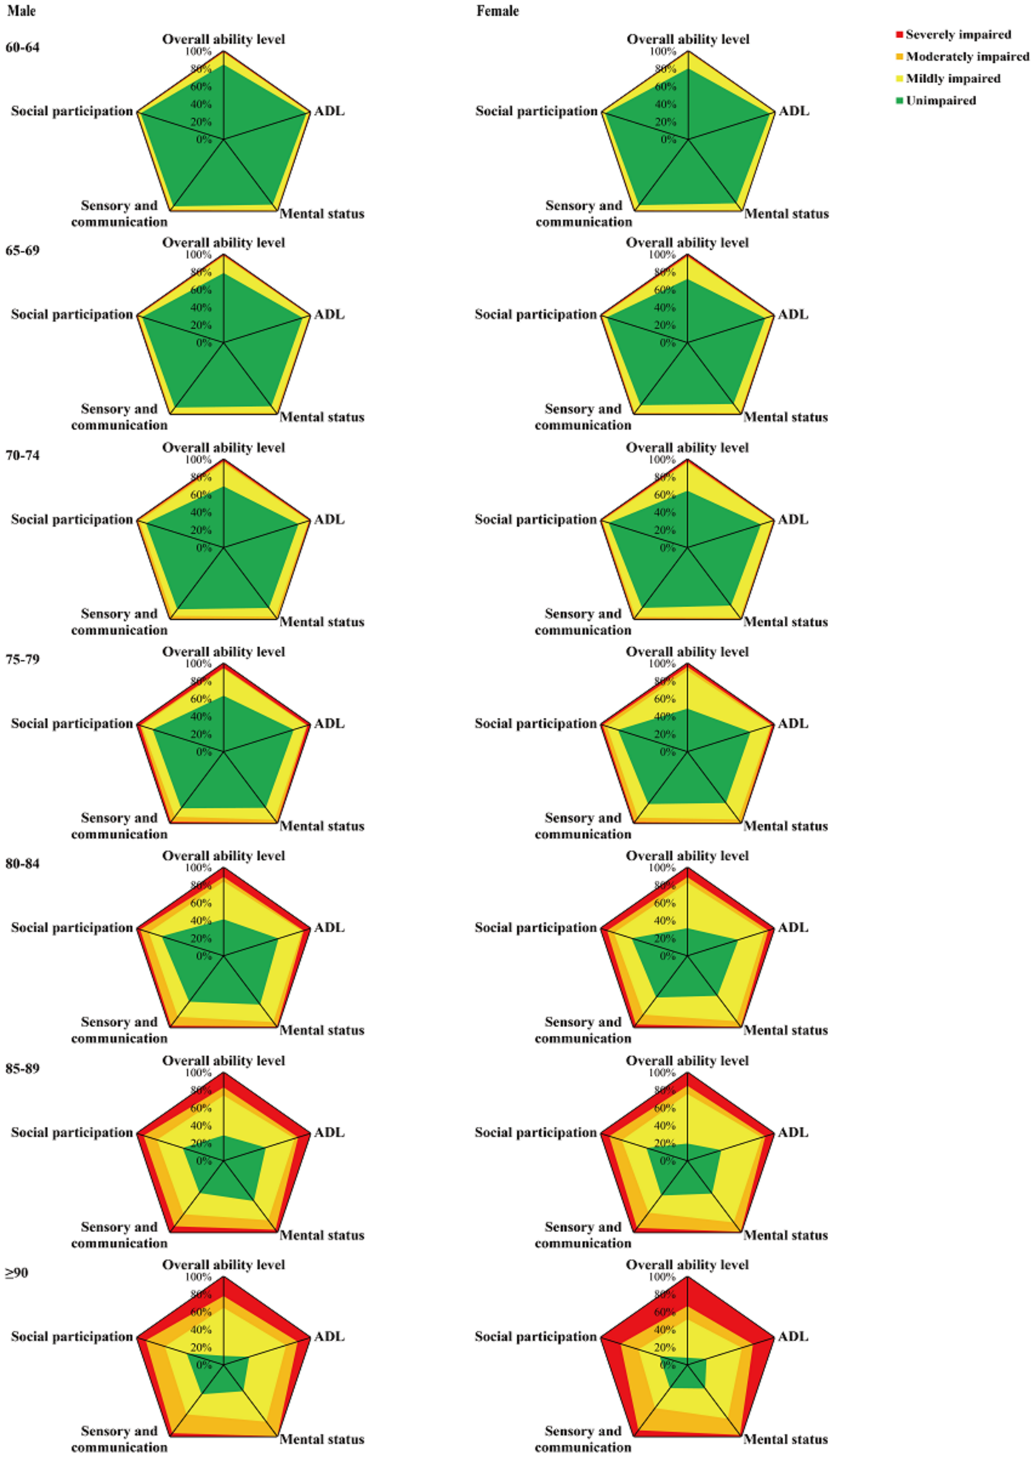
Ability Assessment

In brief, 65.32% of participants' overall ability was assessed as unimpaired, 27.57% as mildly impaired, 2.83% as moderately impaired, and 4.28% as severely impaired (Table 1). For ADL, 81.97% of participants were classified as unimpaired, whereas 13.80%, 1.47%, and 2.76% were classified as mildly, moderately, and severely impaired, respectively. For social participation, 85.63% of participants were classified as unimpaired, whereas 8.63%, 3.23%, and 2.51% were classified as mildly, moderately, and severely impaired, respectively. For sensory and communication, 81.73% of participants were classified as unimpaired, whereas 11.79%, 5.02%, and 1.46% were classified as mildly, moderately, and severely impaired, respectively. For mental status, 80.03% of participants were classified as unimpaired, whereas 15.75%, 3.78%, and 0.44% were classified as mildly, moderately, and severely impaired, respectively.

Impact of Demographic Characteristics on Overall Ability

The association of ability levels with demographic characteristics is summarized in Table 1; detailed results of pairwise comparisons are presented in Multimedia Appendix 3. Age was a key factor that influenced the overall ability of the participants (Table 1, Figure 2). With increasing age, the proportion of impaired participants gradually increased from 17.62% (365/2071) in the age group 60-64 years to 91.34% (253/277) in the age group above 90 years (*P*<.001), corresponding to an approximately 10% rise for every 5-year age increment. In particular, the respective proportion of moderately and severely impaired participants increased from 1.06% and 0.77% in the age group 60-64 years to 14.44% and 30.69% in the age group above 90 years (Table 1). Further, the proportion of overall ability impairment was significantly higher in female participants than in male participants (39.18% vs 28.82%, *P*<.001). The proportion of overall ability impairment was much higher in illiterate or semi-illiterate participants (76.00%) than in those with a college degree or above (18.48%, *P*<.001). The proportion of overall ability impairment was higher in divorced or widowed (62.05%) or never-married (56.52%) participants than in those currently married (27.54%, *P*<.001 and *P*=.02 respectively). A higher proportion of participants who lived alone (61.39%) had an ability impairment compared with those who lived with their spouse (31.21%) or children (30.28%) (all *P*<.001).

Figure 2. Radar maps showing the distribution of various impaired levels of ability dimensions stratified by sex and age groups. ADL: activities of daily living.



Ordinal Logistic Regression Analysis for the Severity of Overall Ability Impairment

The analysis results revealed that age, sex, education, marital status, and living situation were significantly associated with the severity of the overall ability impairment (Table 2). Specifically, the odds of having more severe overall ability impairment increased with age; for participants aged above 90 years, the odds of having more severe overall ability impairment was 23.92 times that of participants aged 60-64 years. The odds of having more severe overall ability impairment in females was 1.15 times that in males. Participants who were divorced or widowed were associated with a higher risk of more severe overall ability impairment than those currently married. In addition, participants living with nonrelatives had an increased risk of more severe overall ability impairment than those living alone. In contrast, higher education levels (college degree or above) emerged as a protective factor of the overall ability impairment.

Table 2. Ordinal logistic regression analysis of demographic characteristics associated with the severity of the overall ability impairment.

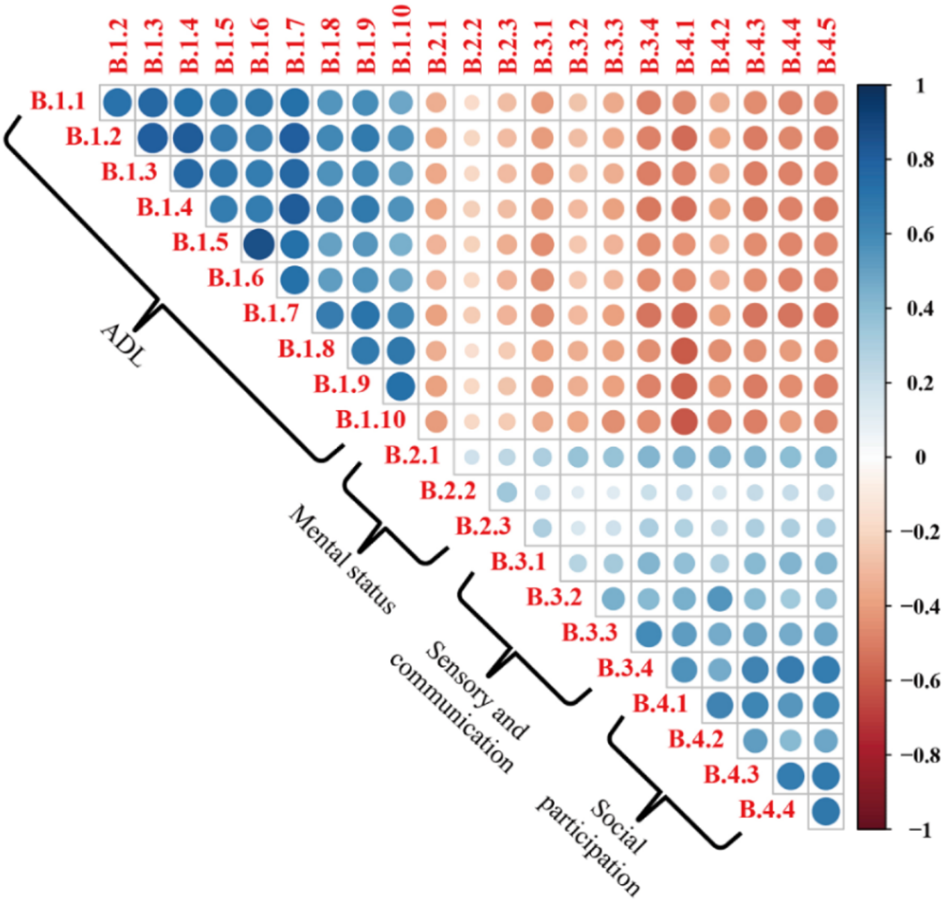
Correlations of Ability Assessment Scores With Various Assessment Dimensions

Figure 3 demonstrates that the four assessment dimensions were significantly correlated. Items within each dimension were positively correlated with other items in the same dimension (all *P*<.001). Overall, poor ADL was significantly correlated with poor mental status, sensory and communication, and social participation (all *P*<.001).

Figure 3. Correlation between the scores of individual items in the ability assessment. ADL: activities of daily living. See Multimedia Appendix 2 for the specific questionnaire items.



Discussion

Principal Findings

Our study assessed the health status of a large older population in the Chinese city of Shenzhen. Since 95% of Shenzhen citizens migrated from other places all over China, our study provides certain generality of the Chinese population. We found that nearly 34.7% of participants' overall ability was impaired, which is higher than the reported older adult disability rate of 28.5% (25.9%-31.2%) in a recently published meta-analysis of other relevant studies from the Chinese population [28]. The proportion of moderately and severely impaired participants (7.11%) is also slightly higher than the findings from the Sixth Population Census of China (2.95%) in 2010 [29]. The differences in population size, the definition of disability, and the time of the investigation may all contribute to the difference in this result. We found that older age, being female, having lower education levels, being divorced or widowed, and living with nonrelatives were important factors associated with ability impairment. In particular, with every 5-year increment in age, the proportion of ability impairment increased by approximately 10%. Our study found that the four dimensions of ADL, mental status, sensory and communication, and social participation were significantly correlated. Poor ability in one dimension also indicated poor abilities in the other three dimensions.

Our study demonstrated that age was a strong risk factor for overall ability impairment in the Chinese community-dwelling older population and its impact increased with age. Our finding is consistent with a previous study indicating that the disability rate in older adults doubles with every 5-year age increment [30]. With aging, physical function deteriorates gradually, and nutrient intake and assimilation may be deficient and imbalanced. The prevalence of multimorbidity increases substantially with age; the proportion of adults over the age of 65 years and 85 years with multimorbidity is more than 60% and 80%, respectively [31]. Multimorbidity such as hypertension, diabetes, and cardiovascular disease can considerably reduce ability levels during a late-life stage [32,33]. Further, the risk of neurodegenerative diseases such as Alzheimer disease and Parkinson disease also increases with age, leading to cognitive dysfunction and a reduced ability level.

Our study found a significant 15% higher risk of more severe overall ability impairment in females than in males. This is in agreement with previous findings [25,26]. A similar sex difference has also been documented in various income-developed countries, including the United States and Korea, and in developing countries such as Mexico and Indonesia [34]. The sex difference may be due to two reasons. First, females generally have a longer life expectancy than males [35]. At the same time, since males are more likely to suffer from common fatal diseases, the number of disability cases in males is lower than that for females [36]. Second, major diseases that lead to disability, such as arthritis and depression, are more common in females [37].

Our finding that a lower education level was associated with a more severe overall ability impairment risk also echoes previous studies [38,39]. Several factors may contribute to this association. First, older adults with a higher education level may have more opportunities in engaging in employment after retirement, leading to a wider social network and better social support [40]. Second, a higher education level also contributes to a better socioeconomic status, giving older adults access to wider and better health care when suffering from diseases [41]. Third, older adults with a higher education level usually have a greater awareness of self-care and self-protection, which results in a healthier lifestyle and lower disability risk.

We identified that older adults who were divorced or widowed were more likely to have severe overall ability impairment compared with those currently married as the reference condition. This finding also echoes the findings of other researchers [42,43]. Marriage is a core relationship for Chinese adults, and in this setting, remaining married in general implies greater satisfaction in the social relationship and well-being of older adults [44]. Further, Chinese couples in stable marriages are often able to accumulate more wealth to secure better health care and medical services than others [45].

Our study found that four dimensions of the ability assessment were highly correlated. Consistently, previous studies also found that ADL ability had a significant impact on cognitive function [46,47] and that more social participation helped maintain the instrumental daily living ability of older adults [48-50]. Our research indicates the need for a comprehensive approach to care for older adults, supporting their physical, mental, and social well-being. By administering the questionnaire employed in this study to assess older adults’ abilities across these dimensions, we can determine and follow their individual status and identify aspects that should be improved, allowing for tailored interventions. To this end, smart devices are becoming a viable option to support the health and independence of the older population. These devices have become increasingly prevalent with rapid advancements in photoelectronics and information technology, which can assist with daily activities, promote mental acuity, enhance sensory function, and facilitate social engagement [51].

The main contribution of our study lies in the use of a more comprehensive assessment tool to assess the ability of older adults. With the increase in aging, there has been a growing emphasis on healthy aging. Achieving healthy aging entails ensuring that older adults are healthy in multiple dimensions, including physical, mental, and social participation [52]. Therefore, as previous studies in China have assessed ability in only one dimension, they failed to provide a comprehensive reflection of the overall ability of older adults. Our study reinforces the importance of a multidimensional assessment of older adults’ ability as a means to develop comprehensive interventions that support healthy aging. Our study provides important evidence to inform the government and health providers about the health profile of community-dwelling older adults, and serves as a valuable reference for the development of services and resource allocation for the older population.

Limitations and Future Implications

Our study has several limitations. First, the data collected were mainly from one district in a southern Chinese city and hence may not be representative of other Chinese settings with different climates. Second, although the sample size of this study was large, there were relatively fewer participants in categories with certain demographic characteristics, such as the number of never-married (single) participants with moderately impaired overall ability. Third, due to missing data on other potential confounders such as disease and lifestyle factors, we were unable to include them in our study. This may affect our results; for instance, disease complications are more likely to affect the ability of older adults at a higher age and therefore the effect of age on the ability assessment may have been overestimated in our study. Fourth, our study followed a cross-sectional design; therefore, evidence for causal associations will need to be further investigated. Nevertheless, our multidimensional assessment has provided valuable evidence to inform the health status of the older population. As a part of future investigations, we plan to integrate these community-based data with hospital-based electronic medical records. This integration may form a much larger database and enable us to investigate the complex factors that affect the health of the older population in greater detail to provide additional evidence to support healthy aging initiatives.

Conclusions

In conclusion, this study found a high level of disability among the older population living in Shenzhen, China. The proportion of disability increased with age, being female, having lower education levels, being divorced or widowed, and living with nonrelatives. Impairment in ADL ability was significantly correlated with poor mental status, social participation, and sensory and communication ability. Holistic interventions targeting these factors should be implemented to prevent or delay the development of disability in the Chinese older population.

Acknowledgments

We thank all of the participants for their contribution in participating in this project and the nursing home staff for helping with data collection. LZ is supported by the National Natural Science Foundation of China (grant number 81950410639), Outstanding Young Scholars Support Program (grant number 3111500001), Xi'an Jiaotong University Basic Research and Profession Grant (grant numbers xtr022019003, xzy032020032), Epidemiology Modeling and Risk Assessment (grant number 20200344), and Xi'an Jiaotong University Young Scholar Support Grant (grant number YX6J004). Abstract

Background: Developmental trauma depending on several factors may lead to later adult health risks and is an increasing public health concern, especially in states with predominantly rural populations. Oklahoma remains one of the states in America with the highest count of adverse childhood experiences (ACEs); therefore, more refined research methods for quantifying ACEs are vital for ensuring proper statewide interventions.

Objective: While data sets already exist at the state level measuring specific ACEs like divorce or child abuse, the state currently lacks a single source for specific ACEs that can incorporate regions to allow for the identification of counties where ACEs are especially high. This county identification will allow for assessing trends in adversity prevalence over time to indicate where targeted interventions should be done and which counties experience amplified long-term consequences of high ACE rates. Thus, the model for the Oklahoma Adversity Surveillance Index System (OASIS) was born—a public health tool to map ACEs at the county level and grade them by severity over time.

Methods: County-level data for 6 ACEs (mental illness, divorce, neglect, child abuse, domestic violence, and substance use) were collected from the Oklahoma Department of Human Services, Oklahoma State Department of Health, and Oklahoma Community Mental Health Centers for the years 2010 to 2018. First, a potential ACEs score (PAS) was created by standardizing and summing county rates for each ACE. To examine the temporal change in the PAS, a bivariate regression analysis was conducted. Additionally, an ACEs severity index (ASI) was created as a standardized measure of ACE severity across time. This included scoring counties based on severity for each ACE individually and summing the scores to generate an overall ASI for each county, capturing the severity of all ACEs included in the analysis.

Results: Mental illness and substance use showed the highest rates at the state level. Results from the regression were significant ($F_{1,76}$=5.269; P=.02), showing that county PAS showed an increase over years. The ASI scores ranged from 0 to 6, and 4 Oklahoma counties (Adair, McCurtain, Muskogee, and Pittsburg) received a score of 6.

Conclusions: OASIS involves the identification of counties where ACEs are most prevalent, allowing for the prioritization of interventions in these “hot spot” counties. In addition, regression analysis showed that ACEs increased in Oklahoma from 2010 to 2018. Future efforts should center on adding additional ACEs to the ASI and correlating adverse outcome rates (such as violence and medical disorder prevalence) at the county level with high ASI scores.

Introduction

Background

The Adverse Childhood Experiences Study, published in 1998, is a sentinel publication in modern health care [1]. This study demonstrated several important factors. First, childhood adversity is associated with poor outcomes as an adult, including cardiovascular disease, diabetes, obesity, liver and digestive diseases, and cancer [2-4]. Second, this correlation is dose-dependent—the more adversity, the higher the likelihood of poor outcomes [1]. Third, adversity in childhood extends beyond personal factors such as abuse and neglect and includes household dysfunction [1]. Since this study was first published, adverse childhood experiences (ACEs) have become common terminology in medicine [4,5]. With the strong correlation with adverse health outcomes, measuring the burden of ACEs can be important for public health and prevention. Secondary to the burden of disease and dysfunction, it is important to quantify the effect of ACEs on a community. Understanding this burden is essential for the deployment of limited resources and the implementation of evidence-based primary, secondary, and tertiary prevention programs.

A definitive list of ACEs does not exist. Those listed in the original Adverse Childhood Experiences Study questionnaire included physical, emotional, and sexual abuse; physical and emotional neglect; violence toward one's mother; mental illness; substance abuse; and incarceration of a household member [1]. Other ACEs that should be considered according to the Behavioral Risk Factor Surveillance System (BRFSS) and Child Trends include educational and financial opportunities, chronic and infectious diseases, maternal health, risky behavior, injury, violence outside of the home, neighborhood safety, homelessness, bullying, racial and ethnic discrimination, and parent or guardian death [6,7].

Screening for childhood adversity and trauma is gaining acceptance and is recommended by the American Academy of Pediatrics [8]. It is unclear whether or not assessing ACEs at the patient level can alter health outcomes [9,10]. However, it has been demonstrated that patients are not averse to discussing the topic [11]. The more uptake there is in the use of patient instruments such as the ACEs questionnaire, the more useful this method can be in public health surveillance.

Assessing ACEs Through Instruments

There are many different instruments available for assessing the number of ACEs an individual experiences. Most of these instruments will score the presence of an ACE in a dichotomous fashion, such as yes or no for the exposure. This method does not account for the intensity or duration of a particular traumatic experience. Further, this method does not allow for the experience to be evaluated in context. For example, a patient who is the child of a divorce may become separated from an abusive caregiver. Such circumstances underline the problems in attempting to understand and contextualize social dysfunction and the need for further development in methods for measuring and analyzing ACEs.

Perhaps the most common method of assessing ACEs is what was used in the Adverse Childhood Experiences Study, which was a retrospective survey [1]. This method can be used for public health programming and also for basic research. In the public health field, an ACE module was added to collect information on child abuse and neglect and household challenges through the BRFSS [12]. The ACE module was included at least once in the BRFSS of every state by the end of 2020 [13]. The BRFSS ACE module asks an individual to reflect on their childhood and answer a series of questions surrounding abuse, violence, drug use, and mental illness in the home which are adapted from the original Adverse Childhood Experiences Study [14]. Since 2009, the BRFSS has been collecting data on ACEs, and the module was updated in 2019 to include questions about neglect. Most recently, it was updated in 2021 with questions about childhood support and caregiver involvement.

Another important survey is the National Survey of Children's Health (NSCH). This is an annual survey conducted in the United States that began in 2003 and has been reported as recently as 2021 [7,15]. One child under the age of 18 in each household is selected to be the focus of the survey. Specific ACE questions in the survey include parent or guardian divorce, separation, death, or incarceration; mental illness; suicide; illicit drug use; alcohol use; depression of a household member; domestic violence; neighborhood violence; income; and housing or food security [7]. In 2016, data collected by the NSCH indicated that 45% of children experienced at least one ACE, and 10% experienced 3 or more ACEs [7,16]. The most common ACEs reported were parental separation and low socioeconomic status [7].

Another method used to measure ACEs is by directly asking an individual as they intersect with the health care system [4,17]. This includes having the patient complete a screening instrument, such as the Adverse Childhood Experiences Questionnaire (ACE-Q), which can then be analyzed at a larger clinical level [11,18,19]. However, patient questionnaires also have shortcomings. First, they measure individuals presenting to a health care setting [18-20]. This is important because of well-known disparities in individuals accessing health care, including lack of a provider (such as in rural areas) or lack of ability to pay [21]. And while there is research indicating some patients feel comfortable discussing childhood trauma or ACEs with a health care provider [22], there are also patients with concerns about medical record storage in general, as issues with privacy arise in the increasingly digital world [23].

Knowledge of ACEs in a community could be important for primary, secondary, and tertiary prevention planning. Improved knowledge of prevalence rates could lead to larger gains in positive outcomes and more efficient use of precious resources. This is especially important in high-burden, low-resource areas, such as Oklahoma [24-27]. Oklahoma has consistently been recognized as leading the nation in childhood adversity, with 28.5% of Oklahoma children experiencing 2 or more ACEs [28]. Oklahoma also experiences poor social determinants of health (SDOH), such as health care shortages, violence, and food insecurity, among others [29]. Further, there is a lack of access to care due to a lack of primary care providers outside of metropolitan areas in rural communities, which make up the majority of Oklahoma [24-27]. These upstream deficiencies lead to high levels of adverse health outcomes such as diabetes, obesity, substance use disorders, and overdose mortality [24,30].

While it is known that Oklahomans have high rates of childhood adversity, there is no condensed source of data to which stakeholders can turn to receive aggregated, targeted information on ACEs at a granular (county) level. While there are great data sets like the BRFSS and NSCH, these lack county-level statistics for all of Oklahoma [31]. Currently, data is spread out across various state agencies, such as the Oklahoma State Courts Network (OSCN), the Oklahoma Department of Health Services (OKDHS), and Oklahoma community mental health centers (CMHCs). With multiple agencies doing different parts of the work in silos, Oklahoma does not have a coordinated trauma-response system in place to capture and publish all ACE data in one location.

To address this lack of a coordinated system and to combat this epidemic of childhood adversity and subsequent negative health consequences, the Oklahoma Adversity Surveillance Index System (OASIS) was created. OASIS was initiated in 2021 through a collaboration between the Oklahoma State University Center for Health Sciences and multiple state agencies. Data-sharing agreements were used to obtain data that were not publicly available. This system relies on several concepts. First, the adversity burden shared by a population should have a footprint in interaction with public agencies that collect or could collect data. Second, while there may be inaccuracies in data collection, these inaccuracies should be equally inaccurate over space and time. This allows for hot spot determination and comparisons among similar geographical entities (ie, county, zip code) and time (ie, years). Third, the data should be regularly collected and analyzed to monitor emerging areas and trends. Identifying trends can allow for the examination of intercounty differences and temporal variations between geographical entities. These trends can indicate where further analyses should be done to determine the factors that may contribute to the observed variations in ACE burden across counties and years. Such factors could include socioeconomic conditions, access to health care and support services, community resources, education levels, and public health initiatives. Finally, all efforts should be made to review and refine the system so that it becomes more accurate and insightful over time.

With the implementation of OASIS, the state of Oklahoma now has access to a public health tool that encapsulates county-level statewide data on ACEs that were previously unavailable or difficult to obtain. Additionally, with OASIS in place, the state will be able to carry out targeted interventions in the counties that need it the most. Without this surveillance system, high-burden counties would have been previously unidentifiable, and it would not have been possible to specifically target them with additional resources and prevention strategies. We hope that other states will replicate our methodology and identify their own hot spots to ultimately better serve areas that need more ACE-related support, resources, and services.

Methods

Overview

Data were obtained from various state agency sources for the years 2010 to 2018. Counts of abuse and neglect were obtained from the OKDHS. The OKDHS reports these data as a combination of physical, sexual, and psychological abuse, listed as a single "abuse" category. Ideally, these data would be separated, but currently, a county-level data set with these distinctions is unavailable. Neglect is listed separately. Data were available at the zip code and county level. OKDHS receives data from reports substantiated by child protective services (CPS). Data for divorce were obtained from the Oklahoma State Department of Health (OSDH). The OSDH collects divorce data for all counties in Oklahoma from county clerks. Unfortunately, Oklahoma does not inquire about whether or not children are involved when an individual files for divorce.

Data for parental mental illness and substance use were obtained at the zip code level for patients treated at Oklahoma CMHCs. CMHCs aggregate their data from appointments and patient files. This data are then submitted to the Oklahoma Department of Mental Health and Substance Abuse Services (ODMHSAS). Rates of mental illness and substance use were calculated at the population level. For divorce, mental illness, and substance use, information is not obtained as to whether an individual has children, so only raw numbers were used. Domestic violence rates were calculated through the number of charges filed as listed in the OSCN. Through the use of a publicly available application programming interface, records were searched at the county level. Again, this information may not be specific to parents. Data from the US Census Bureau were used to calculate population data for all counties. Counties were coded as metro or nonmetro following US Department of Agriculture Economic Research Service Rural Urban Continuum Codes.

Potential ACE Score

To calculate additive totals, county crude rates for each ACE were standardized to 100 (average county crude rates per year are reported in the Results section). The available ACEs were added to create a potential ACE score (PAS). The PAS ranges from 0 to 600, representing the potential for children in each county to experience ACEs. Rates of determinants like divorce and substance use at the county level were used as proxies for the potential ACEs experienced by the children in that county.

Statistical Analysis

Data were uploaded into SPSS (version 28.0.1.1; IBM Corp) for analysis. To examine the temporal changes in ACEs, a bivariate regression analysis was conducted. The PAS was used as the dependent variable, and the year was treated as the independent variable. This analysis allowed for the assessment of how the PAS changed over time. Results were visualized using Tableau (version 2021.4.5; Tableau Software, LLC).

ACE Severity Index

In addition to the PAS, we developed the ACE severity index (ASI) as a standardized measure to assess the burden and severity of ACEs over time. The ASI aimed to identify counties more heavily impacted by ACEs, considering both the depth and duration of ACEs. To determine the impact of ACEs on specific counties, we scored each county based on ACE severity. Severity was measured for each ACE individually, assessing the extent of its occurrence over time. Counties were classified as “severe” for a particular ACE if its rate was above the state average. Severity scores ranged from 0 (indicating the county had an average or below-average rate for that ACE in all years) to 9 (indicating the county had an above-average rate for that ACE in all years). We calculated severity scores for each county for all 6 ACEs included in the analysis. Counties with severity scores above the average were given a point for that ACE, contributing toward their total ASI. This process was repeated for all 6 ACEs analyzed. The outcome was an ASI for each county, encompassing the severity of all ACEs included in the analysis and ranging from 0 to 6.

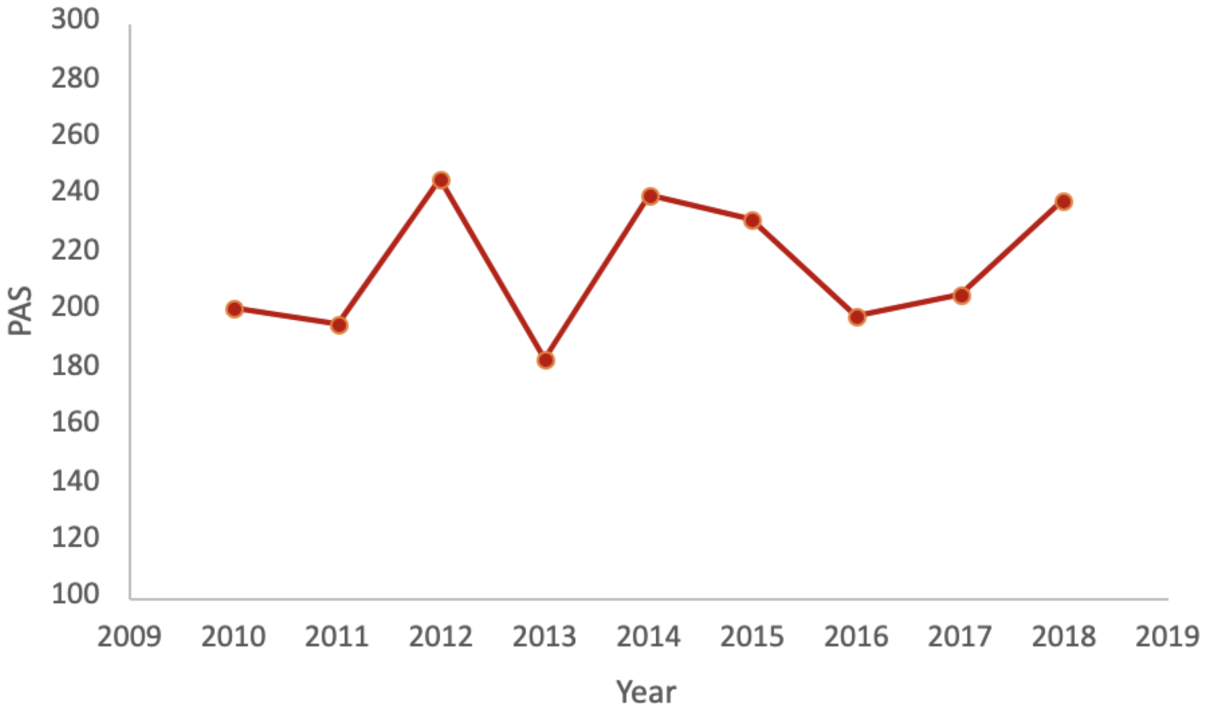
Ethical Considerations

Data-sharing agreements were obtained before the project start. The project was approved as non–human subjects research by the institutional review board at Oklahoma State University Center for Health Sciences (#2021009). The requirement for informed consent was waived due to the retrospective nature and minimal risk of this study.

Results

Over the study period (2010-2018), the average PAS was 215.08, with an overall increasing trend from 2010 to 2018 (Figure 1). An analysis of the data set revealed notable trends in several Oklahoma counties regarding their PAS from 2010 to 2018. Specifically, Choctaw and Greer counties showed an increasing trend over the study period, while Cimarron and Harper counties consistently remained below the average PAS. Adair, Woodward, Coal, Muskogee, Pittsburg, and Brian counties consistently maintained a PAS above the average.

Figure 1. Yearly Oklahoma average PAS. PAS: potential adverse childhood event score.



Choctaw County exhibited a consistent upward trend in PAS over the years, with a score of 274.637 in 2010 and 322.841 in 2011, reaching a peak of 439.225 in 2012, and still maintaining a score in the top 10 of counties in 2018 (335.35). Greer County also experienced an increasing trend, starting at 171.454 in 2010 and steadily rising to 302.128 in 2018. On the other hand, Cimarron County consistently remained below the average PAS throughout the study period. The county had a relatively low PAS of 83.137 in 2010 and showed slight fluctuations over the years, but remained consistently below average, reaching 108.26 in 2018. Similarly, Harper County started with a PAS of 163.285 in 2010 and remained consistently below average, with a score of 114.229 in 2018.

In contrast, Adair County consistently displayed remarkable PAS well above the average throughout the study period. Starting with a high PAS of 408.354 in 2010, Adair County maintained consistently elevated scores, reaching its peak of 433.736 in 2018. Similarly, Woodward County demonstrated a pattern of consistently scoring above the average. Beginning at 295.013 in 2010, Woodward County steadily increased its PAS over the years, culminating in a peak of 369.031 in 2018. Joining them in consistently exhibiting higher-than-average PAS were several other notable counties. Coal County, despite experiencing some fluctuations, maintained relatively high scores throughout the study period, with its highest PAS of 404.271 recorded in 2010 and remaining significantly above average at 309.158 in 2018. Muskogee County followed a similar trajectory, with a starting PAS of 277.018 in 2010 and a peak of 322.252 in 2018. Pittsburg County consistently scored above the average as well, reaching a peak PAS of 319.14 in 2018. Notably, Bryan County had a consistent above-average pattern, starting at 281.216 in 2010 and reaching its peak of 242.676 in 2018. These counties, including Adair and Woodward, stood out for their remarkable and consistent above-average PAS throughout the study period. Notably, the top 10 counties in 2018 had higher PAS values compared to the top ten counties in 2010 (Table 1).

Table 1. Top 10 Oklahoma counties for PAS[a] in 2010 and 2018.

Ranking	2010		2018	
	County	PAS	County	PAS
1	Adair	408.354	Adair	433.74
2	Coal	404.271	Woodward	369.03
3	Beckham	331.141	Kay	347.2
4	Marshall	307.987	Seminole	345.48
5	Seminole	304.522	Choctaw	335.35
6	Woodward	295.013	Muskogee	322.25
7	Okfuskee	283.525	Pittsburg	319.14
8	Bryan	281.216	Ottawa	319.08
9	Muskogee	277.018	Blaine	316.2
10	Pittsburg	275.589	Latimer	312.23

[a] PAS: potential adverse childhood event score.

Our analysis revealed a significant relationship between year and PAS ($F_{1,76}$=5.269; P=.02) (Table 2). For each 1 unit increase in the year variable, there was a corresponding 2.193 increase in the PAS (SE 0.955, $t_{1,76}$=2.295; P=.02). The model summary indicates that the regression model explains a small proportion of the variance in the PAS.

Table 2. Model summary of regression analysis assessing the relationship between year and potential adverse childhood event score. The dependent variable was potential adverse childhood event score.

Model	R	R^2	Adjusted R^2	Estimate SE	Change in statistics		
					Change in R^2	Change in F (df)	P value
1	0.087[a]	0.008	0.006	64.94422332	0.008	5.269 (1,691)	.02

[a] Predictors were (constant), year.

When visualized, the difference between county PAS in 2010 and 2018 shows an overall increase (Figures 2 and 3).

Figure 2. Oklahoma PAS county distribution in 2010. PAS: potential adverse childhood event score.

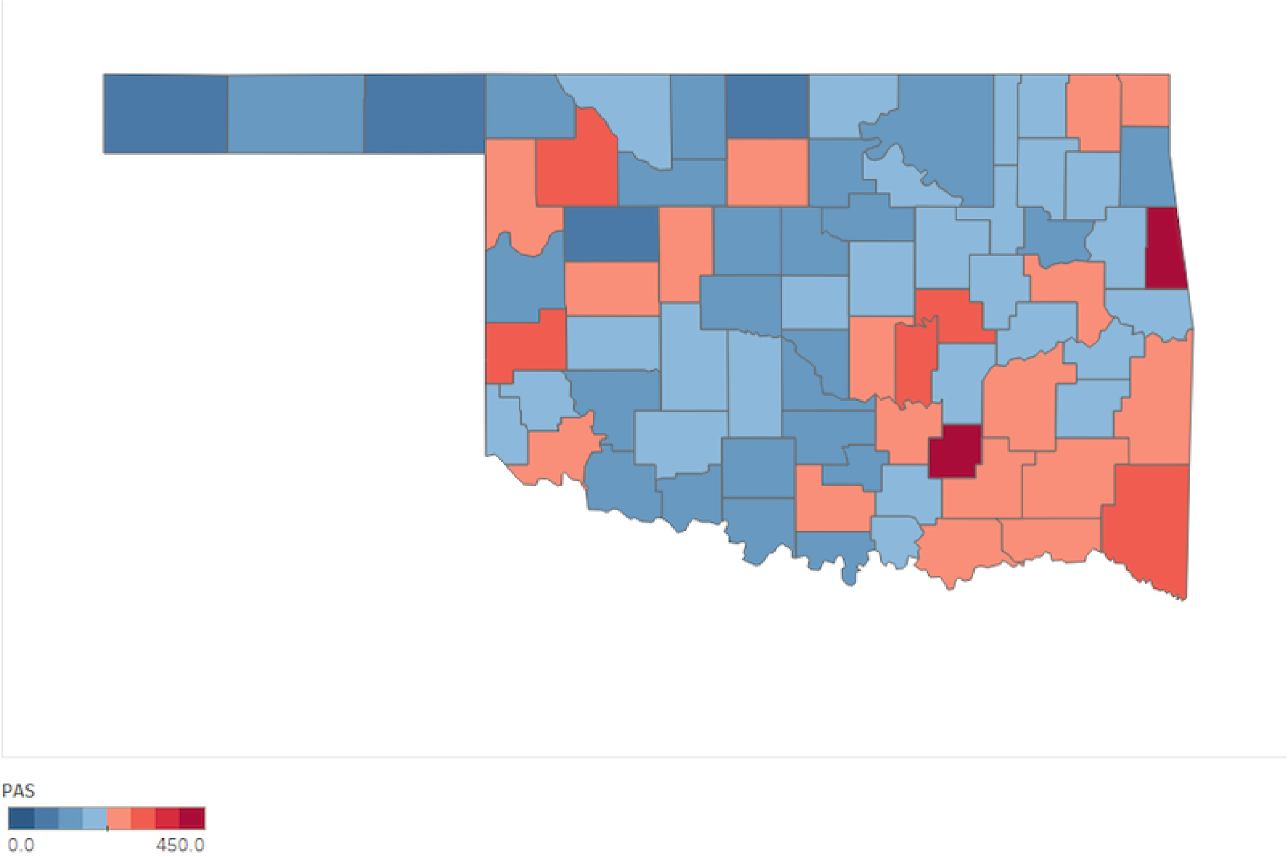


Figure 3. Oklahoma PAS county distribution in 2018. PAS: potential adverse childhood event score.

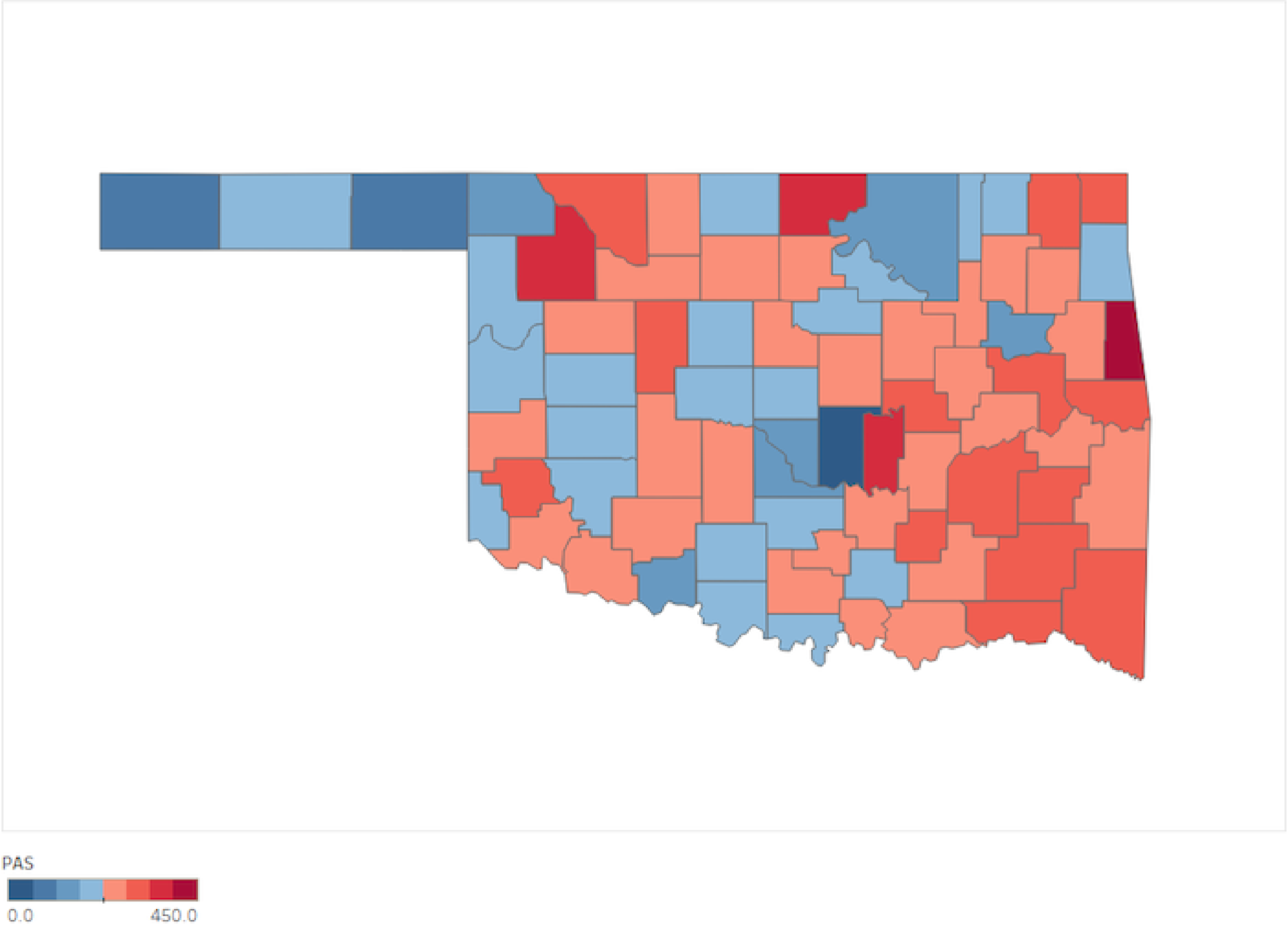
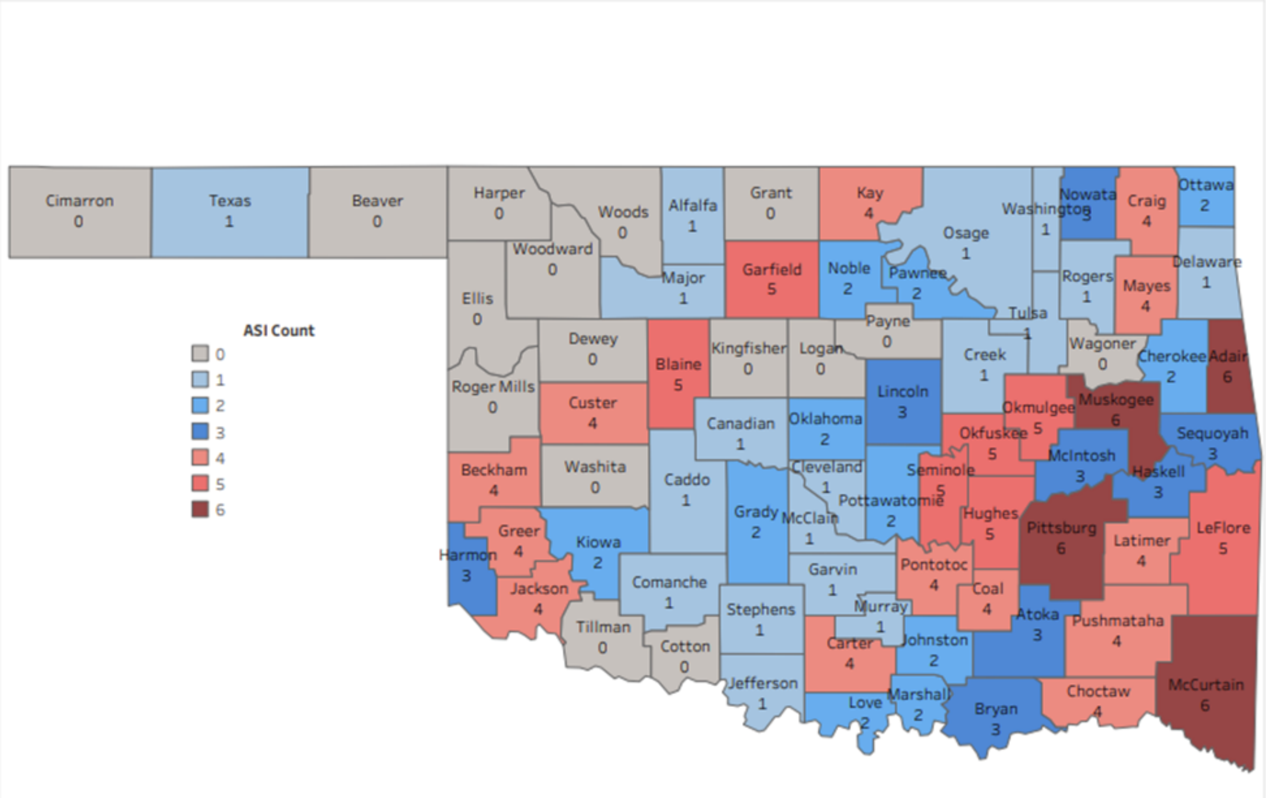


The results for the ASI showed that 4 nonmetro Oklahoma counties—Adair, McCurtain, Muskogee, and Pittsburg—had scores of 6 (Figure 4). Garfield, Blaine, Seminole, Okfuskee, Okmulgee, Hughes, and LeFlore counties received scores of 5.

Figure 4. Map of Oklahoma Adversity Surveillance Index System (OASIS) showing the ASI for each Oklahoma county. Zero represents the lowest burden and 6 the highest burden encompassing all 6 adverse childhood events included in our analysis. ASI: adverse childhood event severity index.



Discussion

Principal Findings

In this study, we aimed to examine the prevalence of ACEs and their variations across counties in Oklahoma using OASIS. Our findings provide valuable insights into the burden of ACEs in the state and highlight the need for targeted interventions and resource allocation. The analysis of the PAS revealed an increasing trend in ACE burden from 2010 to 2018, and our regression analysis demonstrated a significant relationship between the year and PAS, indicating a continuous rise in ACE burden over time.

The ASI allowed us to identify counties more heavily impacted by ACEs. After indexing counties on the ASI, 4 counties stood out, with scores of 6 of 6. All 4 counties are rural, nonmetro, located in Indian Country, are significantly below the national median income, have a greater percentage of persons living in poverty, and have higher unemployment rates than the national average [32]. All of these poor SDOH are known upstream risk factors for ACEs [7]. Much more in-depth analysis of these counties, along with others with high ASI scores, should be done to ascertain how their poor SDOH are driving childhood adversity.

The average county in Oklahoma exhibited rates of ACEs that were consistently above the state average for 4 or more years. This increasing trend is concerning and shows the need for further expansion of OASIS with the addition of other ACEs, for example, incarceration of a family member; Oklahoma consistently ranks in the top 10 for incarceration rate in the United States over the past decade [33]. Our analysis of the PAS showed that there was a significant relationship between year and PAS ($F_{1,691}$=5.269; P=.02). For every 1 unit increase by year, there was a 2.193 (SE 0.955) unit increase in PAS ($t_{1,76}$=2.295; P=.02).

OASIS has several strengths and limitations. The strengths include the creation of a framework that can be built upon and improved over time. With OASIS, we have designed and implemented a framework for data sharing and analysis across state data sets, an accomplishment that is not necessarily easy to do given the sensitivity around information on ACE variables. Having created a proof of concept, legislators and agency heads can understand how the way they collect data intersects with other agencies and allows judicious spending of resources. Another strength is the ability to compare geographical entities together. Comparing zip codes in large urban areas could be valuable to understanding population disparities, as survey studies of ACE prevalence have known weaknesses [34]. To generalize the results of a survey to the general population, it should be administered to a sufficiently large and randomized sample of the general population. This can be difficult to achieve. For example, the population mixture of the original Adverse Childhood Events Study was primarily White, health-insured individuals [35]. The BRFSS has similar concerns. Analysis has shown that individuals answering the ACEs module are more likely to have higher education than the US average [6,35]. These differences are notable in health care because it is well documented that there are significant health disparities among races, insured and uninsured people, and different levels of education [36-40]. Thus, with OASIS, the state of Oklahoma now has a way to easily access county-level ACE-related data that are generalizable to the whole state. This public health tool allows stakeholders to better identify areas that need more ACE-related support, resources, and services. Understanding why is the first step toward prevention.

Another strength is the ability to identify hot spots by depth and time. The PAS allows for counties to be compared across time to see if their rates of childhood adversity are increasing or decreasing. In addition, the PAS allows for counties to be compared to each other and trends identified between counties. We found that some counties, such as Adair, ranked consistently higher on the PAS compared to other counties. On the other hand, some counties, such as Harper and Cimarron, consistently ranked below the average PAS. These counties showing lower rates over time should be studied further; they can serve as models for successful prevention strategies that could be replicated in other areas.

OASIS is not without limitations, however. First is the lack of data on all known ACEs. For example, at one time, Oklahoma was the second most prevalent place in the world to incarcerate women and incarcerated more men and women combined than any other state in the United States [41,42]. Yet the Oklahoma Department of Corrections does not systematically collect data on inmates and their children. This prevents the understanding of this trauma as it relates to other ACEs and also prevents understanding the damage mass female incarceration can have on a community. One additional limitation of the surveillance system is the absence of validity testing, which means that the extent of error or inaccuracy within the system is unknown. Consequently, there is a risk of incorrectly identifying hot spots. However, it should be noted that since all data were collected using the same method, any inaccuracies should be consistent across different areas. Nonetheless, it is crucial for future efforts to develop methods that can test the validity of the system and address its identified weaknesses. By doing so, improvements can be made to enhance accuracy and ensure more reliable identification of hot spots. Another weakness lies in the extrapolation of population data without accounting for the number of children involved. The collected data for divorce, for example, are based on raw divorce numbers, without considering divorces that specifically affect children, as that information is not available from ODMHSAS court records. Consequently, there is a possibility of overcounting divorces involving children. However, it is important to note that this overcounting issue is consistent across all counties, as the same calculation method is used. Therefore, while the accuracy may be compromised, it is uniformly inaccurate across all counties.

A final limitation are the data themselves. OASIS relies on individuals accessing services and does not include those that do not. For example, if a mother accessed mental health treatment outside of a CMHC, that would not be measured. This is less of a problem in rural areas that have limited providers. However, in the urban areas of Oklahoma City and Tulsa, this likely leads to undercounting. This limitation is highlighted again in divorce. Individuals do not have to be married to raise children together. Therefore, when unmarried parents separate, that would not be reflected in OSDH divorce data, and this would lead to an undercounting of events.

Conclusions

The findings of our study have significant implications for the field of public health and can shape future interventions and strategies. The identification of counties with a high prevalence of ACEs through OASIS allows for targeted interventions and prioritization of resources in these hot spot areas. Tailored interventions at the county level are crucial, considering the variations in ACE burden across different regions.

Our study highlights the value of the ASI in revealing geographic disparities in the severity and persistence of ACEs. Four counties in particular stood out, with an ASI score of 6, indicating an elevated prevalence of ACEs and consistently above-average rates across all ACE types examined. This signifies a pressing need for urgent and coordinated action from policymakers, health practitioners, social care providers, and researchers in addressing this public health issue. Counties with high ASI scores are likely to experience amplified long-term consequences associated with ACEs, including increased risks for chronic diseases, reduced educational achievement, and a higher likelihood of involvement with the criminal justice system [43,44]. It is imperative to respond promptly with both ACE prevention and effective management strategies to mitigate these outcomes. The ASI also serves as a valuable guide for targeted resource allocation. By identifying counties burdened by ACEs, resources can be efficiently prioritized, focusing on services such as trauma-informed care, community health initiatives, and educational interventions tailored to address ACEs. Future research should explore community-level factors (eg, poverty, community violence, service accessibility) as well as individual and family-level dynamics to design effective prevention and intervention strategies.

While acknowledging the limitations of this study, OASIS provides a foundation that can be refined and improved over time. This surveillance system facilitates collaboration and coordination across sectors, states, and agencies, enabling a comprehensive response to high-need areas. Future efforts should focus on expanding the range of ACEs, improving data collection, adding adverse outcome rates, and conducting validity testing. The ultimate objective of OASIS should be to develop effective strategies that not only address the present situation in counties with high childhood adversity indicated by the ASI but also prevent future generations from experiencing similar levels of adversity.

Abstract

Background: Bisphenol A (BPA), bisphenol S (BPS), and bisphenol F (BPF) are widely used in various consumer products. They are environmental contaminants with estrogenic properties that have been linked to various health outcomes. Understanding their impact on body composition is crucial for identifying potential health risks and developing preventive strategies. However, most current studies have only focused on their relationship with BMI.

Objective: This study aimed to investigate the association between urinary levels of BPA, BPS, and BPF and body composition, including BMI, lean mass, and fat mass, in a large population-based sample.

Methods: We conducted a cross-sectional analysis using data from the National Health and Nutrition Examination Survey 2003-2016. Body composition data were assessed using dual-energy X-ray absorptiometry, which provided precise measurements of lean mass, fat mass, and other indicators. We used multivariate linear regression models to estimate the associations, adjusting for potential confounders such as age, gender, race, socioeconomic factors, and lifestyle variables.

Results: The results revealed significant associations between bisphenol exposure and body composition. After adjusting for covariates, BPS showed a positive association with BMI, with quartiles 3 and 4 having 0.91 (95% CI 0.34-1.48) and 1.15 (95% CI 0.55-1.74) higher BMI, respectively, compared with quartile 1 ($P<.001$). BPA was negatively associated with total lean mass (TLM) and appendicular lean mass, with quartiles 2, 3, and 4 having –7.85 (95% CI –11.44 to –4.25), –12.33 (95% CI –16.12 to –8.54), and –11.08 (95% CI –15.16 to –7.01) lower TLM, respectively, compared with quartile 1 ($P<.001$). BPS was negatively associated with TLM, with quartiles 3 ($\beta=-10.53$, 95% CI –16.98 to –4.08) and 4 ($\beta=-11.14$, 95% CI –17.83 to –4.45) having significantly lower TLM ($P=.005$). Both BPA and BPS showed a positive dose-response relationship with trunk fat (BPA: $P=.002$; BPS: $P<.001$) and total fat (BPA: $P<.001$; BPS: $P=.01$). No significant association was found between BPF and any body composition parameter.

Conclusions: This large-sample study highlights the associations between urinary levels of BPA and BPS and alterations in body composition, including changes in lean mass, fat mass, and regional fat distribution. These findings underscore the importance of understanding the potential health risks associated with bisphenol exposure and emphasize the need for targeted interventions to mitigate adverse effects on body composition.

Introduction

Background

Bisphenol A (BPA) is an endocrine disrupter used globally in the manufacture of various plastic products including food containers, baby bottles, toys, and medical supplies [1,2]. It not only exhibits estrogen-like effects but also antagonizes thyroid hormone receptors, which may lead to adverse metabolic effects and diseases such as cardiovascular conditions, tumors, and other metabolism-related ailments [2,3].

Countries including Canada, the European Union, the United States, and China have prohibited the use of BPA in certain plastic products due to these health risks. The US Food and Drug Administration has set strict acceptable daily intake levels for BPA, but studies have indicated that even levels below the acceptable daily intake can contribute to obesity and related metabolic disturbances. Consequently, BPA substitutes, bisphenol S (BPS) and bisphenol F (BPF), were introduced [4].

These BPA derivatives (BPS and BPF), obtained by replacing the propane group in the molecular structure of BPA, are found to have estrogenic effects similar to those of BPA, indicating that they could also be unsafe [4]. They are prevalent in everyday packaging products and can be ingested through diet, air inhalation, or skin contact [5]. These chemicals can interfere with the nuclear hormone receptor signaling pathway, thereby affecting adipocyte proliferation and differentiation, which could potentially lead to a variety of metabolic diseases [4].

Body composition, including not only BMI but also fat mass and lean body mass, is a critical aspect of health [6]. Excessive body fat has been linked to adverse health outcomes including breast cancer [7,8] and cardiovascular risk factors [9]. Abdominal fat distribution is associated with an increased risk of type 2 diabetes [10], arterial stiffness [11], and cardiovascular disease [12,13], whereas lean body mass, predominantly composed of skeletal muscles, influences bone health and optimal aging [14,15]. Skeletal muscle is the largest and most plastic component of lean body mass (accounting for approximately 50% of lean body mass). Therefore, changes in lean body mass are primarily attributed to skeletal muscle mass. The maintenance of skeletal muscle is the basis of exercise, energy balance, and overall quality of life [16,17] and is critical for the risk of heart metabolic diseases [18].

Studies have shown that BPA promotes adipocyte differentiation and insulin resistance [19,20]. Previous studies have explored the relationship between urinary BPA and body composition, but these studies have been largely limited to specific populations, such as women who are nonobese and in the premenopausal stage or older adults [21,22]. At present, research on the association between BPA analogs (BPS and BPF) and body composition is scarce.

Objective

We aimed to bridge this gap by assessing the relationship between urinary BPA, BPS, BPF, and body composition in adult National Health and Nutrition Examination Survey (NHANES) participants using dual-energy X-ray absorptiometry (DXA) scans. By doing so, we hope to provide valuable insights into the health implications of BPA and its analogs in a broader population.

Methods

Patients Selection

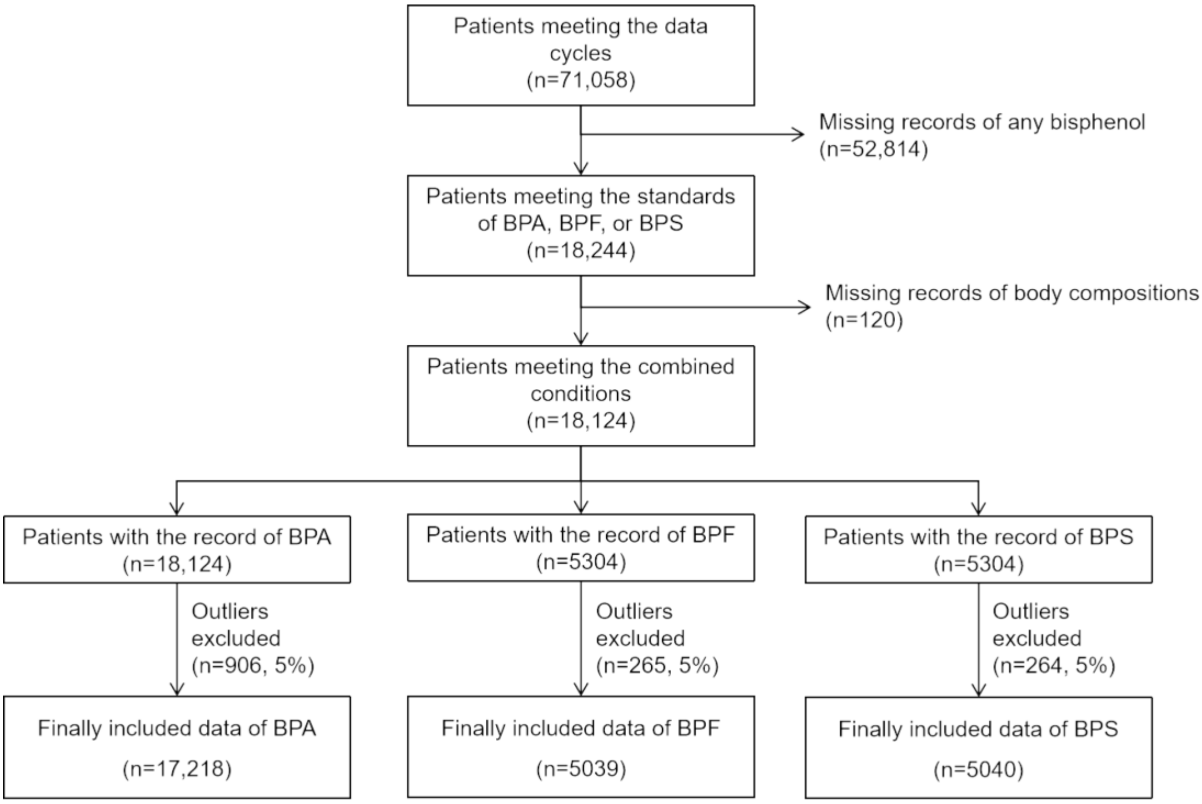
The NHANES database is a research program designed to assess the health and nutritional status of nonhospitalized adults and children in the United States. The unique feature of this survey is that it combines interviews and physical examination [23]. More specifically, nearly 7000 residents are randomly selected and invited to the NHANES interviews every year. The interviews include population-, socioeconomic status–, diet-, and health-related issues. The examination section includes medical, dental, and physiological measurements as well as laboratory tests conducted by trained medical personnel.

Because NHANES used the DXA method to measure body composition, only people aged 8 to 59 years were measured in this database. In addition, pregnant women, people who have used radiocontrast agent (barium) in the past 7 days, and people who weigh >204 kg or are taller than 195.58 cm have also been initially excluded from the NHANES surveys. Our study included and analyzed data from 7 NHANES survey cycles (2003-2004, 2005-2006, 2007-2008, 2009-2010, 2011-2012, 2013-2014, and 2015-2016). Missing data on bisphenols (BPA, BPS, and BPF); BMI; or body compositions (total lean mass [TLM], appendicular lean mass [ALM], trunk fat [TRF], bone mineral content [BMC], and total fat [TOF]) were excluded.

Exclusion criteria were as follows: (1) data regarding BPA, BPS, or BPA were missing; (2) body composition data were missing; (3) the percentage of bisphenols (BPA, BPS, or BPF) >95% was defined as an outlier, and outliers were excluded.

We included 71,058 original records at first. After excluding the missing data and outliers, 17,218 data were finally included in the BPA analysis study, whereas 5039 and 5040 data were finally included in the BPF and BPS analysis studies, respectively. Detailed inclusion and exclusion criteria are shown in Figure 1.

Figure 1. Flowchart of inclusion and exclusion criteria among American adults from the National Health and Nutrition Examination Survey 2003 to 2016. BPA: bisphenol A; BPF: bisphenol F; BPS: bisphenol S.



Ethical Considerations

All study participants signed written informed consent forms, and the NHANES data collection was approved by the Research Ethics Review Board of the National Center for Health Statistics [24]. The NHANES has stringent consent protocols and procedures for ensuring confidentiality and protection against identification. This study was a secondary data analysis, which lacked personal identifiers, and the NHANES data are free for public use and available on the web [23]. Therefore, this study did not require an institutional review board review [24].

Measurement of Bisphenols

A sensitive phenol-detection method was used in this study [25]. This method is a web-based solid-phase extraction method coupled with high-performance liquid chromatography and tandem mass spectrometry. In addition, urine creatinine in each urine sample was measured and used to adjust the urine dilution. The specifics of the bisphenol measurements were provided by NHANES [26]. We sought to access the NHANES, gleaned the relevant data successfully, and recorded them in their database duly, corresponding to the measurements undertaken.

Measurement of Body Composition

The body composition included TLM, ALM, TRF, BMC, and TOF. DXA is the most widely accepted method for measuring body composition, partly because of its speed, ease of use, and low radiation exposure [27,28]. The NHANES DXA examination provides data on body composition (bone and soft tissue) as well as data on age, gender, and race and ethnic groups, which are generally representative of the United States, to study the association between body composition and other health conditions and risk factors, such as cardiovascular disease, diabetes, hypertension, and patterns of physical activity and dietary intake. DXA scans provide bone and soft tissue measurements of the entire body, arms and legs, trunk, and head.

The whole-body scan was obtained using the Hologic Discovery model A densitometer (version Apex 3.2; Hologic) [29]. The radiation exposure of whole-body DXA scanning was extremely low, less than 20 μSv. DXA examinations were performed by trained and certified radiologists. Further details of the DXA examination protocol are recorded in the Body Composition Procedure Manual on the NHANES website.

Covariates

Age, race, education level, marital status, and income:poverty ratio were among the demographic factors recorded. The income:poverty ratio was determined by dividing household income by the poverty threshold, specifically the size of the household, in the corresponding year and the state. BMI, which was determined by dividing weight by height squared, was one of the variables examined. Laboratory test results included serum calcium and phosphorus levels. The variables in the questionnaire included the coronary artery disease (CAD) score, alcohol use, physical activity, and smoking status. The CAD score was obtained from the Cardiovascular Disease and Health section of the NHANES database defined by the Rose questionnaire [30]. Energy (kcal) was calculated as the energy intake in food and beverages consumed within 24 hours before the interview (midnight to midnight), based on the energy of each food item in the US Department of Agriculture Food and Nutrient Database for Dietary Studies.

Data Analyses

We used appropriate survey procedures to explain the complex sampling design and weights of the NHANES [31]. The weights of the NHANES data consider several survey features, including the differential probabilities of selection for the sampling domains, survey nonresponse, and differences between the final sample distribution and the target population distribution. Each of the 3 levels of data collection for the NHANES (screening, interview, and examination) had a response rate. Subsequently, the sample weights were calculated for each level of data collection by the statistician of the National Center for Health Statistics. The selection of weights was carried out by the researchers based on the NHANES analysis protocol and the study content. This study selected the full sample of the 2-year mobile examination center exam weight. When we combined the weights of 7 cycles of the NHANES study, we divided the raw weight data by 7. Continuous variables were expressed as mean (95% CI), whereas categorical variables were expressed as percentages. The Student 2-tailed *t* test or Mann-Whitney *U* test was used to compare continuous variables, and the chi-square test or Fisher exact test was used to compare categorical variables.

A multivariate linear regression model was used to estimate the association between the body composition of phenolic substances, including an unadjusted model (nonadjusted); a minimally adjusted model (adjust I; adjusted only for gender, age, race, energy [kcal], and creatinine, urine [mg/100 mL]); and a fully adjusted model (adjust II; adjusted for gender, age, race, ratio of family income to poverty, education level, marital status, CAD score, smoking status, alcohol intake, physical activity, energy [kcal], and creatinine, urine (mg/100 mL]).

In the aforementioned models, body composition and body weight were used for adjustment in all analyses, except BMI and body weight. In addition, for missing covariate data, the method of missing value interpolation was supplemented. The interpolation threshold was set to 5%. Phenolic substances (BPA, BPS, or BPF) were considered continuous independent variables and categorical variables (divided into quartiles), and the lowest quartile was used as the reference. As the detection rate of BPF was low, quartiles 1 and 2 of the original data were combined to form a new quartile.

We performed tests for linear trends by entering the median value of each category as a continuous variable in the models. Interactive and stratified analyses were performed. Each stratification was adjusted for all factors (gender, age, alcohol intake, race, smoking status, and physical activity) except for the stratification factor itself.

All statistical analyses were performed using the software packages R (version 4.2.0; The R Foundation) and Empower (X&Y Solutions Inc) [32]. Double-tailed *P*<.05 was considered statistically significant.

Results

In total, 18,124 participants were selected for our study. Among them, 8988 were male and 9133 were female, the median age was 39.49 (IQR 38.94-40.04) years, and the median BMI was 27.22 (IQR 27.03-27.41) kg/m^2. Among the 18,124 participants, we conducted statistical analysis on 17,218 (95%) participants with BPA data, 5039 (27.8%) people with BPS data, and 5040 (27.8%) people with BPF data according to the information from the NHANES database. In addition, urinary BPA, BPS, and BPF were 2.27 (95% CI, 2.22-2.33), 0.70 (95% CI, 0.65-0.75), and 0.72 (95% CI, 0.66-0.78) ng/mL, respectively. Detailed characteristics of the participants are presented in Table 1.

Table 1. Characteristics, including baseline, urinary bisphenols and body compositions, of American adults from the National Health and Nutrition Examination Survey 2003-2016.

Characteristics[a]	Total (n=18,124)	BPA[b] (n=17,218)	BPS[c] (n=5039)	BPF[d] (n=5040)
Age (years), median (IQR)	39.49 (38.94-40.04)	39.65 (39.10-40.21)	40.13 (38.99-41.27)	40.18 (39.02-41.35)

[a] The data showed for continuous variables were survey-weighted mean (95% CI) and for categorical variables, survey-weighted percentages (the absolute values cannot be provided due to being adjusted by weighting).

[b] BPA: bisphenol A.

[c] BPS: bisphenol S.

[d] BPF: bisphenol F.

[e] TLM: total lean mass.

[f] ALM: appendicular lean mass.

[g] TRF: trunk fat.

[h] BMC: bone mineral content.

[i] TOF: total fat.

[j] N/A: not applicable.

[k] CAD: coronary artery disease.

Associations between bisphenols (BPA, BPS, and BPF) and body compositions are presented in Table 2. A dose-response relationship was observed between BPA and BMI in the crude model (*P*<.001). The relationship did not exist after full adjustment; however, there was a positive association between BPS and BMI, with 0.91 and 1.15 higher BMI in quartiles 3 and 4, respectively, compared with quartile 1 (*P*<.001). In addition, there was also a dose-response relationship between BPA and TLM in the minimally and fully adjusted models (all *P*<.001), whereas a negative association was found between BPS and TLM after adjusting for all potential confounders, compared with quartile 1; participants in quartiles 3 and 4 had significantly lower TLM (quartile 3, model 2: β=–10.53, 95% CI –16.98 to –4.08; quartile 4, model 2: β=–11.14, 95% CI –17.83 to –4.45; *P*=.005). After adjusting for all confounders, a dose-response relationship was also found between BPA and ALM, with those in quartiles 2, 3, and 4 having significantly lower ALM than those in quartile 1 (quartile 2: β=–3.31, 95% CI –5.73 to –.90; quartile 3: β=–5.46, 95% CI –8.01 to –2.90; quartile 4: β=–4.80, 95% CI –7.55 to –2.05; *P*=.01). However, there was no substantial association between BPS and ALM. In addition, there was a dose-response relationship between BPA and TRF or TOF. For TRF, participants in quartiles 2, 3, and 4 (model 2: β=3.55, 95% CI 1.17-5.93; β=8.29, 95% CI 5.78-10.79; β=5.68, 95% CI 2.98-8.37, respectively; *P*=.002) had a significantly higher TRF than those at quartile 1. Similarly, there was a dose-response relationship between BPA and TOF (model 2: *P*<.001). For BPS, a positive association was identified between BPS and TRF or TOF; those in quartiles 3 and 4 had 5.16 and 8.41 higher TRF, 9.92 and 10.34 higher TOF when compared with quartile 1, respectively (for TRF, model 2: *P*<.001; for TOF, model 2: *P*=.01). Furthermore, although there was no significant association between BPA and BMC, there was a negative association between BPS and TOF (model 2: *P*<.001). After complete adjustment, there was no substantially association between BPF and body composition indicators (Table 2 and Multimedia Appendix 1).

[a] Model I was adjusted for gender, age, race, energy, creatinine, and urine.

[b] Model II was adjusted for gender, age, race, ratio of family income to poverty, education level, marital status, CAD score, smoking, alcohol intake per day, physical activity, energy, and creatinine, urine.

[c] *P* value for trend.

[d] Ref: reference.

[e] TLM: total lean mass.

[f] ALM: appendicular lean mass.

[g] TRF: trunk fat.

[h] TOF: total fat.

[i] BMC: bone mineral content.

The results of the interaction and stratified analyses are shown in Table 3. The associations between BPA, BPF, and body compositions were not significantly modified by gender. However, the association between BPS and body composition parameters (TLM, TRF, and TOF) was stronger among female participants (for interaction: *P*=.002, *P*=.007, and *P*=.003, respectively). A dose-response relationship was found between BPS and body composition parameters (TLM, TRF, and TOF; for trend *P*<.001, *P*<.001, and *P*=.001, respectively). In addition, the association of BPA and BPS with BMI was significantly modified by age (for interaction, *P*=.02 and *P*=.04, respectively). BPA was inversely associated with BMI in patients aged ≤20 years (for trend, *P*<.001). Compared with quartile 1, the BMI level decreased by 1.11 in quartile 4 (95% CI –1.61 to –.62; *P*<.001), whereas there was a dose-response association between BPA and BMI in people aged 20 to 50 years (*P*=.01, *P*<.001, and *P*=.003, respectively). For BPS, the association between BPS and BMI was stronger in people aged 20 to 50 years, and a dose-response association was found (for trend, *P*=.02). Furthermore, alcohol intake was a potential confounder in the association between BPF and ALM (for interaction, *P*=.001). Finally, the observed associations between bisphenols (BPA, BPS, and BPF) and body composition parameters were not significantly modified by race, smoking status, and physical activity (data not shown; Multimedia Appendix 2).

Discussion

Principal Findings

In this study, we discovered that there was no significant association between BPA and BMI, whereas BPA was negatively associated with TLM and ALM and had a positive dose-response with TOF and TRF. BPS was positively associated with BMI, TRF, and TOF and negatively associated with TLM, and there was no discernible relationship between BPS and ALM. However, no significant association was observed between BPF and body composition. Although previous studies have revealed that BPA is positively associated with human BMI [33-35], and urinary BPA content and phthalate metabolites are positively associated with body fat content in older adults and premenopausal women [1], it is unclear whether BPA and its derivatives (BPS and BPF) have similar effects on the specific body composition of the general population.

Eating habits may have influenced the study results. Wang et al [36] conducted a survey that included 360 primary and junior high school students in Shanghai as participants and found a positive association between BMI and BPA [36]. Regarding the possible effects of BPA exposure on adult BMI, the study by Carwile and Michels [33] that included 2747 adults participating in the 2003 to 2006 NHANES found that despite the nonlinear association between BPA and BMI, the BMI of the participants in the second, third, and fourth BPA quartiles were higher than those in the primary BPA quartile. Other studies investigated the relationship between BPA and BMI in young Indian women (age: mean 21.2, SD 2.37 years) and revealed that there was a significant association between BPA and BMI (P=.03) [37]. None of the 3 studies included diet as a possible covariate. In contrast, Braun et al [38] found no significant association between urinary BPA levels and BMI of prenatal women and 2-to 5-year-old children in the Cincinnati region after adjusting for diet, exercise, and di(2-ethylhexyl) phthalate. Thus, the differences among these findings may lie in whether diet was selected as a possible covariate and was well adjusted. Diet is an important source of exposure to BPA [39-41], whereas obesity is associated with certain dietary patterns, such as the Mediterranean diet [42] or ketogenic diet [43]. Previous studies indicated that consuming a substantial amount of plant-based foods in the Mediterranean diet may potentially reduce the severity of nonalcoholic fatty liver disease–related outcomes [44] and relate to favorable measures of adiposity [45]. Furthermore, a highly restrictive ketogenic diet is considered an effective and safe therapeutic intervention for patients who are obese [46,47], favoring their body composition [48]. In our study, total calorie intake, TOF intake, and alcohol intake were included as possible dietary covariates; the participants in the 2003 to 2004 and 2005 to 2006 NHANES were selected as participants of this study, and their body composition and urinary BPA level were well measured. No significant association was found between BMI and BPA in the fully adjusted model. This was consistent with the trend described by Braun et al [38].

There was a positive association between BPS and BMI, which is consistent with the findings of Jala et al [37]. In the study of the effect of BPS on male sperm quality, Ghayda et al [49] also found that men with high BMI have correspondingly higher urine BPS levels. For lean mass, both BPA and BPS showed a negative dose-response relationship with TLM, and there was a negative association between BPA and ALM in the fully adjusted model. Corbasson et al [1] found a negative association between BPA and TLM in the male group after adjusting for the covariates of waist circumference and BMI. However, this association was not observed in the female group. For body fat, urinary BPA and BPS levels in the NHANES participants were positively associated with TRF and TOF. Inconsistent with our findings, there was no significant relationship between BPA and fat mass in the study by Corbasson et al [1]. However, because of the use of NHANES as a data source for us and this study, our study incorporated an extended range of data periods, which may engender more inferences. Zhang et al [50] found that abnormal liver metabolism in mice, glycolysis, trichloroacetic acid metabolic pathway effects, and decreased succinic acid levels were related to visceral fat synthesis, indicating that BPS may also lead to an increase in TRF and TOF [51].

BPF was not significantly associated with TRF or TOF, possibly because current environmental BPF exposure is insufficient as a decisive factor for obesity. For example, Liu et al [52] used the data of 1521 participants in the NHANES 2013 to 2014 to evaluate the relationship between BPF and obesity. They also found that BPF and obesity were not significantly associated with obesity after adjusting for factors such as demographic, socioeconomic, lifestyle, and urinary creatinine concentration; however, a significant association was observed in the nonadjusted model. However, this might be an adjustment for sensitive populations, such as low-income individuals who are prone to overexposure. In their study, the exposure of BPF before and after adjustment was 0.4 versus 0.3 ng/mL, respectively, which was much less than the BPA exposure of 1.5 versus 1.1 ng/mL [52], and studies have shown that BPF can interfere with the IRS-1/PI3K/AKT signal transduction pathway and subsequently affect the insulin-dependent glucose metabolism pathway of adipocytes (3T3-L1 adipocytes), resulting in obesity [53].

According to the stratified analyses, the association between bisphenols and body composition was influenced by gender, age, and the potential impact of alcohol. Previous research has reported gender differences in the effects of BPA on obesity [54], and our study has also demonstrated such differences. On the basis of previous studies, this may be attributed to the differences in BPA metabolism and estrogen receptor expression, as well as gender-related BPA exposure [55,56].

Gender-related hormonal variations can lead to different responses to bisphenol exposure [57,58]. The Environmental Obesogen Hypothesis suggests that prenatal or early life exposure to estrogen-like environmental pollutants may increase the risk of fat accumulation and obesity [59]. For instance, BPA may have the greatest impact during early developmental stages, potentially due to epigenetic modifications related to stem cells [60]. In addition, alcohol consumption is associated with obesity, as it can affect liver metabolism and function [61]. The interaction between alcohol consumption and bisphenol compounds requires further research and validation.

Estrogen receptors play a crucial role in regulating lipid accumulation and improving insulin sensitivity and are therefore regarded as therapeutic targets for preventing obesity and metabolic disorders [57]. In vitro studies have previously observed that BPS and BPF exhibit similar toxicity and estrogenic effects as BPA, exerting an influence on cellular metabolism through pathways such as growth inhibition, oxidative stress, and gene expression [62]. Another study demonstrated the estrogenic agonistic effects of BPA, BPS, and BPF, individually, and the synergistic effect of these 3 bisphenols when combined, exhibiting a more potent action [63]. By contrast, obesity and metabolic disorders have been associated with oxidative stress [64]. Insulin resistance, a key factor in the pathogenesis of obesity and diabetes, is intricately linked to oxidative stress [65]. BPA and its derivatives, BPS and BPF, can disrupt the endogenous antioxidant system, leading to a severe imbalance in enzymes, such as superoxide dismutase and catalase, in liver cells exposed to BPS [66]. Furthermore, studies have indicated that adult exposure to BPF results in a significant imbalance in catalase activity [67]. Regarding the findings of this study, it is evident that both BPA and BPS have a significant impact on body composition, particularly on the content and distribution of adipose tissue. The potential mechanisms of BPS toxicity may involve interactions with estrogen receptors [68], DNA, and protein binding [69], as well as oxidative stress effects [70].

In this study, both BPA and BPS exhibited significant associations with body composition, displaying trends similar to those of BMI, TLM, TRF, and TOF. Furthermore, BPA was correlated with ALM, whereas BPS demonstrated an additional association with BMC. However, no significant correlation was observed between BPF and body composition. Studies suggest that BPS has a lesser obesogenic effect compared with BPA, with its ability to induce triglyceride accumulation being only 1% of that of BPA [71]. Nevertheless, for BPF exposure, some studies indicate an association with developing obesity, whereas others yield inconclusive results [72]; thus, further research is needed to elucidate its role.

In this cross-sectional study, although we were unable to establish a causal relationship between BPA and its derivatives, BPS and BPF, and body composition, we identified an association between them. The analysis conducted in this study not only provides a reference value for understanding the mechanisms of bisphenols but also holds potential value in guiding individuals to reduce adverse changes in body composition and mitigate metabolic-related reactions by proper exposure management or avoidance of bisphenols. Furthermore, it presents potential references for exploring the pathogenic mechanisms and preventive measures for obesity and other metabolic-related disorders. These findings underscore the importance of understanding the potential health risks associated with bisphenol exposure and emphasize the need for targeted interventions to mitigate the potential adverse effects on body composition.

Furthermore, to our knowledge, this is an innovative study to evaluate the association between specific body compositions, including ALM, TLM, TOF, TRF, and urinary BPA derivatives, such as BPS and BPF. Compared with previous studies, we included alcohol, calorie, and fat intake as possible covariates in the analysis to exclude the possible effects of diet on obesity based on the association between obesity and BPA as well as its derivatives. Thus, this study’s findings more accurately reflect the association between endocrine disrupters and body components. Another advantage of our study is that the American NHANES cohort has a large population base and ethnic diversity. Statistics was used for weighted analysis to represent a larger population. We also evaluated the association between BPS and TLM and found that BPS was negatively associated with TLM, which has not been previously reported. Lean body mass is significant for bone health and optimal aging [1]. The skeletal muscle is the largest and most malleable component of lean body mass (accounting for approximately 50% of lean body mass). Therefore, the change in lean body mass is mainly attributed to skeletal muscle mass. The maintenance of skeletal muscle is fundamental to locomotion, energy homeostasis, and overall quality of life [73]. This suggests that exposure to BPS may lead to a decline in exercise capacity, as the substitution of BPA also has safety issues. In fact, some studies have shown that BPS and BPA are positively associated with oxidative stress, which is associated with an increase in triglycerides and indirectly affects the physical fitness of healthy young adults (age: mean 23.5, SD 2 years). Jing et al [74] also found that the myotube diameter and distribution area of C2C12 myoblasts that were exposed to 10 to 4 M BPS decreased significantly compared with the control group.

Limitations

Our study has several limitations. First, bisphenol exposure was measured using the urine of the NHANES participants. However, it is widely acknowledged that urinary BPA and its derivatives do not fully reflect bisphenol exposure. In fact, their levels change greatly over a short period, which may lead to uncertain relationships between BPA, BPS, BPF, and body composition [1]. Therefore, it is important to conduct repeated sampling measurements of the population. In addition, our covariates were limited and did not include other possible disrupters, such as exposure to other endocrine disrupters or drug intake, which can affect metabolism during the study period and the menopausal state of female individuals. Moreover, the data we used were collected from the urine of each participant only once, so it could not fully reflect the exposure to BPA and its derivatives. However, repeated sample collection may also have affected the enthusiasm of the participants, resulting in bias in the results. Nevertheless, urine collection is the most effective and widely adopted method for detecting BPA and

BPS (bisphenol derivatives). The NHANES and other studies have generally used indirect methods to detect BPA levels. However, some studies have suggested that the bisphenol content in the human body may be disputable due to different detection methods. In 2020, a study proposed that direct methods measure BPA levels nearly 20 times higher than indirect methods, which may change our understanding of BPA levels in humans [75]. Nevertheless, the trend in the results obtained using mainstream detection methods is unquestionable. We found a negative dose-response between BPF, BPA, and TLM, which provides a basis for future research. However, the specific mechanism remains unclear and should be further explored in future studies. Additionally, the characteristics of human exposure to bisphenols are mixed. In this study, we analyzed the independent records of bisphenol compounds in the database, and we will analyze the effects of all bisphenol mixtures together by experimental methods for future research.

Conclusions

Our study found that BPA, as a representative bisphenols, is related to changes in body composition. Although people have begun to pay more attention to BPA, the impact of its derivatives on humans cannot be ignored. As a derivative of BPA, BPS is related to the changes in various body components and has a stronger association with women and changes in age. BPF was not significantly associated with various body components in this study. We speculate that the degree of environmental exposure to BPF is not sufficient to cause a significant impact, but this conjecture needs to be elucidated through additional experiments.

Acknowledgments

The authors thank Dr Chi Chen, Changzhong Chen, and Xing-Lin Chen for providing the statistical methodology consultation.

Data Availability

The data used for this study were obtained from the National Health and Nutrition Examination Survey (NHANES) database, 2003 to 2016 [23], and only publicly available data were used in this study. The datasets generated or analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

JL, ZZ, and CZ contributed equally as the first authors of this manuscript. SQ and QW were responsible for the conception and design of this study. QZ, JW, HZ, TT, Q Deng, YZ, Q Dong, and YL interpreted the data. CZ, JL, ZZ, JZ, RW, EW, BS, and SQ were responsible for the data acquisition. JL, ZZ, and CZ wrote the first draft, interpreted the data, and wrote the final version of the manuscript. JZ was committed to the language editing of the manuscript. All authors critically revised the manuscript for important intellectual content and approved the final version of the manuscript. The authors have read and approved the final manuscript. SQ, BS, and QW contributed equally as the corresponding authors of this manuscript.

Abstract

Background: In light of the COVID-19 pandemic, the distribution of social support for mental health problems has likely become unequal. Family- and community-based social support has been recognized as a promising approach for mental disorders; however, limited global frameworks have been applied to developing countries such as Vietnam.

Objective: The aim of this study was to evaluate the quality of life and social support among patients with mental health disorders in Vietnam and to investigate the factors associated with quality of life among these patients.

Methods: A cross-sectional study was conducted on 222 psychiatric patients in Hanoi from 2020 to 2022. A structured questionnaire was developed based on four standardized scales: Mental Well-Being-5 scale, Multidimensional Scale of Perceived Social Support, EuroQoL-visual analog scale (EQ-VAS), and EuroQoL-5 dimensions-5 levels (EQ-5D-5L) scale. Tobit regression was used to identify factors associated with the EQ-5D-5L and EQ-VAS scores. Structural equation modeling was applied to verify the relationship between quality of life and social support.

Results: The results showed that perceived support from family scored the highest compared to support from friends and significant others. Patients with depression reported the lowest quality of life and perceived social support. Structural equation modeling showed a root mean square error of approximation of 0.055 (90% CI 0.006-0.090), comparative fit index of 0.954, Tucker-Lewis index of 0.892, and standardized root mean squared error of 0.036 (*P*<.001). The hypothetical model indicated statistically significant correlations between EQ-VAS score and social support (*P*=.004), EQ-5D-5L and mental well-being (*P*<.001), and social support and mental well-being (*P*<.001). Critical deterioration of quality of life and inconsistency in social support for patients with mental illness were also recorded.

Conclusions: There is a need to enhance social support and service delivery in Vietnam, focusing on occupation and quality of life. The correlations between social support, quality of life, and mental health issues suggest the potential of a clinical-social integrated intervention model of care.

Introduction

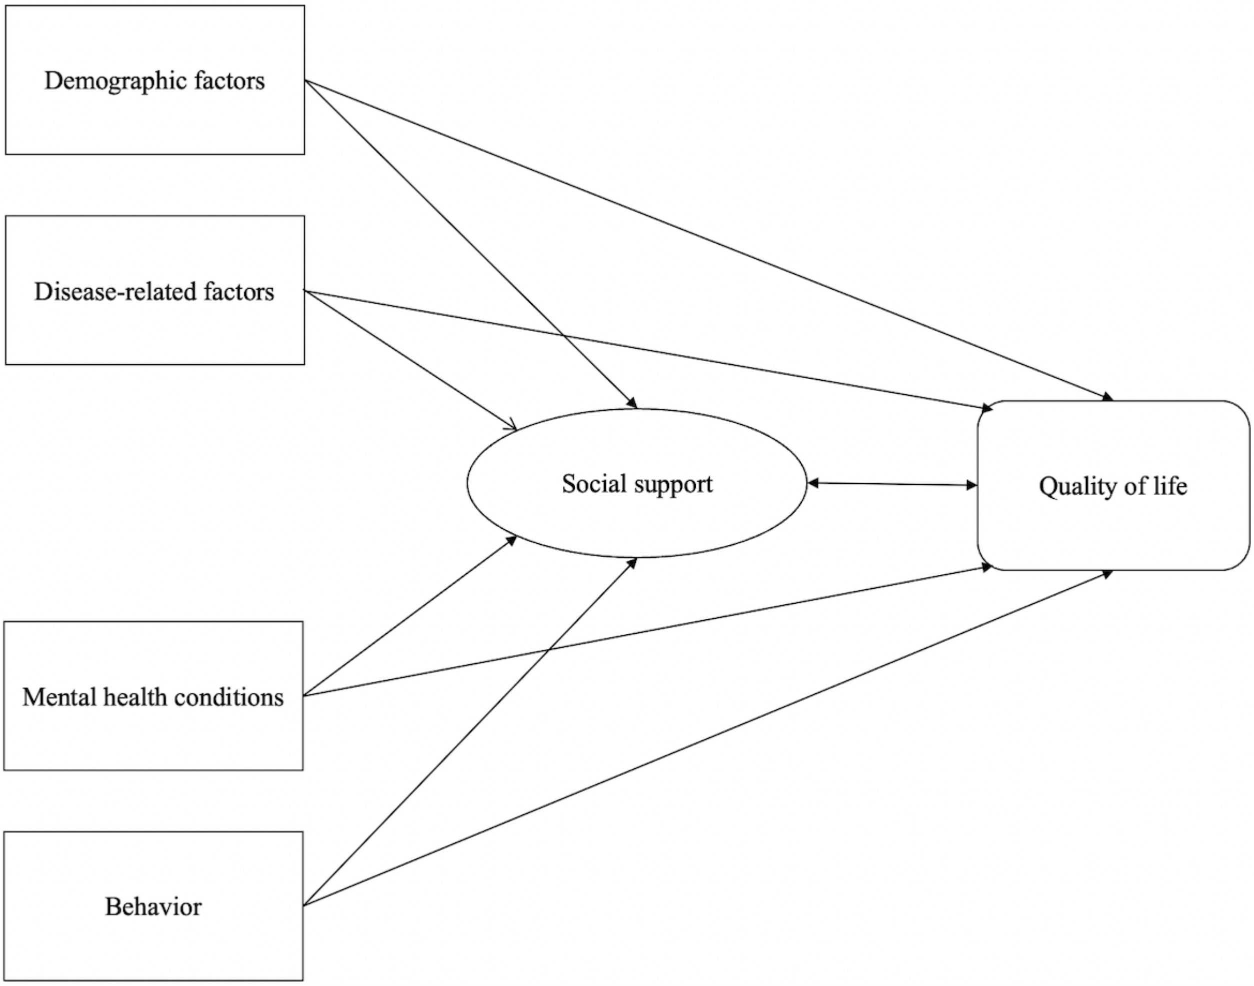
Awareness of the burden posed by mental health disorders is steadily growing on a global scale, particularly in low- and middle-income countries [1]. According to a report by the World Health Organization (WHO), mental health disorders affected approximately 970 million people worldwide, constituting 12.8% of the population. These disorders are measured in terms of disability-adjusted life years (DALYs) and years lived with disability (YLDs), with mental health disorders accounting for over 40% of YLDs [2] and 15% of DALYs [3] globally. The prevalence of mental health disorders saw a sharp increase in 2020 due to the COVID-19 pandemic. Depressive symptoms were reported in 48.3% of the Chinese population, 32.7% of the Italian population, and 23.6% of the Spanish population [4]. In Vietnam, 45.8% of the population reported mild to moderate symptoms of stress following an extended period of social restrictions [5]. COVID-19 significantly impacted patients with pre-existing mental health disorders [6,7]. Strict social restrictions led to heightened stress levels and feelings of isolation among hospitalized patients [8]. Patients with mental illness were profoundly affected by changes in daily routines, social rhythms, and their sense of stability [9]. Additionally, socioeconomic factors such as remote working, wage cuts, and increased household expenditures were linked to the worsening of pre-existing disorders [10]. Given that mental health outcomes are influenced by a variety of biological, social, cultural, economic, and religious factors, it is crucial to approach mental health from a multidimensional perspective. The COVID-19 pandemic emphasizes the urgent need to shift the approach to mental health from a biomedical and therapeutic standpoint to a psychosocial perspective that maximizes family- and community-based interventions.

An increasing body of research has been dedicated to examining the influence of social determinants on health care outcomes. The WHO has officially acknowledged the significant impact of social factors on the prevalence and duration of mental disorders, attributing them to be responsible for shaping, sustaining, and enhancing overall health quality [11,12]. The UK National Health Service has emphasized the vital role of community connectors and advocated for an integrated approach that blends clinical treatment, mental health care, and social support [13]. Both frameworks acknowledge social support as a potent public health intervention, encompassing multitiered collaborations, including personal-interpersonal, personal-community, and interpersonal-community interactions. Furthermore, social support can function as a consistent source of care and a therapeutic approach for individuals with mental illnesses, without relying heavily on facility resources as is the case for many clinical interventions. Nevertheless, standardized models encounter the challenge of not fully capturing the influence of social support on diverse determinants of health, such as societal, cultural, and religious factors. Furthermore, since current frameworks are primarily rooted in Western contexts, there exists limited evidence regarding the effectiveness of the social support model in developing countries and resource-constrained settings [14-16].

As COVID-19 presented unique challenges to individuals with mental health disorders, it is critical to understand the role of social support in their quality of life (QoL). The standardized social support frameworks have been found to be limited in their applicability to the context of resource-scarce settings. While previous studies have identified unfavorable social outcomes for patients with mental health disorders, including social dysfunction, lack of social networks, severe stigma, and interpersonal challenges, contextualized social support models have neither been implemented nor studied for this population in Vietnam [17,18]. To contribute to the growing body of research on mental health care and social support in Vietnam, shedding light on the unique challenges faced by this population and identifying potential areas for intervention and improvement, we conducted this study with two main objectives: (1) to measure social support and QoL among patients with mental health disorders in Vietnam, and (2) develop and verify a structural model linking various factors that influence the QoL of patients with mental health disorders, particularly the social support aspect. Furthermore, we sought to confirm the bidirectional association between social support and QoL, where patients with mental health disorders suffer from low QoL, which in turn leads to a lack of social support; conversely, a lack of social support is identified as an underlying cause of mental disorders, resulting in lower QoL. Particularly in this time of COVID-19, where the pandemic has even further magnified the challenges faced by individuals with mental health disorders, such information can be invaluable in the development of tailored interventions that can strengthen social support and improve the QoL of patients.

After reviewing the existing literature, we identified demographic, behavioral, illness-related, mental health–related, and social support factors that contribute to influencing the QoL of individuals with mental health conditions [19-21]. The conceptual framework employed in this study is presented in Figure 1.

Figure 1. Conceptual framework of the study.



Methods

Study Setting and Participants

From January 2020 to June 2022, a cross-sectional study was conducted in Hanoi, Vietnam. The eligibility criteria included patients who were 18 years old or above, currently being treated at the Mai Huong Daycare Psychiatric, willing to participate in the study through providing informed consent, and had the physical and mental capacity to answer the interviewer's questions. Patients who had serious cognitive impairment or were unable to answer the data collectors' questions were excluded from the recruitment process. A day psychiatric hospital model is currently being applied by Mai Huong Daycare Psychiatric, making the participants outpatients. The day-hospital model allows patients to spend less time at the hospital, reducing the potential negative effects of prolonged hospital stays, while facilitating faster recovery and improved QoL [22].

There were five investigators who were members of the research team and well-trained medical staff from Hanoi Medical University. The interview was conducted in a separate room where patient privacy was guaranteed. The patient was interviewed in a face-to-face manner using the questionnaire. The questionnaire required approximately 10-15 minutes to complete.

Measure and Instruments

A structured questionnaire was used consisting of five main components: (1) demographic characteristics, (2) clinical history (chronic diseases, family psychiatric history, number of outpatient medical examinations, and number of mental health disorders examinations), (3) mental well-being (Mental Health Inventory-5 [MHI-5] scale), (4) social support (Multidimensional Scale of Perceived Social Support [MSPSS]), and (5) QoL (EuroQoL-5 dimensions-5 levels [EQ-5D-5L] scale and EuroQoL-visual analog scale [EQ-VAS]).

Variables

Outcome Variables

The EQ-5D-5L scale was used to measure the QoL of participants through five domains: Mobility, Self-care, Usual Activities, Pain/Discomfort, and Anxiety/Depression. Each question had a score from 1 ("extreme problems") to 5 ("no problems"), which resulted in 3125 possible health states from 1111 (worst health) to 55,555 (full health) [23]. One single "utility" score was defined for each health state and could be transformed using the interim scoring for EQ-5D-5L. This study used the validated Vietnamese version of the EQ-5D-5L with a score ranging from –0.5115 to 1 [24]. Higher scores indicated better QoL. The EQ-VAS is a vertical visual analog scale to self-assess health states from a score of 100 (best imaginable health) to 0 (worst imaginable health) [25].

The MSPSS was used with 12 items to measure the social support from the following subscales: family (4 items), friends (4 items), and significant others (4 items) [26]. Participants reported the MSPSS using a 7-point Likert scale ranging from 1 "strongly disagree" to 7 "strongly agree." The score of subscales is the average score of the corresponding 4 items. Higher scores indicated higher support from family, friends, or significant others [26]. The maximum total score was 84, with a higher score indicating greater perceived social support. The MSPSS has been used widely for several groups such as those with infertility, people living with HIV/AIDS, and adolescents [27-29].

Covariates

Socioeconomic Status

Respondents were asked about their sociodemographic background, including age, gender, marital status, and occupation.

Substance Use Behaviors

We asked participants one question each about their current smoking and alcohol consumption behavior.

Clinical Characteristics

Participants were asked about their clinical characteristics, including comorbidities, chronic diseases, acute symptoms, family history of mood disorders, type of disorders (schizophrenia, bipolar disorder, depression, anxiety disorders, mixed anxiety-depressive disorder, sleep disorders, emotional disturbance, epilepsy, and other), family history of mental health disorders, the number of outpatient medical examinations, and the number of mental health disorders examinations.

The MHI-5 scale was used to measure the general mental health status of participants. There was a total of five items with each item scored from 1 to 5. The total score was measured by adding the total score of 5 questions and multiplying by 4. The total score ranged from 20 to 100 [30]. Higher scores indicated more severe mental health problems. The MHI-5 scale has been used for several groups such as adolescents and the general population [31,32].

Sample Size and Sampling Method

Total population sampling was used in this study. The sample size was calculated using the formula to estimate the mean score of EQ-VAS among participants according to EQ-VAS scores reported from another study conducted in Vietnam [33]. This was selected for two main reasons. First, the study was conducted on adult patients quite similar to our study group. In Vietnam, there is still very little research on patients with mental illness. Second, the previous study used the same tool to measure the QoL of patients (EQ-VAS). Hence, we used α=.05, the mean score of EQ-VAS from the previous study of 66.3 (SD 12.5) [33], and a relative error of 0.025 to calculate the required sample size, resulting in a sample size of 219 patients. It was expected that 5% of those recruited would refuse to participate; therefore, we set the final sample size to N=230. At the end of data collection, 222 participants were recruited for the study.

Statistical Analysis

The data analysis was conducted using Stata version 16 and missing data were managed using the listwise deletion method. Descriptive statistics are presented as the mean (SD) for continuous variables and frequencies and proportions for categorical variables. The Wilcoxon-Mann-Whitney test and Kruskal-Wallis test were used to test for differences in perceived social support and QoL scores across individual characteristics.

Individual characteristics, clinical history, mental well-being, and social support were considered potential covariates for the full models' QoL. Multivariate Tobit regression was utilized to identify factors related to the EQ-VAS and EQ-5D-5L scores. Stepwise forward techniques were employed to create reduced models, with a significance level of P<.20 as the inclusion threshold. Statistical significance was set at P<.05. In contrast, the inferential statistics applied in this study utilized structural equation modeling, which involved employing maximum-likelihood estimation and path analysis to establish the implicit connection between the variables as originally hypothesized in Figure 1. Goodness-of-fit tests such as the goodness of fit index, comparative fit index (CFI), root mean square error approximation (RMSEA), Tucker-Lewis index (TLI), and standard root mean squared residual (SRMR) were used to evaluate the models.

Ethical Considerations

This analysis used a part of the data set of a longitudinal study on individuals with and without mental health disorders in Vietnam, Vietnam's Brain and Behavior Cohort, led by authors BXT and RCMH. The study monitors changes in functional near-infrared data and self-reported health outcomes using portable, functional near-infrared spectroscopy and clinical-behavioral assessments among Vietnamese patients, in an effort toward developing an artificial intelligence–based diagnosis system for psychiatric disorders in Vietnam.

The protocol of this study was approved by the Institutional Review Board of Hanoi Medical University (58/GCN-HĐĐNCYSH-ĐHYHN). We confirmed that all procedures were performed in accordance with relevant guidelines and regulations. Written informed consent was required from participants before participating in the study. Patients invited to participate were fully explained the content, purpose, and benefits of the study. The collected information was kept confidential and only used for research purposes. The data were encrypted to ensure confidentiality of the information.

Results

Table 1 provides demographic information of the respondents, with a mean age of 43.1 (SD 13.4) years and a majority being men, single, having a high school education, and working as freelancers. The prevalence of chronic diseases was moderate (45%), with schizophrenia and bipolar affective disorder being the most commonly reported mental disorders. Participants reported an average of 8.9 outpatient medical examinations and 8.2 mental health disorder examinations in the past year.

Table 1. Individual characteristics of participants (N=222).

Characteristics	Value
Gender, n (%)	
Man	122 (55.0)
Woman	100 (45.0)
Marital status, n (%)	
Single	106 (47.8)
Married	96 (43.2)
Divorced/separated/widow	20 (9.0)
Education, n (%)	
Below high school	75 (33.8)
High school	78 (35.1)
University	69 (31.1)
Occupation, n (%)	
Unemployed	50 (22.5)
White-collar worker	18 (8.1)
Blue-collar worker	22 (9.9)
Student	28 (12.6)
Retired	20 (9.0)
Freelancer	84 (37.8)
Chronic diseases, n (%)	
None	122 (55.0)
One disease	62 (27.9)
Two or more diseases	38 (17.1)
Family history of mental health disorders, n (%)	28 (12.7)
Drinking alcohol, n (%)	35 (15.8)
Smoking, n (%)	48 (21.6)
Type of mental health disorder, n (%)	
Other	45 (20.5)
Sleep disorders	27 (12.3)
Schizophrenia	44 (20.0)
Schizoaffective disorder	15 (6.8)
Anxiety disorders	10 (4.6)
Bipolar affective disorder	29 (13.2)
Mixed anxiety disorder-depression	18 (8.2)
Emotional disturbance	7 (3.2)
Depression	14 (6.4)
Psychosis	11 (5.0)
Age (years), mean (SD)	43.1 (15.4)
Number of outpatient medical examinations, mean (SD)	8.9 (11.6)
Number of mental health disorders examinations, mean (SD)	8.2 (10.9)

Table 2 presents the perceived social support scores, with mean scores of 5.08 (SD 1.09) for the family group, 4.32 (SD 1.52) for the friend group, 4.18 (SD 1.68) for significant others, and 54.33 (SD 13.52) for total perceived social support. Married participants reported higher scores for significant other support and total perceived social support than single participants

(*P*=.03). Unemployed participants had the lowest perceived social support total score, while blue-collar workers had the highest perceived social support total score.

Table 2. Perceived social support regarding individual characteristics (N=222).

Characteristics	Family group support		Friend group support		Significant other support		Total perceived support	
	Mean (SD)	*P* value	Mean (SD)	*P* value	Mean (SD)	*P* value	Mean (SD)	*P* value

Table 3 shows the QoL scores of the respondents, with mean scores of 67.99 (SD 20.51) for the EQ-VAS and 0.88 (SD 0.17) for EQ-5D-5L. Women had lower EQ-VAS scores than men (*P*=.01). Patients who were white-collar workers had the highest EQ-VAS and EQ-5D-5L scores, retired patients had the lowest EQ-VAS scores, and students had the lowest EQ-5D-5L scores. No significant differences were found between groups in EQ-5D-5L scores.

[a] EQ-VAS: EuroQoL-visual analog scale.

[b] EQ-5D-5L: EuroQoL-5 dimensions-5 levels.

Table 4 shows the characteristics of QoL and perceived social support based on the type of mental health disorder. Patients with psychosis had the highest EQ-5D-5L score, followed by schizophrenia and emotional disturbance (*P*=.03). Patients with sleep disorders had the highest total perceived social support score, followed by those with anxiety disorders (*P*=.01). In addition, patients with anxiety disorders had the highest family support scores (*P*=.06), whereas patients with sleep disorders had the highest support scores for the friend group (*P*=.04) and significant others group (*P*=.02).

Table 4. Characteristics of quality of life and perceived social support regarding the type of mental health disorders (N=222).

Mental health disorder	Quality of life, mean (SD)		Perceived social support, mean (SD)

[a] EQ-VAS: EuroQoL-visual analog scale.

[b] EQ-5D-5L: EuroQoL-5 dimensions-5 levels.

Table 5 displays the factors related to the QoL of participants. Older age, being a woman, being married, and drinking alcohol were negative factors that decreased the QoL score. Greater mental well-being was a positive factor that increased both the EQ-VAS and EQ-5D-5L scores. Patients who had higher perceived social support had a higher EQ-VAS score. The full multivariate tobit regression models to identify factors associated with the QoL of participants are presented in Multimedia Appendix 1.

Table 5. Factors related to the quality of life of participants (N=222).

Figure 2 presents the results of the structural model and standardized path coefficients of the hypothetical model. The analysis of the structural equation model using the study variables in the hypothetical model resulted in an RMSEA of 0.055 (90% CI 0.006-0.090), CFI of 0.954, TLI of 0.892, and SRMR of 0.036 (*P*<.001). The structural equation model showed that mental well-being was significantly related (*P*<.001) to the QoL score (coefficient=0.37, 95% CI 0.27-0.47 for EQ-VAS; coefficient=0.003, 95% CI 0.002-0.004 for EQ-5D-5L) and with social support (coefficient=0.01, 95% CI 0.004-0.013). Additionally, the model revealed a bidirectional relationship between social support and EQ-VAS (coefficient=2.27, 95% CI 0.74-3.81; *P*=.004). Table 6 illustrates the full models, including the outcome and both tier-1 and tier-2 predictors.

Figure 2. Structural model and standardized path coefficients (N=222). EQ-5D-5L: EuroQol-5 dimensions-5 levels; EQ-VAS: EuroQoL-visual analog scale.

Discussion

Principal Results

This study revealed a decline in QoL and unequal distribution of social support among patients with mental health disorders, as students experienced the lowest social support and workers perceived the highest levels of social support. Depression, sleeping disorders, and bipolar-related problems were the most significant mental health concerns recorded. The current resource allocation scheme was problematic, as all common mental health issues had critically lower levels of social support than other disorders. This study found that QoL decreased with age, among women, and for those with alcohol consumption. The most prevalent source of support across all patient groups was family support, followed by friend groups, implying a potential design of integrated community- and family-based interventions for mental health issues in resource-scarce settings.

Comparison With Prior Work

This study did not measure any COVID-19–related variables; however, since the study was conducted during the severe COVID-19 epidemic, the results can provide a comprehensive picture of mental health disorders in Vietnam during COVID-19. Overall, the QoL among patients with mental health disorders was lower than that of the general Vietnamese population [34]. Patients with mental health disorders experience impairments in daily tasks; isolation; and a decrease in self-sufficiency, self-confidence, and self-esteem.

In this study, participants only received outpatient treatments. Therefore, in addition to attending medical appointments, many patients still work and carry out daily tasks. Our study revealed that patients with mental health disorders had the lowest scores related to perceived support from friend groups. Amal et al [35] conducted a study on psychiatric patients in Egypt and reported similar findings. This finding is likely related, in part, to stigma and prejudice, which have a direct impact on the social opportunities for individuals with mental illnesses. Furthermore, the general population is unaware of the consequences of mental illness and many are often terrified by people with these health conditions. By contrast, this study revealed that the patients had the highest social support from family. This result can be explained by the fact that since our participants were outpatients, they spent most of their time with their family members. Family relationships are strong in Southeast Asia, which may be beneficial if they are used as social support rather than social coercion. Many patients with major mental illnesses either live with their families (parents, spouses, siblings, and children) or have regular contact with them. Goldberg et al [36] evaluated the impact of social networks among individuals with mental impairments in the United States, and discovered that the closest relatives were the most commonly utilized source of support. Furthermore, Brunt and Hansson [37] discovered that patients in in-patient and assisted community settings in Sweden had a large proportion of family members in their social networks.

Our study revealed inconsistent patterns in QoL and support availability among different occupations and mental disorders. Students experienced the lowest social support and EQ-5D-5L scores. Blue-collar workers received the highest levels of social support but experienced the lowest QoL compared to other occupation groups. Understandably, stable employment tends to provide certain benefits such as secure incomes, health insurance (though not yet covering mental disorders), and support systems [38]. The work characteristics of many blue-collar workers in Vietnam and other countries involve intensive and heavy manual labor tasks and appalling working environments, which could lead to a low QoL, even in the usual context that is amplified in the presence of mental disorders. Likewise, for treated and returning-to-work patients, sudden re-exposure to hectic work routines could also lead to loss of job satisfaction or even to relapse of previous conditions [39]. This study highlights the urgent need to develop workplace-based management standard practices that support and distribute the workload to help address the health status of treated and returning-to-work patients.

According to several studies, depression, a mix of anxiety-depression, and sleeping disorders are common determinants of low QoL, not only among mental health patients but across all population groups [40-42]. Patients with these conditions have been found to have the lowest QoL [40-42]. However, our study found that the level of social support provided for depression in particular was critically lower than that for other illnesses. This finding suggests that the distribution of social support is not linked to the needs of patients with mental health disorders [43]. The social support system focuses on illness severity as an indicator rather than on QoL. Although the impairment caused by most cases of depression, anxiety, and sleeping disorders is generally not as severe as that associated with other mental health conditions such as schizophrenia or psychosis, the symptomology of conditions is constantly present in daily life, hardly eradicated, and often only treated with outpatient care [43]. This means that patients diagnosed with these conditions have to bear the burden of their illnesses while maintaining normal social functioning such as working, caregiving, or housekeeping. As a result, patients with mental health disorders are subject to induced stress and feelings of inadequacy or become overwhelmed when their responsibilities are not met, which amplifies their mental health disorders and can create a vicious cycle that significantly impacts their holistic well-being. Instead of relying on illness severity to allocate social support resources, health care professionals should focus on QoL as an indicator for more effective distribution. Moreover, patients may deliberately avoid social support due to insecurity about their health conditions and fear of the social stigma associated with such conditions [44,45]. Interian et al [46] suggested that social stigma not only prohibits patients from seeking social support but also from seeking care altogether. Therefore, additional studies should be conducted on the correlation between social stigma and social support among patients with mental health conditions to better understand and promote help-seeking behavior among this vulnerable population.

Patients with mental disorders have lower QoL and lack social support. The structural equation model analysis confirmed the bidirectional relationship between social support and EQ-VAS scores. Previous research has linked the lack of social support to social isolation, loneliness, and higher risks of physical health problems [47], which can lead to the development of mental health issues. However, various studies, such as the meta-analysis performed by Harandi et al [48] or the cross-sectional study by Connell et al [49] have confirmed the relationships between social support, QoL, and mental health disorders, but only separately. The present study suggests that interventions to improve each of these domains can be achieved through the two other domains, which are rarely included in the literature. For example, strengthening family support has major impacts on reducing mental health symptoms immediately and in the long term [50,51], while social support availability and QoL should be integrated into the screening standard for early diagnosis and prevention. A longitudinal study conducted over the course of 23 years with 1-year, 4-year, 10-year, and 23-year follow-ups indicated the sustainability of family members as a source of support during treatment and recovery [52]. However, further clinical studies are needed to determine the extent to which social support and QoL can serve as indicators for diagnoses of mental health problems. Given the bidirectional association between social support and QoL and the impacts of their interplay on mental health issues, efforts should be directed to both ends to optimize treatment outcomes and prevent long-term impacts on well-being [52].

Implications

This study offers several implications for mental health treatment and interventions. First, given the outpatient nature of treatment where patients continue to work and carry out daily tasks alongside their therapy appointments, and considering the long-term and often lifelong nature of mental health treatment, it is crucial to provide stable and lifelong sources of social support such as family-based support, which has been shown to have a substantial impact on treatment outcomes [53,54]. Family-based interventions should be standardized to suit the Vietnamese context, based on successes and challenges in countries that have adopted social support using prior standardized frameworks [14,55,56]. Guidelines for family engagement should be provided for the care and service delivery of patients with mental health conditions. Additionally, constant feedback and follow-ups between clinicians and patients are essential to optimize treatment quality and measure progress. Second, a model of "work therapy" should be implemented to provide treatments as work tasks in the workplace, especially for labor workers who experience low levels of social support, to prevent detachment from the working routine and help patients quickly readapt to work after treatment. Finally, mental health treatment should be delivered through a combination of approaches, including social support, psychological therapy, family-based interventions, and work-related treatments.

Strengths and Limitations

The main strength of this study is that the majority of participants only received outpatient treatments, allowing for the investigation of variables in general settings such as daily life and the workplace.

However, our study had several limitations. First, we were unable to analyze causal relationships due to the cross-sectional study design. As a result, we cannot be certain whether the capacity of the patients was impacted by social support or other reasons. Second, self-reported data may suffer from a limitation of recall bias, and social desirability bias may cause certain answers to be underestimated or overestimated. Furthermore, because the time of data collection varied, recall bias might be a concern that leads to inaccuracies, especially for patients with mental health disorders. The population sampling technique may have limited the generalizability of the results for Vietnamese patients. Finally, our study was conducted during the COVID-19 pandemic, limiting the generalizability of the study results in a postpandemic period. Despite these limitations, the study identified significant determinants and trends, enabling a proposal of multilevel interventions for mental health issues and social support.

Conclusions

Our study sheds light on the challenges faced by individuals with mental health disorders in Vietnam, including a decrease in QoL and barriers to accessing social support. The QoL model was used to fit a structural equation model to systematically verify and analyze the relationship between QoL and other variables with social support as a mediator. We found that mental well-being, QoL, and social support are interconnected in a complementary manner, suggesting that improving one factor can positively impact the others. However, further research is needed to generalize these findings to other populations before implementing a standardized framework. Our study identified several issues within the current social support system, including inadequate support for labor workers with mental health issues and a severity-based approach to resource allocation rather than one that prioritizes QoL. Finally, our study highlights the need for a shift in the mental health intervention approach, and we propose an integrated model of family-based and therapeutic interventions to address mental health disorders.

Acknowledgments

BXT is the principal investigator of this project, which is a ministerial-level study managed by the Vietnam Ministry of Health (decision number 850/QĐ-BYT) and implemented by the Institute for Preventive Medicine and Public Health, Hanoi Medical University. This research is supported by Gia Lam Urban Development And Investment Company Limited, Vingroup, and by the Vingroup Innovation Foundation (VINIF) (grant number VINIF.2019.DA14); National University of Singapore (NUS) Department of Psychological Medicine (R-177-000-100-001/R-177-000-003-001); and NUS iHeathtech Other Operating Expenses (R-722-000-004-731). Abstract

Background: Urticaria presents a significant global health challenge due to its sudden onset and potential for severe allergic reactions. Past data on worldwide prevalence and incidence is inconsistent due to differing study methodologies, regional differences, and evolving diagnostic criteria. Past studies have often provided broad ranges instead of specific figures, underscoring the necessity for a cohesive global perspective to inform public health strategies.

Objective: We aimed to assess the global burden of urticaria using the 2019 Global Burden of Disease (GBD) study data and systematically analyze urticaria prevalence, incidence, and disability-adjusted life years (DALYs) at global, regional, and national levels, thereby informing more effective prevention and treatment strategies.

Methods: We analyzed the global, regional, and national burden of urticaria from 1990 to 2019 using the 2019 GBD study coordinated by the Institute for Health Metrics and Evaluation. Estimations of urticaria prevalence, incidence, and DALYs were derived using DisMod-MR 2.1, a Bayesian meta-regression tool. The Socio-demographic Index (SDI) was used to correlate development status with health outcomes. The GBD's division of the world into 21 regions and 204 countries and territories facilitated a comprehensive assessment. Age-standardized estimated annual percentage changes were generated for urticaria metrics to quantify temporal trends, with age standardization adjusting for potential confounding from age structure.

Results: From 1990 to 2019, the global age-standardized prevalence, incidence, and DALY rates of urticaria showed marginal changes. In 2019, 65.14 million individuals were affected, with a prevalence rate of 841.88 per 100,000 population. The DALY rate was 50.39 per 100,000 population. Compared to 1990, the global age-standardized prevalence, incidence, and DALY rates saw increases of 2.92, 4.84, and 0.31 per 100,000 population, respectively. Women persistently had higher rates than men. At a regional level in 2019, low-middle SDI regions exhibited the highest age-standardized metrics, whereas high SDI regions reported the lowest. Central Europe showed the highest rates, contrasting with Western Europe's lowest rates. Nationally, urticaria prevalence in 2019 varied dramatically, from a low of 27.1 per 100,000 population in Portugal to a high of 92.0 per 100,000 population in Nepal. India reported the most DALYs at 749,495.9, followed by China, Pakistan, and the United States. Agewise data showed higher rates in younger age groups, which diminished with age and then experienced a slight resurgence in the oldest populations. This pattern was pronounced in women and younger populations, with the largest rises seen in those aged less than 40 years and the smallest in those aged more than 70 years.

Conclusions: Urticaria remains a significant global health issue, with considerable variation across regions, countries, and territories. The increased burden among women, the rising burden in younger populations, and the regional differences in disease burden call for tailored interventions and policies to tackle this emerging public health issue.

KEYWORDS

urticaria; burden of disease; prevalence; incidence; disability-adjusted life years

Introduction

Urticaria, commonly known as hives, is a dermatologic condition characterized by the sudden onset of itchy, red, and raised welts or bumps on the skin [1,2]. These hives can appear anywhere on the body and vary in size and shape, often causing discomfort and distress to patients [2,3]. In addition to the physical symptoms, urticaria can also have a significant impact on patients' quality of life, affecting their social and psychological well-being [4,5]. The global burden of urticaria has been a growing concern in recent years, with its high prevalence and potential to cause severe allergic reactions and even anaphylaxis in some cases [1,6]. Understanding the global epidemiology of urticaria is crucial for improving prevention and treatment strategies and reducing its impact on public health [7-9].

Despite the high prevalence of urticaria, there is limited information on its global burden [10]. A systematic review and meta-analysis of 52 studies from different regions of the world found that the prevalence of chronic urticaria ranged from 0.1% to 8.9%, with a median of 0.8% [11]. The variation in reported prevalence could be due to differences in study design, sample size, and diagnostic criteria. Furthermore, the burden of urticaria in terms of incidence has not been well documented. A study from the United States estimated that the annual incidence of acute urticaria was 119 per 100,000 population, while the incidence of chronic urticaria was 20 per 100,000 population [12]. Another study from Germany reported a higher incidence of chronic urticaria: 0.15% among a total of 3.53 million individuals [9]. However, these estimates may not be generalizable to other regions of the world.

Understanding the burden of urticaria is crucial for guiding the allocation of health care resources and developing effective prevention and treatment strategies. For instance, a study from Brazil found that adults with chronic urticaria have substantially worse outcomes than people living without chronic urticaria, including health-related quality of life decrements, anxiety, and sleep difficulties [13]. Chronic urticaria was also associated with significant impairments in work and nonwork activities and greatly elevated health care resource use [13]. Another study found that the quality of life of patients with chronic urticaria was significantly lower than that of the general population, underscoring the impact of urticaria on patients' well-being [4].

More research is needed to understand the epidemiology and burden of urticaria worldwide. The Global Burden of Disease (GBD) study aims to provide a systematic analysis of the burden of various human diseases, including urticaria, from 1990 to 2019, offering insights into their prevalence, incidence, disability-adjusted life years (DALYs), and trends. The study can identify areas with the highest burden and inform public health policies and resource allocation. Our study's purpose is to assess the global burden of urticaria using the 2019 GBD study data, examining prevalence, incidence, and DALYs at global, regional, and national levels. The significance lies in informing prevention and treatment strategies, reducing urticaria's impact on human health, and improving quality of life worldwide.

Methods

Data Sources and Study Design

The 2019 GBD study was used to analyze the global, regional, and country urticaria burden from 1990 to 2019. The Institute for Health Metrics and Evaluation (IHME) coordinates the GBD study, which assesses illness, injury, and risk factor burden in 204 nations and territories. The GBD Results tool, an online data repository, provided the latest GBD estimations for our investigation.

To estimate the prevalence, incidence, and DALYs of urticaria, we used DisMod-MR 2.1, a Bayesian meta-regression tool developed by the IHME for modeling disease epidemiology. This tool allows for the integration of various data sources, including surveys, administrative records, and published studies, while accounting for potential biases and heterogeneity in the data.

Socio-Demographic Index

The Socio-demographic Index (SDI) is a composite indicator expressed on a scale of 0 to 1 of development status that is strongly correlated with health outcomes. It is the geometric mean of indices of lag-distributed income per capita, mean years of schooling for individuals aged 15 years or more, and total fertility rate for individuals aged less than 25 years. A location with an SDI of 0 indicates a theoretical minimum level of development status relevant to health outcomes, while a location with an SDI of 1 indicates a theoretical maximum level.

The SDI is stratified into quintiles to provide nuanced distinctions in sociodemographic development. Specifically, a low SDI spans from 0 to 0.454743, followed by a low-middle SDI ranging from 0.454743 to 0.607679. The middle SDI encompasses values between 0.607679 and 0.689504. Subsequently, the high-middle SDI covers the range of 0.689504 to 0.805129, and finally, a high SDI is defined from values of 0.805129 up to 1.

Regions, Countries, and Territories

The GBD study divides the world into 21 regions based on geographical location and epidemiological similarity. These regions are further subdivided into 204 countries and territories. In our analysis, we assessed the burden of urticaria for each region and country, enabling us to identify areas with the highest disease burden and potential targets for intervention.

Statistical Analysis

Urticaria prevalence, incidence, and DALYs were computed for each SDI, area, and nation. We generated age-standardized estimated annual percentage changes (EAPCs) to quantify urticaria incidence, prevalence, and DALYs. Age-standardized incidence, prevalence, and DALY rates of urticaria were compared across populations after they were adjusted for potential age structure confounding by applying the age-specific rates for each location, gender, and year to a GBD world standard population.

The EAPC is a widely used measure of the age-standardized rate trend over a specified time interval [14]. We fitted a regression line to the natural logarithm of the age-standardized rate to calculate the EAPC: $y = \alpha + \beta x + \varepsilon$, where $y = \ln$ (age-standardized rate) and x = calendar year. This was then expressed as a percentage: $100 \times (e\beta - 1)$. The 95% CI of the EAPC was calculated to reflect the temporal trend in the age-standardized rate. An upward trend in the age-standardized rate was indicated when the EAPC and the lower boundary of the 95% CI were positive, while a downward trend was indicated when the EAPC and the upper boundary of the 95% CI were negative. We calculated the EAPCs for age-standardized incidence rates, age-standardized prevalence rates, and age-standardized DALY rates of urticaria to reflect their temporal trends. All data analyses were conducted using R (version 4.2.1; R Foundation for Statistical Computing) and Origin (2022 version; OriginLab).

Ethical Considerations

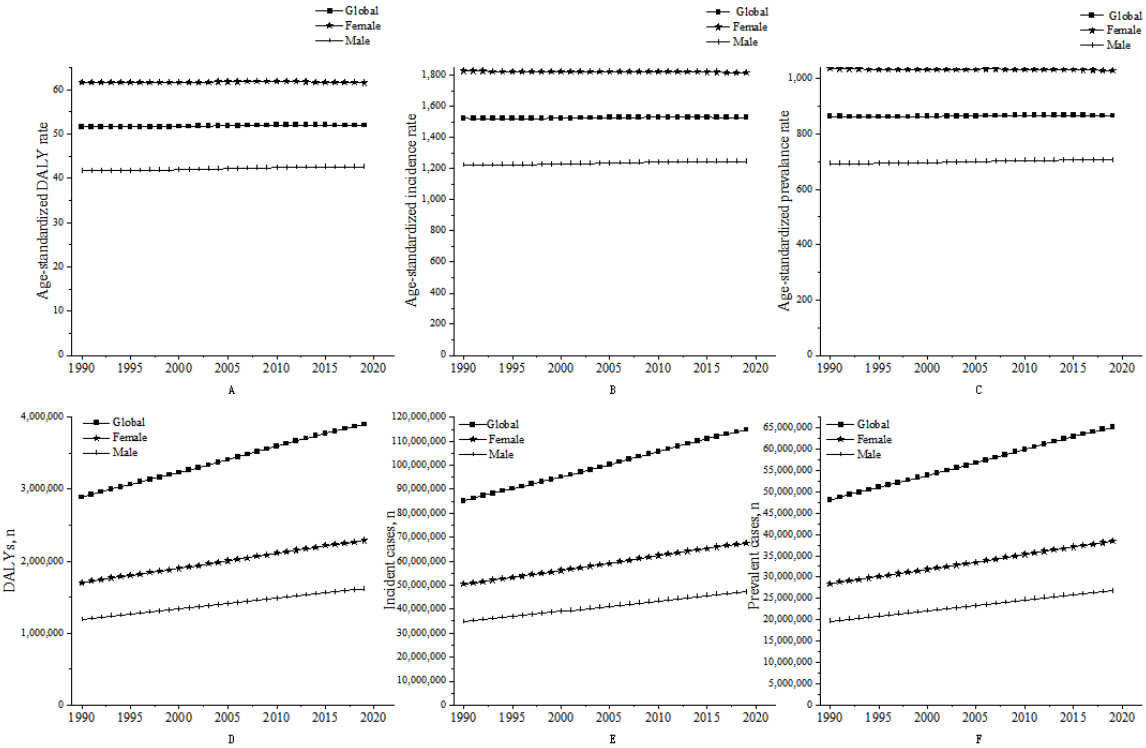
Our research is based on the secondary analysis of data derived from the 2019 GBD study. This comprehensive study integrated data from a diverse array of primary sources, including various surveys, censuses, vital statistics, and other health-related data sets that previously received ethical approval from their respective institutional review boards. Given that our study leverages secondary data, which is an aggregation and anonymization of these primary data sets, our analysis did not necessitate a separate institutional review board approval or exemption [14].

Results

Global Level

From 1990 to 2019, the global age-standardized prevalence, incidence, and DALY rates of urticaria remained stable, with women having higher rates than men. The number of cases, DALYs, and incidence increased during this period. In 2019, 65.14 million people had urticaria, with a prevalence of 841.88 per 100,000 population and an age-standardized prevalence rate of 865.51 per 100,000 population. The global DALY rate was 50.39 per 100,000 population, with an age-standardized rate of 51.91 per 100,000 population. Compared to 1990, the global age-standardized prevalence, incidence, and DALY rates increased by 2.92, 4.84, and 0.31 per 100,000 population, respectively, in 2019 (Figure 1; Multimedia Appendix 1, Tables S1 and S2).

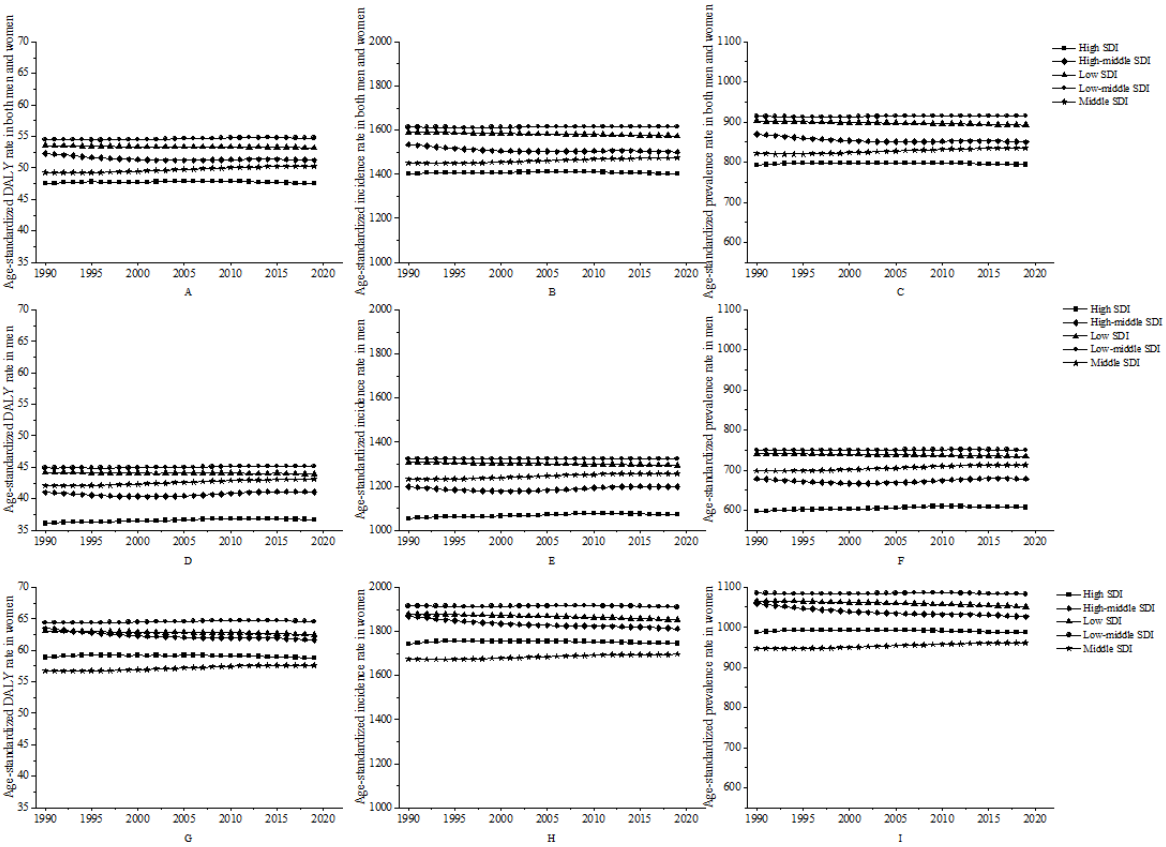
Figure 1. Global, female, and male age-standardized urticaria DALY rate (A), incidence rate (B), prevalence rate (C), DALY number (D), incident cases (E), and prevalent cases (F) from 1990 to 2019. DALY: disability-adjusted life year.



Regional Level

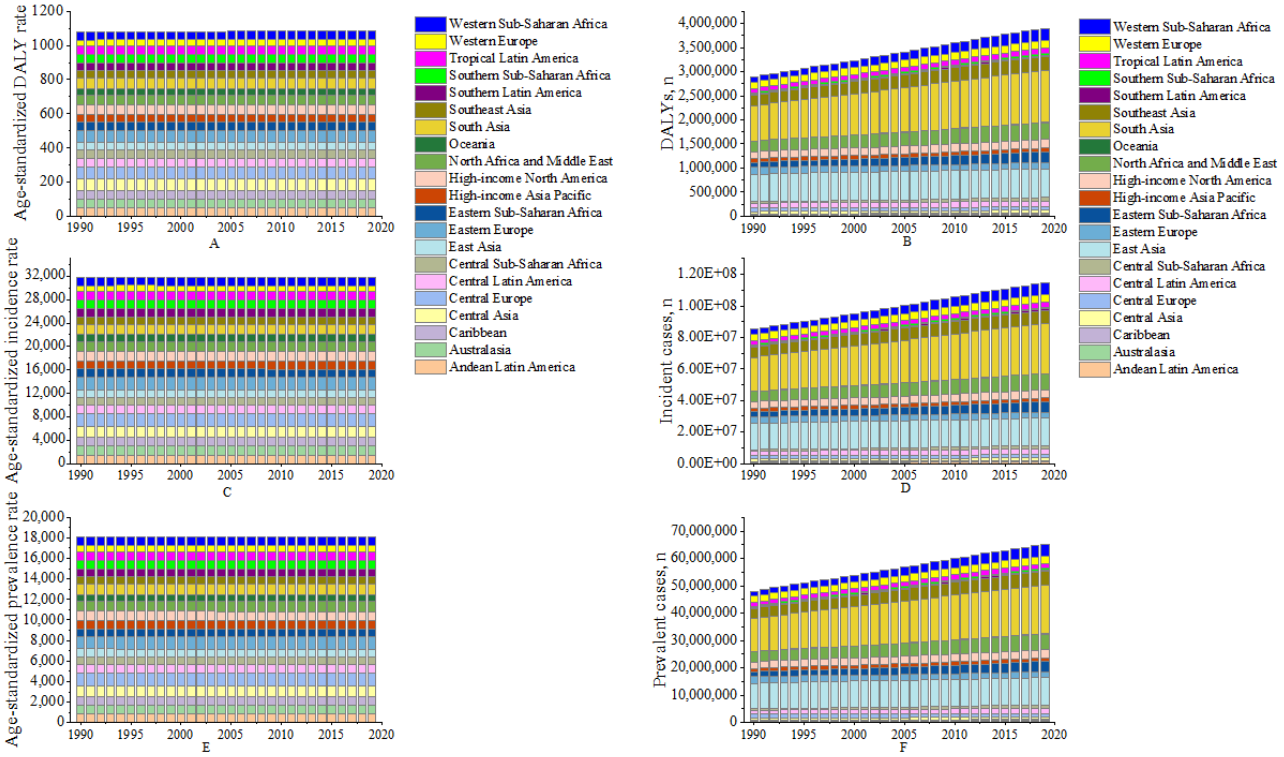
In 2019, low-middle SDI regions had the highest age-standardized prevalence, incidence, and DALY rates, while high SDI regions had the lowest. Middle SDI regions experienced the most significant percentage changes from 1990 to 2019 in all 3 health indicators. All levels of SDI showed a decline in age-standardized DALY rates over the past 30 years, especially for the high-middle SDI group, which decreased from 52.25 per 100,000 population in 1990 to 51.18 per 100,000 population in 2019. However, the decline in the low-middle SDI group was smaller, from 54.44 per 100,000 population in 1990 to 54.72 per 100,000 population in 2019. Overall, the age-standardized DALY rates for women were higher than those for men in all SDI groups. In terms of different SDI groups, the high SDI group consistently had the lowest age-standardized DALY rates, while the low SDI group consistently had the highest rates. The age-standardized DALY rates for women were consistently higher than those for men, especially in the high SDI and high-middle SDI groups (Figure 2; Multimedia Appendix 1, Table S1).

Figure 2. Urticaria age-standardized DALYs, incidence rate, and prevalence rate for both men and women (A, B, C), women (D, E, F), and men (G, H, I) in different SDI areas from 1990 to 2019. DALY: disability-adjusted life year; SDI: Socio-demographic Index.



Incidence rates declined for all SDI groups, with the greatest decrease observed in the high-middle SDI group, from 1534.30 per 100,000 population in 1990 to 1499.49 per 100,000 population in 2019. However, the change in incidence in the low-middle SDI group was not obvious, from 1613.38 per 100,000 population in 1990 to 1613.91 per 100,000 population in 2019. Women had higher incidence rates than men, especially in high SDI and high-middle SDI groups. Prevalence rates remained stable across different SDI levels, with women having higher rates than men. In 2019, Central Europe had the highest age-standardized prevalence, incidence, and DALY rates, while Western Europe had the lowest. From 1990 to 2019, all 21 regions showed stable age-standardized rates but increasing DALY, prevalence, and incidence numbers, with South Asia and East Asia having significantly higher numbers (Figure 2-3; Multimedia Appendix 1, Table S1).

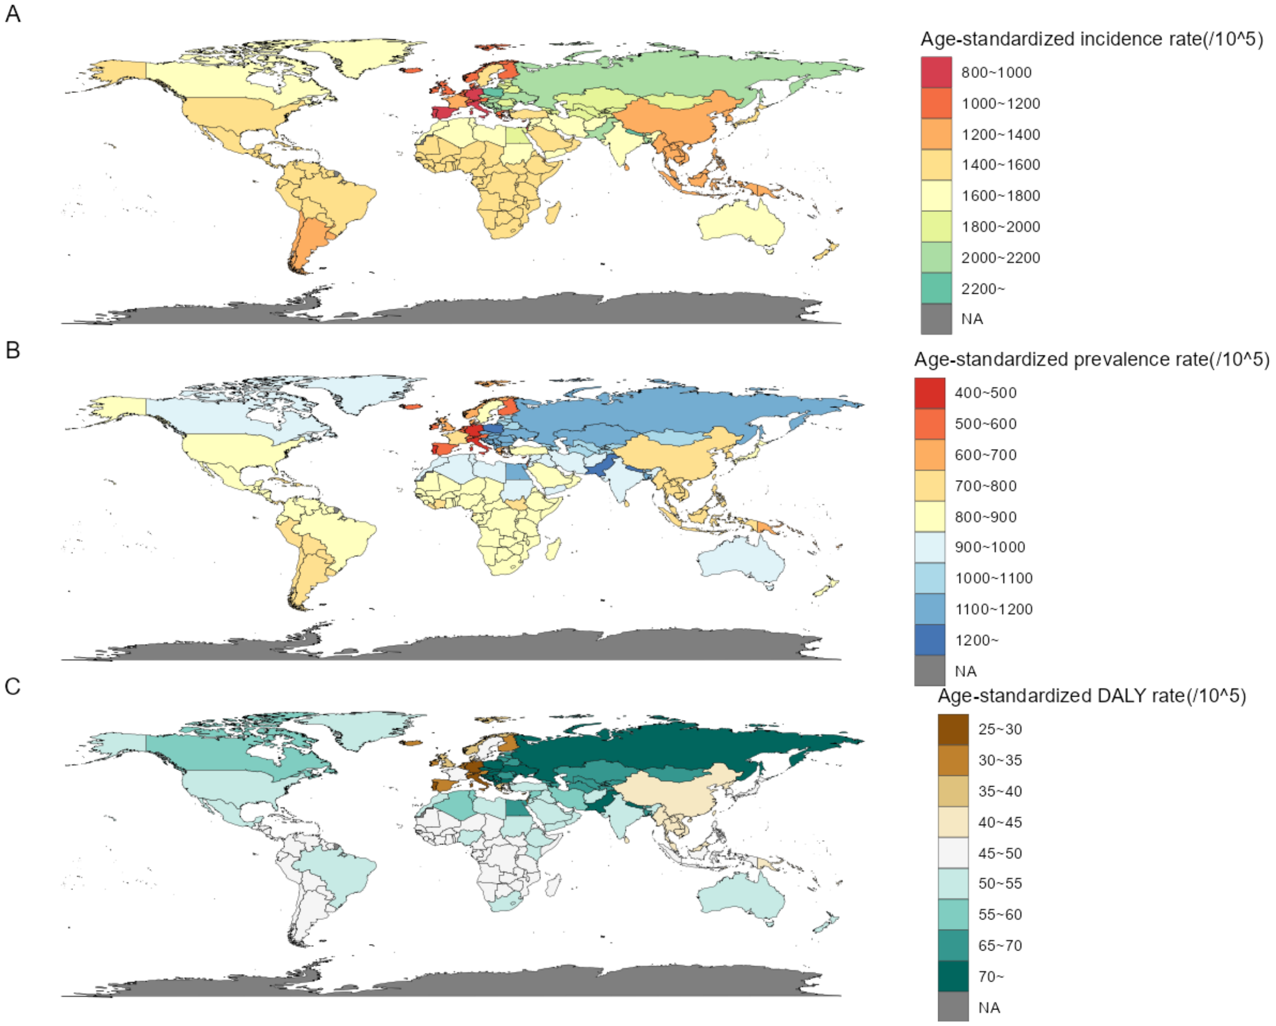
Figure 3. Age-standardized DALY rate (A), number of DALYs (B), incidence rate (C), incident cases (D), prevalence rate (E), and prevalent cases (F) for urticaria in 21 disease burden regions from 1990 to 2019. DALY: disability-adjusted life year.



National Level

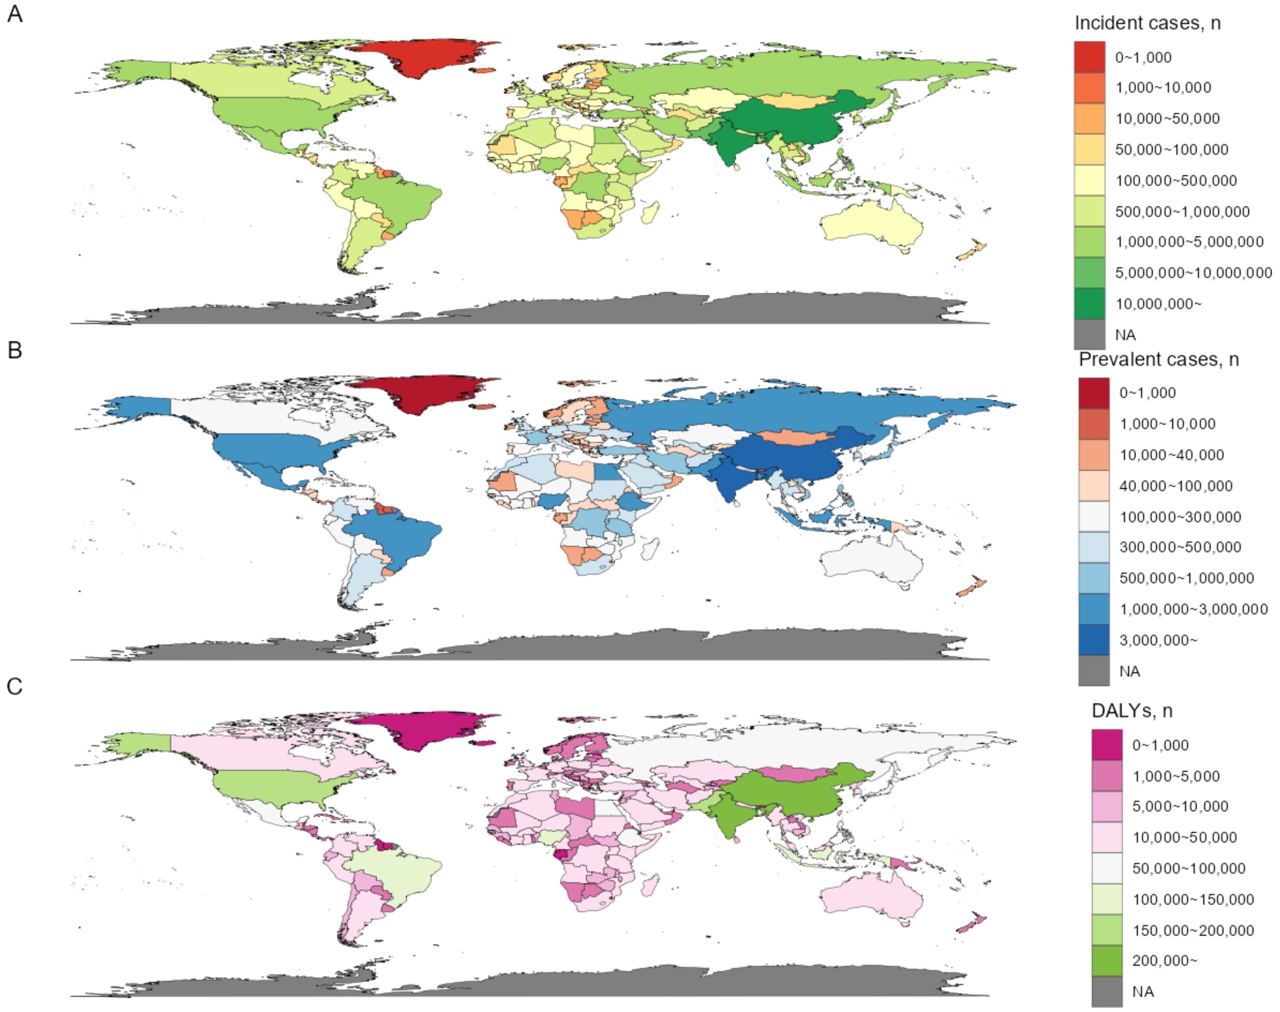
The DALYs of urticaria varied significantly between countries and territories. In 2019, the lowest rate, 27.1 (95% uncertainty interval [UI] 17.7-38.1) per 100,000 population, was reported for Portugal, while the highest rate, 92.0 (95% UI 60.3-130.2) per 100,000 population, was reported for Nepal. The data include the DALY numbers for each country and territory in 2019, with India having the highest number at 749,495.9 (95% UI 490,301.3-1,074,876.0), followed by China at 576,544.5 (95% UI 379,886.1-818,597), Pakistan at 180,580.9 (95% UI 117,789.7-263,500.0), and the United States at 153,479.1 (95% UI 102,752.9-213,697.0), among others. The countries and territories with the lowest DALY numbers included Tokelau (0.60, 95% UI 0.39-0.87), Niue (0.67, 95% UI 0.43-0.96), and Nauru (4.74, 95% UI 3.09-6.93). From 1990 to 2019, the annual percentage change in age-standardized DALY rate differed, with the highest decrease in Qatar at –0.0719% (EAPC –0.0719, 95%CI –0.0906 to –0.0532) (Figure 4-5; Multimedia Appendix 1, Table S3).

Figure 4. Age-standardized incidence rate (A), age-standardized prevalence rate (B), and age-standardized DALY rate (C) for urticaria per 100,000 population in 2019 in 204 countries and territories. DALY: disability-adjusted life year; NA: not available.



For incidence, the age-standardized rate and number of new cases also varied widely across countries and territories. In 2019, out of 204 countries and territories, Portugal reported the lowest rate, 818.2 (95% UI 728.6-917.3) per 100,000 population, while Nepal had the highest rate, 2665.5 (95% UI 2904.2-2445.1) per 100,000 population. Incident cases in the 204 countries and territories varied greatly, ranging from as low as 17.8 (95% UI 15.6-20.5) in Tokelau to as high as 22,065,409 (95% UI 19,265,922-25,287,089) in India. Between 1990 and 2019, the annual percentage change in age-standardized incidence rate varied across countries and territories, with Qatar having the highest decrease at –0.0774% (EAPC –0.0774, 95% CI –0.0961 to –0.0587) (Figure 4-5; Multimedia Appendix 1, Table S3).

Figure 5. Incident cases (A), prevalent cases (B), and DALY numbers (C) for urticaria in 2019 in 204 countries and territories. DALY: disability-adjusted life year.



In terms of prevalence, there was considerable variation in age-standardized rates and the number of cases across countries and territories. Portugal reported the lowest age-standardized prevalence rate, 456.4 (95% UI 406.2-512.2) per 100,000 people in 2019, while Nepal reported the highest rate, 1534.6 (95% UI 1416.2-1662.5) per 100,000 people. Prevalence numbers for the 204 countries and territories ranged widely, from as low as 10.0 (95% UI 8.7-11.5) in Tokelau to as high as 12,552,793 (95% UI 10,916,085-14,379,341) in India. From 1990 to 2019, annual percentage changes in age-standardized prevalence rate varied across countries and territories. Qatar had the highest decrease, with a decline of 0.0795% (EAPC –0.0795, 95% CI –0.0988 to –0.0603) (Figure 4-5; Multimedia Appendix 1, Table S3).

Age

We analyzed global data on rates and numbers for DALYs, prevalence, and incidence across age groups between 1990 and 2019. Rates were higher in younger age groups, decreased with age, and slightly increased in the oldest groups. Women had higher rates than men. A general increase in rates and numbers was observed across age groups between 1990 and 2019 that was more pronounced in younger populations and women. The largest increases occurred in age groups younger than 40 years, while the smallest increases were in groups older than 70 years. In both age groups, women consistently had higher numbers for DALYs, prevalence, and incidence, indicating an overall rising trend in disease burden, prevalence, and incidence (Multimedia Appendix 2, Figure S1).

Regional and SDI-level urticaria disease burden were also analyzed, focusing on rates and numbers for DALYs, prevalence, and incidence across age groups and genders. The youngest age group generally had the highest rates and numbers, decreasing with age. Women consistently had higher rates and numbers across most age groups and regions. Significant regional and SDI-level variations existed, with regions like South Asia, Western sub-Saharan Africa, North Africa, and the Middle East having higher burdens. Central and Eastern Europe had higher rates and numbers than Western Europe. DALY numbers decreased with age across SDI regions and genders, with women having higher numbers. DALY rate trends were similar, but differences between SDI regions and genders were less pronounced (Multimedia Appendix 2, Figures S2-S5).

At the SDI level, urticaria prevalence rates were analyzed across age groups, genders, and SDI regions. The rates were highest in the low-middle SDI group and generally decreased with age, with women consistently having higher rates. High and high-middle SDI groups had lower prevalence rates than low and low-middle groups. The prevalence number also decreased with age and was higher in women. High SDI and high-middle SDI regions had lower prevalence numbers (Multimedia Appendix 2, Figure S6).

Urticaria incidence rates varied across age groups and SDI regions, with women generally having higher rates. The highest incidence rate was in children younger than 5 years, and rates decreased with age. Low-middle SDI regions had the highest incidence rates, while middle SDI regions had the lowest. Incidence numbers followed similar trends, with higher numbers in low SDI and low-middle SDI regions and a decrease with age. The incidence was consistently higher in women across all groups (Multimedia Appendix 2, Figure S7).

Discussion

Our study examines global, regional, and national urticaria trends by age, gender, and SDI regions. Women had higher prevalence, incidence, and DALYs from 1990 to 2019. Urticaria rates were highest in low-middle SDI regions and lowest in high SDI regions. Central Europe had the highest age-standardized rates, while Western Europe had the lowest. Portugal had the lowest rate in 2019 and Nepal the highest. Annual age-standardized rates fluctuated over 30 years. Women had higher urticaria rates across all age categories. Between 1990 and 2019, disease burden, prevalence, and incidence increased across most age categories, particularly in younger people and women.

One of the main findings in our study is the higher burden of urticaria among women compared to men. This observation is consistent with previous studies that have reported a higher prevalence of autoimmune diseases in women [15,16]. The higher rates of urticaria in women may be attributed to several factors, including hormonal differences, genetic predispositions, and environmental exposures [17-19]. Hormonal fluctuations, particularly estrogen levels, have been implicated in the regulation of immune responses and may contribute to the increased susceptibility of women to autoimmune diseases [20,21]. Genetic factors may also play a role, as certain genes related to immune function are located on the X chromosome, potentially resulting in a higher risk of autoimmune diseases in women [22]. Further research is needed to better understand the underlying mechanisms and develop targeted interventions to reduce the burden of urticaria in affected individuals [23-25].

The observed increase in the global burden of urticaria from 1990 to 2019 is a concerning trend that warrants further investigation. Several factors could potentially contribute to this increase, such as changes in environmental exposures, lifestyle factors, and diagnostic practices. Increased exposure to allergens and irritants, such as air pollution and chemical substances, may have contributed to the rise in urticaria prevalence [1,26]. Additionally, changes in lifestyle factors, such as diet, stress, and sedentary behavior, may also have contributed to the increase in urticaria cases [27,28]. Lastly, improvements in diagnostic practices and increased awareness of the condition may have led to a higher detection rate of urticaria cases over time [29,30].

Our findings also highlight substantial regional variations in the burden of urticaria, with low-middle SDI regions exhibiting the highest rates and high SDI regions displaying the lowest. These disparities can be attributed to differences in socioeconomic conditions, health care infrastructure, and access to care, which may influence the overall disease burden in these regions [31-34]. Moreover, regional variations in environmental exposures, such as air pollution and allergen prevalence, could contribute to the observed differences in urticaria burden across regions [35-38].

At the national level, we found significant variation in urticaria's disease burden, with age-standardized rates and numbers of DALYs, incidence, and prevalence differing substantially across countries and territories. These findings highlight the importance of understanding the unique factors that contribute to the burden of urticaria in different countries and territories and the need for tailored interventions to address these factors. For instance, countries and territories with a high burden of urticaria may benefit from increased investment in health care infrastructure, improved access to care, and targeted public health interventions to reduce exposure to environmental risk factors [39-44].

Our study also revealed that the burden of urticaria is generally higher in younger age groups and decreases with age, with a slight increase observed in the oldest age groups. This pattern may be partially explained by differences in immune system function and regulation across different age groups, with younger individuals potentially being more susceptible to immune-mediated conditions such as urticaria [45,46]. Additionally, the increased burden of urticaria in the youngest age groups may be related to the high frequency of infections in children, which can trigger urticaria in susceptible individuals [47,48]. The slight increase in urticaria burden among the oldest age groups may be attributed to age-related changes in the immune system, known as immunosenescence, which can result in a higher risk of autoimmune diseases [1,49].

Our study has several strengths, including the use of a comprehensive data set spanning 3 decades and covering multiple aspects of urticaria burden at the global, regional, and national levels. However, several limitations should also be acknowledged. First, the quality and availability of data on urticaria burden may vary across countries and territories and time periods, potentially affecting the accuracy of our estimates. Second, our study primarily focused on a descriptive analysis of trends in urticaria burden and did not explore the underlying causal factors contributing to these trends. Future research should aim to identify the specific risk factors and mechanisms that contribute to the observed disparities in urticaria burden across different populations and age groups.

In conclusion, our findings highlight the increasing burden of urticaria at the global, regional, and national levels, with substantial disparities observed across age, gender, and SDI groups. The higher burden of urticaria among women, the increasing burden among younger populations, and the regional variations in disease burden underscore the need for targeted interventions and policies to address this growing public health concern. Further research is required to identify the specific risk factors and mechanisms underlying the observed disparities in urticaria burden and inform the development of effective interventions and strategies to reduce the global burden of this condition.

Data Availability

The data sets generated during and/or analyzed during this study are available in the Global Burden of Disease (GBD) study’s public database [50].

Authors' Contributions

WW had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis. All authors contributed to concept and design; critical revision of the manuscript for important intellectual content; administrative, technical, or material support; and supervision. XL contributed to acquisition, analysis, and interpretation of data and drafting of the manuscript. XL and WW contributed to statistical analysis.

Abstract

Background: Tuberculous pleurisy (TP) presents a serious allergic reaction in the pleura caused by *Mycobacterium tuberculosis*; however, few studies have described its spatial epidemiological characteristics in eastern China.

Objective: This study aimed to determine the epidemiological distribution of TP and predict its further development in Zhejiang Province.

Methods: Data on all notified cases of TP in Zhejiang Province, China, from 2017 to 2021 were collected from the existing tuberculosis information management system. Analyses, including spatial autocorrelation and spatial-temporal scan analysis, were performed to identify hot spots and clusters, respectively. The prediction of TP prevalence was performed using the seasonal autoregressive integrated moving average (SARIMA), Holt-Winters exponential smoothing, and Prophet models using R (The R Foundation) and Python (Python Software Foundation).

Results: The average notification rate of TP in Zhejiang Province was 7.06 cases per 100,000 population, peaking in the summer. The male-to-female ratio was 2.18:1. In terms of geographical distribution, clusters of cases were observed in the western part of Zhejiang Province, including parts of Hangzhou, Quzhou, Jinhua, Lishui, Wenzhou, and Taizhou city. Spatial-temporal analysis identified 1 most likely cluster and 4 secondary clusters. The Holt-Winters model outperformed the SARIMA and Prophet models in predicting the trend in TP prevalence.

Conclusions: The western region of Zhejiang Province had the highest risk of TP. Comprehensive interventions, such as chest x-ray screening and symptom screening, should be reinforced to improve early identification. Additionally, a more systematic assessment of the prevalence trend of TP should include more predictors.

Introduction

Humanity has been affected by tuberculosis (TB) for centuries, which is an infectious agent–caused disease considered the leading cause of mortality worldwide since the beginning of recorded history. Among people who contract TB each year, the majority are adults, with the incidence of TB being higher in men than in women. According to the Global Tuberculosis Report of 2022 released by the World Health Organization, the estimated TB incidence rate in 2021 increased by 3.6% from 2020, and China accounted for 7.4% of TB cases worldwide. Furthermore, the number of TB deaths worldwide successively increased from 1.4 million in 2019 to 1.6 million in 2021, only after the onset of the COVID-19 pandemic [1]. *Mycobacterium tuberculosis* generally affects not only the lungs but also other sites such as the pleura [2].

Tuberculosis pleurisy (TP) is a common clinical manifestation of TB post primary infection or due to the reactivation of latent TB [3]. Available documentation shows that TP accounts for about 4% of total tuberculosis cases in the United States and Brazil, 20% of cases in South Africa, and 7.3% of cases in Korea [4]. In the United States, the incidence of both TP and TB has been declining, but to a lesser degree for TP [5]. In 2018, it was categorized as pulmonary tuberculosis (PTB) in China [6]. TP can be divided into dry and exudative pleurisy. Dry pleurisy is an early inflammatory reaction of the pleura, usually without obvious imaging abnormalities. Exudative pleurisy is characterized by unilateral or bilateral pleural effusions, which often occur as thickened pleural adhesions with slow absorption [7]. The recommended standard regimen for TP is up to 8 months, which is longer than the usual treatment period for TB [8]. Previous studies have shown that the prevalence of TP is low in women, while the number of patients with TP is higher in eastern China, among farmers and patients with AIDS [9-11]. However, the temporal periodicity and spatial clustering characteristics of TP have not been explored in eastern China.

Zhejiang Province is located in the eastern region of China and has a developed economy. In recent years, certain parts of the province have experienced a high burden of TB. Understanding the spatial and temporal patterns of TB incidence can provide insights into the clusters of this disease [12]. Spatial-temporal analysis has been widely used to describe the epidemiological distribution and aggregation of infectious diseases in both space and time; however, few studies have explored the spatial epidemiological characteristics of TP. In comparison to traditional epidemiological techniques, tools using geographic information systems have significant advantages in tracking disease, identifying areas of clustering, and analyzing the spread of disease across communities [13]. Spatiotemporal cluster detection has played a crucial role in understanding infectious disease spread, with its dynamic course and dimensions of time and place, and a combination of both [14]. In addition, time-series models were selected to provide scientific clues for predicting the prevalence of diseases such as desiccation syndrome and AIDS [15,16]. However, there are few such studies on TP.

Therefore, this study aimed to use spatial-temporal analysis to identify the epidemiological characteristics of TP. Furthermore, the spatial differentiation of TP can provide a visual map depicting the diversity of TP occurrence across different regions. Additionally, this study used time-series models to provide scientific clues for the control of and interventions targeting TP infections in the province.

Methods

Overview of the Study Area

Zhejiang Province is located on the eastern coast of China, with a land area of 101,800 km^2, accounting for 1.06% of the country’s land area [17]. The province encompasses plains, mountains, coasts, islands, and lakes. Zhejiang Province comprises 90 counties and cities, including 2 subprovincial cities and 9 prefecture-level cities [17,18].

Data Source

All recorded cases of TP in Zhejiang Province from 2017 to 2021 were obtained from the TB Information Management System (TBIMS), which is a first-generation web-based information system designed and built by the National Tuberculosis Control and Prevention Center in 2005 [19]. The system collected data on demographics, diagnosis, laboratory results, and treatment outcomes of all patients with TB during the specified period. In addition, demographic data for Zhejiang Province were obtained from the China Information System for Disease Control and Prevention.

Definition

Diagnostic criteria for TP were as follows: (1) confirmed patients: cultures of pleural biopsy specimens were positive, and the strain was identified as *M tuberculosis*, changes in tuberculosis confirmed through pleural tissue biopsy; and (2) clinically diagnosed patients: imaging examination showing pleural effusion with (i) a moderately positive or strongly positive outcome on the tuberculin pure protein derivative skin test, (ii) a positive outcome on the γ-interferon release test, or (iii) a positive outcome on the *M tuberculosis* antibody test [20]. Delays in seeking medical treatment were indicated when the interval between the appearance of the first symptom and the visit to the designated hospital was > 2 weeks, and the delay in diagnosis was the time between the first consultation and a confirmed diagnosis [21].

General Epidemiological Characteristics of Patients With TP

The features of patients with TP in Zhejiang Province from 2017 to 2021 are described in the context of sex, age group, city, antituberculosis treatment, mode of case finding, treatment history, delay in access to care and final diagnosis, and treatment outcomes.

Spatial Autocorrelation Analysis

In this study, the Moran I index and local indicators of spatial association (LISA) were used to analyze global and local spatial autocorrelation. The global Moran I index is a comprehensive measure of spatial autocorrelation in the whole study area, and it can indicate the average degree of spatial differences between each unit and the surrounding area. If partial positive and partial negative spatial correlations coexist in the overall study area, LISA are needed to reveal the possible spatial variability [22].

Space-Time Scan Statistics

For the spatiotemporal analysis, we used the Kulldorff spatial-temporal scan statistic to identify clusters based on specific time and location combinations. This statistic uses a Poisson probability distribution mode. The Kulldorff method uses a moving cylindrical window to scan the study area. The height of the cylinder represents the possible clustering time, the bottom represents the clustering area, and the radius serves as the scanning risk population [23]. The significance of the clusters identified at a 95% confidence level was tested using Monte Carlo simulations to identify the clusters.

Prediction Models

Three models were used in this study. The Holt-Winters exponential smoothing model eliminated some random fluctuations, which can assign different weights to the data of each period and reasonably predict the future development trend [16]. The seasonal autoregressive integrated moving average (SARIMA) model divided the observed value into 3 parts: residuals, seasonal feature, and true trend [24]. The Holt-Winters exponential smoothing model and SARIMA model were introduced more specifically in a previous study [16]. The Prophet model, developed by Meta, allowed using time as a regressor to fit both linear and nonlinear functions of time [25], and a more specific introduction to this model is provided in Xie et al’s [26] study.

Statistical Analysis

Descriptive analysis was conducted using Excel (Microsoft Corp) and SPSS (version 28; IBM Corp). The Moran I index was calculated using GeoDa (version 1.20), and SaTScan software (version 10.1; Harvard Medical School) was used to determine the spatial and temporal aggregation of TP. All visual results are presented using the ArcGIS software (version 10.8; SERI Inc). The prediction of TP prevalence was model-fitted using R (version 4.2.0; The R Foundation) and Python (version 3.8; Python Software Foundation).

Ethical Considerations

This study was approved by the Ethics Committee of the Zhejiang Provincial Center for Disease Control and Prevention (audit number 2022-032-01), which waived the requirement for informed consent. All personal information obtained in this study was treated and kept confidential in accordance with the required protocols.

Results

General Epidemiological Characteristics of Patients With TP

During the study period, a total of 11,531 patients with TP were identified, with a notification rate of 7.8 cases per 100,000 population in 2017, 8.2 cases per 100,000 population in 2018, 7.7 cases per 100,000 population in 2019, 6.6 cases per 100,000 population in 2020, and 5.0 cases per 100,000 population in 2021, respectively (Figure 1).The male to female ratio was 2.18:1. Among all cases of TP, the top notified cases and notification rate were noted in 2018 (n=2594; 8.2 cases per 100,000 population). The number of cases peaked in the second quarter (n=3354) and plummeted in the fourth quarter (n=2558) during the study period, indicating seasonal distribution characteristics. In terms of age distribution, 74 (0.64%) individuals were aged 0-18 years, 6359 (55.15%) were aged 19-59 years, and 5098 (44.21%) were aged ≥60 years. In terms of geographical distribution, 2319 (20%) cases were notified in Hangzhou, while 1294 (11.22%), 1393 (12.08%), 1452 (12.59%), and 1259 (10.92%) cases were reported in Wenzhou, Ningbo, Jinhua, and Taizhou, respectively. Passive findings was the main source of TP identification in Zhejiang Province. Nearly all patients (n=11,326, 98.22%) were treated for the first time, with nearly 90% of them having completed treatment. Delayed access to medical care was observed among 6317 (54.78%) patients with TP, and diagnosis was delayed among 1462 (12.68%) patients. In addition, 86.26% (n=9949) of patients with TP were treated with a duration of ≥9 months (Table 1).

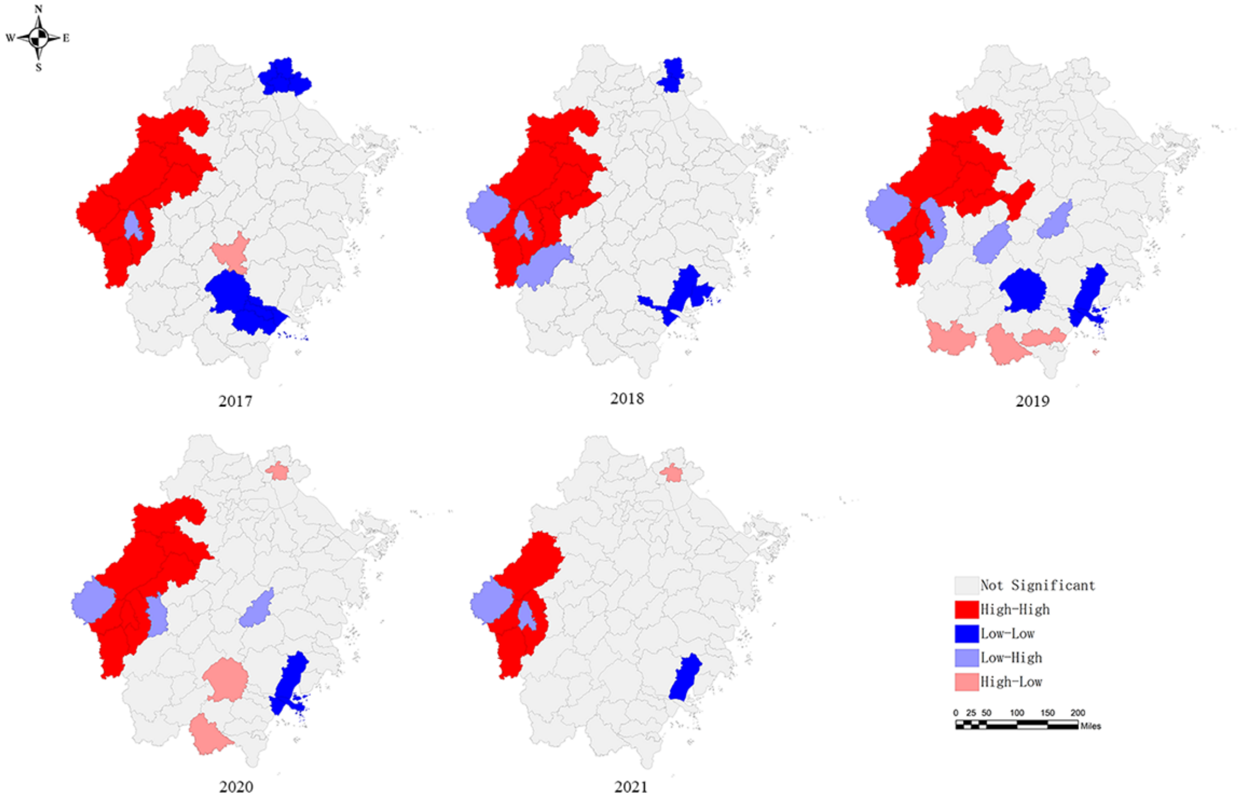
Spatial Autocorrelation Analysis

On spatial autocorrelation analysis, the global Moran I index ranged from 0.187 to 0.362, indicating spatial heterogeneity in the distribution of patients with TP in Zhejiang Province from 2017 to 2021. Furthermore, there was a positive correlation between the notification rate and spatial distribution ($P<.01$; Table 2). The local autocorrelation LISA cluster plot showed that in Zhejiang Province, hot spot areas were located in parts of Quzhou, Jinhua, and Hangzhou, and cold spot areas were clustered in Jiaxing, Wenzhou, and Lishui. Although the hot and cold spots changed every year, Jiangshan, Qujiang, Changshan in Quzhou City, and Chun'an in Hangzhou City emerged as hot spots throughout the study period. Furthermore, Longwan and Yueqing in Wenzhou City were identified as cold spots in 4 out of the 5 years (Figure 2).

Table 2. Spatial autocorrelation analysis of the tuberculosis pleurisy notification rate.

Year	Moran I index	*z* score	*P* value
2017	0.362	5.275	.001
2018	0.296	4.099	.001
2019	0.187	2.632	.007
2020	0.209	3.026	.006
2021	0.241	3.864	.003

Figure 2. Local indicators of spatial association of the tuberculosis pleurisy notification rate in Zhejiang Province.



Spatial-Temporal Scan Statistics

Spatial-temporal scan statistics of TP in Zhejiang Province from 2010 to 2021 identified 1 most likely cluster and 4 secondary clusters. The most likely cluster was the high-risk cluster, which encompassed 32 counties in western and southwestern Zhejiang Province, including all counties and districts of Quzhou, Jinhua, and Lishui; Wencheng and Taishun in Wenzhou; and Xianju in Lishui. The most likely cluster period ranged from April 2017 to September 2019, with 2383 cases of TP and a relative risk of 1.98 (log likelihood ratio=382.55, *P*<.01; Table 3 and Figure 3).

Table 3. Spatial-temporal scanning of the tuberculosis pleurisy notification rate in Zhejiang Province, 2017-2021.

Cluster type	Cluster period	Coordinates/radius	Counties, n	Notified (expected) cases, n (n)	Log likelihood ratio	Relative risk	*P* value
Most likely cluster	January 20, 2017, to September 30, 2019	(28.578400° N, 118.595300° E)/199.19 km	32	2383 (1341.84)	382.55	1.98	<.01
Secondary cluster 1	January 1, 2017, to June 30, 2018	(30.042100° N, 120.663400° E)/51.20 km	8	785 (488.22)	80.06	1.65	<.01
Secondary cluster 2	February 1, 2018, to July 31, 2020	(27.885900° N, 120.815300° E)/0 km	1	48 (3.87)	76.84	12.46	<.01

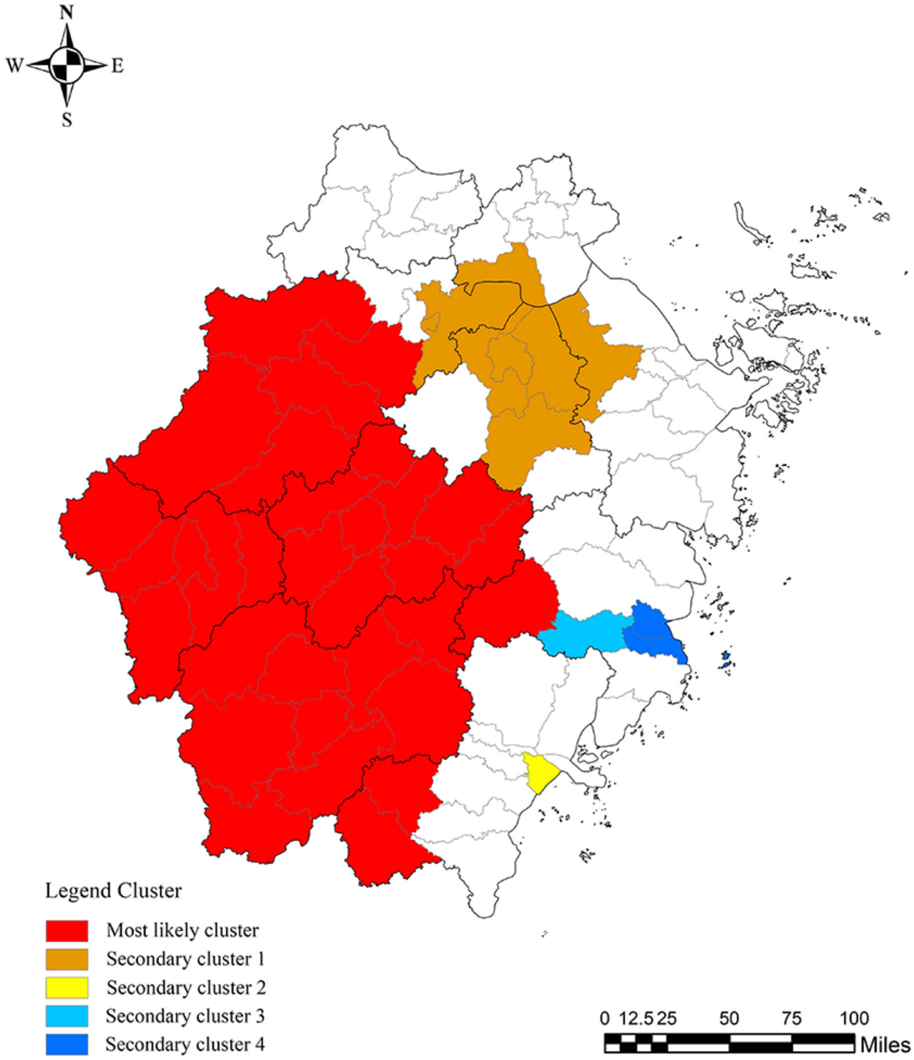
Secondary cluster 4	April 1, 2017, to August 31, 2018	(28.652100° N, 121.475800° E)/12.06 km	2	129 (74.78)	16.25	1.73	<.01

Figure 3. Spatial-temporal clustering of the tuberculosis pleurisy notification rate in Zhejiang Province.



Model Predictions

On comparing the fitness of predicting TP prevalence trends in 2021, the Holt-Winters exponential smoothing model showed better predictive performance than the SARIMA and Prophet models, with lower mean-square error, root-mean-square error, mean absolute error, mean absolute percentage error, and symmetric mean absolute percentage error values (Table 4). The composition of the original sequence and the predictive results determined using the Holt-Winters exponential smoothing model are presented in Table 4. The exponential smoothing model was used to predict the number of notified cases of TP, and its actual values in 2021 are shown in Table 5.

Table 4. Critical indices of the Holt-Winters exponential smoothing, SARIMA[a], and Prophet models.

Indices	SARIMA	Holt-Winters	Prophet
MSE[b]	978.593	479.170	579.114
RMSE[c]	31.282	21.890	24.065
MAE[d]	25.247	17.380	17.501
MAPE[e]	16.270	11.130	N/A[f]
SMAPE[g]	16.883	12.080	N/A

[a] SARIMA: seasonal autoregressive integrated moving average.

[b] MSE: mean-square error.

[c] RMSE: root-mean-square error.

[d] MAE: mean absolute error.

[e] MAPE: mean absolute percentage error.

[f] N/A: not applicable.

[g] SMAPE: symmetric mean absolute percentage error.

Table 5. Holt-Winters exponential smoothing model used to predict the number of notified cases of tuberculosis pleurisy and its actual values in 2021.

Month	Actual value	Estimate	95% CI
January	158	141	104-178
February	122	119	105-133
March	191	162	161-163
April	159	176	134-217

October	133	120	82-157
November	145	115	108-121
December	160	108	107-108

Discussion

Principal Findings

TP, as a subgroup of PTB in China, has attracted increasing attention in recent years due to its severity. According to a bibliometric study, there has been an increasing number of TP-related studies in the past decade, and China had the most studies in this field [27]; furthermore, Mexico, the Philippines, Vietnam, China, and India had the highest prevalences of TP worldwide [5]. Zhejiang Province is a developed coastal area of China, and the notification rate of TP accounts for a certain proportion. Therefore, it is necessary to understand cluster epidemics at the spatial and temporal levels.

In this study, epidemiological characteristics showed that men were more likely to develop TP than women, which is in line with the results of previous studies [28,29]. Given that TP occurs secondary to PTB, we speculated that possible explanations for sex differences were attributed to lifestyle and genetic susceptibility, such as smoking, alcohol use, drug abuse, sex hormones, and genetic variations [30,31]. Therefore, it is necessary to consider men as the key population for prevention and control, such as by strengthening screening and improving the awareness of TP in this specific population. Furthermore, we found that the TP notification rate peaked mainly in the summer. As shown in the literature, when the mean ambient temperature increased from 15.1 °C to 24.5 °C, the cumulative adjusted relative risk of hospitalization for TB was 1.07 (95% CI 1.00-1.14) [32]. Although there is no clear evidence showing a direct correlation between TP and temperature, we postulate that due to the increased temperature, there is a likely increase in the synthesis of mycolic acids, which are vital for the growth of *M tuberculosis* and contribute to its subverting of and escaping from the immune system [33].

In our study, 6317 (54.78%) patients with TP experienced delayed access to medical care. A literature analysis of TB cases from 32 provinces in China showed that patient delays were also common among TB cases, with a median of 20 (IQR 6-46) days [21]. We speculated that a comparatively long patient delay may result in further invasion of the pleura. Furthermore, the median delay in PTB diagnosis in China was 1 (IQR 0-8) day, while a delay of TP diagnosis of more than 14 days accounted for 12.68% of cases in our study [21]. To our knowledge, a definite diagnosis of TP was made by detecting *M tuberculosis* from pleural effusion or pleural tissue [34]. However, culturing *M tuberculosis* takes 2-8 weeks to obtain results in some regions without access to rapid diagnosis tools, which could influence effective medical interventions [35]. Consequently, further delay in anti-TB treatment for TP might result in pleural thickening or TB empyema that requires surgical resolution [36]. Considering the long duration of the disease, insidious onset, and lack of specificity of diagnostic methods for TP [37,38], it is prone to both abovementioned delays, which may further lead to increased transmission of TB [39]. Therefore, timely detection, such as using x-ray imaging or computed tomography, and adequate health education are needed to identify TP in the early stages and improve awareness of TB information [40]. For patients with normal immune function, the current recommended treatment duration is 6 months for isoniazid and rifampicin with 2 months for ethambutol and pyrazinamide [8]. In China, the National Tuberculosis Program guidelines specifically recommend that the treatment period for TP be ≥9 months, while nearly 14% of patients had received insufficient treatment. Therefore, more attention must be paid to the treatment duration of TP.

Spatial-temporal analysis is commonly used to explore disease clusters and identify areas at high risk of infectious disease [41]. Spatial analysis indicated spatial heterogeneity among patients with TP, with hot spots located mainly in the western cities of Zhejiang Province. The relatively large agricultural population and relatively low economic status in these areas, along with limited knowledge related to TP, are the common risk factors for the development of TP [42]. Therefore, the early detection strategy of TP in this population should be strengthened by implementing modern approaches, such as large-scale active screening. Furthermore, the spatial-temporal analysis indicated that the most likely clusters were mainly concentrated in the western part of Zhejiang Province, which were similar to the results of spatial analysis. This result unveils the distribution pattern of TP incidence in Zhejiang Province and provides a theoretical basis for the regional rational allocation of health resources related to TP and effective implementation of comprehensive prevention and control measures [41]. Therefore, exploring the causes and mechanisms leading to the regional clustering of TP should be carried out in the future.

Each predictive model has its own limitations and merits due to the different prerequisites and mechanisms involved in predicting epidemics. In this study, our exponential smoothing model has a good prediction effect, and the actual value of 66.7% falls within the 95% CI of the predicted value. Part of the actual value that is not within the prediction range may be unsatisfactory for clinical applications. The possible reason was the impact of the COVID-19 pandemic, resulting in the deviation of the model prediction.

Limitations

However, this study also has some limitations. First, TP is not easy to diagnose, and it was not mandatory to include TBIMS before 2018, which could cause an underestimation of TP prevalence from our available surveillance system. Second, the combination and breakdown of different areas of the panel data makes it impossible to carry out detailed analysis in some areas. Third, the prediction model did not include other meteorological factors such as humidity and wind. Last, some potential influencing factors were not considered, such as HIV coinfection, which would be considered in the future.

Conclusions

In this study, the male population had a high notification rate of TP, and a high notification rate of this disease was noted during summer. The western region of Zhejiang Province has the highest relative risk of TP. Comprehensive interventions, such as chest x-ray screening and symptom screening, should be strengthened to improve early identification. Additionally, a more systematic assessment of the prevalence trend of TP should include more predictors.

Acknowledgments

We appreciate the local centers for disease control and prevention, community health care centers, and tuberculosis (TB)-designated hospitals in Zhejiang Province to implement TB, including tuberculosis pleurisy, reporting and notification during daily work. This study was supported by the National-Zhejiang Health Commission Major S&T Project (grant WKJ-ZJ-2118), Zhejiang Provincial Medical and Health Project (2021KY618 and 2020KY520).

Data Availability

All data and materials were included in this paper. The corresponding author (JJ) can provide data upon reasonable request after all studies and substudies have been completed.

Authors' Contributions

JP, BC, and KL conceptualized and designed the study. ZL and JJ managed the study. DL and YZ analyzed the data. SC and BC interpreted the study results. YZ, JJ, and DL drafted the manuscript for important intellectual content. KL, JP, and JJ reviewed and edited the manuscript. YZ, DL, KL, BC, SC, JP, ZL, and JJ approved the final version of the manuscript to be published.

Conflicts of Interest

None declared.

Abstract

Background: Rare diseases (RDs) affect millions of people worldwide, and these diseases can severely impact the health-related quality of life (HRQoL) of those affected. Despite this, there is a lack of research measuring HRQoL using the EQ-5D-5L, which is one of the most widely used generic preference-based instruments to measure HRQoL in populations living with RDs.

Objective: This study aimed to measure HRQoL using the EQ-5D-5L in a large number of patients with various types of RDs in China, and to examine the relationship between respondents' socioeconomic characteristics and preference-based health utility scores.

Methods: The data used in this study were obtained from a web-based survey conducted in China. The survey aimed to explore and understand the health and socioeconomic status of patients with RDs in China. We recruited registered and eligible members, including patients or their primary caregivers, from 33 RD patient associations to complete the questionnaires via their internal social networks. HRQoL was measured using the EQ-5D-5L utility score, which was calculated based on an established Chinese value set. Utility scores have been presented based on demographics and disease-related information. Univariate linear regression analysis was used to assess the differences in the EQ-5D-5L utility scores between subgroups.

Results: A total of 12,502 respondents completed the questionnaire and provided valid responses, including 6919 self-completed respondents and 5583 proxy-completed respondents. Data from 10,102 participants over the age of 12 years were elicited for analysis. Among patients with RDs, 65.3% (6599/10,102), 47.5% (4799/10,102), 47.0% (4746/10,102), 24.8% (2506/10,102), and 18.4% (1855/10,102) reported no problems for "self-care," "usual activities," "mobility," "pain/discomfort," and "anxiety/depression," respectively. A full health state was reported by 6.0% (413/6902) and 9.2% (295/3200) of self- and proxy-completed patients, respectively. Among self-completed patients, 69.9% (4826/6902) and 50.4% (3478/6902) reported no problems for "self-care" and "usual activities," respectively, whereas only 17.7% (1223/6902) reported problems for "anxiety/depression." Proxy-completed respondents showed a higher proportion of reporting extreme problems than self-completed respondents in all 5 dimensions. The mean utility scores reported by self- and proxy-completed respondents were 0.691 and 0.590, respectively. Different types of caregivers reported different utility scores, and among them, proxy-completed (mother) respondents reported the highest mean utility score.

Conclusions: The establishment of a normative profile for RD patients can facilitate patients' adaptation and assess the effectiveness of interventions to improve the HRQoL and well-being of this population. Differences between self- and proxy-completed HRQoL assessed by the EQ-5D-5L have been identified in this study. This finding highlights the importance of incorporating perspectives from both patients and their proxies in clinical practice. Further development of the patient cohort is necessary to assess long-term changes in HRQoL in the RD population.

KEYWORDS

EQ-5D-5L; rare disease; normative profile; utility score; caregiver

Introduction

Rare diseases (RDs) are conditions that affect a very small proportion of the population worldwide. Currently, there are approximately 7000 types of RDs, of which over 70% are genetic, and most of them show a chronic course. The prevalence threshold and definition of RDs vary across countries. In the United States and European Union, approximately 25-30 million and 45-60 million people experience RDs, respectively [1,2]. Worldwide, the population prevalence of RDs is estimated to be 3.5%-5.9%, which amounts to approximately 260-440 million people [3]. Since effective treatments for most RDs do not exist, RD patients typically require complex care, resulting in poor health status [4]. Poor access to information, high treatment expenses, and lack of social support can have a significant negative impact on their health-related quality of life (HRQoL) [5].

The EQ-5D is a well-known and widely used health status instrument worldwide. It was developed by the EuroQol Group as a concise, generic, preference-based instrument for measuring, comparing, and evaluating health status in the population aged 12 years or above [6]. It describes a person’s health as a multi-dimensional profile and provides a single utility value for it, which can be used as a HRQoL measure to facilitate the cost-utility analysis of health care and monitoring of population health [7]. The performance of the EQ-5D has been assessed in numerous health conditions and treatments, and it has shown acceptable psychometric properties. Currently, 2 versions of the EQ-5D exist: the 3-level option (3L) and the 5-level option (5L). The EQ-5D-5L is recommended owing to its better performance in reducing the “ceiling effect” compared to that of the EQ-5D-3L [8]. Currently, there is limited research on the use of the EQ-5D to measure HRQoL in the RD population as a whole. For example, Serrano-Aguilar et al used the EQ-5D for assessing HRQoL in approximately 3000 European patients and caregivers with 10 RDs [9]. Efthymiadou et al assessed HRQoL in more than 600 patients with RDs who were mostly from Europe and the United States [10], and Ng et al evaluated HRQoL in 286 patients with RDs in Hong Kong [11].

There are several gaps in the existing literature on HRQoL among individuals with RDs. First, there is a lack of research on HRQoL among Chinese patients with RDs. Currently, there are approximately 70 million Chinese patients with RDs [12], and without sufficient data and research, providing proper treatment and care for these patients is challenging. Second, although studies have recruited relatively large samples of patients with RDs in Europe, no studies with a similar sample size have been conducted in Asian countries. Random variation can have a larger impact on results in the case of small samples, potentially leading to spurious findings that might not be supported by the data. Third, no studies used the EQ-5D-5L to assess HRQoL in patients with RDs as a whole in the Chinese population. Lastly, no studies have reported the inclusion of patients with advanced-stage RDs (either subjective or objective rating). This may have generated obvious selection bias and significantly affected the quality and reliability of the findings. Therefore, the objective of this study was to measure the HRQoL of individuals or caregivers with various types of RDs using a large sample in China. Specifically, we aimed to establish a normative reference of the EQ-5D-5L for the RD population, including individuals who are older than 12 years, as a whole.

Methods

Sample and Data Collection

The data used in this study were obtained from a nationwide, cross-sectional, web-based survey conducted between August 2019 and January 2020. The survey aimed to explore and understand the health and socioeconomic status of patients with RDs in China. The research team comprised members from the China Alliance for Rare Disease, Chinese University of Hong Kong, China Illness Challenge Foundation, and Peking Union Medical College Hospital. In total, 32 patient associations (PAs) for RDs participated in the study. These PAs were selected from a list provided by the National Rare Diseases Registry System of China and the National Network to Collaborate on Diagnosis and Treatment of Rare Diseases. These 2 organizations were established by the Peking Union Medical College Hospital and supported by the National Health Commission of the People’s Republic of China to manage patients with RDs in China. The content of the questionnaire and logic of the survey were confirmed by the research team and representatives of all the PAs via 2 rounds of face-to-face conferences and more than 10 rounds of web-based meetings between June and August 2019.

All participants were registered members of a PA, which indicates that they were either patients with a formal diagnosis or primary caregivers of patients with a formal diagnosis. In this study, a primary caregiver was defined as a person aged ≥18 years who has been designated as a necessary caretaker responsible for managing the patient’s well-being. This may include, but is not limited to, parents, legal guardians, and paid caregivers. Since the EQ-5D-5L is not appropriate for measuring HRQoL in individuals younger than 12 years, only data from patients with RDs who were 12 years or older were elicited for analysis. Patients without cognitive impairments, who could read Chinese and provide informed consent, were encouraged to complete the questionnaire on their own. However, for all eligible participants, the option of proxy completion by caregivers was also available.

Invitations were disseminated to all eligible patients or caregivers via the PAs’ internal social networks. Eligible members who were interested in participating in the survey were invited to join an online survey group, where the study aims, process, and expected results were provided via group communication. The survey link was sent to all survey group members. The research team worked with the PA’s staff to manage the survey and remind the participants to complete it within 10 days. They sent reminders to participants on the second, third, fifth, and seventh days after the survey link was sent. The first page of the questionnaire was the informed consent form. All participants were required to read through it and click the “Agree” button at the end of the page before starting the survey. Information about participants’ background characteristics, HRQoL, symptoms, social support, and medication was collected. The research team could not access personally identifiable information of the participants; only the PAs’ staff could access such information.

Ethics Approval

The study protocol and informed consent form were approved by the Institutional Review Board of the Chinese University of Hong Kong (Reference ID: SBRE-18-268).

Instrument

Both the self- and proxy-completed versions of the EQ-5D-5L were used in this study [13]. The first section of the EQ-5D-5L is a descriptive system, which comprises 5 health-related dimensions (mobility, self-care, usual activities, pain/discomfort, and anxiety/depression) rated on a 5-option Likert scale ranging from no problems to extreme problems. All health states described by the descriptive system could be converted into a single utility score using a scoring algorithm based on public preferences. Utility scores are anchored between 1 (full health) and 0 (a state as bad as being dead) as required by their use in economic evaluation. A utility score of less than 0 represents health states regarded as worse than a state that is as bad as being dead. In this study, the EQ-5D-5L China value set and scoring algorithm were used [14]. The second section of the EQ-5D-5L is a visual analog scale (EQ-VAS). It is a scale that takes values between 100 (best imaginable health) and 0 (worst imaginable health), on which patients provide a global assessment of their health. The main difference between the self- and proxy-completed versions of the EQ-5D-5L is the adopted perspective. The proxy version asked respondents to report how the care receiver would rate his or her own health.

Statistical Analysis

A descriptive analysis was applied for the participants’ demographic and health characteristics. Because self- and proxy-completed HRQoL may be systematically different, self-completed and proxy-completed EQ-5D-5L data were analyzed separately. Continuous variables (eg, EQ-5D-5L utility score) have been presented as mean, median, and SD. Categorical variables (eg, response on EQ-5D-5L dimensions) have been presented as frequency (n) and proportion (%). Pediatric patients were defined as those aged ≤18 years, whereas older patients were defined as those aged ≥60 years. Self-completed patients were defined as those who completed the questionnaire by themselves (must be ≥12 years), and proxy-completed patients (<12 years or ≥12 years but with very poor health status) were defined as those whose primary caregivers completed the questionnaire. The EQ-5D-5L profile was presented as responses on each dimension of the health classification descriptive system. The EQ-5D-5L utility score was presented for subgroups of patients stratified by their characteristics, including sex, age group, educational level, employment, family registry, family annual income, disease duration, number of children, assistive devices used in daily life, disability status, and number of family members living together, as well as the types of RDs. The univariate linear regression analysis was used to assess differences in the EQ-5D-5L utility score between subgroups. In addition, the differences in the mean EQ-5D-5L utility scores for different caregiver types (father, mother, children, spouse, grandparents/relatives, or others) stratified by background characteristics have been presented. All statistical analyses were performed using R software. Statistical significance was considered if $P<.05$ was obtained.

Results

Background Characteristics of Patients With RDs

A total of 20,802 responses were collected. Of these, 8300 were excluded because the respondents either dropped out of the survey or provided incomplete responses. The remaining 12,502 respondents included 6919 self-completed patients and 5583 proxy-completed patients. Table 1 shows their background characteristics stratified by response type. Of the patients, 53.2% (6653/12,502) were of the male sex, 16.2% (2016/12,502) were aged <10 years, and 3.8% (469/12,502) were aged ≥61 years, and more than half (6488/12,502, 51.9%) were urban residents. Table 1 provides a detailed breakdown of the differences. Most of the RD types were never reported previously worldwide, for example, Kallmann syndrome, Dravet syndrome, and Niemann–Pick disease. Among them, 2249 patients had myasthenia gravis, 1504 had hemophilia, and 994 had scleroderma (Multimedia Appendix 1). The self-completed and proxy-completed patients significantly differed in all the background characteristics.

Table 1. Patient background characteristics.

Characteristic	Full sample (N=12,502)	Self-completed sample (n=6919)	Proxy-completed sample (n=5583)	*P* value

[a] A currency exchange rate of CNY 1=US $0.14 is applicable.

[b] RD: rare disease.

EQ-5D-5L Profile for Patients With RDs

Data from 10,102 participants over the age of 12 years were elicited for analysis. Their background characteristics are presented in Multimedia Appendix 2. Table 2 displays the proportion of reported health states for each level of the EQ-5D-5L dimensions. Among patients with RDs, 65.3% (6599/10,102), 47.5% (4799/10,102), 47.0% (4746/10,102), 24.8% (2506/10,102), and 18.4% (1855/10,102) reported no problems for "self-care," "usual activities," "mobility," "pain/discomfort," and "anxiety/depression," respectively. In the case of pediatric patients with RDs, 49.3% (704/1428), 40.2% (574/1428), and 28.6% (408/1428) reported no problems for "usual activities," "pain/discomfort," and "anxiety/depression," respectively, and these proportions were around 10% higher than the proportions in the overall sample. The proportions of having no problems in all 5 dimensions were lower in older patients with RDs than in the overall sample.

Among self-completed respondents, 69.9% (4826/6902) and 50.4% (3478/6902) reported no problems for "self-care" and "usual activities," respectively, whereas only 17.7% (1223/6902) reported problems for "anxiety/depression." Moreover, 6.0% (413/6902) and 0.3% (24/6902) of patients reported full and worst health states, respectively.

Table 2. Health status reported by using the EQ-5D-5L descriptive system.

Variable	All patients (N=10,102)	Pediatric (12-18 years) (n=1428)	Older (≥60 years) (n=503)	Self-completed (n=6902)	Proxy-completed (n=3200)
Mobility, n (%)					
No problem	4746 (47.0)	802 (56.2)	134 (26.6)	3311 (48.0)	1435 (44.8)
Slight problems	2495 (24.7)	219 (15.3)	135 (26.8)	1844 (26.7)	651 (20.3)
Moderate problems	1311 (13.0)	125 (8.8)	84 (16.7)	917 (13.3)	394 (12.3)
Severe problems	744 (7.4)	63 (4.4)	70 (13.9)	477 (6.9)	267 (8.3)
Extreme problems	806 (8.0)	219 (15.3)	80 (15.9)	353 (5.1)	453 (14.2)
Self-care, n (%)					
No problem	6599 (65.3)	872 (61.1)	212 (42.1)	4826 (69.9)	1773 (55.4)
Slight problems	1751 (17.3)	190 (13.3)	113 (22.5)	1221 (17.7)	530 (16.6)

Severe problems	345 (3.4)	45 (3.2)	39 (7.8)	190 (2.8)	155 (4.8)
Extreme problems	661 (6.5)	223 (15.6)	72 (14.3)	199 (2.9)	462 (14.4)
Usual activities, n (%)					
No problem	4799 (47.5)	704 (49.3)	127 (25.2)	3478 (50.4)	1321 (41.3)
Slight problems	2862 (28.3)	322 (22.5)	162 (32.2)	2028 (29.4)	834 (26.1)
Moderate problems	1222 (12.1)	140 (9.8)	89 (17.7)	826 (12.0)	396 (12.4)
Severe problems	638 (6.3)	83 (5.8)	66 (13.1)	374 (5.4)	264 (8.3)
Extreme problems	581 (5.8)	179 (12.5)	59 (11.7)	196 (2.8)	385 (12.0)
Pain/discomfort, n (%)					
No problem	2506 (24.8)	574 (40.2)	77 (15.3)	1606 (23.3)	900 (28.1)
Slight problems	4540 (44.9)	533 (37.3)	198 (39.4)	3292 (47.7)	1248 (39.0)
Moderate problems	2055 (20.3)	196 (13.7)	132 (26.2)	1424 (20.6)	631 (19.7)
Severe problems	647 (6.4)	72 (5.0)	62 (12.3)	399 (5.8)	248 (7.8)
Extreme problems	354 (3.5)	53 (3.7)	34 (6.8)	181 (2.6)	173 (5.4)
Anxiety/depression, n (%)					
No problem	1855 (18.4)	408 (28.6)	72 (14.3)	1223 (17.7)	632 (19.8)
Slight problems	4407 (43.6)	656 (45.9)	178 (35.4)	3066 (44.4)	1341 (41.9)
Moderate problems	2379 (23.5)	220 (15.4)	140 (27.8)	1695 (24.6)	684 (21.4)
Severe problems	888 (8.8)	80 (5.6)	64 (12.7)	571 (8.3)	317 (9.9)
Extreme problems	573 (5.7)	64 (4.5)	49 (9.7)	347 (5.0)	226 (7.1)
Full health[a], n (%)	708 (7.0)	214 (15.0)	21 (4.2)	413 (6.0)	295 (9.2)
Worst health[b], n (%)	74 (0.7)	13 (0.9)	17 (3.4)	24 (0.3)	50 (1.6)

[a] Full health indicates that the respondent selected “no problem” for all 5 dimensions of the EQ-5D descriptive system (1, 1, 1, 1, and 1).

[b] Worst health indicates that the respondent selected “severe/extreme problems” for all 5 dimensions of the EQ-5D descriptive system (5, 5, 5, 5, and 5).

Proxy-completed respondents showed a higher proportion of reporting extreme problems than self-completed respondents in all 5 dimensions. Among proxy-completed respondents, 55.4% (1773/3200) and 44.8% (1435/3200) reported no problems for “self-care” and “mobility,” respectively. Regarding the types of caregivers, fathers reported the highest proportion of care receivers experiencing problems related to extreme mobility and self-care (91/535, 17.0% and 84/535, 15.7%, respectively), whereas children caregivers reported a higher proportion of care receivers experiencing extreme problems with usual activities and pain/discomfort (69/595, 11.6% and 47/595, 7.9%) than other types of caregivers (Table 3). Meanwhile, grandparents/relatives and children caregivers reported similarly high proportions of extreme problems with anxiety/depression (approximately 11%) compared to other types of caregivers.

Table 3. Proxy-completed health status using the EQ-5D-5L descriptive system.

Variable	Father (n=535)	Mother (n=1084)	Children (n=595)	Spouse (n=369)	Grandparents/relatives (n=158)	Others (n=459)
Mobility, n (%)						
No problem	258 (48.2)	570 (52.6)	208 (35.0)	143 (38.8)	56 (35.4)	200 (43.6)
Slight problems	99 (18.5)	188 (17.3)	137 (23.0)	93 (25.2)	35 (22.2)	99 (21.6)

Moderate problems	64 (12.0)	105 (9.7)	89 (15.0)	50 (13.6)	29 (18.4)	59 (12.9)
Severe problems	38 (7.1)	75 (6.9)	66 (11.1)	28 (7.6)	17 (10.8)	40 (8.7)
Extreme problems	76 (14.2)	147 (13.6)	69 (11.6)	41 (11.1)	16 (10.1)	36 (7.8)
Pain/discomfort, n (%)						
No problem	175 (32.7)	391 (36.1)	121 (20.3)	82 (22.2)	25 (15.8)	106 (23.1)
Slight problems	212 (39.6)	424 (39.1)	211 (35.5)	166 (45.0)	65 (41.1)	170 (37.0)
Moderate problems	85 (15.9)	163 (15.0)	153 (25.7)	70 (19.0)	45 (28.5)	115 (25.1)
Severe problems	30 (5.6)	66 (6.1)	63 (10.6)	32 (8.7)	12 (7.6)	45 (9.8)
Extreme problems	33 (6.2)	40 (3.7)	47 (7.9)	19 (5.1)	11 (7.0)	23 (5.0)
Anxiety/depression, n (%)						
No problem	127 (23.7)	272 (25.1)	79 (13.3)	59 (16.0)	16 (10.1)	79 (17.2)
Slight problems	234 (43.7)	485 (44.7)	219 (36.8)	167 (45.3)	63 (39.9)	173 (37.7)
Moderate problems	98 (18.3)	196 (18.1)	144 (24.2)	82 (22.2)	47 (29.7)	117 (25.5)
Severe problems	35 (6.5)	86 (7.9)	88 (14.8)	38 (10.3)	15 (9.5)	55 (12.0)
Extreme problems	41 (7.7)	45 (4.2)	65 (10.9)	23 (6.2)	17 (10.8)	35 (7.6)
Full health[a], n (%)	55 (10.3)	136 (12.5)	36 (6.1)	20 (5.4)	5 (3.2)	43 (9.4)
Worst health[b], n (%)	9 (1.7)	7 (0.6)	17 (2.9)	6 (1.6)	4 (2.5)	7 (1.5)

[a] Full health indicates that the respondent selected “no problem” for all 5 dimensions of the EQ-5D descriptive system (1, 1, 1, 1, and 1).

[b] Worst health indicates that the respondent selected “severe/extreme problems” for all 5 dimensions of the EQ-5D descriptive system (5, 5, 5, 5, and 5).

EQ-5D-5L Utility Score for Patients With RDs

Tables 4-6 show the means and SDs of the EQ-5D-5L utility scores stratified by different background characteristics and types of RDs. The mean utility scores were 0.659 (SD 0.324), 0.691 (SD 0.284), and 0.590 (SD 0.388) for the overall, self-completed, and proxy-completed samples, respectively. In the overall sample, the EQ-5D-5L utility score was significantly associated with belonging to the female sex, being aged ≤10 years, being actively employed, residing in urban areas, having a high family annual income, having a short duration of disease, and not having children. Similar trends were observed in the self- and proxy-completed samples, except for insignificant differences in the utility score between patients with different numbers of children in the self-completed sample and between urban and rural residents in the proxy-completed sample.

Regarding the mean utility score for specific RDs, patients with amyotrophic lateral sclerosis reported a significantly lower utility score than those with other RDs; however, in the self-completed sample, the mean utility score for spinal muscular atrophy was the lowest (Multimedia Appendix 3).

Regarding the EQ-5D-5L utility scores reported by different types of caregivers, we found that mothers reported a higher score (0.633) whereas children caregivers reported a lower score (0.513) compared to other caregivers (0.552). Detailed comparisons of the utility scores of caregivers are provided in Table 7.

Table 4. EQ-5D utility scores and the associations with patients' background characteristics (full sample).

Variable	Utility score, mean (SD)	Coefficient (95% CI)	*P* value
Overall	0.659 (0.324)	N/A[a]	N/A
Gender			
Male	0.633 (0.339)	N/A	N/A
Female	0.685 (0.308)	0.051 (0.039 to 0.064)	<.001
Age (years)

[a] N/A: not applicable.

[b] A currency exchange rate of CNY 1=US $0.14 is applicable.

[c] RD: rare disease.

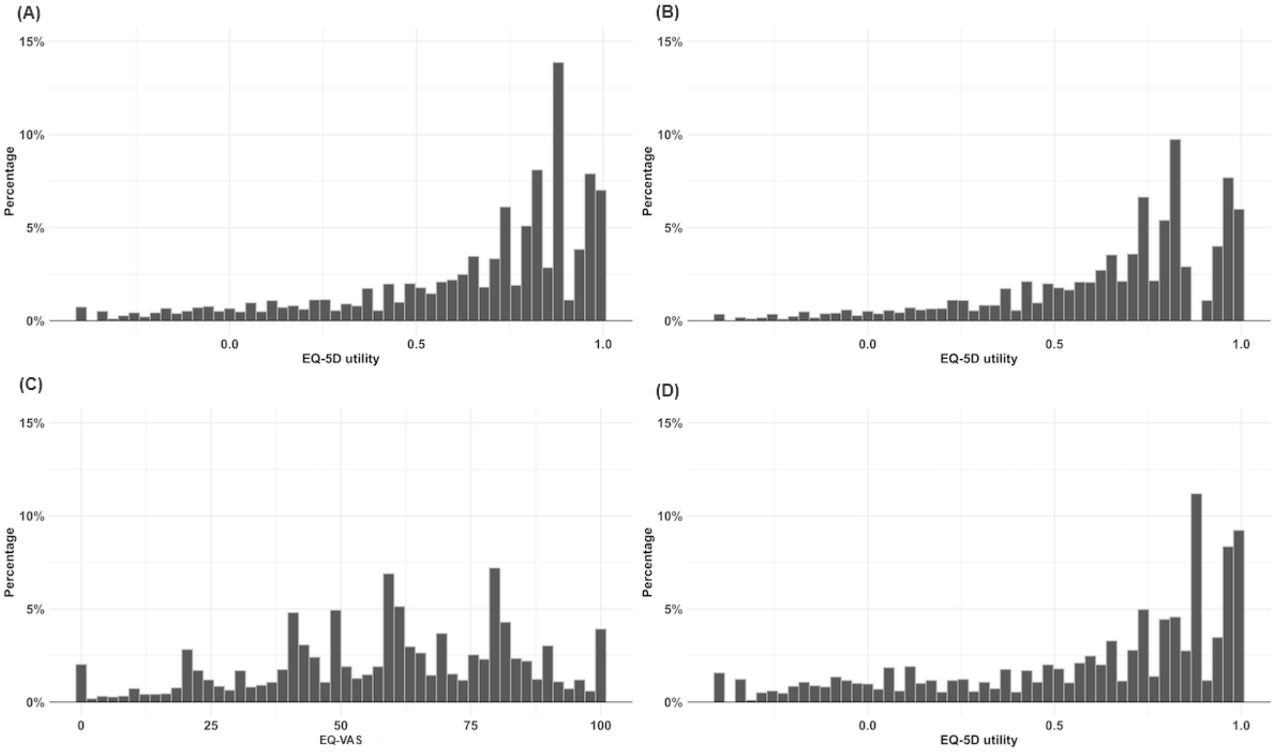
EQ-VAS Profile

The mean and median EQ-VAS scores of the full sample were 59.22 and 61, respectively, with scores ranging from 0 to 100. The mean and median EQ-VAS scores of the self- and proxy-completed samples were 60.19 and 61, and 57.13 and 60, respectively. There was a strong and significant association between the EQ-5D-5L utility score and the EQ-VAS score (r=0.52; *P*<.001). Additionally, Figure 1 presents the distribution of the EQ-VAS and EQ-5D-5L utility scores.

Figure 1. Distribution of the EQ-5D-5L utility scores and EQ-VAS scores. (A) EQ-5D utility score for the full sample; (B) EQ-5D utility score for the self-completed sample; (C) EQ-VAS score for the full sample; (D) EQ-5D utility score for the proxy-completed sample.



Discussion

Principal Findings

This study presents a population norm of HRQoL for patients with RDs in China, using the preference-based value set of the EQ-5D-5L. This is also the largest study estimating the utility scores of the EQ-5D-5L in patients with RDs worldwide, even including studies using the EQ-5D-3L or any other preference-based measures. Although we only included 33 types of RDs, it is still the largest number of RDs included in any EQ-5D-5L–related study worldwide. Additionally, we estimated the EQ-5D-5L profile and utility scores for both pediatric and older patients with RDs, as well as self-completed and proxy-completed patients with RDs, and evaluated the differences between caregiver types. Our study provides valuable information as a reference for health evaluation and comparisons of different health care interventions in RDs, both locally and globally.

Comparisons With Previous Studies

The mean utility score for patients with RDs (0.659) in our sample, as measured by the EQ-5D-5L, was significantly lower than that for the general Chinese population in China (0.957) [15] and Hong Kong (0.92) [16]. This score is comparable to the findings of López-Bastida et al [17], who utilized a sample of 1544 patients with RDs from several European countries. Our mean utility score is similar to theirs, suggesting that our results are consistent with those of other large-scale studies conducted in the RD population. However, López-Bastida et al did not report the respondents’ selections on the dimensions of the EQ-5D. This makes it difficult to compare dimension-level data between the 2 studies. Moreover, given that the value set for China and European countries may be different, the index score between this study and the Europeans study may not be comparable. Compared with another study using the EQ-5D-3L in Chinese patients with RDs in Hong Kong [11], there were higher proportions of “no problems” for the dimensions of “mobility,” “self-care,” and “usual activities,” but lower proportions of “no problems” for “pain/discomfort” and “anxiety/depression.” Additionally, regarding the utility score, the Hong Kong study reported a lower mean score (0.53) than our study. However, the Hong Kong study had a very small sample size, which may have limited the reliability of their findings. Compared to studies assessing HRQoL in Chinese patients with chronic diseases in general [18-22], the utility scores in patients with RDs were significantly lower. It reflects the large negative impact of RDs on HRQoL and the greater health care needs of patients with RDs in China.

Similar to the general population norm [15,16,23-25], demographics and socioeconomics also significantly impacted patients with RDs. For example, older patients with RDs living in rural areas or having lower family annual incomes reported significantly lower utility scores than their counterparts. Regarding disease-related factors, we found a very large difference (0.733) between patients with RDs who did not use assistive devices and those who used them in daily life. Despite the global need and recognized benefits of using assistive products, access to them remains limited [26]. Our findings quantify the importance of assistive devices for improving the HRQoL of patients with RDs and promoting their well-being. Moreover, we have further presented the EQ-5D-5L utility score for all 33 types of RDs. We found that patients with neuromuscular diseases (amyotrophic lateral sclerosis and spinal muscular disease) tended to report lower utility scores compared to the scores in patients with other types of RDs. This is in line with previous findings. For example, Ng et al [11] and Sequeira et al [27] indicated that patients with neurologic diseases reported the lowest utility scores among patients of all RD categories. Despite acknowledging that some studies have measured HRQoL based on disease category (eg, neurologic disease) rather than a single disease, we decided not to categorize the 33 RDs into different categories, because even though some RDs share similar pathologic and physiologic mechanisms, each RD has its own characteristics. Our list can help researchers in flexibly comparing HRQoL in their research based on either a single RD or a category of RDs.

The EQ-5D-5L proxy questionnaire has been shown to be feasible and valid in various populations. However, most studies have focused on people with mental health problems, such as dementia [28,29]. The EQ-5D-5L profile in patients with RDs is limited. Given that a high proportion of RD patients are children or adolescents, owing to the genetic nature of RDs, proxy-completed data are very useful in RD research. Our study provides valuable information about EQ-5D-5L utility scores completed by proxies. We found that the mean utility score of proxy-completed patients was lower than that of self-completed patients, which is consistent with previous findings [30]. This is reasonable as most RD patients who cannot complete the questionnaire themselves have poor physical and mental health. However, for this study, we only used the proxy-patient version of the EQ-5D-5L, and HRQoL measured by the proxy-proxy version may be assessed in the future.

In addition, to provide a more detailed analysis, we have further stratified the EQ-5D utility score based on the type of caregiver. Our findings are similar to those of a previous study reporting that different proxies provide different ratings of patient health [31]. Mothers reported a higher proportion of “no problems” for nearly all dimensions of the EQ-5D-5L than fathers and grandparents or relatives. However, fathers reported a higher proportion of “extreme problems” for 4 out of 5 dimensions than mothers. This may be because when the mother is the primary caregiver, the health condition of the child is usually not very severe, allowing the father to go out to work. However, if the father is the primary caregiver, both parents may have caregiving responsibilities and the child’s health condition is often much more serious. Additionally, most child caregivers reported a lower proportion of “no problems” than other types of caregivers, as the care receivers of these caregivers are usually older patients with RDs. These data are useful because, compared to patients with normal disease, more adult patients with RDs cannot complete the EQ-5D by themselves owing to their poor health status. Measuring HRQoL by caregivers is therefore important to examine the effectiveness of interventions that are designed to improve the practice of RD care.

Strengths and Limitations

This study presents a comprehensive analysis of a normative profile of the EQ-5D-5L for patients with RDs in China. We used a large sample size and included both self- and proxy-completed data to provide a more complete picture of HRQoL for this population than that provided by previous studies worldwide. Our findings can serve as a baseline for future comparisons of HRQoL with RD populations, both locally and globally. Moreover, the results can be used to evaluate the efficacies of various policies, strategies, or interventions aimed at improving the HRQoL of the RD population. Furthermore, the study provides EQ-5D-5L utility values for the future cost-effectiveness analysis of interventions for RDs. By providing a detailed and nuanced understanding of the EQ-5D-5L normative profile for patients with RDs, this study can help inform future research and policy initiatives designed to address the unique health needs of this population.

Despite these strengths, several limitations should be addressed. The primary limitation of this study is that all data were collected voluntarily, which may have led to a lack of information from patients with a poor health status or caregivers with low willingness to participate in the survey, generating selection bias. Additionally, all data were collected via a web-based survey, which could exclude patients not familiar with or not having easy access to the internet, potentially leading to selection bias. Moreover, in this study, we used the EQ-5D-5L instead of the EQ-5D-Y to collect HRQoL data from children and adolescents with RDs. Given that the EQ-5D-Y is a youth-friendly version that has demonstrated high feasibility and reliability in young patients, the estimation of the utility score in this population in our sample might be less reliable. In the future, it is highly encouraged to conduct studies that use EQ-5D-Y to assess HRQoL in young patients with RDs. Finally, although the sample size in our study is larger than that in previous studies, it is important to note that there may be over 20 million people living with RDs in China. Therefore, our sample may not be fully representative, and the generalizability of our findings could be limited.

Conclusion

This study assessed the HRQoL of Chinese patients with RDs using the preference-based EQ-5D-5L. Our findings contribute new knowledge to the existing literature on the relationship among HRQoL, demographics, and health status in patients with RDs. The established normative profile of HRQoL reveals disparities and heterogeneities existing in the health status, as measured by the EQ-5D-5L, across different socioeconomic groups and disease categories. Additionally, our study revealed important differences between self- and proxy-completed HRQoL assessments in the RD population. This finding underscores the need to incorporate perspectives from both patients and their proxies in clinical practice. Further development of the patient cohort is necessary to assess the long-term changes in HRQoL in the RD population.

Abstract

Background: Although social determinants of health (SDH) are an underlying cause of poor cardiovascular health (CVH), there is insufficient evidence for the association between SDH and CVH, which varies by sex and age among Mongolian adults.

Objective: We aimed to explore whether education, household income, and health insurance were associated with CVH according to sex and age among Mongolian adults.

Methods: The final sample included data on 5691 participants (male: n=2521. 44.3% and female: n=3170, 55.7%) aged 18-69 years from the 2019 World Health Organization STEPwise approach to noncommunicable disease risk-factor surveillance. CVH was measured using a modified version of Life’s Simple 7 with 4 health behaviors (cigarette smoking, BMI, physical activity, and a healthy diet) and 3 biological factors (blood pressure, fasting glucose, and total cholesterol blood levels) and classified into poor, intermediate, and ideal levels as recommended by the American Heart Association. Multinomial logistic regression analyses examined the associations between SDH and CVH by monthly equivalized household income after adjusting for age, sex, work status, area, history of myocardial infarction or stroke, use of aspirin, and use of statin. Subgroup analyses were conducted to examine the associations between SDH and CVH based on sex and age, considering monthly equivalized household income as a key variable.

Results: Using the ideal level of CVH as a reference, among those with the lowest household income, having less than 12 years of education, and not having health insurance were associated with poor CVH (education level: odds ratio [OR] 2.42, 95% CI 1.30-4.51; *P*=.006; health insurance: OR 2.17, 95% CI 1.13-4.18; *P*=.02). These associations were more profound among female individuals (education level: OR 2.99, 95% CI 1.35-6.63; *P*=.007; health insurance: OR 2.54, 95% CI 1.09-5.90; *P*=.03) and those aged 18-44 years (education level: OR 3.22, 95% CI 1.54-6.72; *P*=.002; health insurance: OR 2.03, 95% CI 0.98-4.18; *P*=.06).

Conclusions: Participants in the lowest household income group with lower educational levels and without health insurance were more likely to have poor CVH, and these results were more pronounced in female individuals and young adults. These findings suggest the need to develop strategies for CVH equity in Mongolian female individuals and young adults that consider income levels, education levels, and health insurance.

Introduction

The trend toward universal health coverage in Mongolia seems to have stagnated. Service coverage related to cardiovascular health (CVH) risk factors such as hypertension, diabetes, and smoking is also below the global average; there was no improvement between 2000 and 2019 [1]. Of the 4 noncommunicable diseases (NCDs) most common among Mongolian adults aged 30-70 years, cardiovascular disease (CVD) accounted for the largest proportion (17.3%) of deaths [2]. In a cross-sectional study that examined a nationally representative sample of 70,380 people aged 35-75 years in Inner Mongolia, 25% of the study participants were at high-risk for CVD, with more than 10% at risk of developing CVD after 10 years [3]. However, Mongolian adults' low rates of hypertension control treatment, along with high rates of smoking, sodium intake, and obesity, indicate that CVH is not adequately managed in Mongolian adults [4-7].

There is substantial evidence for the effectiveness of individual lifestyle changes to reduce CVH risk [8-10]; nevertheless, it is necessary to examine situations such as the structural social determinants of health (SDH) in Mongolia, where essential service coverage is not guaranteed. SDH, such as education and health insurance coverage, can be more important than lifestyle choices in influencing population health and health equity because of their connection to CVD pathogenesis. Chronic psychosocial stress can be induced among individuals who are susceptible to SDH, and this stress can lead to chronic inflammation by activating the sympathetic nervous system linked to altered stress hormone. For example, glucocorticoid receptor resistance due to chronic activation of the sympathetic nervous system blunts the anti-inflammatory response; it could contribute to enabling CVD development and progression. [11]. Further, the Denmark study showed that a low education level was independently associated with a higher risk of CVD among 1.6 million Danish employees [12]. In Colombia, people with lower education levels have a higher risk of dying prematurely from CVD, and these education inequalities affect female individuals more than male individuals [13]. A prospective cohort study that examined 390,881 Chinese adults aged 18-64 years with a mean follow-up of 10.4 years revealed that having private health insurance coverage was associated with a 21% lower risk of CVD mortality compared to being uninsured [14].

However, there are insufficient studies showing the influence of SDH on CVH among Mongolian adults. Thus, the identification of SDH should be the foundation for developing strategies that promote CVH and reduce long-term health inequality [15]. Research on this topic can provide critical information that can be used for evidence-based planning and decision-making based on priorities regarding CVH equity. As prevalence of CVD risk differed according to sex and age among Mongolian adults [3,4], the population group characteristics should be considered when confirming the influence of SDH on CVH. Thus, this study aimed to explore the sex and age differences in the independent associations between SDH (educational level and health insurance) and CVH among Mongolian adults.

Methods

Data and Study Participants

Data were obtained from the 2019 Mongolia STEPwise approach to noncommunicable disease risk-factor surveillance (STEPS). The World Health Organization (WHO) initiated STEPS in various countries, recognizing a need for standardized worldwide risk-factor data on NCD risk factors for surveillance systems [16,17]. STEPS was conducted in Mongolia to assess the impact and effect of the integrated national program on "NCD Prevention and Control" [5]. STEPS is a repeated household survey that is population based and cross-sectional. It uses multistage cluster sampling to extract and investigate a nationally representative sample [18]. The fourth Mongolia STEPS survey was carried out using 377 sampling clusters selected from 21 provinces and 9 districts of Ulaanbaatar in 2019 [5]. Of the 6654 people who participated in the 2019 Mongolia STEPS, participants aged younger than 18 years (n=173, 2.6%) and those who had missing data on key variables (n=790, 11.9%) were excluded and 5691 (85.5%) participants were finally included in this secondary data analysis.

Ethical Considerations

All participants provided written informed consent prior to participating in the 2019 Mongolia STEPS. This study was granted an exemption by the institutional review board (4-2021-1341) of Severance Hospital at Yonsei University College of Medicine, Republic of Korea, which allows secondary analyses without additional consent.

SDH Factor

Information about education level, possessing health insurance, and average household earnings in the past year were assessed through face-to-face interviews [16]. Educational attainment was categorized into 2 groups: <12 years of education and ≥12 years of education (reference group). Current health insurance was assessed using the question "Do you currently have any kind of health insurance or health care coverage?" [16]. The average monthly household income was calculated by dividing the average household income in the previous year by 12. Equivalized household income was defined as the average monthly household income divided by the square root of the number of household members [19]. The study participants were divided into 4 groups according to the quartiles of equivalized household income.

CVH Factor

We used the modified Life's Simple 7 by the American Heart Association to measure CVH. It addresses 4 health behaviors, including BMI, smoking, physical activity, and diet, and 3 health risk factors, including blood pressure, fasting glucose levels, and total cholesterol [20]. A cutoff of 23 kg/m^2 for BMI, which has been validated for the Asian population, was used in this study [21]. Smoking, physical activity, and diet were assessed through face-to-face interviews using standardized questionnaires [16]. Salt consumption for diet was used instead of the American Heart Association's guidelines [22]. Blood pressure was measured 3 times for 3-minute intervals. Each measurement was taken on the left arm, with the participants in a seated posture [18]. The mean of the last 2 measurements was used in the analysis [18]. Overnight fasting blood samples were collected at a local clinic or health center [18]. CVH metrics were scored as poor (0 points), intermediate (1 point), and ideal (2 points). The total CVH scores were calculated as the sum of the scores for each component for a possible range of 0-14 (Table S1 in Multimedia Appendix 1). Scores of 0-7 were considered as poor, 8-11 as intermediate, and 12-14 as ideal for CVH [23].

Covariates

We adjusted for sex, age (18-39, 40-59, and ≥60 years), work status (employee, self-employed, or others), area (rural or urban), history of myocardial infarction or stroke (yes or no), use of aspirin (yes or no), and use of statin (yes or no). The history of myocardial infarction or stroke was investigated using the question "Have you ever had a heart attack or chest pain from heart disease (angina) or a stroke (cerebrovascular accident or incident)?" The use of aspirin or statin was assessed using the questions "Are you currently taking aspirin regularly to prevent or treat heart disease?" and "Are you currently taking statins (Lovastatin/Simvastatin/Atorvastatin or any other statin) regularly to prevent or treat heart disease?" respectively. The covariate data were collected by self-reporting.

Statistical Analysis

Descriptive values were calculated for the total participant group as well as the male and female groups, represented as a weighted mean (95% CI) and number (weighted proportion). The differences in variables according to CVH categories in male and female participants were calculated using ANOVA for continuous variables and the chi-square test for categorical variables. Independent associations between SDH (education level and health insurance) and CVH were assessed through multinomial logistic regression analyses between the sexes after adjusting for covariates. Subgroup analyses regarding associations between SDH and CVH according to monthly equivalized household income were conducted among the total participants. This subgroup analysis according to monthly equivalized household income was also performed by sex and age to identify different sex and age associations between SDH and CVH by household income. The period of public education in Mongolia gradually changed from 10 years in 2004 to 12 years in 2013; students who graduated in 2013 were the first to have received 12 years of public education. Therefore, sensitivity analyses were conducted by defining low education level as less than 11 years of education and examining the association between education level and CVH according to monthly equivalized household income. Adjusted odds ratios (ORs) and 95% CIs were calculated using the PROC SURVEYLOGISTIC procedures to apply population weights, and all statistical tests were performed using SAS (version 9.4; SAS Institute Inc).

Results

The general characteristics of study participants by sex according to CVH are described in Multimedia Appendix 2. Of the total 5691 participants, 29.6% (n=1685), 56.4% (n=3208), and 14% (n=798) showed poor, intermediate, and ideal CVH, respectively. The mean CVH score of study participants was 8.80 (SD 2.46). The weighted mean age of study participants was 37.5 (SE 0.26) years, and more than two-thirds (2888/5691, 69.3%) were aged 18-44 years. Approximately half (n=3075, 49.6%) of the participants had less than 12 years of education, and one-fifth (n=888, 19.5%) had no health insurance. In male participants, 41.1% (n=1036), 50.2% (n=1265), and 8.7% (n=220) showed poor, intermediate, and ideal CVH, respectively. The mean age, the proportion of employees, self-employment, and use of aspirin were likely to be higher in participants with poor CVH (all *P*<.001). In female participants, 20.5% (n=649), 61.3% (n=1943), and 18.2% (n=578) showed poor, intermediate, and ideal CVH, respectively. The mean age and the proportion of aspirin and of statin use were likely to be higher in those with poor CVH (all *P*<.001). Those with less than 12 years of education were more likely to have poorer CVH (*P*=.001).

Table 1 shows the results of multinomial logistic regression regarding the association between education, health insurance, and CVH categories. Of the total participants, using ideal CVH as a reference, those with less than 12 years of education were not associated with intermediate and poor CVH after adjusting for potential covariates (intermediate CVH: OR 1.12, 95% CI 0.91-1.40; poor CVH: OR 1.00, 95% CI 0.78-1.29). Similarly, of the total participants, those without health insurance were not associated with intermediate and poor CVH, respectively (intermediate CVH: OR 0.97, 95% CI 0.73-1.28; poor CVH: OR 1.19, 95% CI 0.85-1.67). For both male and female participants, low education level and absence of health insurance were not associated with intermediate and poor CVH.

However, as a result of stratification according to quartiles of monthly household income, participants with less than 12 years of education in the Q1 (lowest household income) and Q2 groups were associated with a 2.42 (95% CI 1.30-4.51) and 1.90 (95% CI 1.08-3.33) times higher likelihood of poor CVH, respectively (Figure 1 and Table S2 in Multimedia Appendix 1). These associations were consistently found when defining low education level as less than 11 years (data not shown). Participants without health insurance in the Q1 group were also associated with a 2.17 (95% CI 1.13-4.18) times higher likelihood of poor CVH.

Table 1. Results of multinomial logistic regression of the association between education, health insurance, and CVH[a] by modified Life's Simple 7[b,c].

Variables	Intermediate CVH		Poor CVH	
	n (%)	OR[d] (95% CI)	n (%)	OR (95% CI)

[a] CVH: cardiovascular health.

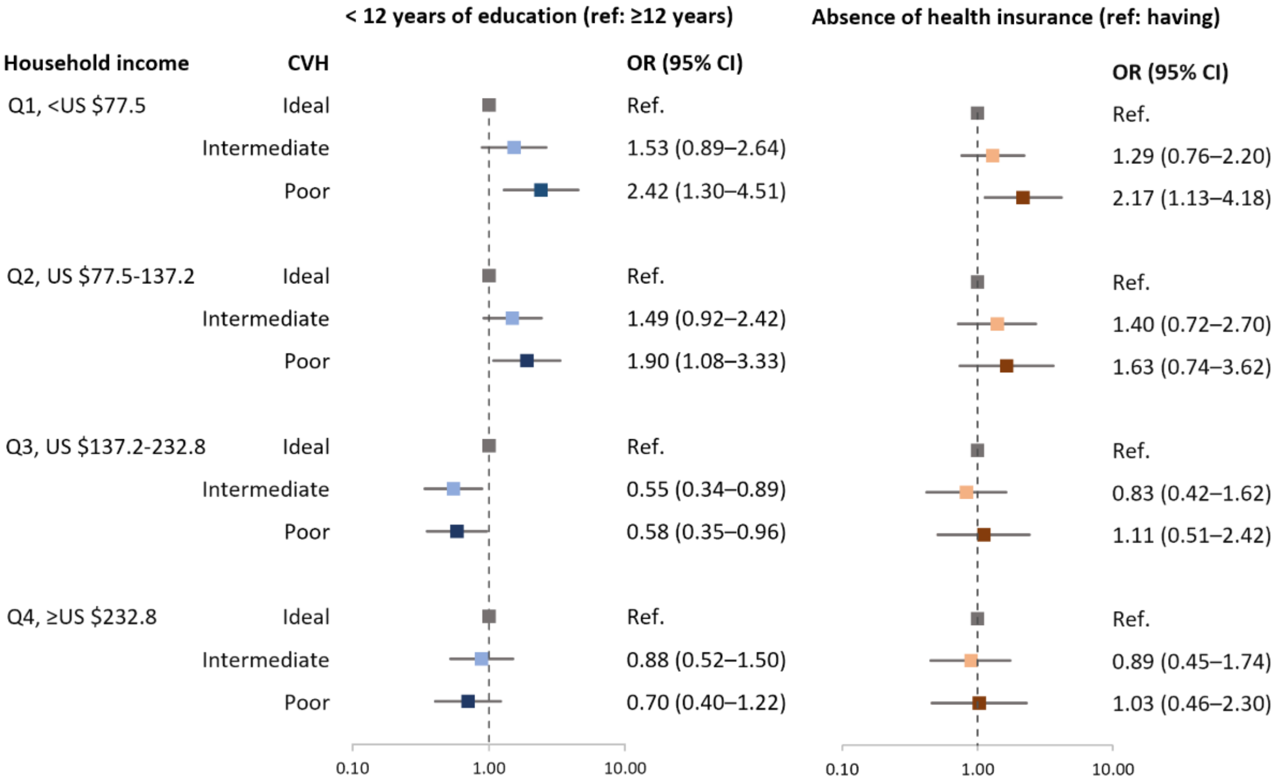
[b] The estimates are in reference to the ideal CVH group.

[c] Age, sex, work status, area, history of myocardial infarction or stroke, use of aspirin, and use of statin were adjusted.

[d] OR: odds ratio.

[e] N/A: not available.

Figure 1. Results of multinomial logistic regression of the association between social determinants of health and CVH according to household income. Age, sex, work status, area, history of myocardial infarction or stroke, use of aspirin, and use of statin were adjusted. CVH: cardiovascular health; OR: odds ratio; Ref: reference.



The associations between education level and CVH according to monthly household income quartile by sex and age are illustrated in Figure 2. Female participants in the Q1 (lowest household income) group with less than 12 years of education were associated with a 2.99 (95% CI 1.35-6.63) times higher likelihood of poor CVH compared to female participants with more than 12 years of education (Table S3 in Multimedia Appendix 1). However, male participants with less than 12 years of education were not associated with intermediate and poor CVH in the Q1 group (intermediate CVH, OR 0.78, 95% CI 0.31-1.96; poor CVH, OR 1.44, 95% CI 0.56-3.72). Participants in the Q1 group who were aged 18-44 years and had less than 12 years of education were also associated with a 3.22 (95% CI 1.54-6.72) times higher likelihood of poor CVH. Participants in the Q3 and Q4 groups, aged 45-69 years, with less than 12 years of education were associated with a lower likelihood of poor CVH (Q3, OR 0.25, 95% CI 0.10-0.60; Q4, OR 0.36, 95% CI 0.13-0.97).

Similarly, female participants in the Q1 (lowest household income) group without health insurance were associated with a 2.54 (95% CI 1.09-5.90) times higher likelihood of poor CVH compared to female participants with health insurance (Figure 3 and Table S4 in Multimedia Appendix 1). However, male participants in the Q1 group without health insurance were not associated with poor CVH (OR 2.02, 95% CI 0.73-5.57). Participants in the Q1 group, aged 18-44 years, without health insurance were marginally associated with a 2.03 (95% CI 0.98-4.18) times higher likelihood of poor CVH. Participants in the Q1 group, aged 45-69 years, without health insurance were not associated with poor CVH (OR 2.67, 95% CI 0.60-11.95). The OR for the Q3 group of participants aged 45-69 years was not accounted for as the model did not converge due to quasi-complete separation.

Figure 2. Results of multinomial logistic regression of the association between low education level and CVH according to household income by sex and age. The reference is ≥12 years of education. Adjusted for all other factors not involving the subgroup, including age, sex, work status, area, history of myocardial infarction or stroke, use of aspirin, and use of statin were adjusted. CVH: cardiovascular health.

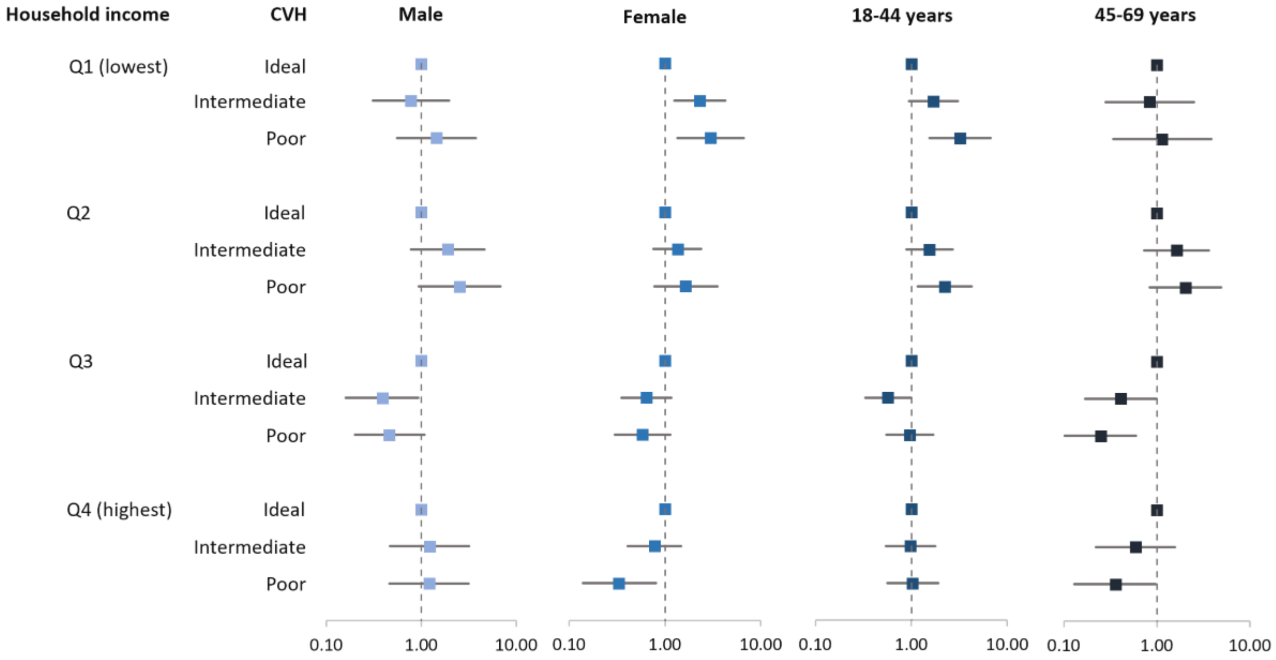


Figure 3. Results of multinomial logistic regression of the association between absence of health insurance and CVH according to household income by sex and age. The reference is having health insurance. Adjusted for all other factors not involving the subgroup, including age, sex, work status, area, history of myocardial infarction or stroke, use of aspirin, and use of statin were adjusted. CVH: cardiovascular health.

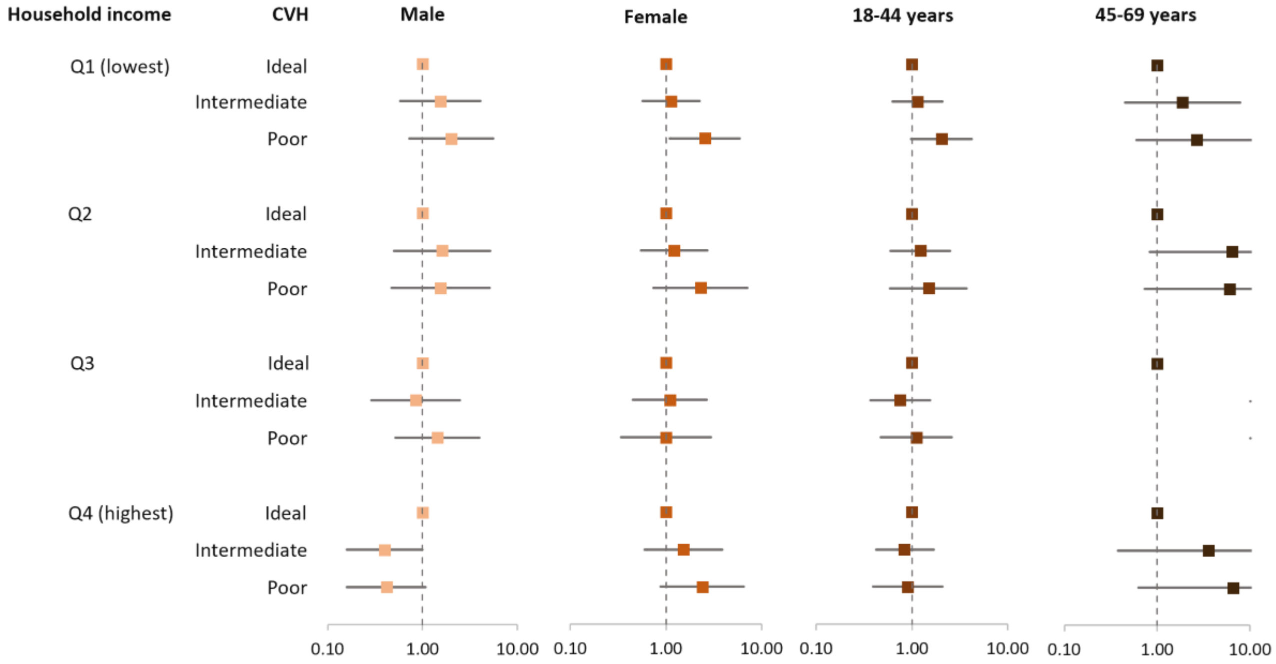

Discussion

Principal Findings

For all participants, having less education or no health insurance was not associated with CVH; however, stratified analyses by monthly household income quartiles showed that having less education or no health insurance was associated with poor CVH in the lowest household income groups. These CVH disparities were more pronounced among female individuals and young adults. This study contributes to establishing policies implementation that reduces the disparity of CVH, the most notable cause of disease burden, by presenting the basis for prioritizing a vulnerable population. For example, health service delivery guidelines should include consideration of the link between SDH and CVD, and training for health care providers should emphasize this. Low levels of education may be associated with low levels of health literacy for CVD prevention and management practices [24,25]. Therefore, health care providers should assess the health literacy levels of their target population and provide interventions that take this into account.

There was a gap in the prevalence of CVD risk factors according to the WHO region or income level; Mongolia is a country with a high prevalence of CVD risk factors [26]. For example, nonelevated blood pressure, one of the tracer indicators for calculating the universal health coverage service coverage index, was 29, indicating the low coverage of blood pressure management in Mongolia [26]. Further, the linear trends in cardiovascular risk factors such as smoking, obesity, and elevated blood pressure among Mongolian adults are all projected to be significantly higher than the global target by 2025 [27]. Thus, there is a need for the adoption and dissemination of cardiovascular risk-factor management guidelines. The WHO-initiated STEPS in 2002 is practical and helpful in monitoring the status of CVH and can identify the achievement rate for each cardiovascular risk factor, thereby aiding the formulation of effective health policies for managing risk factors at a country level [16]. Establishing a high-vulnerability priority population in population health is essential for ensuring universal health in which no one is excluded.

The association between education level and CVH is inconsistent in previous studies. A cross-sectional study of 7771 nationally representative participants aged ≥25 years in the United States reported that participants with at least a college degree were 4.12 times more likely to have ideal CVH status than participants with less than a high school education [28]. However, a recent cross-sectional study of 1634 Asian American adults aged ≥20 years in the United States revealed that low educational attainment was associated with a low likelihood of having ideal CVH compared to high educational attainment after adjusting for age and sex; however, this association became nonsignificant after additionally adjusting for income category and nativity status [26]. Further studies are needed to comprehensively understand the relationship between educational attainment and CVH in the contexts of including other SDH, such as income and race, for health equity in populations that are vulnerable to CVH problems.

Mongolia implemented a social health insurance system in 1994 to maintain equity in access to health care. Consequently, 95.6% of the population has been covered by social health insurance since 2017 [29,30]. Despite this high health insurance coverage rate, health expenses are significantly related to poverty in Mongolia, with pronounced consequences in households with patients with NCD [31]. Our study also showed that the population without health insurance had a higher risk of poor CVH status in the lowest income group than in the higher income groups, which is consistent with the previous study [32].

In this study, the CVH disparities according to SDH were predominant in female individuals and young adults. Mongolia is ranked 69th out of 156 countries in the global gender gap index, and the score of estimated earned income among the subitems measuring this index was 0.67 (0.00=imparity, 1.00=parity) [33]. Numerous previous studies support the sex differences in cardiovascular risk factors and diseases [34-36]. Our study revealed that low education level or lack of health insurance contributed more to poor CVH, especially among low-income female individuals. Furthermore, a history of CVD in Mongolians currently appears in relatively young population groups; an increase in CVD at a young age is a remarkable health issue [5]. Therefore, efforts to promote CVH that consider sex and age, such as interventions for modifying CVH for young adults or creating strategies that target gender equality, might be needed to achieve health equity in Mongolia. In countries with limited universal health coverage such as Mongolia, a strategy of using text messages to target younger populations may be useful in managing hypertension to prevent CVD, as identified in a previous research review [37].

The strength of this study was that, to the best of our knowledge, this study is the first to identify the sex and age differences in the association between SDH and CVH according to income among Mongolian adults. Further, we used nationally representative Mongolian data to minimize external validity threats.

Limitations

This study has some limitations. First, it is possible that participants who had less than 12 years of education but completed all public education courses were grouped together with those who did not complete public education courses. This can be attributed to the gradual change of public education in Mongolia from 10 years in 2004 to 12 years in 2013. Thus, we performed the sensitivity analysis by dividing the education level based on 11 years and confirmed that the results were similar to our primary results. Second, we measured salt consumption as the diet component of CVH, which is not a guideline in Life’s Simple 7. Third, there is a possibility of misclassification of self-reported variables. Fourth, we used the most recent fourth survey to determine the latest findings on the association between SDH and CVH. The STEPS Mongolia cross-sectional survey began in 2005 and has been conducted 4 times every 4 to 6 years. Further research is needed to identify trends in CVH following structural SDH in order to prioritize risk factors that have not been improved over time. Fifth, the STEPS data did not provide information on individual residence, limiting our ability to determine the impact of residence on health. Although we found that living in a rural area was associated with lower CVH compared with urban area, we suggest including variables related to residence because even within the same rural area, there may be differences in the environment in which people live (Table S5 in Multimedia Appendix 1). Lastly, although we adjusted potential cofounders, there might still be a chance of residual confounding we did not control for.

Conclusions

In conclusion, we confirmed that in Mongolia, where universal health coverage is low, the population group that has low structural socioeconomic levels and health care coverage is more vulnerable to CVH problems. As in other low-income countries, female individuals are more vulnerable to poor CVH than male individuals, suggesting that this vulnerability can only be improved when fundamental problems such as structural health determinants are addressed. Strategies and interventions aimed at reducing the CVH disparity in the Mongolian population should be prioritized for female individuals and young adults (aged 18-44 years) with low socioeconomic status and without health insurance.

Acknowledgments

This paper uses data from the Mongolia 2019 STEPwise approach to noncommunicable disease risk-factor surveillance survey, implemented by the Minister of Health, Mongolia, with the support of the World Health Organization. This research was supported by the Brain Korea 21 FOUR Project funded by National Research Foundation of Kora, Yonsei University College of Nursing.

Data Availability

The data sets generated or analyzed during this study are available in The World Health Organization noncommunicable disease microdata repository (World Health Organization, June 20, 2023, STEPwise approach to noncommunicable disease risk-factor surveillance 2019 Mongolia).

Abstract

Background: The World Health Organization has proposed a worldwide target of eliminating hepatitis C virus (HCV) by 2030. A better understanding of HCV, testing behaviors, and associated factors in the general population is essential.

Objective: This study aimed to assess HCV knowledge, self-reported HCV testing behavior, and willingness to undergo HCV screening in the general Chinese population.

Methods: A cross-sectional online survey of the general Chinese population aged ≥15 years was conducted from November 2021 to May 2023. Participant characteristics were assessed based on their knowledge level and uptake of HCV testing. Participants ever having heard of HCV were recognized as being aware of HCV and asked additional HCV knowledge questions using a brief, validated 9-item scale. Participants with 0-3 points and who were unaware of HCV were categorized as having poor knowledge, and those with 4-6 points and ≥7 points were categorized as having fair and good knowledge, respectively. Participant uptake of HCV testing, testing results, reasons for undergoing or not undergoing HCV testing, and willingness to undergo HCV screening were collected through self-reports. Ordinal and binary logistic regression analyses were used to assess factors associated with the HCV knowledge level and the uptake of HCV testing, respectively.

Results: A total of 1491 valid participants' questionnaires were included. Of these, 714 (47.6%) participants were aware of HCV. The proportion of participants with poor, fair, and good HCV knowledge was 63.4% (945/1491), 9.3% (139/1491), and 27.3% (407/1491), respectively. A total of 465 (31.2%) participants reported ever undergoing HCV testing, and 4 (0.9%) were anti-HCV antibody positive. Most participants were tested for HCV following blood donation (353/465, 75.9%). The most common reasons for not undergoing HCV screening were a lack of HCV awareness (665/1026, 64.8%), followed by a low self-perceived risk of infection (176/1026, 17.2%). Of 1026 participants who had never undergone HCV testing, 937 (91.3%) were willing to undergo HCV screening if universal screening was provided at no cost. The HCV knowledge level was positively associated with the HCV testing rate. Participants who were less educated, lived in rural areas, resided in West China, and were currently alcohol drinkers had lower HCV knowledge and reduced odds of having undergone HCV testing. In contrast, participants with a blood donation history and a family history of hepatitis B virus or HCV infection had higher HCV knowledge and increased odds of prior testing. Participants aged ≥60 years had lower knowledge, and women had reduced odds of having undergone previous HCV testing.

Conclusions: The general population of China has low HCV knowledge and testing rate. There is an urgent need for enhanced HCV awareness and scaled-up HCV screening and treatment. Individuals who are less well educated, reside in less-developed areas, currently drink alcohol, and are female should be prioritized for health education and interventions.

Introduction

Hepatitis C virus (HCV) infection is a major cause of acute and chronic liver diseases (eg, liver cirrhosis and hepatocellular carcinoma) worldwide and is linked to an estimated 29,000 deaths each year [1]. About 58 million people have HCV, with approximately 1.5 million new infections occurring annually [1]. China has the largest number of patients with HCV infection, accounting for approximately 14% of worldwide HCV infections [2,3].

In 2016, the World Health Organization (WHO) responded to the high worldwide burden of HCV by aiming to reduce new infections by 80% and deaths by 65% by 2030 [4]. Given the lack of an effective vaccine, WHO prioritized improving HCV knowledge and scaling up screening, care, and treatment to meet its targets. Adequate HCV knowledge is critical for the prevention of HCV infection and transmission and for individuals to seek appropriate testing, care, and treatment [5]. In China, studies have explored HCV knowledge among groups at high risk of HCV infection and transmission, including people receiving methadone maintenance treatment (MMT) [6] and men who have sex with men (MSM) [7]. However, no studies have assessed HCV knowledge in the general population. Although most new HCV infections are among high-risk groups, many people are either not aware of or refuse to report risk behaviors because of potential discrimination and therefore remain hidden in the general population. This puts additional people at risk of HCV exposure through contaminated blood, unsafe sexual contact, and mother-to-child transmission [8,9]. A meta-analysis found that the national prevalence of HCV infection in the general Chinese population was about 0.91% [10], constituting a large subgroup with the ability to further spread HCV. Thus, an assessment of HCV knowledge and associated factors in the general Chinese population is important to inform HCV elimination plans.

Scaling up screening, care, and treatment is also critical to achieve WHO targets. People with HCV infection can be easily screened with an anti-HCV antibody test, and more than 95% of these individuals can be cured using highly effective oral direct acting antiviral (DAA) treatment regimens [11]. In China, DAAs have been approved for use against HCV infection since 2017 and have been listed in the medical insurance directory since 2020. However, because HCV is often asymptomatic, only 18% of people with HCV infection are diagnosed, leading to a low treatment rate [12]. As a result, a low HCV testing rate is the main barrier to HCV elimination. In China, HCV screening is primarily limited to high-risk groups [13]. Economic analyses have revealed that screening alongside DAA treatment is cost-effective for both the high-risk population and the general population [14-17]. Thus, this strategy may be necessary to achieve the WHO target. However, there is a lack of information about HCV testing behavior and willingness to undergo HCV screening in the general Chinese population.

This study was conducted to assess HCV knowledge, self-reported HCV testing behavior, and willingness to undergo HCV screening in the general Chinese population to inform policy decision-making aimed at eliminating HCV. The characteristics of patients who have less knowledge and are less likely to undergo testing were also explored.

Methods

Design and Setting

A cross-sectional, online survey was conducted in China from November 2021 to May 2023. The convenience sampling method was used to recruit participants. Individuals who lived in China and were ≥15 years of age were eligible for the study. Those who were health care workers, including physicians, nurses, nurse assistants, pharmacists and pharmacy technicians, radiographers, community health workers, health officers, hospital orderlies, and other health care professionals, or health care students, were excluded.

Participant Characteristics

The following information was collected: (1) sociodemographic characteristics, including age, gender, marital status (married, single/divorced/widowed), years of education (<7 years, 7-12 years, >12 years), ethnicity (Han, minority), occupation (student, not working/unemployed, others), residence (rural, urban), and geographic region (east, central, west) [17]; (2) behavioral characteristics, including alcohol consumption (never, current, ever) and history of blood donation (yes, no); and (3) family history of hepatitis B virus (HBV) or HCV (yes, no) infection.

HCV Knowledge

Initially, awareness of HCV was determined based on participant responses to the following question: “Have you ever heard of hepatitis C disease or hepatitis C virus (HCV)?” Individuals who replied yes were considered as being aware of HCV and asked additional questions to assess the depth of their HCV knowledge based on surveys conducted previously [18,19]. After meeting the standards for reliability and validity, a brief 9-item scale including questions about the nature of hepatitis C disease and modes of transmission was developed for this study. Correct answers scored 1, and incorrect or “don’t know” answers scored 0. Overall HCV knowledge scores ranged from 0 to 9. Participants were categorized into 3 groups based on their knowledge scores. Those scoring 0-3 points were categorized as having poor knowledge, those scoring 4-6 points were categorized as having fair knowledge, and those scoring 7-9 points were categorized as having good knowledge of HCV. Participants who had never heard of hepatitis C disease or HCV were recognized as being unaware of HCV and categorized as having poor knowledge.

Participant HCV Testing Behavior and Willingness to Undergo HCV Screening

Participant uptake of HCV testing, testing results, reasons for undergoing or not undergoing HCV testing, and willingness to undergo HCV screening were collected through self-reports.

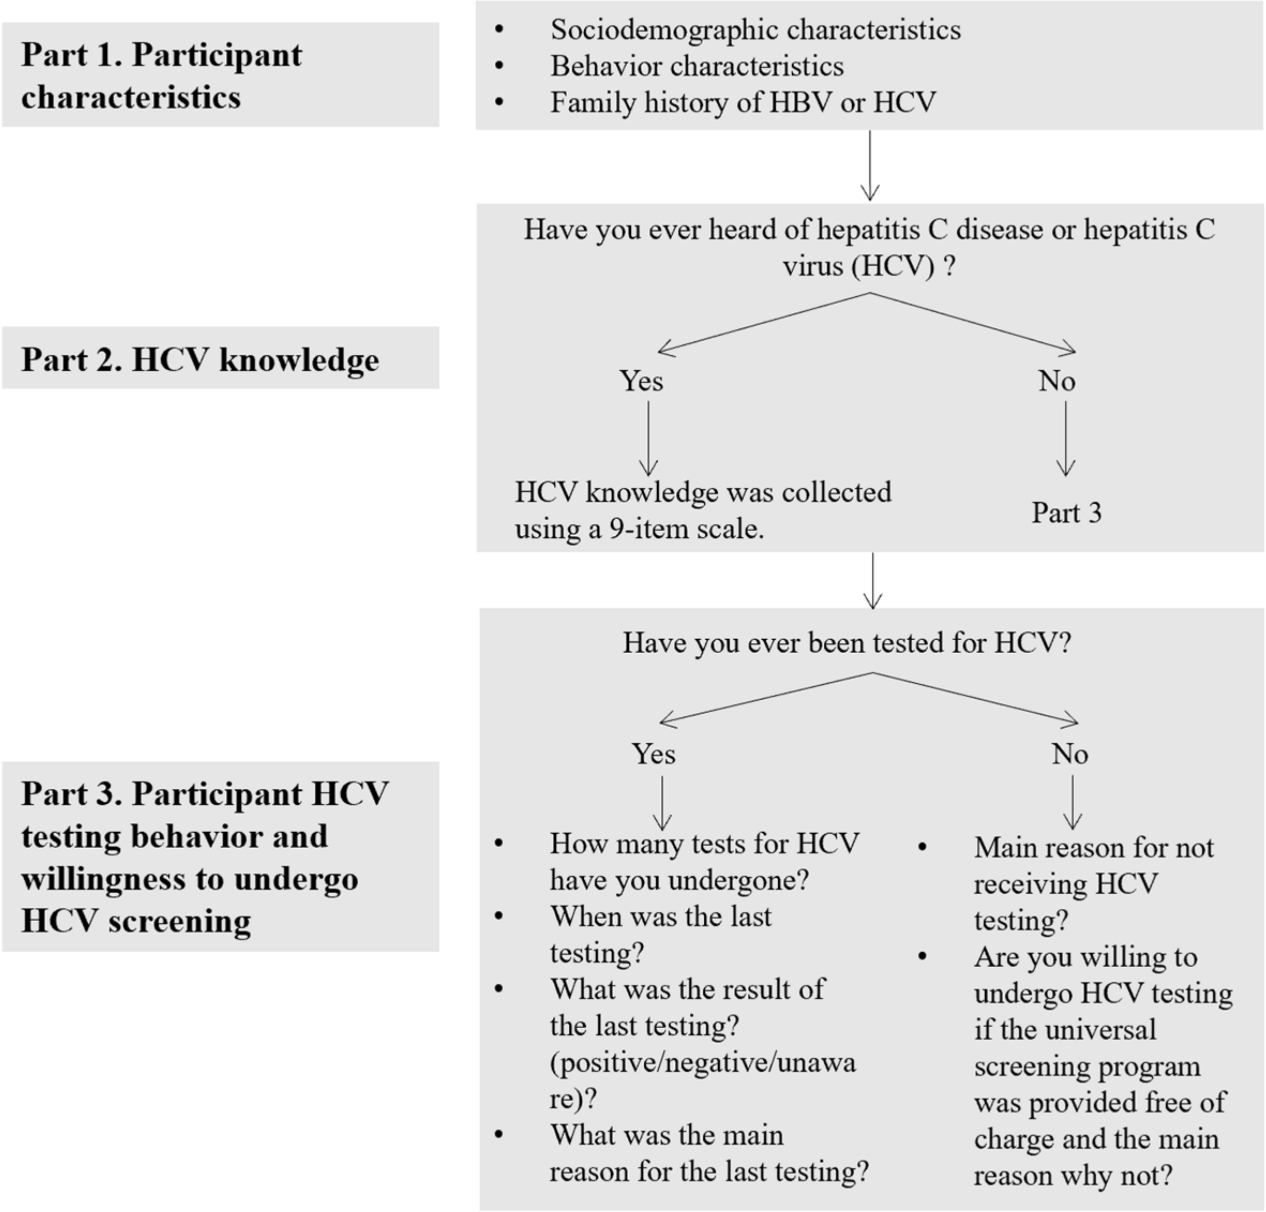
The uptake of HCV testing was determined from responses to the following question: “Have you ever been tested for HCV? (yes/no)”. Participants who reported yes were asked the following questions: “How many tests for HCV have you undergone?,” “When was the last testing?,” “What was the result of the last testing? (positive/negative/unaware),” and “What was the reason for the last testing?” Participants who reported no were further asked about their main reason for not undergoing HCV testing and whether they were willing to undergo HCV testing if universal screening was provided free of charge. Those not willing to undergo screening were asked to provide the main reason why not.

In China, potential blood donors are required to undergo HCV testing since 1993 [20]. All participants in this study with a history of blood donation after 1993 were informed in advance about undergoing HCV testing in order to reduce any self-reporting biases.

Data Collection

WeChat and Weibo were the primary method of recruiting eligible participants. An anonymous, self-administered questionnaire was developed that comprised 3 parts. The structure of the questionnaire is shown in Figure 1. Wenjuanxing, the most popular social media platform in China, was used to disseminate the electronic questionnaire.

Figure 1. The structure of the questionnaire. HCV: hepatitis C virus.



Sample Size

The level of HCV knowledge (poor, fair, good) was used as the main outcome to evaluate the sample size, and the following formula was used to determine the multinomial proportions [21]:

It was assumed that the proportion of participants with poor knowledge (p_1), fair knowledge (p_2), and good knowledge (p_3) was 60%, 15%, and 25%, respectively; the confidence level ($1 - \alpha$) was 95%, and precision (d) was 5%. Thus, the target sample size was calculated as 551 respondents. Considering a nonresponse rate of 10%, it was determined that at least 613 participants should be enrolled in the study.

Statistical Analysis

The data collected in Wenjuanxing were exported into Microsoft Excel and then imported into SAS V9.4 for data analysis. The reliability and validity of the HCV knowledge scale were determined. The Cronbach coefficient was calculated to determine reliability. The average variance extracted (AVE) and composite reliability (CR) were calculated for convergent validity. The square roots of the AVE and the absolute values of correlation coefficients between factors were measured for discriminant validity. Confirmatory factor analysis (CFA) was performed for the goodness of fit.

Mean (SD) values were used for normally distributed continuous variables, and medians, the first quartile (Q1), and the third quartile (Q3) were used for nonnormally distributed continuous variables. The frequency distribution and percentage were used to describe categorical variables.

Factors independently associated with HCV knowledge were assessed using univariate and multivariate ordinal logistic regression analyses, with the HCV knowledge level (poor, fair, good) as the dependent variable and participant characteristics as potential independent variables. The proportional odds assumption was assessed, with $P>.05$ being considered statistically significant. Factors independently associated with the uptake of HCV testing were assessed using univariate and multivariate binary logistic regression analyses, with the uptake of HCV testing (yes, no) as the dependent variable and participant characteristics as potential independent variables. A correlation matrix was used to exclude the confounding variables with strong collinearity. Variables with $P<.1$ in univariate models were used in multivariate regression models. Statistical significance was set as $P<.05$. A crude odds ratio (cOR) with 95% CI was reported for univariate models, and an adjusted odds ratio (aOR) with 95% CI wAs reported for multivariate models. Sensitivity analyses were conducted by limiting the data set to participants without a history of blood donation to control for the impact of blood donation on HCV testing behavior.

Ethical Considerations

Ethical approval was obtained from Henan Cancer Hospital (2023-KY-0139). The electronic questionnaire was written in standard Chinese. The participants received a cover letter informing them of the study aims and procedures and that their participation was anonymous and voluntary. It was assumed that individuals who completed the survey had read the cover letter and consented to participate. To ensure the effectiveness of data collection, participants were required to answer a question to receive the next question. All completed questionnaires were kept private and were accessible only to the study staff responsible for data analysis.

Results

Participant Characteristics

A total of 1929 complete questionnaires were obtained, and after excluding those from health care workers or health care students, 1491 (77.3%) participants from 26 provinces were included in the final analysis. The geographical distribution of the included participants is shown in Figure S1 in Multimedia Appendix 1. Characteristics of the included participants are shown in Table 1. Of the 1491 participants, 476 (31.9%), 364 (24.4%), and 651 (43.7%) were from East, West, and Central China, respectively. In total, the average age of the participants was 41.4 (SD 15.4) years. Slightly over half of the participants were female (n=819, 54.9%) and located in urban areas (n=843, 56.5%). Most participants were married (n=1060, 71.1%), educated for >7 years (n=1160, 77.8%), of Han nationality (n=1405, 94.2%), and employed/self-employed (n=1286, 86.3%). About 26.4% (n=394) of the participants currently drank alcohol, 25.3% (n=377) had ever donated blood, and 12.4% (n=185) had a family history of HBV or HCV.

Table 1. Characteristics of the included participants (N=1491).

Characteristics	Total	East China	West China	Central China
Age (years)				
<60, n (%)	1230 (82.5)	433 (91.0)	310 (85.2)	487 (74.8)

[b] HCV: hepatitis C virus.

Reliability and Validity of the HCV Knowledge Scale

The HCV knowledge scale was found to have good reliability and validity. The total Cronbach coefficient was 0.941(95% CI 0.936-0.945) and the Cronbach coefficients of disease nature and modes of transmission were 0.824 (95% CI 0.798-0.848), and 0.932 (95% CI 0.927-0.937), respectively.

The factor loading of each item of disease nature and modes of transmission was 0.779-0.985 and 0.648-0.967, respectively. The AVE values of the 2 factors were 0.514 and 0.640, respectively, and the CR values were all >0.7, demonstrating strong convergent validity of the questionnaire constructs (Table 2).

Table 2. Factor loading of each item and convergent validity and composite reliability measurement results.

Construct and item	Factor loading
Disease nature (AVE[a]=0.514, CR[b]=0.769)	
HCV[c] infection is usually asymptomatic and must be detected with testing.	0.822
Chronic HCV infection may develop into cirrhosis and liver cancer.	0.985
Hepatitis C can be cured.	0.779
Modes of transmission (AVE=0.640, CR=0.923)	
Can HCV be transmitted via kissing a person with HCV infection?	0.697
Can HCV be transmitted by sharing water and food with people with HCV infection?	0.648
Sexual contact with multiple partners will increase the risk of HCV transmission.	0.707
Can HCV be transmitted during pregnancy or birth in the case of a mother with HCV infection?	0.914
Can HCV be transmitted by using unsterilized syringes, needles, or surgical instruments?	0.967
Can HCV be transmitted by getting a tattoo/piercing?	0.768

[a] AVE: average variance extracted.

[b] CR: composite reliability.

[c] HCV: hepatitis C virus.

The square roots of the AVE values were higher than the absolute values of the correlation coefficients between the disease nature and modes of transmission, indicating that the questionnaire had good discriminant validity (Table 3).

CFA results indicated that the 2-factor model with 9 items had a good fit: root mean square error of approximation (RMSEA)=0.034, comparative fit index (CFI)=0.953, Tucker-Lewis index (TLI)=0.954, and standardized root mean square residual (SRMR)=0.093.

Table 3. Correlation matrix of disease nature and modes of transmission.

Construct	Disease nature	Modes of transmission
Disease nature	0.717[a]	N/A[b]
Modes of transmission	0.675[c]	0.800[a]

[a] Square roots of the average variance extracted (AVE).

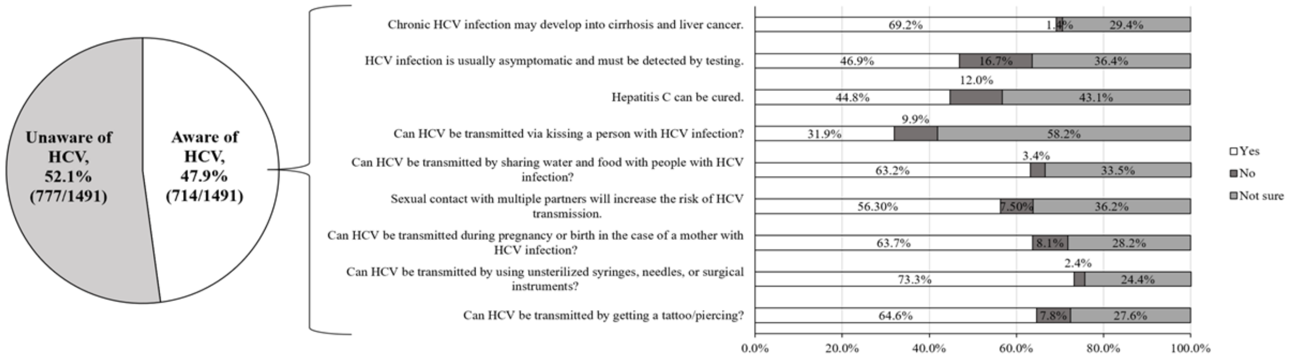
[b] N/A: not applicable.

[c] *P*<.05.

Participant Knowledge of HCV

Less than half (714/1491, 47.9%) of the participants were aware of HCV. Of these, the proportions of participants who correctly answered the items related to disease nature ranged from 44.8% (320/714) to 69.2% (494/714) and of those who correctly answered the items related to modes of transmission ranged from 33.5% (239/714) to 73.3% (523/714). A detailed description of each item is presented in Figure 2.

Figure 2. Awareness of HCV and knowledge regarding hepatitis C disease's nature and modes of transmission. HCV: hepatitis C virus.



Participants who were unaware of HCV were regarded as having poor knowledge. Overall, the proportion of participants who had poor, fair, and good knowledge was 63.4% (945/1491), 9.3% (139/1491), and 27.3% (407/1491), respectively.

Participant HCV Testing Behavior and Willingness to Undergo HCV Screening

A total of 465 (31.2%) participants had ever undergone HCV testing. Of these, 4 (0.9%) were anti-HCV antibody positive and 288 (61.9%) were unaware of their results. Most participants underwent 1-time testing (419/465, 90.1%) and had undergone their last HCV test at a median of 16.0 (Q1, Q3: 10.0, 63.0) months previously.

The reasons for the last testing are shown in Figure 3. Most participants (353/465, 75.9%) were tested for HCV following blood donation, 13.1% (61/465) were tested during a routine health exam, and 6.7% (31/465) were tested due to a concern about being infected.

Figure 3. Participants' reasons for undergoing their last HCV test. HCV: hepatitis C virus.
