To investigate the potential change in vaccine misinformation in terms of its types, contents, prevalence, and impact, we used 2 key time points to define 3 phases in this review: prevaccination phase (phase 1), from the outbreak of COVID-19 to the first dose of COVID-19 vaccines being injected at December 8, 2020 [22]; postvaccination and pre-Omicron phase (phase 2), from the end of phase 1 to the date that the new variant Omicron was officially reported (November 26, 2021) [23]; post-Omicron phase (phase 3), after November 26, 2021. If the time frame in data collection covered the time point and the ending/beginning date was not close to the time point (over 1 month), the study phase was considered to have crossed 2 phases.

Framework of Classifying Misinformation Types and Contents

Like the identification process of misinformation-related keywords, we first adapted the codebook by Kata [10] to construct a framework to classify the types and contents of COVID-19 vaccine misinformation. To cover the emerging and evolving COVID-19 vaccine infodemic, we further referred to the CDC fact sheet to revise the framework [21]. Our primary framework consisted of main classifications and contents from Kata's work as well as contents from the CDC fact sheet. New types or contents of misinformation may have occurred when we extracted data from the included studies, and would be considered to finalize our framework. The original misinformation contents extracted from articles were rechecked using the final framework. Discrepancies in misinformation classification were discussed and reconciled.

Framework of Solutions for Combating Misinformation

For clarity and consistency in data extraction, we sorted solutions for combating misinformation into a 5-step framework, which was adapted from the disinfodemic policy brief by the United Nations Educational, Scientific and Cultural Organization (UNESCO) [24]. In this policy brief, solutions to debunk the misinformation consisted of 4-part responses: identifying misinformation, regulating producers and distributors, cutting production and distribution, and supporting the target audiences of misinformation. As the dissemination of trustworthy information deserved more attention, it was added as the fifth part of the framework.

Quality Assessment

As study designs varied across eligible studies, we used 3 kinds of quality assessment tools to assess their quality. The Appraisal tool for Cross-Sectional Studies (AXIS) was used to evaluate survey-based cross-sectional studies, and its modified version was applied to assess internet-based studies [25]. The version 2 of the Cochrane risk-of-bias tool for randomized trials (RoB 2) tool and the Critical Appraisal Skills Programme Checklist were used to assess methodological quality in experimental studies and interviews, respectively [26,27]. Quality assessment was conducted by 2 reviewers (SH and SZ), and the risk of bias for each eligible study was classified as "low risk," "some concerns," or "high risk." The detailed scoring criteria of quality assessment are shown in Multimedia Appendix 3.

Patient and Public Involvement

Patients or the public were not involved in the design, or conduct, or reporting, or dissemination plans of our research.

Ethical Approval

Ethical approval was waived as this is a secondary analysis on the published articles.

Results

Basic Characteristics of Included Studies

In total, we identified 23,398 studies from 5 peer-reviewed databases (Figure 1). After removing duplicates, 8864 studies were initially screened based on their titles and abstracts, and after initial screening, 313 studies underwent full-text assessment for eligibility. A total of 102 studies met the inclusion criteria, including 91 observational studies and 11 interventional studies. According to the quality assessment criteria, the majority (90/102) of included studies were in the low risk of bias category. Eight studies were classified as “some concerns” and 4 were classified as “high risk.” The basic characteristics of included studies are presented in Table 1, and further details about each study are listed in Multimedia Appendix 4 (see also [28-71]).

Among the 91 observational studies, 38 conducted surveys, 42 analyzed data from the internet, 10 used interviews, and the remaining 1 performed mixed methods of cross-sectional survey and interview. In terms of study region, the American region was the most studied (n=25), followed by the European (n=19) and Eastern Mediterranean (n=11) regions. By contrast, the African (n=6), South-East Asian (n=5), and Western Pacific (n=4) regions were the less investigated.

According to the prior defined attitudes toward COVID-19 vaccines in study populations, survey- and internet-based studies can be divided into the following: survey-based study on general population (n=31), survey-based study on antivaccine/vaccine hesitant population (n=4), internet-based study on general online data (n=22), and internet-based study on antivaccine/vaccine hesitant data (n=19). A total of 3 survey-based studies and 1 internet-based study reported results from both general population/data and antivaccine/vaccine hesitant population/data.

Online article database	1
Multiple platforms[f]	1

[a] Study phase was defined as follows: phase 1, from November 2019 to December 8, 2020; phase 2, from December 8, 2020, to November 26, 2021; phase 3 from November 26, 2021, to the latest ending date of data collection in included studies.

[b] Studies covering worldwide, including internet-based study with no limit in data collection (n=24), and survey-based study in multiple countries (n=2).

[c] Studies covering more than 1 region: 3 studies on American, European, and Western Pacific regions; and another 3 on American and European regions.

[d] Study populations differ by their prior defined attitudes toward COVID-19 vaccines: studies reporting misinformation among the vaccine hesitancy or refusal group (“antivaccine/vaccine hesitant group” and “antivaccine/vaccine hesitant data” in the table), and studies which did not prior define the vaccine hesitancy or refusal group (“general population” and “general online data” in the table).

[e] Multiple social media platforms in 3 studies [28,72,73] were Facebook, Instagram, and Twitter; Instagram and Facebook; and YouTube, Twitter, Facebook, and Instagram.

[f] Multiple platforms included Google, Google Fact Check, Facebook, YouTube, Twitter, fact-checking agency websites, and websites of television and newspaper.

Most internet-based studies used social media platforms as data source, of which the most frequently discussed was Twitter (n=20), followed by YouTube (n=5), Facebook (n=4), TikTok (n=1), and Parler (n=1). Besides social media, 4 studies used general internet information, such as Google and online news database, as data source. A total of 4 studies used data from multiple platforms or multiple social media. Most internet-based studies did not limit the region of data source (n=24). Among those internet-based studies reporting study regions, the Americas (n=8) and Europe (n=6) were more commonly addressed, whereas the Western Pacific (n=2), Eastern Mediterranean (n=1), Africa (n=1) were less studied, leaving no internet-based study in South-East Asia. Most internet-based studies analyzed information written in English (n=33), whereas non-English information were less studied: 3 for Spanish, 2 for Arabic, 1 for both English and Spanish together, and 1 each for Chinese, Italian, and Turkish.

Types, Sources, and Prevalence of Misinformation

About 90% (91/102, 89.2%) of studies mentioned the types of COVID-19 vaccine–related misinformation. Using the coding framework mentioned in the “Methods” section, we divided vaccine-related misinformation into 7 types: conspiracy, concerns on vaccine safety and efficacy, no need for vaccines, morality, liberty, humor, and overstatement. We further divided these types into 54 different contents (Table 2). Conspiracy, being discussed in 77 studies, was the most commonly studied misinformation, and it could be further specified as vaccine existence conspiracy, political conspiracy, vaccine development and promotion conspiracy, and conspiracy related to a certain group. Concerns on vaccine safety and efficacy, emphasizing the unsubstantiated concerns on safety and efficacy, were the secondary most studied misinformation (n=63). Misinformation about the necessity of vaccines (no need for vaccines) was found in 23 studies, and its subtypes included simple claims such as vaccines are unnecessary, preference of natural immunity and protective behavior, claims about mild COVID-19, COVID-19 denial, underestimation of personal need, and overstatement of vaccine refusal. Misinformation on morality and liberty was found in 15 and 13 studies, respectively; 2 studies investigated humor and another 2 found the overstatement on the effect of COVID-19 vaccines.

Vaccine-related misinformation changed in its contents over time. We compared the misinformation among 3 phases, and found that some conspiracy theories and concerns on vaccine safety circulated in all 3 phases: depopulation, control people, microchip for monitor/control, and financial incentives behind vaccine development in terms of conspiracy; vaccines would alter DNA, and cause fertility, death, or other diseases; the worry of no one would be responsible for potential side effects; beliefs in alternatives such as natural immunity and protection behaviors; referring to vaccines as immoral human experiments and comprising fetal tissue; and individual freedom. Meanwhile, there were emerging and disappearing topics on misinformation. The claims that vaccines were a hoax/fraud only appeared in phase 1. With the progress of COVID-19 vaccination, especially after the massive immunization (phase 2), misinformation about registration (false claims that some vaccines were rejected), against government control (such as fake news that some government will make COVID-19 vaccination mandatory), and conspiracy about vaccine promotion (claims that physicians or people will get financial benefit through promoting vaccination, and that the news about celebrities getting vaccinated are fake: they did not really get vaccinated; rather, they were injected with saline) emerged.

Table 2. Types and contents of COVID-19 vaccine–related misinformation.

Type of misinformation and subtype	Explanation	Contents
Conspiracy		
Vaccine existence conspiracy	Conspiracy about the existence of COVID-19 vaccines	• No vaccine: COVID-19 vaccines are a conspiracy, hoax, or fraud.
Political conspiracy	Conspiracy about political purpose related to the vaccines	• Device for track/control: Vaccines contain microchip/nanochips and are used for tracking or control people. • Population control and new world order: The vaccines are used for the control of population or to create new world order. • Depopulation: Vaccines are used for reducing population or for genocide. • Bioweapon: Vaccines are a bioweapon. • Other conspiracy to a certain subject: Certain people or groups are behind the vaccines for their own good, such as government officials, pharmacy company, Bill Gates.
Vaccine development and promotion conspiracy	Conspiracy about COVID-19 in vaccine development and vaccination promotion	• COVID-19 for vaccines: COVID-19 vaccines existed before the virus, or COVID-19 was made to enforce vaccination. • Financial incentive in developing: Vaccines are created only for the profit of pharmaceutical companies and government. • Political incentive in developing: Vaccines are approved because of political pressure, or because pharmaceutical company has bought/coerced the government. • No enough evidence: Vaccines are untested or not tested enough. • Rush in development: Vaccines are rushed in development, thus cannot be trusted. • Fabricated vaccine efficacy: Data on vaccine efficacy/effectiveness are fabricated. • Cover-up side effect data: Data about the vaccine side effect or death are kept secret. • Rejection in registration: Vaccines (which are approved in fact) are rejected in registration for concern. • Paid for promotion: Physicians issue vaccines for financial profit. • Playacting in promotion: Public figures are vaccinated with inert substances (eg, saline).
Conspiracy related to a certain group	The conspiracy that vaccines will be harmful, used to control, or be tested in a specific group	• Conspiracy of a certain country/region: People in certain country or region are guinea pigs. Vaccines are less effective or is fake in these regions. (eg, African region, Muslim nations). • Conspiracy of ethnic minorities: Vaccines are harmful or for killing ethnic minorities; ethnic minorities are guinea pigs (eg, Asian, Black people). • Conspiracy of other certain groups: Vaccines are used to reduce these people (eg, elder people, less educated people, low-income group).
Concerns on vaccine safety and efficacy		
Effectiveness	Beliefs that vaccines are ineffective	• Vaccines would not work: Vaccines will not work (a simple claim without further explanation). • Ineffective in certain groups: Vaccines will not be effective on people with comorbidities such as diabetes, hypertension. • Ineffective claim from authority: Government officers or doctors admit vaccines would not work. • New strain for cover-up: The new variant of COVID-19 is a hoax and is a cover-up for ineffectiveness of the vaccines. • Fake vaccines: Vaccines are water. • Same as other vaccines: COVID-9 vaccines are no different from the flu vaccine. • Fail before vaccination: Vaccines cannot be preserved properly.

Type of misinformation and subtype	Explanation	Contents
Safety	Unsubstantiated safety concern	• Cause COVID-19: Vaccines will make people catch COVID-19. • Worse than COVID-19: Vaccines are more dangerous than the disease itself. • Alter DNA: Vaccines will change people’s DNA. • Infertility and offspring: Vaccines will make women infertile or affect their offspring. • Cause death: Vaccines kill people. • Cause other diseases: Vaccines make people get chronic disease, autism, autoimmune disease, paralysis, cancer, physical destruction, impotency, etc. • Change people: Vaccines make people magnetic, or turn people into robots, vampires, zombies, etc. • Poison: Vaccines contain poisonous materials, such as mercury, toxic ingredients, chemicals. • Live virus: COVID-19 vaccines contain a “live strain” of the virus. • Unspecified danger: Vaccines are dangerous (a simple claim without further explanation). • Side effect responsibility: No one is responsible for the potential side effects of the vaccines.
No need for vaccines		
Unnecessary	A simple claim that COVID-19 vaccines are unnecessary without explanation	• Unnecessary: COVID-19 vaccines are not needed.
Natural immunity and protective behavior	Beliefs that it is better to get natural immunity or get immunity through naturally protective ways, etc.	• Alternative: Prefer or believe in natural immunity, herd immunity, or protective behaviors.
Mild COVID-19	Believe COVID is a mild disease and no need for vaccines	• Mild COVID-19: COVID-19 is not dangerous; thus, vaccines are not needed.
COVID-19 denial	Denial of COVID-19 pandemic leading to COVID-19 vaccines	• COVID-19 denial: COVID-19 is a hoax, or a fraud, thus no vaccines are needed.
Personal need	Beliefs that it is unnecessary for the vaccines because of their health status	• Underlying disease: I get autoimmune disease, thus cannot take vaccines. • Immune from infection: I am already immune from a past COVID-19 infection. • Not a risk group: I am young/healthy/a certain blood type, thus have a low risk of getting COVID-19 or developing serious disease.
Overstatement of vaccine refusal	Exaggeration about vaccine refusal rate in other places	• Refusal exaggeration: 1 in 6 people will refuse COVID-19 vaccines.
Morality		
Religion	Vaccines go against religious belief, or are viewed as a sign of demon	• Religion: Vaccines may go against religious beliefs. Devil led people to receive vaccines.
Human experiment	Vaccine campaign is a human experiment	• Human experiment: It is a part of a secret research. Vaccinated ones are guinea pigs.
Fetal tissue	Fetal remains in vaccines	• Fetal tissue: COVID-19 vaccines are made from cells of aborted fetuses.
Liberty		
Against mandatory vaccines/control	False claims about mandatory vaccination, and refusal to obey “control”	• Mandatory vaccination: They are forcing us. • Against government control: Opposition to the government’s control.
Support for freedom	Claims that vaccine infringes individual freedom	• Freedom: Vaccines are an attempt to take away personal freedom.
Ignore consent	Concerns that children will be forced to get vaccinated without parents’ consent	• Ignore consent: Children getting vaccinated without parental consent.
Humor		

Type of misinformation and subtype	Explanation	Contents
N/A[a]	A humorous but exaggerated way to express unsubstantiated vaccine rumor	- Humor: Parody/meme of an adverse reaction.
Overstatement		
Overstatement of the protection/progress of vaccines	Exaggeration about the effect and the scientific progress in COVID-19 vaccines	- Overstatement: COVID-19 vaccines are ready; able to cure a patient within 3 hours. After getting the vaccines, we will not have the infection anymore. After getting the COVID-19 vaccines, one can stop wearing the mask and taking safety precaution. As vaccines for COVID-19 have been developed, we can make vaccines for the common cold, HIV, and others.

[a] N/A: not applicable.

Eight studies surveyed the sources of misinformation. Three studies reported social media as main source [74-76]. Two studies found that family and friends also played a role [74,77]. One study measured proportions of different sources: social media (57.6%), followed by family or friends (13.1%), and television (5.7%) [74]. On social media, misinformation was generated majorly by antivaccine groups or well-known antivaccine individuals [78-80]. Two studies found that online celebrity tended to contribute more misinformation [80,81]. One Twitter-based study showed that the highly polarized antivaccine information was mainly from political and nonmedical users, while health care workers were less engaged in COVID-19 vaccine conversation on online platforms [78].

A total of 57 studies reported the prevalence of misinformation (Table 3), including 27 survey-based studies and 30 internet-based studies; further details on the prevalence reported in each study are presented in Multimedia Appendix 5 (see also [29,30,34,36,37,41-43,46-50,52-57,60,62,67,68,70,71]). Among 27 surveys, some investigated both general population and antivaccine groups. The 24 surveys on general population reported a prevalence of general misinformation ranging from 2.5% to 55.4%; concerning the prevalence of specific types of misinformation, conspiracy beliefs varied from 2.5% to 48.4%, concerns about vaccine safety and efficacy from 2.78% to 55.4%, "no need for vaccine" from 3.8% to 28.1%, morality from 1.4% to 20.6%, and liberty from 6% to 36.3%. A total of 6 surveys [29-32,76,82] on antivaccine/vaccine hesitant groups reported a higher prevalence of misinformation: conspiracy, 6.0%-22%; concerns on vaccine safety and efficacy, 12.2%-96.7%; and no need for vaccines, 6.3%-70.4%. The 96.7% prevalence rate was simply driven by 1 study [30] that reported the prevalence on concerns and no need for vaccines; after excluding this outlier, the prevalence of misinformation varied between 6.0% and 20.1%.

Among 30 internet-based studies, 16 investigated general online data and reported the prevalence of general misinformation ranging from 0.1% to 41.3%; for the prevalence of specific types of misinformation, conspiracy ranged from 5.3% to 21.7%, concerns on vaccine safety and efficacy from 0.4% to 11.1%, humor at 26%, no need for vaccines at 10.1%, and vaccine morality from 3.9% to 20.6% (Table 3). Regarding social media platforms, YouTube showed the lowest prevalence of misinformation, ranging from 1.7% to 10.7%, and the prevalence on Twitter varied from 0.4% to 56%; the prevalence of conspiracy is 3% on TikTok and 12.44%-40% on Reddit. Humor accounted for up 26% of all COVID-19 vaccine–related videos in TikTok. In addition, antivaccine/hesitant online posts from the remaining 16 internet-based studies reported a 0.5%-56% prevalence of misinformation; specifically, conspiracy ranged from 3.9% to 55.4%, concerns on vaccine safety and efficacy from 1.3% to 44.8%, no need for vaccines from 0.5% to 3.7%, morality from 2% to 10.4%, and liberty from 5% to 46%.

Some studies reported that the prevalence of misinformation fluctuated over time, and both increasing and decreasing trends were noted [83,84]. One study showed that the change in misinformation was in close association with news or events related to vaccine developments [81].

Table 3. Prevalence of COVID-19 vaccine–related misinformation.

Study design and subtype of misinformation	Study, n	Prevalence, %
Surveys on general population	24	2.5-55.4
Conspiracy	22	2.5-48.4
Concerns on vaccine safety and efficacy	12	2.78-55.4
No need for vaccines	6	3.8-28.1
Morality	2	1.4-20.6
Liberty	2	6-36.3
Surveys on the antivaccine/vaccine hesitant group	6	6.0-96.7
Conspiracy	4	6.0-22
Concerns on vaccine safety and efficacy	4	12.2-96.7
No need for vaccines	5	6.3-70.4
Internet-based studies on general online data	16	0.1-41.3
Conspiracy	8	5.3-21.7
Concerns on vaccine safety and efficacy	3	0.4-11.1
No need for vaccines	1	10.1
Morality	2	3.9-20.6
Liberty	1	41.1
Humor	1	26
Internet-based studies on antivaccine/vaccine hesitant data	15	0.5-56
Conspiracy	10	3.9-55.4
Concerns on vaccine safety and efficacy	8	1.3-44.8
No need for vaccines	3	0.5-3.7
Morality	2	2-10.4
Liberty	5	5-46

Factors That Affect Misinformation Believing and Spreading

In total, 37 articles reported factors that affected the believing and spreading of misinformation. Textbox 1 summarizes individual characteristics and information-seeking behaviors that affect (enhance or reduce) beliefs in misinformation (n=25) as well as misinformation features that promote its spread (n=14).

In terms of geographical areas, 2 studies found a relatively higher prevalence of misinformation in the United States [85,86]. Another study found that Wyoming had the highest level of misinformation in the United States [87]. Living in a village instead of a city was also found to relate to misinformation [88]. Concerning demographic factors, a younger age was found to enhance beliefs in misinformation in 5 studies [89]. The role of sex remained controversial: 5 studies found that females were more likely to accept conspiracy theories than males, while 2 studies found that males were more fragile [90-92]. In the United States, 2 studies found ethnic minorities were related to beliefs in misinformation [93,94], whereas 1 study found that Whites were more susceptible to misinformation than racial/ethnic minorities [91]. Christians or those with a higher level of religiosity were more likely to be influenced by misinformation [91].

Social economic status and occupation also affected beliefs in misinformation. Most studies documented that lower education and economic status were linked to accepting misinformation [89,90,92-100], although 1 study in African and Middle East countries indicated that individuals with higher education levels believed rumors such as changes in human genome due to vaccines [101]. Medical workers were less susceptible to misinformation than the general population in the UK and Jordan, and among medical workers, juniors were more susceptible to misinformation [94,102]. In addition, the unemployed were less likely to trust misinformation than the employed in the UK [91].

For political orientation, right-wing and conservative ideology would increase the conspiracy belief [90,97], and in the United States, Republicans were more likely to accept vaccine conspiracy than Independents [82,103,104]. For disease and migration experience, having basic diseases, no experience of COVID-19 infection or vaccination, and migration could enhance beliefs in misinformation [97,101]. For psychological status and beliefs, depression, perceived ethnic discrimination, national narcissism, and general conspiracy-mindedness were more likely to accept misinformation [93,97,105,106].

Textbox 1. Factors that affect misinformation believing and spreading.

Individual characteristics that "enhance" beliefs in misinformation

Geographic areas:

- United States
- Living in a village instead of a city

Age:

- Younger adults

Sex:

- Mixed influence

Ethnicity:

- Mixed influence in the United States

Religion:

- Christians
- Higher level of religiosity

Socioeconomic status:

- Lower education level
- Lower income
- Lower social economic status

Occupation:

- Employed people

Political orientation:

- Republicans
- Conservatives
- Far-right
- Not being affected or vaccinated

Disease experience:

- Having basic diseases

Migration experience:

- Having migration experience

Psychology status and beliefs:

- Depression
- National narcissism
- Perceived ethnic discrimination
- General conspiracy-mindedness

Information-related behaviors that "enhance" beliefs in misinformation

Source of information:

- Social media
- Conservative media
- Family and friends

Awareness of information:

- Feeling less informed about science
- Perceive higher incidence of fake news

Online posting:

- Posting more online

Individual characteristics and information-related behaviors that “reduce” beliefs in misinformation

Occupation:

- Medical workers

Channels to accessing information:

- Taking lectures about COVID-19 vaccines
- Trust celebrities for information

Features of misinformation that “promote” its spread

Type of misinformation:

- Safety concern
- Conspiracy
- Efficacy concern

Content of misinformation:

- Positive valence (positive emotion)
- Concreteness

Format of misinformation:

- Number of hashtags
- Language or format that mimics news/scientific reports

Source of misinformation:

- Antivaccine group
- Social media influencer
- Health care workers
- Unregulated bot

Platform:

- Different platforms present different misinformation
- Newer social media

The following information-seeking behaviors also enhanced beliefs in misinformation: usage of social media and conservative media [1,92,107,108], posting more online [109], feeling less informed about science [97], and trusting friends or family for COVID-19 information [91]. People who take lectures about COVID-19 vaccines or trust celebrities for COVID-19 information tended to refuse misinformation [91].

In addition, some features of misinformation promoted its spread. Safety concerns, conspiracy, and efficacy concerns were reported as the most popular misinformation types [85,110]. Misinformation posts that had a higher level of positive valence and concreteness would spread [111]. The hashtags and the language or format mimicking news/scientific reports helped misinformation spread [72,110,111]. Misinformation from antivaccine groups, social media influencers, health care workers such as Sherri Tenpenny, and unregulated bots can speed its spread [79,81,112-114]. Each social media has its prevailing misinformation topics [115], and a newer social media platform was more likely to bolster vaccine conspiracy [110].

Impact of Misinformation on Vaccine Hesitancy and Behaviors

A total of 29 studies indicated that misinformation is related to vaccine hesitancy or negative vaccine perception, and 3 experimental studies also supported this finding [75,91,116].

Misinformation would ignite concerns and fears about the safety profile of vaccines and lead to vaccine hesitancy and refusal [94]. Four studies found a negative relationship between misinformation and vaccine uptake rate [84,87,89,99]. One experimental study in the UK and United States verified that the misinformation exposure significantly reduced both intentions of self-vaccination and vaccination to protect others by around 6% [91]. Skepticism also attenuated the effect of public service messages on promoting vaccination willingness [116]. Besides vaccination behaviors, misinformation reduced the uptake of self-protection behaviors such as mask wearing, distancing, and compliance with health guidance [1,90,107].

The impacts of misinformation may change across different study phases. Impacts of misinformation on protective behaviors were mainly studied in phase 1 (n=4). One study in phase 3 showed a negative relationship between some religious beliefs on COVID-19 vaccines and protective behaviors such as masks and distancing remained [99]. After mass vaccination (phase 2), the negative impact of misinformation on vaccine uptake rate was uncovered and lasted up to phase 3. The negative association of misinformation with attitudes and intention of taking vaccines was consistent among all 3 phases.

Interventions to Address Misinformation

Overview

A total of 65 studies proposed solutions to address COVID-19 vaccine misinformation, and 9 studies assessed the effects of various interventions to combat misinformation. Table 4 summarizes the proposed solutions according to our 5-step framework and specific solutions in each study are detailed in Multimedia Appendix 6 (see also [28, 31, 32, 37-41, 43-45, 48, 50, 52, 54, 56-58, 60, 63-66]).

Table 4. Proposed solutions to address COVID-19 vaccine-related misinformation.

Framework and meaning	Detailed solutions	No. of articles	Main actors	Targets
Identifying misinformation				
Identifying misinformation through diverse channels	• Routine monitoring and fact-checking • Investigation	5	Government and health officers	Misinformation
Regulating producers and distributors				
Regulating the source of misinformation	• Legislation and national campaign	3	Political power	Sources of misinformation
Cutting production and distribution				
Cutting the circulation of misinformation	• Technical response: more effective moderation policies	5	News media, social media	Misinformation
	• Economic response: The boycott of harmful content by advertisers	1	News media, social media	Misinformation
	• Curatorial response: dissemination of truth to debunk misinformation	4	News media, social media	The public
Supporting the target audiences of misinformation				
Improving target population's health literacy and helping the public identify misinformation	• Tailored intervention to improve health literacy by suggestion, advocacy, and health education	13	Multiple	Different misinformed groups
	• Empowerment by public awareness campaigns and credibility warning labels	3	Multiple	The public
Disseminating trustworthy information				
Implementing multitiered strategies to convey the message by multiple media	N/A[a]	23	Multiple: public health agencies, medical professionals, religious leaders, etc.	The public

[a] N/A: not applicable.

Identifying Misinformation

This step contained the routine fact-check and monitoring and investigation of misinformation. A total of 7 articles emphasized that government and health officers should develop a public health surveillance system to track the emergence of misinformation and the outlets of antivaccine groups through data mining applications [97].

Regulating Producers and Distributors

Producers and distributors of misinformation need to be regulated by political power. A total of 6 articles mentioned that policy and legal actions should be implemented by the government.

Cutting Production and Distribution

This step underlined the reaction to communication platforms, including news media and social media. A total of 11 articles in our review specified this part, which consisted of technical, economic, and curatorial responses. Technical response required social media companies to build and execute more effective moderation policies, such as checking information, altering keyword searches, redirecting individuals to correct sources, banning overt conspiracy groups, and flagging or rapidly removing misinformation [104]. The economic response could be either the boycott of harmful content by advertisers or the monetization limit of the channels producing misinformation [24,108]. The curatorial response emphasized that messages should be directly debunking misinformation. The “backfire effect” (ie, factual counterargument entrenches false beliefs) was found when using debunking messages to address misinformation [117,118]. Therefore, pre-debunking message (inoculation message) before public message communication should be piloted [73,119].

Supporting the Target Audiences of Misinformation

A total of 20 studies outlined the importance of supporting the target audiences. Tailored interventions targeting different misinformed groups were considered an important approach to counter the misinformation. Empowerment of the public was recommended to improve health literacy and awareness. Public awareness campaigns were also mentioned in 2 studies [74,102].

Disseminating Trustworthy Information

This step seems similar to the curatorial response, yet it focused not only on messages that directly debunk misinformation, but also aimed to pass correct and scientific information. Most studies (n=39) mentioned or exemplified how to disseminate evidence-based information, and they recommended to mobilize trusted medical professionals and scientists to engage in social media conversation. Health care workers and public health agencies should engage in social media and learn how to produce short scientific videos [78,102,120]. Further, collaboration with social media influencers allowed a wider reach to the public [121,122]. Both social media and mass media should be utilized to spread information [123], which can express vaccine support, emphasize scientific procedure, appeal to altruism, picture the meaning and importance of vaccination, create a sense of companionship in the battle of infodemic, or encourage participation through peer pressure. Evidence-based messages should be delivered in ways understandable to individuals from a variety of socioeconomic and educational background. Therefore, youth, religious leaders, community stakeholders, faith-based organizations, and schools could be engaged to co-design culturally compelling and context-appropriate messages [85].

Although many studies proposed solutions, only 9 assessed effects of some interventions to combat misinformation. One observational study detected a limited active impact of the policies developed by Twitter [113]. Among 8 experimental studies, 4 assessed the effect of debunking message/video, 3 assessed the effect of inoculation messages, and 1 assessed the effect of warning tag/cover. All 4 experiments found that debunking message/video could reduce the belief in misinformation [118,124-126]. Yet, 1 experiment found that this effect worked well for people without strong beliefs in misinformation; when it comes to people who strongly believe in misinformation, the result became counterproductive because it may evoke small backfiring effects of vaccination intention [118]. One experiment further showed that partisans exposed to ingroup media (media held the same political preference as participants) perceived debunking messages as more credible and held higher engagement [125]. For inoculation messages, 2 experiments found that simple inoculation message/video could protect people from misinformation [119,127], while the remaining 1 found it had no significant effect, but was useful when combined with viewing or writing comments on the inoculation message [128]. In terms of warning tag/cover, interstitial warnings or cover warnings, which require individuals to click through to continue, were found to be more effective to help participants identify misinformation while warning tags showed no effect [104].

Discussion

Principal Findings

This review revealed the features, influencing factors, impacts, and solutions for COVID-19 vaccine misinformation and provided evidence to combat vaccine-related misinformation. The included articles were predominantly from American and European regions, and there was less evidence from African, South-East Asian, and Western Pacific regions. Social media was considered as the main source of COVID-19 vaccine misinformation. Conspiracy, concerns on vaccine safety and efficacy, and no need for vaccines were the most prevalent types of misinformation.

Our review documented the high but wide prevalence of COVID-19 vaccine misinformation. The great variation may be due to the ambiguity in misinformation classification and the difference across social media platforms, regions, and study participants. On social media, antivaccine or misinformation tweets accounted for 0.1%-41.3% of all vaccine-related tweets. Its prevalence varied from 2.5% to 55.4% among the general population, which was consistent with a previous review on general COVID-19 misinformation [18]. Another systematic review also illustrated that the prevalence of misinformation on general vaccines ranged from 1% to 65% on social media between 2012 and 2018 [129]. The prevalence of misinformation posed challenges to the COVID-19 vaccination. As the most prevalent type of COVID-19 vaccine misinformation, conspiracies were usually presented as half-truths, which made it hard to recognize them as misinformation. Therefore, dealing with conspiracy or skepticism should be the priority to combat the prevalent vaccine misinformation.

Social media is considered a “double-edged sword” to inform the public [7]. The endorsement of COVID-19 misinformation was strongly associated with the information sources. People who rely on print media and mainstream print were less apt to endorse COVID-19 misinformation, while the use of social media was positively associated with misperceptions regarding COVID-19 facts. In our review, as the main source of COVID-19 vaccine misinformation, social media usage was related to misinformation believing. Because of its wide usage, social media should be used to debunk misinformation and disseminate trustworthy information [121]. Public health authorities and health professionals should change their low engagement status and be more actively engaged in COVID-19 vaccine conversation on online platforms [78,120]. Social media platforms should also make rules and policies to combat misinformation [113].

The global acceptance of COVID-19 vaccine remains at a low level [2]. Misinformation is negatively associated with vaccine acceptance and self-protection behaviors. In our review, geographic areas, demographic characteristics, education, occupation, political orientation, disease and migration experience, psychological status and beliefs, and information-seeking behaviors were found to influence the believing and spreading of vaccine misinformation. However, there is less clarity on the induced pathway between these factors and misinformation. For example, the higher prevalence of COVID-19 vaccine misinformation in African and West Mediterranean regions was associated with feeling less informed, and the less informed were further linked to poor socioeconomic status, low education level, and lack of information [130]. Future research should thus focus on how these factors influence the believing and spreading of misinformation, and verify targeted populations and intervention strategies to combat vaccine misinformation.

It is urgent to implement effective intervention strategies to combat COVID-19 vaccine misinformation. Through the solutions proposed by 65 included studies, we constructed a 5-step framework to address vaccine-related misinformation. The dissemination of trustworthy information was the most frequently mentioned, followed by supporting target audiences of misinformation and cutting its production and distribution, whereas identifying misinformation and regulating its producers and distributors were less mentioned. However, most proposed solutions were not verified regarding their effects on misinformation. With the limited experimental studies, the debunking message/video was considered as effective interventions against misinformation during the COVID-19 pandemic [118,124-126].

Combating misinformation is a persistent and complex work. More scientific evidence is needed to support misinformation surveillance, punishment of misinformation producers, and dissemination of trustworthy information [24]. As many countries reported the first case of mpox, another epidemic in the shadow of the COVID-19 pandemic is looming [131]. In this context, it is particularly important to synthesize potential intervention strategies to combat vaccine misinformation for future anti-infodemic campaign.

Limitations

Our review has several limitations. First, most included studies were observational, leading to low quality of evidence. More interventional studies are needed to evaluate the effect of misinformation interventions and identify effective interventions. Second, we only included publications in English, and social media platforms in non-English languages were not included in our review. The feature, prevalence, and impact of COVID-19 vaccine misinformation may differ by languages. Third, nearly one-half of the included articles were based on the internet; however, the internet penetration rates are low in low-income countries. Our review may thus not provide enough data and evidence of COVID-19 vaccine misinformation in low-income countries. Fourth, the included studies were published from January 2020 to August 2022, therefore this period may be insufficient to observe and explore the long-term impact of COVID-19 vaccine misinformation.

Conclusion

Our review provides comprehensive and up-to-date evidence on COVID-19 vaccine misinformation and helps responses to vaccine infodemic in future pandemics. Its prevalence was high but widely varied worldwide. The most frequent misinformation types were conspiracy and concerns about vaccine safety and efficacy. Information features, information-seeking behaviors, and demographic factors influenced the spreading and believing of misinformation. More evidence is needed to verify potential intervention strategies to combat vaccine misinformation.

Abstract

Background: Face mask use has been associated with declines in COVID-19 incidence rates worldwide. A handful of studies have examined the factors associated with face mask use in North America during the COVID-19 pandemic; however, much less is known about the patterns of face mask use and the impact of mask mandates during this time. This information could have important policy implications, now and in the event of future pandemics.

Objective: To address existing knowledge gaps, we assessed face mask usage patterns among British Columbia COVID-19 Population Mixing Patterns (BC-Mix) survey respondents and evaluated the impact of the provincial mask mandate on these usage patterns.

Methods: Between September 2020 and July 2022, adult British Columbia residents completed the web-based BC-Mix survey, answering questions on the circumstances surrounding face mask use or lack thereof, movement patterns, and COVID-19–related beliefs. Trends in face mask use over time were assessed, and associated factors were evaluated using multivariable logistic regression. A stratified analysis was done to examine effect modification by the provincial mask mandate.

Results: Of the 44,301 respondents, 81.9% reported wearing face masks during the 23-month period. In-store and public transit mask mandates supported monthly face mask usage rates of approximately 80%, which was further bolstered up to 92% with the introduction of the provincial mask mandate. Face mask users mostly visited retail locations (51.8%) and travelled alone by car (49.6%), whereas nonusers mostly traveled by car with others (35.2%) to their destinations—most commonly parks (45.7%). Nonusers of face masks were much more likely to be male than female, especially in retail locations and restaurants, bars, and cafés. In a multivariable logistic regression model adjusted for possible confounders, factors associated with face mask use included age, ethnicity, health region, mode of travel, destination, and time period. The odds of face mask use were 3.68 times greater when the provincial mask mandate was in effect than when it was not (adjusted odds ratio [aOR] 3.68, 95% CI 3.33-4.05). The impact of the mask mandate was greatest in restaurants, bars, or cafés (mandate: aOR 7.35, 95% CI 4.23-12.78 vs no mandate: aOR 2.81, 95% CI 1.50-5.26) and in retail locations (mandate: aOR 19.94, 95% CI 14.86-26.77 vs no mandate: aOR 7.71, 95% CI 5.68-10.46).

Conclusions: Study findings provide added insight into the dynamics of face mask use during the COVID-19 pandemic. Mask mandates supported increased and sustained high face mask usage rates during the first 2 years of the pandemic, having the greatest impact in indoor public locations with limited opportunity for physical distancing targeted by these mandates. These findings highlight the utility of mask mandates in supporting high face mask usage rates during the COVID-19 pandemic.

Introduction

The rapid spread of SARS-CoV-2 worldwide led to the declaration of a global pandemic by the World Health Organization in March 2020 [1,2]. SARS-CoV-2 infection causes COVID-19, which, in extreme cases, results in severe lung damage, multiorgan failure, and death. Person-to-person spread of SARS-CoV-2 is mediated through aerosolized droplets that are generated during activities such as talking, singing, coughing, or sneezing [1,3,4]. When worn appropriately, face masks and other face coverings limit the spread of aerosolized droplets by trapping them within their fibers [5,6]. The utility of face masks and other face coverings in reducing person-to-person transmission of SARS-CoV-2 has been demonstrated in epidemiological and laboratory-based studies, as well as in real-world settings [5,7-12]. This efficacy, alongside the widespread availability and ease of use of face masks has prompted public health officials worldwide to advocate for, or mandate, face mask use in indoor public spaces and in settings with limited opportunity for physical distancing, as part of efforts to control the spread of the virus [13,14].

Public health mandates provide a blanket order for the application of interventions to reduce disease transmission rather than providing a choice for the adoption of those interventions. Hence, these mandates may be perceived as infringing on freedom of choice in those settings. Consequently, mask mandates and recommendations were met with resistance from certain groups [15,16]. The lack of consensus among global political and public health leaders on the need for face masks during the early stages of the COVID-19 pandemic, as well as misinformation and disinformation regarding the utility of masks and potential adverse effects of face mask use, may also explain this resistance [14,16-19]. Specific reasons for the lack of face mask use in a survey conducted among participants from several Western countries included discomfort, difficulty breathing, and skepticism about the ability of face masks to prevent infection [20]. Nevertheless, mask mandates and recommendations have contributed to decreased incidence of COVID-19 cases and related deaths worldwide [21-23]. The advent of COVID-19 vaccines and increasing vaccination coverage has prompted the relaxation of mask mandates and recommendations in various countries worldwide [13,24]. However, recent resurgences in COVID-19 cases in regions where mask mandates were rescinded [25-27] underscore the continued need for the use of face masks in certain regions as global vaccination efforts progress and more is learned about the efficacy of current vaccines in reducing the transmission of new and highly contagious variants. Understanding factors associated with face mask use and quantifying the impact of mask mandates is, therefore, important for health communication and decision-making by public health leadership, especially in the context of repeated outbreaks. Recent studies investigating the factors associated with nonuse of face masks in Canada provided much needed information on the motivation and belief systems underlying face mask use in the country [28,29]. However, limited information is available on face mask usage patterns, with and without provincial mask mandates, during the COVID-19 pandemic in Canada. This information could have important policy implications, now and for future respiratory virus-driven pandemic(s). In this study, we bridge this knowledge gap by assessing face mask usage patterns in the presence and absence of the provincial mask mandate and the factors associated with mask use among respondents of a population-based survey in British Columbia (BC), Canada.

Methods

Context

Initial public health measures to control the spread of COVID-19 were introduced in BC, Canada, on March 18, 2020 [30]; however, the provincial mask mandate requiring face masks in all indoor public spaces did not come into effect until November 19, 2020 [31,32]. Nevertheless, major retail locations in the province mandated the use of face masks between July and August 2020 [33], prior to the provincial mask mandate, as did BC public transit on August 24, 2020 [34]. Due in part to increasing COVID-19 vaccination rates, the provincial mask mandate was lifted on July 1, 2021, although the mandatory requirement for face mask use remained in effect at major retail locations [35]. The provincial mask mandate was reinstated for select indoor public places on August 25, 2021, remaining in effect until March 11, 2022 [36-38]. By April 8, 2022, all other public health requirements, including proof of vaccination for admission to certain locations, were no longer mandated [38].

Study Population and Variable Definitions

The BC COVID-19 Population Mixing Patterns (BC-Mix) survey is an ongoing web-based survey developed to assess population mixing patterns during the COVID-19 pandemic among BC residents [39]. The survey, launched on September 4, 2020, is composed of 94 questions across six key domains: (1) demographic information; (2) COVID-19 testing and results, symptoms, and health behaviors; (3) activities and behavior in and outside of the home; (4) internet and social media use; (5) perceptions and attitudes around COVID-19; and (6) COVID-19 vaccine acceptance (added March 8, 2021). It is administered on the Qualtrics platform to English-speaking persons aged ≥18 years and residing in BC. Anonymous links to the survey were circulated via advertisements placed on Google and social media platforms, namely Instagram, Facebook, WhatsApp, YouTube, and Twitter. Detailed descriptions of survey design, domains, and recruitment methods have been published elsewhere [39]. Participants completed a baseline survey (for first-time respondents), and those who consented were invited to complete shorter follow-up surveys every 2 to 4 weeks.

This analysis was restricted to the baseline responses received between September 4, 2020, and July 31, 2022. Survey respondents who left home at least once the previous day (survey question: "How many times did you leave your home [or property, apartment] yesterday?") were asked whether or not they used a face mask ("Did you use a face mask yesterday?"). Survey respondents who provided valid answers to the face mask question ("Yes," "No," or "Prefer not to answer") were included in this analysis. As people who left their homes either did or did not wear a mask, those who answered "Prefer not to answer" either did not want to anonymously report not wearing masks or did not want to report wearing masks to researchers for some reason. Assuming the former formed the majority of this subgroup and wanting to capture as many types of nonusers of face masks as possible, responses to the face mask use question were recategorized as "Yes" and "No" ("No" + "Prefer not to answer") for the purpose of this study. Other questions addressed ethnicity, education, employment status, location of face mask use, duration of face mask use, number of trips outside the home, distance travelled, destination, and mode of travel (Table S1 in the Multimedia Appendix 1). Time period was grouped by calendar month; thus, the periods during which the provincial mask mandate were in effect were defined as from November 2020 to June 2021 and from September 2021 to February 2022.

Statistical Analyses

Descriptive analyses were done with and without sampling weights. Sampling weights were based on age, sex, geography (Health Authority region), and ethnicity; derived with a weighting adjustment technique [40] using available participant and BC 2016 Canadian Census data; and applied so that response frequencies were representative of the BC population. All comparisons between face mask users (face mask use="Yes") and nonusers of face masks (face mask use="No") were made with weighted data. Chi-square tests were used to ascertain between-group differences in variable distribution. Factors associated with face mask use were assessed with a multivariable logistic regression model, adjusting for time period, age group, sex, ethnicity, destination, number of trips taken, distance travelled, mode of travel, and Health Authority of residence—incorporating sampling weights. The association between the provincial mask mandate and face mask use was also assessed with multivariable logistic regression models, and a stratified analysis was done to examine effect modification by the mandate.

Data preparation, descriptive analyses, and data visualization were done with R statistical software (version 3.5.2; R Foundation for Statistical Computing) [41]. Weighted logistic regression modeling was done with SAS statistical software (version 9.4; SAS Institute) [42]. Statistical significance was assessed at the *P*<.05 level.

Ethical Approval

This study complied with the ethical standards of the Helsinki Declaration. Participation was voluntary and electronic informed consent was sought from all participants on the survey start page. Analytical data sets were deidentified and included no personally identifiable information. Ethical approval for this study was provided by the University of British Columbia Behavioral Research Ethics Board (H20-01785).

Results

Respondent Characteristics

A total of 44,301 respondents were eligible for inclusion in this analysis (see Table 1). Survey respondents who answered the face mask question were mostly male (52.4%), not part of a visible minority group (63.3%), aged 25-34 years (18.81%) and 45-54 years (18.6%), employed full time (33%), and residing in the Fraser Health region (26.3%; Table 1).

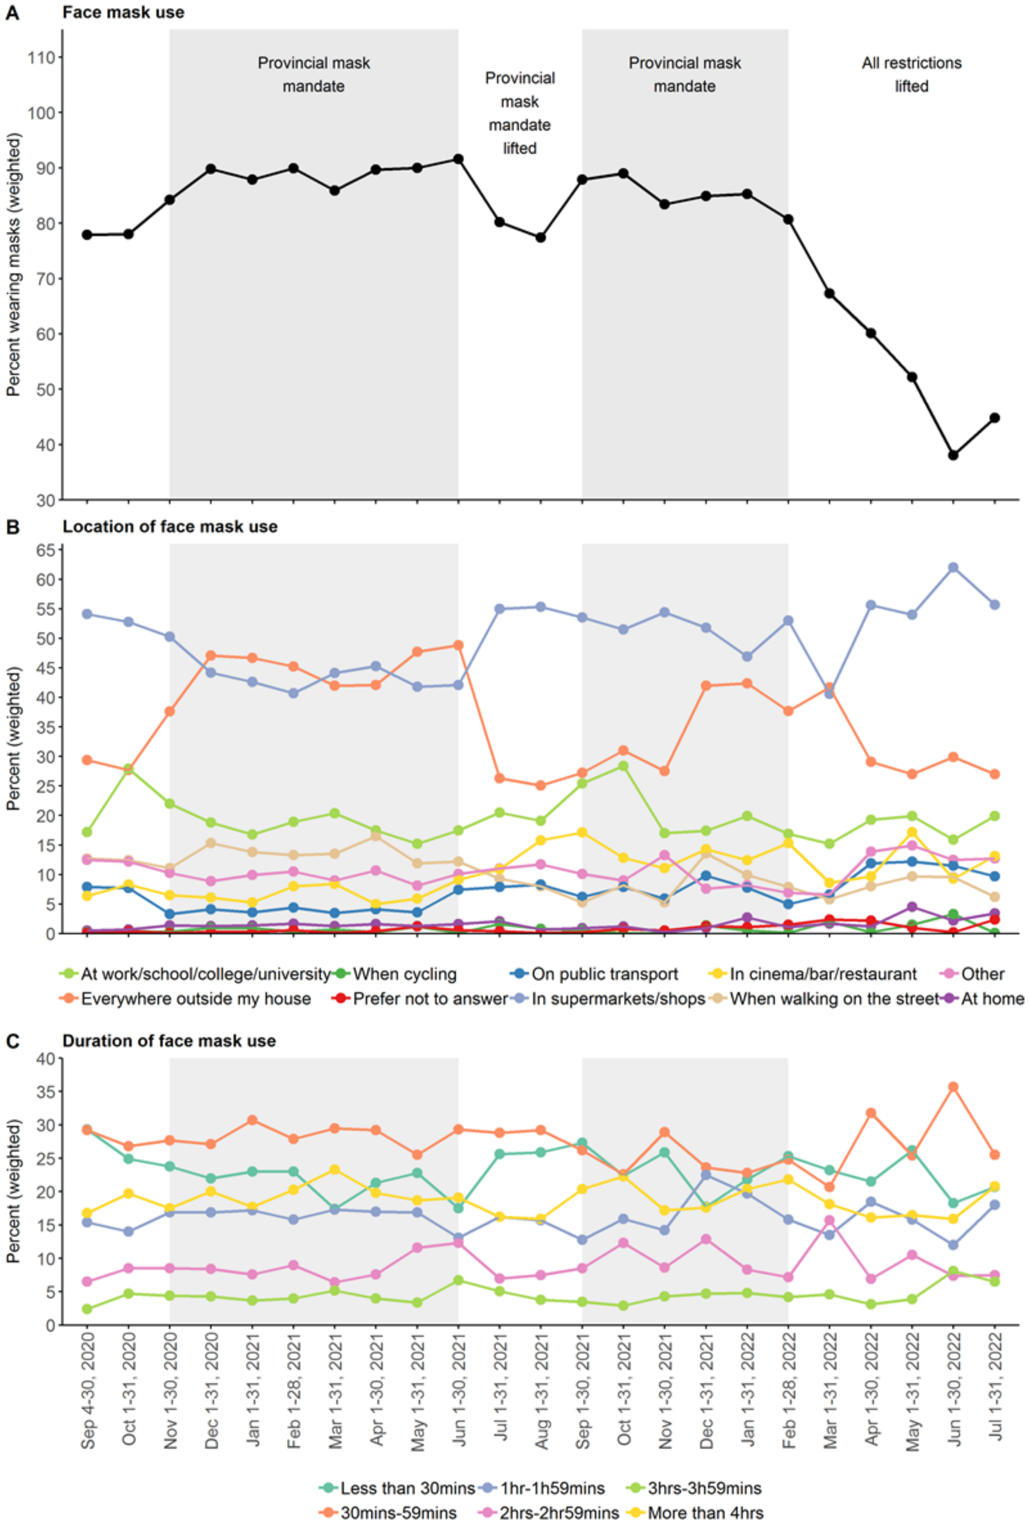
Face Mask Usage Patterns and the Impact of the Provincial Mask Mandate

Between September 2020 and July 2022, 81.9% of survey respondents reported wearing a face mask outside their homes the day before completing the survey (face mask use: yes, n=36,716; no, n=7585 [*prefer not to answer*, n=155 + *no*, n=7430]). Face mask usage rates were approximately 78% between September and October 2020 when face masks and coverings were required in major retail locations in BC but not provincially mandated. Face mask usage rates increased following the introduction of the provincial mask mandate in November 2020 and remained at or above 84% each month thereafter until the mandate was first lifted in July 2021 (Figure 1A). After a 2-month decline in face mask usage rates to pre–provincial mandate levels, usage rates rebounded to 87.9% in September 2021 once the provincial mask mandate was reinstated at the end of August 2021. As before, face mask usage rates remained above 80% when the provincial mandate was in effect until March 2022, when the mandate was lifted a final time as an important step in the winding down of control measures across the province. Face mask usage rates fell rapidly soon afterward, reaching 38.1% in June 2022.

Figure 1. Face mask usage patterns among British Columbia COVID-19 Population Mixing Patterns (BC-Mix) survey respondents by month, from September 2020 to July 2022. (A) Face mask use rates. (B) Location of face mask use: percentages calculated independently for each option provided. (C) Duration of face mask use. Shaded gray region: provincial mask mandate in effect.



Face mask usage patterns were generally consistent over the 23-month period (Figure 1A). Masks were primarily worn in supermarkets and shops (48.2% of face mask users) and everywhere outside the house (38.2% of face mask users; Figure 1B and Figure S1A in the Multimedia Appendix 1).The proportion of people who wore face masks everywhere outside their homes remained at or above 25%, with face mask users being more likely to have worn face masks everywhere outside their homes when provincial mask mandates were in effect. Regardless of time period, most face mask users reported wearing their mask for 59 minutes or less (Figure 1C and Figure S1B in the Multimedia Appendix 1).

Travel patterns were distinct between users and nonusers of face masks between September 2020 and July 2022. The majority of face mask users (53.2%) and nonusers (43.5%) left home only once the previous day, although nonusers of face masks were at least twice as likely to leave home 4 times or more (18.2% vs 7.3%; Figure S2A in the Multimedia Appendix 1 and Figure 2A). Retail locations including grocery stores, pharmacies, and liquor stores were the most frequented destinations for face mask users throughout the 23-month period (≥45%; Figure S2A in the Multimedia Appendix 1 and Figure 2A). Among nonusers of face masks, however, parks or public spaces were the most common destinations visited prior to June 2021, which was gradually surpassed by retail locations after the lifting of provincial mask mandates (Figure 2B). Face mask users mostly travelled alone in a car, although the mode of travel was more heterogeneous among nonusers of face masks during the 23-month period (Figure 2C and Figure S2C in the Multimedia Appendix 1). Statistically significant differences were observed in the distributions of face mask users and nonusers by sex, where larger proportions of females than males opted for wearing masks (85% vs 79%; *P*<.001; Table 1). This difference was more evident when survey respondents were grouped by destination (Table 2, Table 3). In terms of face mask group composition, males formed a large majority of people who opted out of wearing face masks when visiting retail locations (74.9%); restaurants, bars, or cafés (76.1%); or workplaces (78%).

Figure 2. Travel patterns of British Columbia COVID-19 Population Mixing Patterns (BC-Mix) survey respondents by face mask use by month, from September 2020 to July 2022. (A) Number of trips taken outside the home. (B) Destination: percentages calculated independently for each option provided. (C) Mode of travel: percentages calculated independently for each option provided. Shaded gray region: provincial mask mandate in effect.

[a] Selected individually—percentages were calculated for each option provided.

[b] Weighted percentages.

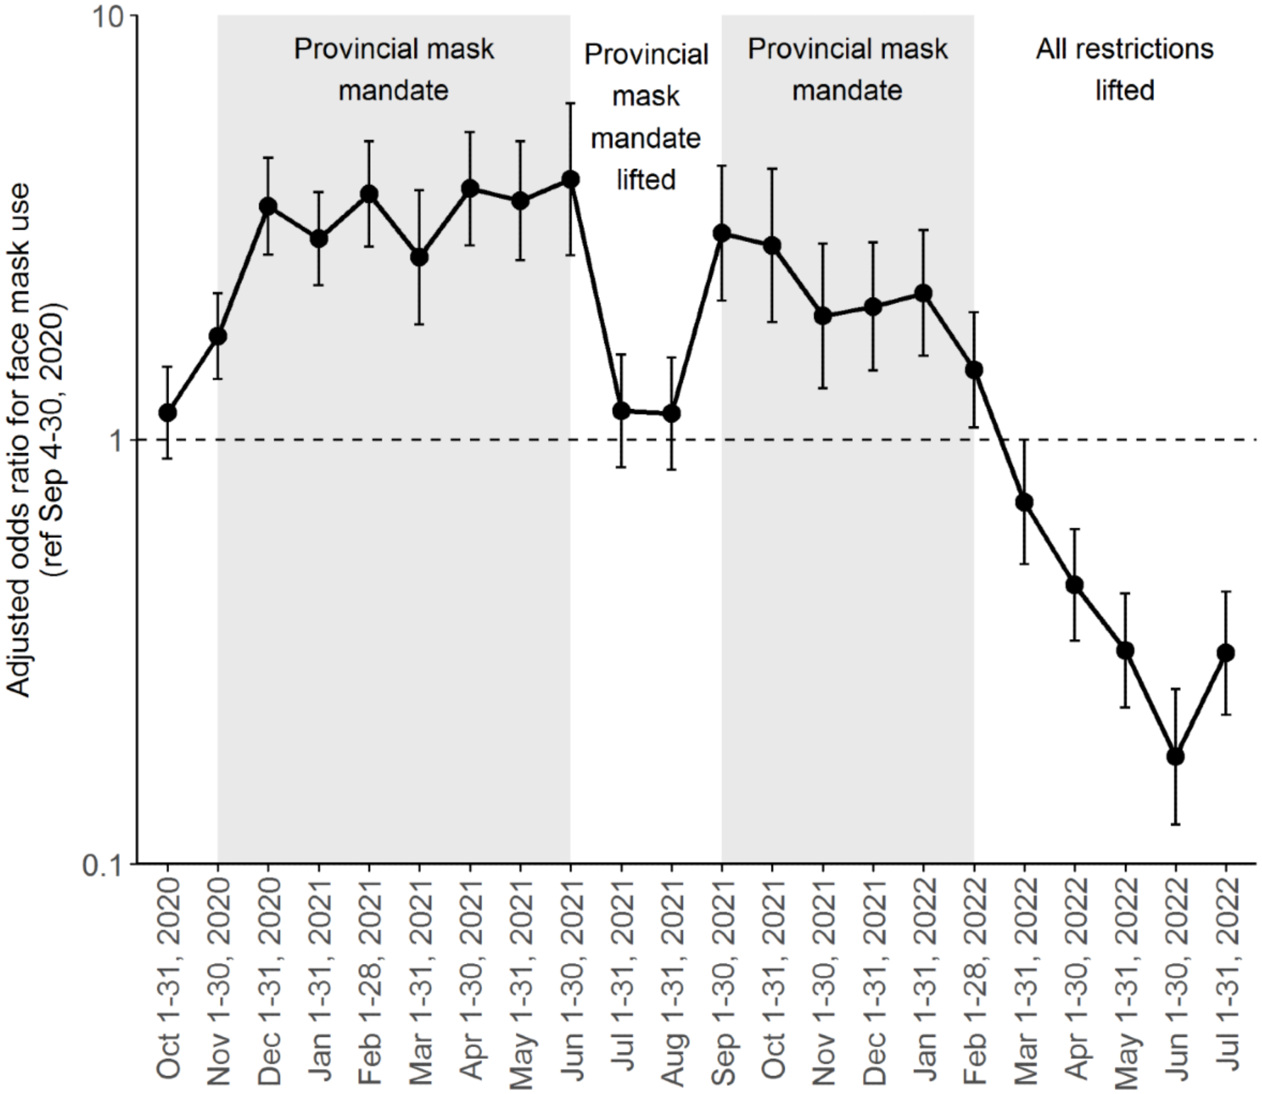
There were small differences in the demographic distributions of people who reported wearing or not wearing face masks in the presence and absence of the provincial mask mandate (Table S3 in the Multimedia Appendix 1). However, the shift toward decreased face mask use when the provincial mask mandate was not in effect was evident across people of all sexes, age groups, and ethnicities, regardless of their level of education, occupation, or employment status.

Factors Associated with Face Mask Use

In a multivariable logistic regression model, the odds of wearing a face mask were statistically significantly greater during the months when the mask mandate was in effect (all $P<.05$; Figure

3 and Table S2 in the Multimedia Appendix 1). The destination and mode of travel were associated with face mask use, where people going to retail locations, including grocery stores, pharmacies, and liquor stores, had greater odds of wearing face masks than those going to parks or other public spaces (adjusted odds ratio [aOR] 14.23, 95% CI 11.69-17.31), as did persons travelling alone in a car (aOR 2.15, 95% CI 1.86-2.50) or in a car with someone else (aOR 1.59, 95% CI 1.36-1.86) relative to those who only walked to their destinations (Table S2 in the Multimedia Appendix 1). Compared to people who were not part of a visible minority group, Chinese people (aOR 2.02, 95% CI 1.54-2.65), South Asian people (aOR 1.80, 95% CI 1.27-2.56), and others who were part of a visible minority group (aOR 1.89, 95% CI 1.49-2.40) had greater odds of wearing face masks. The odds of face mask use were also greater among females, people aged ≥65 years, and people living in the more populous health regions.

Figure 3. Odds ratios for face mask use among British Columbia COVID-19 Population Mixing Patterns (BC-Mix) survey respondents by time period, from September 2020 to July 2022.



The impact of the provincial mask mandates was even more evident when examined directly, with 3.68 times greater odds of face mask use when the provincial mask mandate was in effect (aOR 3.68, 95% CI 3.33-4.05; Table S4 in the Multimedia Appendix 1). The odds ratios for face mask use increased more than 2-fold among people whose destinations were indoor public spaces such as restaurants, bars, or cafés (aOR 7.35, 95% CI 4.23-12.78 vs aOR 2.81, 95% CI 1.50-5.26) or retail locations (aOR 19.94, 95% CI 14.86-26.77 vs aOR 7.71, 95% CI 5.68-10.46) with the mask mandate versus without. Slight shifts in odds ratios were also noted by mode of travel in the presence versus the absence of a provincial mask mandate.

Discussion

Principal Findings

Prior to the availability and high coverage of COVID-19 vaccines, masks and other nonpharmaceutical interventions were mainstays for preventing infection and reducing disease transmission, with the ultimate goal of reducing the impact of the COVID-19 pandemic on population health. Face mask use was mandated in certain settings across many countries to reduce SARS-CoV-2 transmission. Establishing the factors associated with and the patterns of face mask use, with or without mask mandates, is necessary to assess the impact of mask mandates and to inform health communication strategies and decision-making by public health leadership. In this study, based on survey responses from a voluntary sample of BC residents conducted between September 2020 and July 2022, 81.9% of respondents reported wearing a face mask during outings. Over the 23-month period, face masks were mostly worn for less than an hour, being primarily used in supermarkets and shops; at workplaces; and in schools, colleges, or universities. In a multivariable logistic regression model, factors associated with face mask use included age, sex, ethnicity, time period, destination, and mode of travel. Face mask usage rates were sustained by in-store mandates in the fall of 2020 and further boosted by the provincial mandates. The odds of face mask use increased 3-fold when the provincial mask mandate was in effect. These findings highlight the role of mask mandates in facilitating high levels of face mask use at the population level.

Studies based in the United States have shown an increased likelihood of face mask use in indoor public spaces, such as grocery stores, compared to outdoor public spaces, such as parks or beaches [43,44]. Similarly, retail locations and workplaces were among the major destinations associated with face mask use in BC, whereas parks were favored among people who opted against wearing masks. This finding was to be expected, as in-store and regional mask mandates were in effect in most of these locations for the majority of the study period. Differences in face mask use at retail locations have been reported in the United States, where females [45], individuals aged ≥65 years [45], non-Hispanic Black and Hispanic/Latino persons [46], and people shopping in urban or suburban locations [45] were among the most likely to have worn face masks prior to the introduction of mask mandates or recommendations. Similarly, females and people aged ≥55 years had greater odds of adopting face masks across Canada [28]. This was congruent with our findings in BC, where statistically significant differences in face mask use were noted by age and sex—males were more likely to be nonusers of face masks, especially in commonly frequented settings.

Our findings, and those of others, highlight the impact of mask mandates in promoting face mask use during the COVID-19 pandemic [45,47]. Province-wide in-store mask mandates sustained face mask usage rates in BC at approximately 80%, both before the introduction of the provincial mask mandate and during the 2-month period when the mandate was first lifted. Moreover, face mask usage rates were at or above 84% when provincial mask mandates were in effect, similar to findings in the United States and Australia [45,47]. The greatest impact of the mask mandate on the odds of face mask use was seen at key locations such as workplaces, restaurants, bars, cafes, grocery stores, liquor stores, and pharmacies. Once removed, alongside other control measures, face mask usage rates declined 2-fold to 38%, possibly reflecting baseline midpandemic mask usage rates in the absence of mask mandates.

Limitations

Study findings should be interpreted with the following limitations in mind. Data collection began after face masks were made mandatory on public transit and in many retail locations in BC; thus, we were unable to fully quantify premandate willingness to voluntarily wear face masks at these locations. Nevertheless, our data does contribute to the body of knowledge about (un)willingness to wear face masks in the face of regional or in-store mandates, as a sizeable proportion of respondents fell into this category. Our findings are also subject to selection bias, as survey respondents were recruited mainly on social media platforms (Instagram, Facebook, YouTube, and Twitter) and participated on a voluntary basis. Thus, persons who did not use these social media platforms would not have been able to participate without referral. Furthermore, we were not able to quantify nonparticipation as recruitment was done in a passive manner. In addition, we did not assess type of face masks used, which may have provided additional insights into the characteristics and behaviors of survey respondents. Nevertheless, our study provides valuable insight into the dynamics of face mask use during the COVID-19 pandemic.

Conclusions

Various studies have shown the association between face mask use and declines in SARS-CoV-2 transmission [21-23]. Thus, in the absence of vaccines for disease prevention and therapeutics for the treatment and prevention of severe disease, mask mandates were introduced during the COVID-19 pandemic to limit the spread of the disease and to reduce its impact on society. We found a pattern of high mask usage rates with retail location and public transit mask mandates in BC, which was further enhanced by the provincial mask mandate. These findings demonstrate the utility of mask mandates in sustaining high rates of face mask use during the COVID-19 pandemic and provide concrete evidence for their use in regions with low vaccination rates and recurrent surges in COVID-19 cases and in the event of future respiratory virus-driven pandemics or severe respiratory disease outbreaks. Lessons learned from the COVID-19 pandemic do suggest, however, that mask mandate imposition should require a sound ethical analysis beforehand to ensure that the benefits achieved with their use outweigh the harms related to infringement on individual choices.

Acknowledgments

We gratefully acknowledge the residents of British Columbia who participated in the British Columbia COVID-19 Population Mixing Patterns (BC-Mix) survey, for whom this work is intended to benefit.

This study was funded by the Michael Smith Foundation for Health Research COVID-19 Research Response Fund (COV-2020-1183) and the Canadian Institutes of Health Research (VR5-172683).

The funder had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and decision to submit the manuscript for publication.

Data Availability

Data are available upon reasonable request.

Authors' Contributions

NZJ, PAA , BM, and TBT designed the survey. NZJ and PAA contributed to survey dissemination and data collection. MB, PAA and NZJ conceptualized the study. MB carried out data analyses and drafted and revised the manuscript. All authors contributed to data interpretation and manuscript revision.

Conflicts of Interest

NZJ participated in advisory boards and has spoken for AbbVie and Gilead, not related to current work. All other authors declare no other conflicts of interest.

Abstract

Background: The COVID-19 pandemic has created devastating health, social, economic, and political effects that will have long-lasting impacts. Public health efforts to reduce the spread of COVID-19 are the priority of national policies for responding to the pandemic globally. Public health and social measures (PHSMs) have been shown to be effective when used alone or in combination with other measures, reducing the risk of spreading COVID-19. However, there is insufficient evidence on the status of compliance with PHSMs in the general population for the prevention of COVID-19 in public areas, including Korea.

Objective: The aim of this study was to assess levels of compliance with the recommended PHSMs against SARS-CoV-2 infection and their predictors among the general population by using national data.

Methods: This study was a secondary data analysis of the National Survey of Infectious Disease Preventive Behaviors in Community, which was conducted by the Korea Centers for Disease Control and Prevention Agency (KDCA) between October 12 and October 30, 2020. The primary study was cross-sectional, using stratified sampling via an adjusted proportional allocation method to select representative samples and ensure the stability of samples. The data were collected through phone interviews conducted by trained enumerators using a structured questionnaire. PHSM adherence was measured using a 10-item comprehensive infectious disease prevention behavior (CIDPB) scale, and each sociocognitive factor, including perceived susceptibility to SARS-CoV-2 infection, perceived severity of SARS-CoV-2 infection, perceived confidence in performing preventive behaviors related to COVID-19, information comprehension ability, and trust in information from the KDCA, was measured. A total of 4003 participants were included in the final analysis. Tobit regression and a decision tree analysis were performed to identify the predictors of preventive measures and the target groups for intervention.

Results: We discovered that women scored 1.34 points higher on the CIDPB scale than men (*P*<.001). Compared to the group aged 19 to 29 years, those aged 50 to 59 years and those older than 60 years scored 1.89 and 2.48 points higher on the CIDPB scale (*P*<.001), respectively. The perceived severity of infection, confidence in preventive behaviors, information comprehension ability, and trust in information from the KDCA were significant positive determinants of CIDPBs (*P*<.001). The perceived susceptibility to infection showed a significant negative relationship with CIDPBs (*P*<.001).

Conclusions: Female sex, older age, lower income, and sociocognitive factors were found to be significant determinants of adhering to PHSMs. The findings suggest the need for tailored interventions for target groups; specifically, the age group that was the most active at work indicated the highest potential to spread infection. Adequate public health education and health communication for promoting adherence to PHSMs should be emphasized, and behavior change strategies for those with low perceived confidence in performing PHSMs should be prioritized.

KEYWORDS

COVID-19; preventive measures; health literacy; trust; national survey; Tobit regression

Introduction

The COVID-19 pandemic is a global health crisis. The pandemic has created devastating health, social, economic, and political effects that will have long-lasting impacts in many parts of the world [1,2]. SARS-CoV-2 is a novel virus causing an outbreak of mild to severe respiratory diseases. COVID-19 has affected millions of people around the world. As of September 2021, a total of 219 million cases and over 4.55 million deaths were reported. Korea is no exception to this devastating crisis. More than 276,000 total cases and 2367 deaths were reported as of September 2021 [3]. Although COVID-19 vaccines are now available in many countries, vaccination does not guarantee complete protection from contracting COVID-19, and it will take a while to achieve herd immunity, as a substantial proportion of the population needs to be vaccinated [4]. Research is still ongoing to find out how strong the vaccines are against COVID-19, how effectively they would reduce transmission, and how long the effects of vaccination last. Until herd immunity is achieved, preventive measures should still be important means for reducing the transmission of COVID-19 and protecting ourselves from contracting an evolving infectious disease in the future [4].

Public health efforts to reduce the spread of COVID-19 are still the priority of national policies for responding to the pandemic globally. Most countries have announced public health and social measures (PHSMs) against COVID-19. PHSMs include personal protective measures, such as handwashing and mask wearing in public areas; environmental measures, such as disinfection and ventilation; surveillance and response measures, such as contact tracing, isolation, and quarantine; physical distancing measures, such as limiting the size of gatherings and maintaining distance in public areas; and limitations on international travel [5]. These protective measures have been shown to be effective when used alone or in combination with several measures, reducing the risk of spreading COVID-19 [6-8]. The Korea Centers for Disease Control and Prevention Agency (KDCA) has also announced guidelines for PHSMs that are similar to WHO guidelines [9]. Nevertheless, there is insufficient evidence on the status of compliance with PHSMs in the general population for the prevention of COVID-19 in public areas, including Korea.

Researchers have reported the disparities in compliance with PHSMs by socioeconomic groups. In general, being male, having a lower education and a lower income, living in rural areas, and being younger are associated with performing fewer preventive behaviors. [10-13]. Mistrust toward the health care system and health literacy are other important factors that contribute to the disparities in PHSM compliance. People who do not trust the health care system are less likely to follow recommendations if the recommendations are from the system that they do not trust, especially when these recommendations are inconsistent and difficult to understand [14]. An effective and rapid response to COVID-19 requires the public to follow recommended behaviors, and public health information plays a crucial role [15]. However, people vary in terms of their abilities to obtain and understand health information and use services to make informed decisions (ie, health literacy) [16], and conflicting messages about PHSMs for COVID-19 have created confusion in the public, which has caused delays in following PHSMs [17]. In fact, McCaffery et al [15] reported disparities in COVID-19–related knowledge, attitudes, and behaviors by health literacy level. However, more studies are needed to confirm the relationships among mistrust in the health care system, health literacy, and preventive behaviors in the new era of the COVID-19 pandemic.

Health beliefs are closely related to health behaviors. According to the Rosenstock Health Belief Model [18], perceived susceptibility (beliefs about acquiring a disease), perceived severity (beliefs about the seriousness of risk), and self-efficacy (confidence in the ability to control a situation to achieve a goal) are important concepts that could influence people’s decisions to engage in health behaviors. Although sparse, recent research revealed that health beliefs are significant predictors of COVID-19 preventive health behaviors [13,19,20]. Public health efforts reduce the spread of COVID-19 both globally and within countries, including Korea. Examining the factors that influence preventive health behaviors would provide opportunities to target interventions toward those who are in need. To date, there is a lack of knowledge about factors related to PHSMs against COVID-19. Thus, the purpose of this study was to assess levels of compliance with the recommended preventive measures against SARS-CoV-2 infection and their predictors among the general population by using national data.

Methods

Data Source and Sample

This study was a secondary data analysis of the National Survey of Infectious Disease Preventive Behaviors in Community, which was conducted by the KDCA between October 12 and October 30, 2020. The survey was developed based on the following steps: (1) a literature review on previous studies related to infectious diseases and associated preventive behaviors; (2) in-depth interviews with experts in infectious diseases on preventive behaviors and their predictors; (3) the pooling of items based on the literature review and in-depth interviews with experts; (4) the development of a pilot questionnaire based on the pooled items; (4) content validity index calculation with 11 experts; and (5) a pilot test with 20 adults on the difficulty, relevance, and comprehensiveness of the questionnaire. The survey included data on adherence to PHSMs, socioeconomic characteristics, experiences of respiratory and intestinal infectious disease symptoms, experiences of isolation or hospitalization due to SARS-CoV-2 infection, perceived susceptibility to COVID-19, perceived severity of COVID-19, confidence in performing preventive behaviors, COVID-19–related information comprehension ability, and trust in information from the KDCA.

A representative sample of the population aged 19 to 69 was stratified based on sex (male and female) and age groups (19-29 years, 30-39 years, 40-49 years, 50-59 years, and 60-69 years) in 17 cities or provinces nationwide. Stratified sampling via an adjusted proportional allocation method was used to select representative samples and to ensure the stability of samples in 17 cities or provinces. First, 50 people from each city or province were allocated. Second, a proportional allocation method was used to reduce or increase the sample size based on the number of people residing in each city or province. Therefore, the number of people selected from each city or province ranged from 25 to 1050. To increase the representativeness of the sample, a quota ratio was used to allocate samples based on sex and age groups; thus, the characteristics of the samples selected were consistent with those of the population. Trained professional enumerators conducted computer-assisted telephone interviews with participants, using random digital dialing, between October 12 and October 30, 2020. The interviews were stopped when the target proportion was reached. A total of 421,428 phone calls were made, and 5025 individuals completed telephone interviews. We included 4003 participants in this study after carefully reviewing and excluding participants with missing data on the dependent variable.

Ethical Considerations

This study was a secondary analysis of a pre-existing data set, and ethical review and approval were exempted for this study by the institutional review board of the first author's university (Chung-Ang University). The primary study was conducted by the KDCA, and informed consent was obtained prior to the phone interviews. The primary data contained anonymous information.

Measures

Adherence to PHSMs

Adherence to PHSMs was measured by using a comprehensive infectious disease prevention behavior (CIDPB) scale. The preliminary items were developed based on the review of literature published within the last 5 years in PubMed, Embase, Cochrane Library, and the Research Information Sharing Service on prevention behaviors for infectious diseases; existing instruments for COVID-19 prevention behaviors [21]; and the COVID-19 prevention guidelines from the Centers for Disease Control in the United States and Korea. The 10 items, including handwashing, cough etiquette, and social distancing, were constructed after a review by experts and content validity testing. Examples of items include (1) washing hands thoroughly for 30 seconds with soap and running water, (2) covering the nose and mouth with sleeves when coughing or sneezing, and (3) maintaining a 2-m (at least 1 m) distance from others. Each item was answered on a 4-point Likert scale (1=always; 2=most of the time; 3=sometimes; 4=never) and was reverse coded. The participants who answered "not applicable" or "don't know" and those who refused to answer were excluded from the analysis. The total score ranged from 4 to 40, with higher scores indicating the practicing of more preventive behaviors. The Cronbach α was 0.76 (95% CI 0.747-0.770), supporting the instrument's internal consistency.

Sociocognitive Factors

The participants were asked to answer questions related to perceived susceptibility to SARS-CoV-2 infection, perceived severity of SARS-CoV-2 infection, and perceived confidence in performing preventive behaviors related to SARS-CoV-2 infection, using a single question for each factor. Each question was answered on a 7-point Likert scale (1=not at all; 7=very likely), with a higher score indicating higher perceived susceptibility to SARS-CoV-2 infection, perceived severity of SARS-CoV-2 infection, perceived confidence in performing preventive behaviors, and information comprehension ability with regard to COVID-19. Information comprehension ability was assessed by asking the following question: "How easy is it for you to understand the various information given during COVID-19?" Participants were asked to answer on a 7-point Likert scale (1=very hard; 7=very easy), with a higher score indicating the easier comprehension of COVID-19 information.

Trust in information from the KDCA was assessed by asking the following question: "How much trust in information provided by KDCA?" Participants were asked to respond on a 10-point Likert scale (1=never trust; 10=very trust), with a higher score indicating more trust in information from the KDCA.

Demographic Variables

The demographic variables included in this study were age, sex (ie, male or female), educational level (ie, middle school or lower, high school, or college or above), monthly household income (ie, less than US $5000 or greater than US $5000), and living areas (urban or rural areas). Further, 8 metropolitan cities and cities in 9 provinces were categorized as urban areas, and the villages in the provinces were categorized as rural areas. Age was categorized as 19 to 29 years, 30 to 39 years, 40 to 49 years, 50 to 59 years, or ≥60 years.

Statistical Analysis

We analyzed the data by using STATA 15.1 (StataCorp LLC), SPSS 25 (IBM Corp), and R (R Foundation for Statistical Computing). A weighted statistical analysis was performed to increase the representativeness of the data. Descriptive statistics, such as means, SDs, frequencies, and percentages, were used to describe the participants. To examine the relationships that demographics, sociocognitive factors, and trust in information from the KDCA had with CIDPBs, the Mann-Whitney *U* test and the Kruskal-Wallis H test were done, as the CIDPBs were not normally distributed. A post hoc analysis was done by using Bonferroni corrections [22]. We then performed Tobit regression to examine the effects of demographics, sociocognitive factors, and trust in information from the KDCA on CIDPBs. A Tobit regression model, which is also called a *censored regression model*, was performed to estimate linear relationships among variables when the dependent variable was censored to either the left or right [23]. The dependent variable in this study (the CIDPBs) was skewed to the right, and this analysis allows one to specify a threshold to censor the regression. Further, a decision tree analysis was conducted by using the classification and regression tree (CART) technique introduced by Breiman et al [24] via the SPSS statistical package. CART analysis is a nonparametric technique for identifying each predictor in order to identify the most important predictor at each step when a sample is divided into 2 mutually exclusive and homogeneous subpopulations. The starting group is referred to as the *root*, each split is referred to as a *branch*, and the data subset resulting from the split is called a *node*, while the terminal nodes are referred to as *leaves* [24]. A single configuration of hyperparameters was chosen to reduce the complexity of CARTs to ensure sensible bias-variance trade-off. The minimum number of cases in the parent node and child node was 100 and 50, respectively. The chosen parameters for growing trees were a maximum tree depth of 5 and a significance threshold of .05 for splitting. The “±1 SE rule” was applied to prune the tree.

Results

The characteristics of participants are summarized in Table 1. The average age of participants was 45.4 (SD 14.98) years. Of the 4003 participants, 1947 (48.6%) were male. Approximately 57.3% (2265/3953) of participants were educated at a college or higher level. About 58% (1941/3349) earned less than US $5000 per month, and 42% (1408/3349) earned more than US $5000 per month. Most of the participants (3741/4003, 93.5%) resided in the city. Bivariate analyses were performed to examine the association between general characteristics and the CIDPBs (Table 2).

The mean CIDPB scale score was 34.91 (SD 3.74) and ranged from 15 to 40. Sex, age, the level of education, monthly income, and living areas were significantly associated with the CIDPBs. The mean score of male participants was slightly lower than that of female participants (*P*<.001), and the mean score for participants residing in urban areas was lower than that for participants residing in rural areas. The Bonferroni post hoc test revealed that the older age group had more CIDPBs. Specifically, the participants aged 19 to 29 years had the lowest mean score compared to those of other age groups (*P*<.001). The participants aged 30 to 39 years had a lower mean score than those of the participants aged 40 to 49 years (*P*=.001) and the participants aged 50 years and older (*P*<.001). The participants aged 40 to 49 years had a lower mean score than those of the participants aged 50 to 59 years (*P*=.002) and the participants aged 60 years and older (*P*<.001). The participants aged 50 to 59 years had a lower mean score than that of the participants aged 60 years and older (*P*<.001).

[b] N/A: not applicable.

A Tobit regression model analysis was performed to identify predictors of CIDPBs (Table 3). The results revealed that the CIDPB score was 1.34 (95% CI 1.09-1.59) points higher in female participants when compared to that of male participants. The participants who were aged between 50 and 59 years scored higher on the CIDPB scale (performed more CIDPBs) by 1.89 (95% CI 1.45-2.34) points, and the participants who were older than 60 years scored higher on the CIDPB scale (performed more CIDPBs) by 2.48 points (95% CI 2.02-2.93), when compared to those who were aged between 19 and 29 years. The perceived severity of infection, confidence in preventive behaviors, information comprehension ability, and trust in information from the KDCA were statistically significant and positive (*P*<.001). The perceived susceptibility to infection was statistically significant and negative (*P*=.02).

Figure 1 depicts the decision tree produced by the CART analysis. Perceived confidence in performing preventive behaviors (scores of >6.5) was the first classifying dimension, which was mostly associated with CIDPBs. The results suggested that the participants aged 40 to 69 years with trust in information from the KDCA (scores of >9.5) had higher scores on the CIDPB scale (range 34.91-37.21). Men aged 19 to 49 years with scores of <4.5 for perceived confidence in performing preventive behaviors were the least likely to practice CIDPBs, with CIDPB scale scores ranging from 34.91 to 31.10. Perceived confidence in performing preventive behaviors showed the highest normalized importance among variables for explaining CIDPBs, followed by the age group and trust in information from the KDCA variables (Figure 2).

Discussion

Principal Findings

The purpose of our study was to assess levels of compliance with the recommended PHSMs against SARS-CoV-2 infection and their predictors among the general population by using national data. There is a need for health care providers and public health officials to know which groups are in need of education on PHSMs. With regard to socioeconomic factors, sex (female), age, monthly income, and sociocognitive factors were significantly associated with more preventive behaviors. Consistent with previous research, female participants were more likely to perform preventive behaviors. During epidemics of infectious diseases, including the influenza, H1N1, and COVID-19 pandemics, it was shown that women are more sensitive to risk and are more motivated to perform health behaviors than men [25-27]. Interestingly, people who were older were more likely to perform preventive behaviors than those who were younger, which is consistent with a study by Raude et al [28]. The possible explanation for this finding is that people who are older may believe that they are more prone to infection and that they will be sicker and experience more complications once they are infected and thus engage in more preventive behaviors [29].

Surprisingly, those with lower incomes were more engaged in PHSMs. A previous study reported that people with higher incomes tend to stay at home more often when compared to those with lower incomes [29] and show higher compliance with preventive behaviors against COVID-19 when compared to those with a low economic status [11]. People with lower incomes may engage in jobs that are unstable and may work in environments that increase the likelihood of infection (eg, environments in which the proximity between people cannot be maintained or confined areas with limited ventilation), which may place them at risk for infection. However, the relationship between income and preventive behavior needs to be examined in future studies, as the exact pathway for why people with lower incomes are more engaged in preventive behaviors is not well established in the literature.

Consistent with previous findings [13,26,30,31], the influence of confidence in the ability to control a situation on health behavior change was found to be a strong determinant of adherence to PHSMs for preventing COVID-19 and the intention to follow preventive behaviors [32]. Moreover, in this study, we attempted to identify target groups that are in the most need of intervention to increase preventive behaviors, and we found that men aged between 19 and 49 years with lower scores for perceived confidence in performing preventive behaviors are in the most need of intervention. As this age group is the most active at work and in daily life, it should be given a higher priority in terms of their potential to spread infection to others. Given that the majority of the participants were employed (2,933/4003, 73%), policies and guidelines encouraging the practice of preventive behaviors and the provision of essential infection control materials should be established at work. In addition, men tended to dismiss preventive actions when compared to women in this study, which is consistent with the findings from a study of 8 countries [33]. Thus, gender perspectives are taken into account when designing education programs to promote preventive behaviors among a target population.

It is well believed that a person with high perceived susceptibility is more likely to take actions to reduce the risk of acquiring a disease. Thus, perceived susceptibility gained importance as a significant psychosocial factor related to COVID-19 preventive behaviors in earlier studies [32,34,35]. However, the temporal relationship between perceived susceptibility and preventive behaviors should be interpreted with caution. In contrast to these previous studies, we found a negative association between perceived susceptibility to infection and preventive behaviors. Since there was a negative association between perceived susceptibility and preventive behaviors, we may interpret the results as follows: those who do not perform preventive behaviors or perform fewer preventive behaviors may believe that they are at more risk of contracting diseases. In addition, as addressed in an earlier study on the use of mobile apps to trace COVID-19 cases [36], considering the relatively high adherence to PHSMs among the majority of participants in this study (34.91/40), another possible reason could be that the better the preventive action, the lower the perceived risk of contracting COVID-19. However, this study was cross-sectional; thus, we cannot assume this causal inference. Longitudinal studies are needed in the future to examine the causal relationship between sociocognitive factors and preventive behaviors.

The more a person believes that a given disease is serious, the more that person will try to reduce the chance of contracting that disease by performing preventive behaviors [37]. Health literacy is the knowledge and competence required to understand and process health information, and it influences individuals to make proper health decisions [16]. In fact, better health literacy, which we defined as information comprehension ability, was associated with more preventive behaviors in our study, which is consistent with previous studies [37,38]. The most important health information includes knowledge about COVID-19, skills for preventive behaviors, and government policies [38,39]. There is a lot of information about COVID-19 released by the media, which includes false information. Good health literacy enables people to differentiate between facts and myths regarding information about COVID-19, which influence people to perform appropriate preventive behaviors [17]. Health messages about COVID-19 are extremely confusing and change rapidly. People who do not trust information released by the health care system and the government are less likely to follow recommended behaviors [14]. In fact, our study results indicate that people with less trust in the information from the KDCA are less likely to perform preventive behaviors. Adequate government action and policy development are needed to ban the release of false information that may cause irrational panic and prevent people from practicing preventive behaviors. Moreover, demographic variables, such as low education and older age, are known to be associated with low health literacy levels [38,40]; thus, people with low educational levels and those who are older need to be targeted for intervention to increase health literacy.

Some limitations should be noted. First, our study was cross-sectional; thus, temporal inferences should be interpreted with caution. Second, the sample size may be small, although we included nationally representative samples by using stratified sampling and a proportional allocation method. Thus, longitudinal studies with larger sample sizes are needed to confirm the causality between preventive behaviors and predictors. Third, the primary study was conducted by using questionnaires; thus, recall bias may be present. Fourth, some of the variables, such as sociocognitive factors, were measured with a single item; therefore, there is a possibility that we did not capture the multidimensional concepts of each variable. In future studies, more reliable and valid instruments that capture all aspects of sociocognitive factors may need to be used. Fifth, we only included individual factors in the analysis. Thus, multilevel analyses may be necessary, as preventive behaviors could be affected by community and national factors. Sixth, this study was implemented before the outbreaks of COVID-19 variants, including the Omicron variants. Therefore, the study results need to be interpreted with caution in the context of the new COVID-19 variants. Lastly, this study did not include variables related to the vaccine awareness, as this study was conducted before the start of national vaccination in South Korea. Further studies are needed to assess the relationships between vaccination and preventive behaviors. Despite these limitations, our findings add new knowledge to previous literature, as we identified predictors of preventive behaviors by using nationally representative samples collected during the COVID-19 pandemic in Korea.

Conclusion

The purpose of this study was to assess levels of compliance with the recommended preventive measures against SARS-CoV-2 infection and their predictors among the general population by using national data. In addition to identifying predictors, we have provided insights into the specific groups that may need targeted interventions, such as men aged between 19 and 49 years with low perceived confidence in performing preventive behaviors. A theory-driven intervention may need to be carefully designed to meet the needs of the target population, and such an intervention should be delivered at appropriate places, such as workplaces, to reach a large number of people. Moreover, efforts to increase health literacy and trust in the health care system are needed at the community and national levels. However, the lack of a temporal relationship between preventive behaviors and predictors indicates the need for longitudinal studies in the future.

Abstract

Background: The global COVID-19 pandemic disproportionately affected Asian Americans and Pacific Islanders (AAPIs) and revealed significant health disparities with reports of increased discrimination and xenophobia. Among AAPIs, the pandemic exacerbated their social, linguistic, and geographic isolation. Social support may be especially important for AAPIs given the salience of collectivism as a cultural value. Another mechanism for support among AAPIs was technology use, as it is generally widespread among this population. However, older adults may not perceive the same benefits.

Objective: We examined social support and technology use and their relationships with mental and physical health outcomes through the COVID-19 pandemic among AAPIs.

Methods: Data were drawn from the COVID-19 Effects on the Mental and Physical Health of AAPI Survey Study (COMPASS) for the time period of October 2020 to February 2021. COMPASS was a cross-sectional, multilingual, national survey conducted online, by phone, and in person with AAPI adults who were ≥18 years of age, in collaboration with academic and community partners in the United States. Data were analyzed using multivariable linear regression using the outcome variables of mental and physical health with various predictors such as social support and technology use. We tested for interactions specific to age and ethnicity.

Results: Among 4631 AAPIs (mean age 45.9, SD 16.3 years; 2992/4631, 63.1% female), we found that (1) increased social support was associated with better physical health, (2) total social support was positively associated with better mental health, (3) higher technology use was associated with poorer mental health and inversely associated with poorer physical health, (4) the association of technology use with mental health was weaker among those with low social support (vs those with high social support), (5) adults younger than 60 years old (vs ≥60 years old) were more negatively affected with social support and mental health, and (6) Korean Americans appeared to be a high-risk group for poor physical health with increased technology use.

Conclusions: Our paper identified mental and physical health needs along with supportive therapies observed among AAPIs during the pandemic. Future research on how social support can be leveraged, especially among AAPIs younger than 60 years old, and how various types of technology are being utilized are important to guide the recovery efforts to address both mental and physical disparities across communities as a result of the COVID-19 pandemic.

Introduction

The COVID-19 pandemic has had widespread health, social, and economic implications that the world has not experienced in modern history. Asian Americans and Pacific Islanders (AAPIs) are the most rapidly growing and heterogeneous racial group in the United States, with very limited research participation [1-3]. It has been brought to the forefront that significant health disparities, socioeconomic inequalities, and discrimination and xenophobia exist for AAPIs, both prior to and due to COVID-19 [4-6]. As a result of policies (eg, shelter-in-place [SIP], social distancing) that were implemented, persons and communities of color and those who are socially and technologically isolated were among the most vulnerable in terms of the adverse effects of COVID-19 [7,8]. Older AAPIs are especially vulnerable and more likely to be disproportionately affected by COVID-19 policies due to higher rates of poverty, lower educational attainment, limited English proficiency [9], and less access to digital technology [9,10] (eg, internet) or lower digital literacy [11], which has been an integral tool for social, educational, and health purposes during this pandemic [12].

The pandemic has exacerbated the social, linguistic, and geographic isolation of AAPIs [13-15]. Social isolation and the need for support are prevalent among older AAPIs whose English language proficiency is limited. Social support may be especially relevant for AAPIs given the salience of collectivism as a cultural value. Research has shown that having social connections and supportive resources can buffer the effects of social isolation and is a strong determinant of health and well-being [13,16]. Having emotional support lowers the adverse effects of stress, increases emotions that are positive, and decreases the duration and intensity of emotions that are negative [17]. Studies have shown the positive buffering effects of social support on health and well-being in AAPIs for culture and ethnicity-related stressors (eg, discrimination) [18,19].

The use of digital technology became a necessity to communicate and sustain daily activities during the COVID-19 pandemic [20,21]. Digital technology refers to a smartphone, computer, internet service, tablet, and television with cable. English-speaking Asian Americans had the highest technology adoption rates in the United States compared with other racial groups, with 62% of Asian Americans having access to an internet-connecting device such as a router (compared with 47% of Whites, 48% of Blacks, and 45% of Hispanics) and 97% owning a smartphone [22]. Although smartphone ownership and internet use have grown in popularity over the past decade, with the largest adoption rates among older adults, research is still lacking among older AAPIs, specifically those who have limited English or digital literacy and may have wide variations in income.

SIP and social distancing made the use of digital technology crucial for numerous reasons, ranging from health maintenance to social support to information gathering. Social media, for example, can provide individuals with opportunities for widening social circles, maintaining social ties, and increasing feelings of inclusion [23,24]. In examining digital technology, it is imperative to consider the ways in which technology is utilized, as different digital technology uses have different effects on mental and physical health. Nonpassive use of social media, such as interacting with others and posting online, is related with better well-being through social support [25,26]. On the other hand, passive use of digital technology, such as surfing the web, reading the news, and watching movies, is typically related to poorer well-being, as these activities require no interactions between people [27]. Additionally, consistent use of technology can create unhealthy habits (such as psychological dependence and addiction to technology use), which have been associated with higher perceived social isolation [28]. As a result of the pandemic, the use of digital technology became the only source of connection and social support available for many [29]. People have transitioned to Zoom and other video conferencing services for both work and maintaining personal relationships [30]. Patients have utilized telemedicine more than ever to receive care via phone or video [31,32].

The COVID-19 pandemic has greatly driven technology’s role as a source of social support [33-35]. For older adults, the use of digital technology has facilitated access to health resources, with the percentage of older adults who had ever participated in a telehealth visit rising sharply from 4% in 2019 to 30% in 2020 [36]. Similarly, the use of information and communication technology among older adults has facilitated different levels of social support such as making connections and emotional support [37]. Despite these findings, there is a lack of research on how AAPIs, as well as older AAPIs, utilize digital technology as a form of social support as a buffering effect alongside stress and isolation.

Given the importance of social support and technology use in the era of a global COVID-19 pandemic, we sought to collect data in a national survey (COVID-19 Effects on the Mental and Physical Health of Asian Americans and Pacific Islanders Survey Study [COMPASS]) that represent the experiences of AAPIs. The objective of this paper was to examine social support and use of digital technology and their associations with mental and physical health during the COVID-19 pandemic among AAPIs. This study sought to inform mental health providers, public health officials, and community partners about the role of social support in mental and physical health during the pandemic as well as the impact of the increased use of technology in AAPI communities.

Methods

Recruitment

There were 5418 participants who completed the survey from October 24, 2020, to April 10, 2021. The COMPASS survey was distributed through community organizations that serve AAPIs, personal and professional networks via email and listservs, social media, flyers, and directed ethnic media. The Collaborative Approach for Asian Americans and Pacific Islanders Research and Education (CARE) research recruitment registry [38,39] was also used to recruit via email. A US $10 gift card was offered upon survey completion. To encourage participation, the survey could be completed online on the COMPASS website [40], by phone, and limited in-person survey administration assistance by COMPASS' staff and community partners. Of the participants, 86.0% (4563/5304) completed the survey independently, and 14.0% (741/5304) had assistance from family, friends, or research staff. To maximize the use of available data, we excluded 787 participants who did not provide information on social support (n=729) or mental health (n=58) from the mental health analyses. Participants who did not provide information on technology use (n=106) or on their physical health (n=224) were further excluded from the analyses including these variables.

Ethical Approval

We obtained human subject research approval from the Institutional Review Board at University of California, San Francisco (Protocol #20-31925), and informed consent was obtained from the participants prior to completing the COMPASS cross-sectional online survey.

Study Eligibility and Procedures

Eligible participants were required to be 18 years of age or older; live within the United States; self-identify ethnically as an AAPI (full or combined with another race or ethnicity); and comprehend written English or Chinese (traditional or simplified Chinese), Korean, Samoan, or Vietnamese. The World Health Organization's process of adapting instruments [41], including backward and forward translation, was used to guide the multilanguage survey's scale and material development. Most participants completed the survey in English (3503/5418, 64.5%); however, there were 4.8% (261/5418) surveys completed in simplified Chinese, 4.7% (253/5418) completed in traditional Chinese, 12.7% (686/5418) completed in Korean, 3.5% (189/5418) completed in Samoan, and 9.7% (526/5418) completed in Vietnamese.

Measures

Mental health was assessed using the Patient Health Questionnaire-4 (PHQ-4) scale for depressive and anxiety symptoms [42]. The PHQ-4 consists of 2 items that measure depressive symptoms [43] and 2 items that measure anxiety symptoms [44]. Each item had response options ranging from 0 to 3, and a PHQ-4 score was created by summing the 4 items (range: 0-12), with higher scores indicating more severe symptoms. Mental health was measured by summing the responses across each of the 4 questions that generated a PHQ-4 score. PHQ-4 has demonstrated acceptable reliability (Cronbach alpha=.82) and construct validity [45] in the general population. In our population, the Cronbach alpha was .90, suggesting acceptable reliability. Scores of 0 to 2 indicated normal, 3 to 5 indicated mild, 6 to 8 indicated moderate, and 9 to 12 indicated severe depression or anxiety. In descriptive analyses by age, we also examined total PHQ-4 score as a categorical variable by comparing those older and younger than 60 years.

General perceived physical health was measured by asking participants to indicate their health "today" using the EuroQol EQ-5D [46,47]. The scale ranges from 0 (worst) to 100 (the best health you can imagine). EQ-5D has been translated and validated in many languages (including Chinese, Korean, and Vietnamese) [48].

Social support was measured using the 6-item Social Support Inventory from the National Latino Asian American Study. Total social support was examined as an average across 6 items: 3 related to family support and 3 related to friend support. The questions included: "How often do you talk on the phone or get together with relatives/friends?"; "How much can you rely on relatives/friends for help with a serious problem?"; and "How much can you open up to family/friends and talk about worries?" Corresponding points were added for each level of support (from 1 to 5 or 1 to 4, as appropriate), with the responses "Refused" and "Don't know" coded as missing. These were then reverse scored, such that higher values corresponded with more social support. Average scores were computed by summing all the individual items and dividing by 6. The Cronbach alpha across all 6 measures was .78.

The COMPASS team created a survey to assess patterns of technology use during the COVID-19 pandemic (Multimedia Appendix 1). The questions related to this study included "Did your use of technology increase during the COVID-19 crisis?" Response options were in the following 5 categories: "Did not increase," "Increased by 1-2 hours/day," "Increased by 3-4 hours/day," "Increased by 5-6 hours/day," and "Increased by 7+ hours/day." As we were interested primarily in the effects of increased technology use, we combined the 2 lowest categories of "Did not increase" and "Increased by 1-2 hours/day."

For sociodemographic and other COVID-19–related characteristics, participants were asked about their year of birth, sex, sexual orientation, race, ethnic or cultural group, marital status, country of birth, education, employment status, and annual household income in 2019. The question asking about the length of SIP orders was developed by the COMPASS team and asked: "How long was the shelter-in-place (or stay-at-home) order at where you live?" The response options included 0 (no order), 1 (<1 month), 2 (1-2 months), and 3 (≥2 months). The question about perceived severity of COVID-19 was also developed by the COMPASS team and asked the participants: "How would you rate the severity of COVID-19 outbreak where you live in comparison to other locations in the U.S.?" Response options were 1 (a lot less severe than most other places in the

U.S.), 2 (somewhat less severe), 3 (about the same), 4 (somewhat more severe), and 5 (a lot more severe). The effect of COVID-19 on family income or employment was measured by 1 of the items from the Coronavirus Impact Scale [49]. Participants were asked to rate how much the COVID-19 pandemic has changed their family income or employment. Response options included 0 (No change), 1 (Mild. Small change; able to meet all needs and pay bills), 2 (Moderate. Having to make cuts but able to meet basic needs and pay bills), and 3 (Severe. Unable to meet basic needs and/or pay bills).

Statistical Analysis

This study analyzed 2 outcome variables, specifically mental health and physical health. Mental health was measured using the PHQ-4 score (sum of 4 items) that was modeled as a continuous variable using multivariable linear regression analysis, with higher numbers indicating weaker mental health, which is consistent with how previous researchers have analyzed it [42,45]. A total of 3 or more for the first 2 PHQ-4 items is indicative of anxiety, and a total of 3 or more for the last 2 items is indicative of depression. Elevated depression or anxiety was indicated by a total of 3 or more across all 4 items. Physical health was also modeled as a continuous variable using multivariable linear regression analysis, with higher numbers indicating better physical health [46,47]. For the main independent variables of interest, social support was modeled as a continuous variable, while technology use was modeled as a categorical variable.

Descriptive statistics were used to report the sociodemographic characteristics of the sample. In the multivariable linear regression models, we adjusted for sociodemographic variables (age, cultural group, sex, country of birth, language proficiency, marital status, employment, education, income) since these variables are known to influence physical and mental health outcomes. We also adjusted for COVID-19–related variables (change in family income, length of SIP, perceived severity of COVID-19, and region) as they were contextual in the era of the pandemic and hypothesized to influence health outcomes. We examined multicollinearity using the variance inflation factor (VIF). The VIF for each of the variables in all physical and mental health models was <5, suggesting little or no multicollinearity between the variables.

To model interactions, we selected hypothesized modifiers of the relationship between our main independent variables and outcomes, specifically age and ethnicity. Age was categorized as a dichotomous variable representing age 60 years or older versus younger than 60 years old based on the age that is considered elderly by international standards [50]. For ethnicity, we selected the 3 largest groups to represent adequate sample sizes for interaction analyses: Ethnic Chinese (n=1560), Korean (n=1007), and Vietnamese (n=841). We examined interactions with age and ethnicity to detect age-related and ethnic or cultural differences, respectively, that may be related to all of the variables of interest (ie, social support, mental and physical health, technology use). We modeled interactions by multiplying the independent variable with the categorical variable (age and ethnicity) and used the Wald test for statistical significance. Tests for changes in technology use were conducted by modeling increase in technology use as a categorical variable with 5 categories ranging from decreased or stayed the same to ≥7–hour per-day increase, with decreased or staying the same as the reference group and using the Wald test for statistical significance. We also tested for a linear trend in technology use using an ordinal variable for technology use and assessing whether the *P* value was significant.

We sought to test the joint effect of social support and technology use on mental and physical health by modeling social support as both a continuous variable and a dichotomous variable (categorized below and above the median) and technology use as an ordinal variable. For the purposes of interpretability of the results, the interaction between social support and technology use was described using social support as a dichotomous variable (at or above the median vs below) and modeling technology use as an ordinal variable. We then used *P* values to assess whether the interaction was statistically significant for technology and high versus low social support.

All statistical tests were 2-sided with alphas for statistical significance set at ≤.05 for all tests. Statistical analyses were conducted using SAS software [51].

Results

Participant Characteristics

Table 1 describes the participant characteristics (n=4631). The major cultural groups were ethnic Chinese, Korean, and Vietnamese. Participants were mostly female (2992/4631, 63.1%). The mean age of participants was 45.9 (SD 16.3) years. Overall, the majority of participants were foreign-born (2976/4631, 64.3%); these foreign-born participants had lived in the United States an average of 24.7 (SD 15.1) years. The mean physical health score was 78.1 (SD 14.9) on a scale of 0 to 100.

Overall, based on the PHQ-4, 37.7% (1745/4631) of participants had elevated depression or anxiety. The prevalence of mild depression among those older than 60 years was lower than in those younger than 60 years (212/1044, 20.3% vs 1030/3587, 28.7%, respectively). Similarly, the prevalence of moderate (32/1044, 3.1% vs 320/3587, 8.9%) and severe depression (14/1044, 1.4% vs 137/3587, 3.8%) was lower among those aged 60 years and older compared with those younger than 60 years, respectively.

[a] Ethnic Chinese includes mainland Chinese, Hongkonger, Taiwanese, and Huaren.

[b] SIP: shelter in place.

[c] PHQ-4: Patient Health Questionnaire-4.

[d] Additional 12 missing technology use in addition to physical health; means and SD are similar for the available data.

Missing Data

There were up to 13% missing data on social support; however, only 5.4% of the physical health data were missing, and 1.6% of the mental health data were missing. Participants who were missing complete information on social support were similar to participants who were included (ie, age, sex, ethnic group) but more likely to have limited English proficiency (495/4072, 17.4% vs 234/1346, 12.2%; *P*<.001).

Social Support and Mental Health

Higher total social support was associated with better mental health. Total social support was inversely associated with PHQ-4 score in the crude and adjusted analyses. In the crude analysis, a 1-unit increase in average total support was associated with a lower total PHQ-4 score (=–0.51; 95% CI –0.61 to –0.40; *P*<.001). The association was attenuated in the adjusted analysis but remained significant: –0.35 (95% CI –0.45 to –0.25; *P*<.001; Table 2). We found evidence of a statistically significant interaction between age and social support in relation to mental health (*P*=.01), comparing those who were aged 60 years and older to those younger than 60 years old. In the stratified analyses by age, the association with total support was significantly stronger for those aged less than 60 years compared with those aged 60 years or older: =–0.563 (95% CI –0.69 to 0.44; *P*<.001) and =–0.17 (95% CI –0.34 to –0.01; *P*=.049), respectively ($P_{interaction}$=.008; Table 2).

Table 2. Social support in relation to mental health and physical health, overall and stratified by age, for all participants.

Social support	Crude		Adjusted[a]					
	Overall (n=4631), beta (95% CI)	*P* value	Overall (n=4631), beta (95% CI)	*P* value	18-60 years old (n=3587), beta (95% CI)	*P* value	≥60 years old (n=1044), beta (95% CI)	*P* value
Total support for mental health[b]	–0.51 (–0.61 to –0.40)[c]	<.001	–0.35 (–0.45 to –0.25)[d]	<.001	–0.56 (–0.69 to –0.44)[e]	<.001	–0.17 (–0.34 to –0.01)[f]	.049
Total support for physical support[g]	2.94 (2.32 to 3.56)[h]	<.001	2.81 (2.18 to 3.45)[i]	<.001	3.33 (2.60 to 4.07)[j]	<.001	0.95 (–0.36 to 2.26)[k]	.15

[a] Adjusted for age (18-30, 30-39, 40-49, 50-59, ≥60+ years), sex (male, female, other/don't know), marital status (single, married/living with partner, separate/divorced/widowed, declined to answer), employment status (full time, part-time home maker, unemployed, retired, other/declined to answer), cultural group (Asian Indian, ethnic Chinese, Filipino, Hmong, Japanese, Korean, Native Hawaiian and Pacific Islanders, Vietnamese, other/mixed), United States region (Midwest, Northeast, South, West), severity of COVID-19 in participant's location relative to the rest of the United States (a lot less, somewhat less, about the same, somewhat more, a lot more), annual household income (US $; ≤25,000, 25,001-75,000, 75,001-150,000, ≥150,001, declined to answer), education (high school or less, some college or technical school, bachelor's degree, master's degree or higher), length of shelter in place (no order, <1 month, 1 month to <2 months, 2-3 months, don't know), change in family income (no change, mild, moderate, severe), English proficiency (limited, not limited), country of birth (United States, outside the United States).

[k] Model R^2=0.06.

Social Support and Physical Health

Social support was positively associated with the physical health score. In the crude analysis, increased social support was associated with higher physical health scores. For every unit increase in mean total support score, the average physical health score was 2.94 (95% CI –2.32 to 3.56, $P<.001$). This association persisted in the adjusted analysis: A 1-unit increase in mean total support was associated with a 2.81 (95% CI 2.18 to 3.45; $P<.001$) increase in the physical health score (Table 2). This association appeared limited ($P_{interaction}$=.01) to those aged less than 60 years of age (=3.33, 95% CI 2.60 to 4.07; $P<.001$). The association between social support and physical health was not significant among those aged 60 years and older (Table 2).

Technology Use and Mental Health

Technology use at each level was associated with an increase in total PHQ-4 score in the crude models, an association that persisted in the adjusted models. Compared with those for whom technology use decreased or stayed the same during the pandemic, after adjusting for covariates, those whose technology increased by 7 hours or more per day had a 1.32-point (95% CI 1.00 to 1.64; *P* for the trend<.001) higher PHQ-4 score (Table 3). The differences by age group and ethnicity were not statistically significant (data not shown). Table S1 in Multimedia Appendix 2 presents the baseline technology use between ethnic groups.

Table 3. Mental health in relation to amount of technology use for all the participants.

Mental health	Crude[a], beta (95% CI)	*P* value	Adjusted[b,c], beta (95% CI)	*P* value
Decreased or stayed the same	Reference	N/A[d]	Reference	N/A
1-2 hour/day increase	0.33 (0.12 to 0.54)	.002	0.19 (–0.01 to 0.38)	.055
3-4 hour/day increase	1.11 (0.91 to 1.32)	<.001	0.63 (0.43 to 0.83)	<.001
5-6 hour/day increase	1.61 (1.34 to 1.87)	<.001	0.86 (0.61 to 1.12)	<.001
≥7 hour/day increase	2.15 (1.82 to 2.49)	<.001	1.32 (1.00 to 1.64)	<.001

[a] Model R^2=0.06; *P* for trend<.001.

[b] Adjusted for the same variables as in Table 2.

[c] Model R^2=0.22; *P* for trend<.001.

[d] N/A: not applicable.

Technology Use and Physical Health

Technology use was inversely associated with physical health. Compared with the reference group, those whose use increased by 7 hours or more a day reported a –3.48 (95% CI –5.50 to –1.46; *P* for the trend<.001) physical health score in the crude model. There was a statistically significant interaction by cultural group, with Koreans (*P* for the trend<.001) having significantly lower health scores for 7 or more hours of technology use daily compared with the same or decreased use; this was not true for ethnic Chinese (*P* for the trend=.48) or Vietnamese (*P* for the trend=.16; Table 4). The interaction by age was not significant (data not shown).

Table 4. Physical health in relation to technology use, overall and stratified by cultural group, for all participants.

Social Support and Technology Use in Relation to Mental and Physical Health

In exploratory analyses, we examined the joint effects of social support and technology use in relation to mental and physical health. Social support and technology use were independently associated with each other in both models, and the interaction between the two was significant for both mental and physical health. We found that the effect of technology use on mental health was significantly weaker among those with low social support compared with among those with high social support (*P*=.01; Figure 1). Similarly, the effect of technology on physical health was significantly weaker among those with low social support (*P*=.02; Figure 2). The interaction finding with social support and technology use with both mental and physical health was tested for an overall effect but was not specific to certain length of time (hours) of technology use. Although there was a significant overall interaction for the measures, they were more pronounced at higher levels.

Figure 1. Linear regression analyses for joint effects of social support and technology use on mental health.

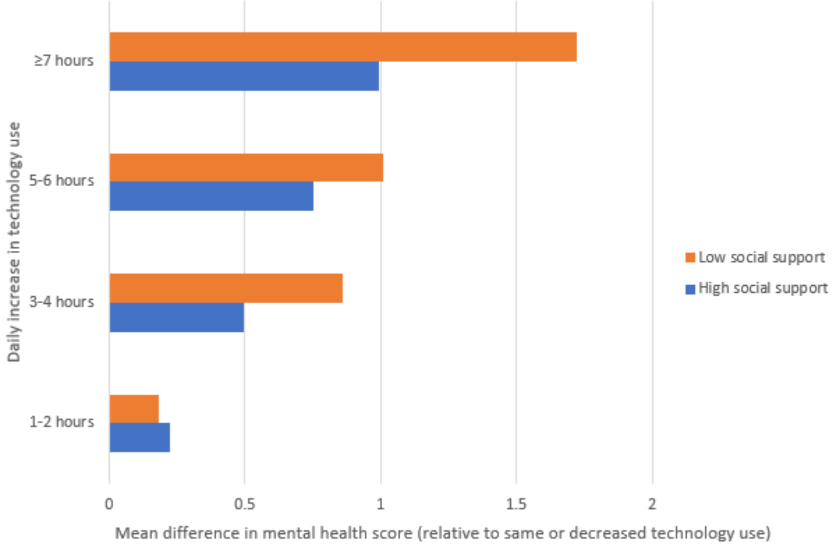

Figure 2. Linear regression analyses for joint effects of social support and technology use on physical health.

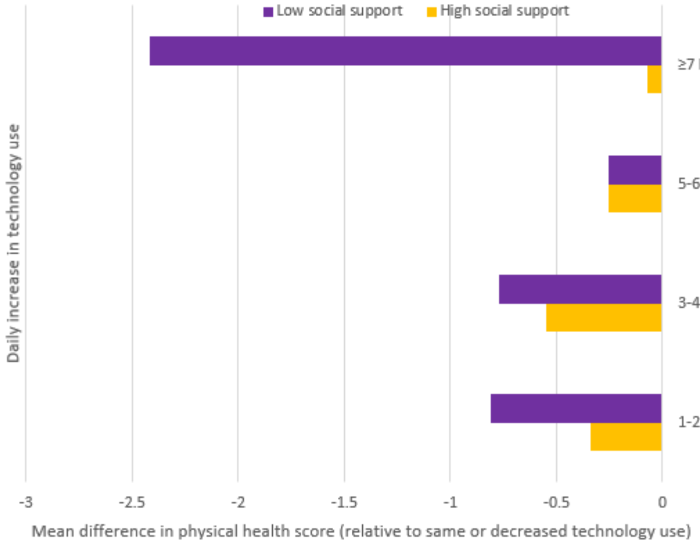

Discussion

Principal Findings

This paper presents the association of self-reported social support and technology use on the outcomes of mental and physical health during the COVID-19 pandemic as reported by over 4600 AAPI community members in a national survey. We found several significant results that represent 10 different AAPI ethnic groups; however, our paper presents stratified analyses in the 3 largest ethnic groups: Ethnic Chinese, Korean, and Vietnamese. Overall, 12.9% and 11.4% of our survey respondents reported depression and anxiety, respectively, which is markedly higher than prepandemic averages. According to the 2019 US Census Bureau assessments prior to the pandemic, only 2.9% and 3.2% of Asian Americans reported depressive and anxiety disorders, respectively (n=31,229) [52]. Among all US adults, there was a 4-fold increase in the likelihood of having depression or anxiety from 2019 to 2020, with the greatest increases among younger people, Asian Americans, and parents [52]. The average physical health score of 78.1 (out of 100) among AAPIs in our study was similar to what was reported in a prior study of over 11,500 diverse adults 18 years and older (eg, score of 79.2) [53].

In this cross-sectional study, we found that low social support was associated with more self-reported mental health symptoms (depression and anxiety) overall. Furthermore, although both age groups had these outcomes, when comparing the 2 age groups in the adjusted analyses, we found all types of social support were more significant for those younger than 60 years of age compared with those 60 years and older, suggesting greater impact of social support among younger adults with more mental health symptoms. A rise in mental health changes (ie, depression, fear, health-related anxiety) would be expected given the increased social isolation due to SIP orders and social distancing, as well as increased concern for self and loved ones (eg, health, financial stability) caused by the COVID-19 pandemic [54]. Reasons for the greater mental health impact in the younger group may be related to being accustomed to more socialization compared with those who are older who may be more resilient to social changes and less socialization [55]. No significant differences were found among AAPI ethnic groups. Potential reasons why depression and anxiety were lower in adults 60 years and older compared with younger adults include the public health message that isolation was protective against COVID-19; in addition to older adults being more used to not socializing as much as younger people, they were also likely more grateful to be alone, due to their awareness of being in an at-risk group. However, the literature on older adults, not specific to AAPI, shows that they were more likely at a high risk for mental illness from social isolation in general and social restrictions due to COVID-19 [56,57].

Beyond mental health outcomes, we found that high social support was associated with positive self-reported physical health scores. After adjusting for possible confounding variables, findings on social support and physical health scores were limited to those who were less than 60 years of age, unlike social support and mental health. Again, we did not detect significant differences among ethnic groups. By examining access and reliance on all forms of social support, our results confer our prepandemic understanding of coping in which forms of social support are used to improve health status and have a protective factor. Compared with this survey, a cross-sectional study of 3649 individuals aged 60 years and older concluded that the predictors of poor self-reported health included a lack of perceived social support in women and lack of social network involvement in men [58].

With regards to technology use during the pandemic, we found incremental increases in self-reported depressive and anxiety scores with increased use of technology; mental health symptoms (ie, higher PHQ-4 scores up to 2.15) were greater with technology use of 3 or more hours after adjusting for all possible confounders. These results are consistent with other research that showed that moderate or severe levels of depression were associated with more than 2-fold time spent watching TV and using a computer (>6 hours per day) [59]. Similarly, increased technology use was associated with poor physical health. Unlike social support, there was no significant interaction with the age groups. We did not detect significant differences among cultural groups.

When examining technology use and physical health, we detected significant changes in self-reported physical health scores with 3 or more hours per day of technology use after adjusting for all possible confounders. Consistent with our results, increased screen time has been linked to potentially harmful physical effects, as it negatively affects physical activity and sleep routine, thereby leading to headaches, neck pain, myopia, digital eye syndrome, and cardiovascular risk factors (obesity, high blood pressure, and insulin resistance) [60]. Additional analyses showed differences between cultural groups, with Korean American individuals reporting lower physical health scores than ethnic Chinese and Vietnamese individuals who had the same or lower amount of technology use. Our survey did not ask participants to specify the reason for using technology, so it is unclear whether this signals more technology use for work, leisure, or both. Based on increases in internet service use (from 40% to 100%) and video-conferencing services (10-fold increase) during the pandemic, we can assume a good portion was used for work purposes across all groups [61].

Comparisons With Prior Work

When examining the joint effects of both social support and technology use, we found significant independent associations with mental and physical health as well as a significant interaction between social support and technology use for both mental and physical health after accounting for all possible confounders. When considering technology, an important factor is social media use, with one study showing that social media exposure was associated with anxiety and combined depression and anxiety when compared with less social media exposure (1.72 and 1.91 greater odds, respectively) [12]. In terms of the interaction effect between social support and technology use on physical health, there are important potential benefits. In a study of 591 older adults, social connectedness via technology prior to the pandemic was associated with significant health benefits including better self-rated health, fewer chronic illnesses, higher subjective well-being, and fewer depressive symptoms [62].

Clinical Implications

There are important clinical implications related to our findings, particularly for mental health providers, public health officials, and community partners. Undoubtedly, the COVID-19 pandemic negatively impacted mental and physical health for the vast majority of adults and children; however, understanding the contributing factors and high-risk groups is critical. Adults younger than 60 years were more impacted by social support, as evidenced by stronger associations with lower mental health and higher physical health scores compared with those who were 60 years or older. In addition, Korean Americans appeared to be a high-risk group for poor physical health with increased technology use. Further work is needed to understand how social support is characterized and how to best operationalize it for each AAPI community to achieve the known mental and physical health benefits in times of emergency [63]. Although access to technology may have buffered loneliness and isolation [64], more research is needed on the potential for different uses of technology to improve self-care and well-being, along with the potential to bring harm to individuals.

Limitations

There are limitations that should be considered when interpreting these results, including a cross-sectional survey study design that did not allow us to assess dynamic changes over time during the pandemic. Another limitation was nonprobability sampling. We had significantly more female participants than male participants, although we adjusted for this in our analyses. Although this was a national survey, there were varying SIP and social distancing policies across regions and states, which may have affected the responses. Since the survey was not conducted in every AAPI language spoken, generalizability is limited and would be improved with more languages added to the survey. In addition, COMPASS is primarily an online survey, limiting its reach to those who lack access or are unable to utilize the internet. As mentioned, our inquiry on technology use did not distinguish between varying technologies nor whether the technologies were used for work or leisure.

Conclusions

The COVID-19 pandemic has taken its toll on both mental and physical health in many individuals and families in the United States and globally. In a large sample of AAPI recruited nationally, a significant portion of our study population reported probable anxiety and depression. The prevalence of moderate and severe depressive symptoms was lower among those aged 60 years and older compared with those younger than 60 years. Despite COVID-19–related deaths being highly concentrated in this older age group, this finding represents the resilience of older AAPI Americans during a pandemic, with less than 5% of older adults reporting moderate to severe depressive symptoms.

Importantly, this study offered new insights into contributing factors for mental and physical health status by examining perceived social support and changes in technology use among AAPI during the pandemic. The key findings suggested that greater social support during the pandemic was associated with lower levels of depression and anxiety and better physical health, whereas increased technology use during the pandemic was associated with poorer mental and physical health in AAPI. Such associations were particularly pronounced among adults younger than 60 years. Although we observed similar associations between social support and mental health across cultural groups, Korean Americans appeared to be more vulnerable to the effect of increased technology use on their physical health. These findings revealed new health disparities observed during the pandemic that require urgent attention on multiple fronts, including individual, social, and community levels. Future research on how social support can be leveraged, especially among those younger than 60 years, and how various types of technology are being utilized is important to guide the recovery efforts to address both mental and physical disparities across communities as a result of the negative impacts from the COVID-19 pandemic.

Acknowledgments

We sincerely appreciate the Asian Americans and Pacific Islander (AAPI) participants who completed the COVID-19 Effects on the Mental and Physical Health of Asian Americans and Pacific Islanders Survey Study (COMPASS) survey. We would like to thank the International Children Assistance Network (ICAN), National Asian Pacific Center on Aging (NAPCA), and other community partners who supported recruitment for this study.

This study was supported by the National Institutes of Health (NIH)/National Institute on Aging (NIA; 3R24AG063718-02S1, NIH/NIA R24AG063718, NIH/NIA R56AG069130). The funders had no role in study design, data collection, analysis, writing, and decision to publish. The content is solely the responsibility of the authors and does not necessarily represent the official views of the NIH.

Authors' Contributions

VMTP, LGP, OLM, MMD, and JYT designed the study and developed the methodology. LGP led the manuscript writing and drafted major sections of the paper. MMD and BG completed all statistical analyses and drafted the results, tables, and figures. VMTP, OLM, MMD, BG, KT, BN, JYT, and MT contributed to writing of the manuscript and reviewing tables and figures. VMTP acquired the research funding. All authors contributed to interpretation of results, reviewing drafts, and approval of the final manuscript for submission.

Conflicts of Interest

Abstract

Background: To date, the association between acute signs and symptoms of COVID-19 and the exacerbation of depression and anxiety in patients with clinically mild COVID-19 has not been evaluated.

Objective: This study was designed to assess the correlation between acute signs and symptoms of COVID-19 and the exacerbation of depression and anxiety in patients with clinically mild COVID-19 at a residential treatment center in South Korea.

Methods: This retrospective study assessed 2671 patients with COVID-19 admitted to 4 residential treatment centers operated by Seoul National University Hospital, South Korea, from March 2020 to April 2022. Depression and anxiety were assessed using the 2-item Patient Health Questionnaire (PHQ-2) and 2-item Generalized Anxiety Disorder (GAD-2) scale, respectively. The exacerbation of depression and anxiety symptoms was identified from the differences in PHQ-2 and GAD-2 scores between admission and discharge, respectively. The patients' clinical characteristics, including acute signs and symptoms of COVID-19, GAD-2 and PHQ-2 scores, were obtained from electronic health records. Demographic characteristics, a summary of vital signs, and COVID-19 symptoms were analyzed and compared between the patient groups with and those without exacerbated PHQ-2 and GAD-2 scores using the chi-square test. We applied logistic regression to identify the association between acute signs and symptoms of COVID-19 and the exacerbation of depression and anxiety.

Results: Sleep disorders were associated with exacerbated depression (odds ratio [OR] 1.09, 95% CI 1.05-1.13) and anxiety (OR 1.1, 95% CI 1.06-1.14), and the sore throat symptom was associated with exacerbated anxiety symptoms (OR 1.03, 95% CI 1.00-1.07). Patients with abnormal oxygen saturation during quarantine were more likely to have exacerbated depression (OR 1.27, 95% CI 1.00-1.62), and those with an abnormal body temperature during quarantine were more likely to experience anxiety (OR 1.08, 95% CI 1.01-1.16). As anticipated, patients who experienced psychological symptoms at admission were more likely to experience depression (OR 1.91, 95% CI 1.52-2.41) and anxiety (OR 1.98, 95% CI 1.54-2.53). Meanwhile, the PHQ-2 and GAD-2 scores measured at admission revealed that lower the score, higher the possibility of exacerbation of both depression (OR 0.15, 95% CI 0.11-0.22) and anxiety (OR 0.13, 95% CI 0.10-0.19).

Conclusions: Results from this study suggest the importance of further interventions for patients with abnormal oxygen saturation, abnormal body temperatures, sore throat, and sleep disorder symptoms or initial psychological symptoms to mitigate the exacerbation of depression and anxiety. In addition, this study highlights the usability of short and efficient scales such as the PHQ-2 and GAD-2 in the assessment of the mental health of patients with clinically mild COVID-19 symptoms who were quarantined at home during the pandemic era.

KEYWORDS

COVID-19; depression; anxiety; vital signs; symptoms; electronic health records

Introduction

The ongoing COVID-19 pandemic has not only affected physical health but also induced mental health issues such as depression, anxiety, stress, or insomnia [1-3]. A systematic review on the prevalence of psychological symptoms in the general population during the COVID-19 pandemic reported that the prevalence of depressive symptoms ranged from 14.6% to 48.3% and that of anxiety ranged from 6.33% to 50.9%, which is more than double the prevalence in the nonpandemic era [4]. South Korea is no exception because of its increased prevalence of psychological symptoms associated with depression and stress [5-7]. These remarkable increases in psychological symptoms are known to contribute to mental health problems such as anxiety, depression, insomnia, somatization, posttraumatic stress disorder, self-harm, and suicidal thoughts and behaviors. Thus, the importance of early detection and management of mental health disorders cannot be overemphasized [6,8].

Patients confirmed with a COVID-19 diagnosis most commonly experience physical symptoms such as fever, cough, and fatigue [9,10]. In particular, nonhospitalized patients with a clinically mild COVID-19 infection have fatigue, headache, and sneezing as the most common acute symptoms, and fatigue and reduced smell and taste as the most severe symptoms [11]. While transitioning to focusing on the post–COVID-19 condition, symptoms such as fatigue may persist as long as 12 weeks in the long-term phase, and these symptoms are known to affect patients' mental health and the quality of life [11,12].

Despite attempts to explore acute and persistent symptoms of COVID-19 and patients' mental health affected by persistent symptoms, little is known about the association between physical and psychological symptoms of acute COVID-19. Ismael et al [13] found that an increased number of COVID-19 symptoms may be associated with depression, anxiety, and posttraumatic symptoms. Perlis et al [14] reported that patients with COVID-19 who reported headaches during acute infection appeared to have an elevated risk of depression. During the transition to post–COVID-19 condition [15], it is necessary to examine the occurrence of acute signs and symptoms, changes in mental health, and their association while community-dwelling confirmed patients were quarantined.

The Korean government has operated a residential treatment center (RTC) in response to the COVID-19 pandemic [16]. In the early stages of the COVID-19 outbreak, patients with COVID-19 could not be admitted to the hospital because of a lack of negative-pressure isolation beds. Accordingly, the government admitted all confirmed patients with clinically mild conditions to RTCs and transferred them to the hospital if their medical condition deteriorated to require admission-based care. Since then, with the rapid increase in the number of patients with COVID-19, high-risk patient groups with mild conditions have been selectively isolated to RTCs because it was difficult to isolate all confirmed patients at RTCs.

As patients with confirmed COVID-19 without symptoms and those with mild symptoms were being monitored in quarantine at home, it was not easy to explore the status of their acute signs and symptoms and psychological diseases such as depression and anxiety. Therefore, it is important to ascertain the association between COVID-19–related acute signs and symptoms, and depression and anxiety, based on the accumulated retrospective data. With this background, we analyzed the association between acute signs and symptoms of COVID-19 and exacerbation of depression and anxiety in nonhospitalized patients with clinically mild COVID-19 symptoms who were admitted to RTCs.

Methods

Study Design

This retrospective study was performed at Seoul National University Hospital (SNUH).

Study Setting

The study setting was 4 RTCs operated by the SNUH in accordance with government guidelines [17]. The government RTC operating guidelines were periodically updated in consideration of the number of newly confirmed cases at the time the RTC operation and distribution of confirmed cases at the national level. The confirmed patients were assigned to each RTC by the government in accordance with this guideline. During the early phase of the pandemic, from December 2020 to November 2021, following the relevant Korean guidelines, all clinically mild cases among the confirmed cases in South Korea were quarantined at the RTC. With a rapid increase in the number of confirmed cases, all quarantine policies were modified to prioritize those who are more vulnerable to deterioration of their COVID-19 infection. Selection criteria for RTC admission include unvaccinated older individuals and patients in residential environments vulnerable to the spread of infection. All patients were quarantined independently in a separate room. All costs related to quarantine at an RTC were fully covered by the government. Quarantined patients requiring oxygen supply due to a persistent saturation of percutaneous oxygen (SpO_2) of <94%, or those with a clinical condition requiring medical intervention, were transferred to the hospital.

Table 1 shows the location, size in terms of the number of beds, operation period, and accumulated confirmed COVID-19 cases at the national level for operated RTCs in detail.

Table 1. Details of residential treatment centers operated by the Seoul National University Hospital.

Name	Location	Beds, n	Operation period (accumulated confirmed COVID-19 cases at the national level during the operational period, n) [17]
A	Near Daegu city in North Gyeongsang province	99	- March 2020 to April 2020 (7834)
B	Nowon-gu, Seoul	124	- August 2020 to October 2020 (12,206)
C	Seongnam city in Gyeonggi province	225	- August 2020 to September 2020 (9506)
D	Seongnam city in Gyeonggi province	334	- December 2020 to January 2021 (43,998) - July 2021 to April 2022 (17,079,907)

Study Participants

Adult patients with a confirmed COVID-19 diagnosis admitted to 4 RTCs operated by the SNUH from March 2020 to April 2022 were included in this study. Patients who tested positive for COVID-19 on the reverse transcriptase–polymerase chain reaction test but had clinically mild conditions were subjected to RTC admission. A total of 5199 patients were admitted during the study period. Patients with missing data were excluded from the analysis.

Data Sources

Using the SNUH information and communication technology–based remote patient monitoring (RPM) system [18], it was mandatory for every patient admitted to the RTC operated by the SNUH to use the mobile app and to self-report their past medical history, vital signs, subjective acute COVID-19 symptoms, and psychological symptoms. Reporting was done once on admission, twice a day during the quarantine period, and once on discharge. These data were automatically stored in the hospital information system at the SNUH. The records were monitored in real time by health care providers. For any missing data in the records, health care providers directly checked the patient and filled in the missing data. We finally extracted these electronic health records using the SNUH Patient Research Environment (also known as “SUPREME”)—a clinical data warehouse at the SNUH. The data sources in the final analysis included RTC admission notes, daily progress notes, and discharge notes in the electronic health record.

Data on patients’ depressive and anxiety symptoms were extracted from the RTC admission and discharge notes. Patients’ self-reported scores on the 2-item Patient Health Questionnaire (PHQ-2)—a subscale of the Patient Health Questionnaire 9 [19]—and 2-item Generalized Anxiety Disorder Scale (GAD-2)—a subscale of the Generalized Anxiety Disorder Scale (GAD-7) [20]—via a mobile app at admission and discharge. One of the PHQ-2 items was, “Over the last 2 weeks, how often have you been bothered by any of the following problems?” with response options of “Little interest or pleasure in doing things,” and “Feeling down, depressed, or hopeless” on a 4-point Likert scale. Scores ranging from 0 to 6, with a cutoff score of ≥3 indicating depressive symptoms. The PHQ-2 was reported to have a sensitivity of 0.79 and a specificity of 0.86 for any depressive disorders [21]. One of the GAD-2 items was, “Over the last 2 weeks, how often have you been bothered by any of the following problems?” with response options of “Feeling nervous, anxious, or on the edge” and “not being able to stop or control worrying” with a 4-point Likert scale. Scores range from 0 to 6, with a cutoff score of ≥3 indicating anxiety symptoms. The GAD-2 was reported to have a sensitivity of 0.65 and a specificity of 0.88 as a general screening tool for anxiety disorders [22].

Patient demographic characteristics (eg, age, sex, and admitted RTC site), medical history (diabetes mellitus, hypertension, cardiovascular disease, respiratory disease, sleep disorder, and psychological treatment), and initial psychological symptoms such as depression and panic were extracted from the RTCs’ admission notes. Patients’ smoking statuses were extracted from the RTCs’ discharge notes.

Patients’ self-measured vital signs and acute COVID-19 symptoms were extracted from the RTCs’ daily progress notes, which were collected via a mobile app at least twice a day. The vital signs included systolic blood pressure, diastolic blood pressure, heart rate, respiratory rate, body temperature (BT), and SpO_2. Acute COVID-19 symptoms consisted of the presence or absence of respiratory and nonrespiratory symptoms. Respiratory symptoms included cough, sputum production, fever, rhinorrhea, sore throat, dyspnea, and chest pain. Nonrespiratory symptoms include nausea, vomiting, abdominal discomfort, pain, constipation, diarrhea, abdominal pain, and sleep disorders.

The loss of taste and smell was extracted from the RTCs’ discharge notes. At discharge, participants reported the presence or loss of smell and taste.

Statistical Analysis

Data preparation was conducted before data analysis. The exacerbation of depressive symptoms’ and anxiety symptoms’ cases were identified from the differences between PHQ-2 scores and GAD-2 scores at admission and discharge, respectively. Criteria for abnormal vital signs, in consultation with an infection medicine specialist, are as follows: a systolic blood pressure above 140 mm Hg or below 60 mm Hg, a diastolic blood pressure above 90 mm Hg or below 30 mm Hg, a heart rate above 110 bpm or below 40 bpm, respiratory rate above 21/minute or below 8/minute, BT above 38.0 °C or below 35.0 °C, and an SpO_2 below 94%. The number of days with each abnormal vital sign and acute COVID-19 symptom was calculated.

Demographic characteristics, summary of vital signs, and COVID-19 symptoms were analyzed and compared between the patient groups with and those without exacerbated PHQ-2 and GAD-2 scores, using the chi-square test. We then applied logistic regression with exacerbation of depressive and anxiety symptoms as dependent variables, and sociodemographic features, past medical history, initial psychological symptoms, initial PHQ-2 or GAD-2 scores, average number of days with abnormal vital signs, and average number of days with acute COVID-19 symptoms as independent variables, using R statistical software (version 4.2; R Project for Statistical Computing). Statistical significance was tested at α=.01.

Ethical Considerations

This study was approved by the SNUH's institutional review board (H-2105-158-1221) and was conducted in accordance with the relevant guidelines and regulations. Informed consent was waived by the institutional review board considering the study design and adherence to the relevant guidelines. In particular, study data were deidentified to protect privacy and preserve the confidentiality of the study participants.

Results

Patients' Clinical Characteristics

In total, 2671 individuals reported COVID-19 infection without any missing values. The clinical characteristics of the patients are presented in Table 2. The mean age was 41.1 (SD 14.1) years, and the mean quarantine period was 7.07 days. Overall, 1242 (46.5%) participants were female, and 44 (1.6%) were admitted at RTC A, 324 (11.8%) at RTC B, 819 (30.7%) at RTC C, and 1494 (55.9%) at RTC D. A total of 746 (27.9%) patients were infected by the alpha variant of SARS-CoV-2, 1563 (58.5%) by the delta variant, and 362 (13.6%) by the omicron variant. Overall, 141 (5.3%) participants had a past medical history of diabetes mellitus, 361 (13.5%) had a medical history of hypertension, 168 (6.3%) had a medical history of sleep disorders, 158 (5.9%) had a history of psychological treatment. Upon admission, 1273 (47.7%) participants had initial psychological symptoms. Detailed clinical characteristics upon exacerbation of PHQ-2 and GAD-2 scores are presented in Multimedia Appendix 1.

Table 2. Patients' clinical characteristics (N=2671).

Clinical characteristics	Participants, n (%)
Demographic data	
Females	1242 (46.5)
Aged under 30 years	748 (28.0)
Aged 30 to 39 years	500 (18.7)
Ages 40 to 49 years	545 (20.4)
Aged 50 to 59 years	556 (20.8)
Aged 60 years or older	322 (12.1)
Admitted to residential treatment center A	44 (1.6)
Admitted to residential treatment center B	314 (11.8)
Admitted to residential treatment center C	819 (30.7)
Admitted to residential treatment center D	1494 (55.9)
Infected with the SARS-CoV-2 alpha variant	746 (27.9)
Infected with the SARS-CoV-2 delta variant	1563 (58.5)
Infected with the SARS-CoV-2 omicron variant	362 (13.6)

Loss of smell	1264 (47.3)
Loss of taste	1243 (46.5)

PHQ-2 and GAD-2 Scores Measured at Admission and Discharge

The PHQ-2 and GAD-2 scores measured at admission and discharge are presented in Figure 1. At admission, the mean PHQ-2 score was 0.76 (SD 1.17). Of a total of 2671 patients, 663 (24.8%) had a PHQ-2 score of 2 or higher. The mean GAD-2 score was 0.93 (SD 1.27), and 856 (32.0%) had a score of 2 or higher. At discharge, the mean PHQ-2 score was 0.77 (SD 1.18), and 675 (25.3%) had a score of 2 or higher. The mean GAD-2 score was 0.84 (SD 1.21), and 744 (27.9%) had a score of 2 or higher.

A total of 535 patients showed exacerbation of depression. In fully adjusted models, an abnormal SpO_2 was associated with increased odds of exacerbation of depression (odds ratio [OR] 1.27, 95% CI 1.00-1.62). Among acute COVID-19 symptoms, presence of sleep disorder was associated with exacerbation of depression (OR 1.09, 95% CI 1.05-1.13). Women demonstrated higher odds of exacerbation of depression than men (OR 2.33, 95% CI 1.78-3.05) and higher odds of exacerbation of depression with increasing age (>60 years; OR 4.01, 95% CI 2.71-5.93). Patients admitted at RTC A demonstrated higher odds of exacerbation of depression than those who were admitted at RTCs B, C, and D (OR 2.93, 95% CI 1.24-6.93), and those diagnosed with COVID-19 due to the alpha variant of SARS-CoV-2 showed lower odds of symptom exacerbation than those with the delta variant (OR 0.57, 95% CI 0.36-0.90). Past medical history of sleep disorders demonstrated lower odds to associate with exacerbation (OR 0.60, 95% CI 0.36-0.98), whereas presence of initial psychological symptoms was associated with exacerbation (OR 1.91, 95% CI 1.52-2.41). The higher patients' PHQ-2 scores at admission demonstrated lower odds of exacerbation of depression (OR 0.15, 95% CI 0.11-0.22). Figure 2 illustrates the ORs from the regression models adjusted for the patients' clinical characteristics.

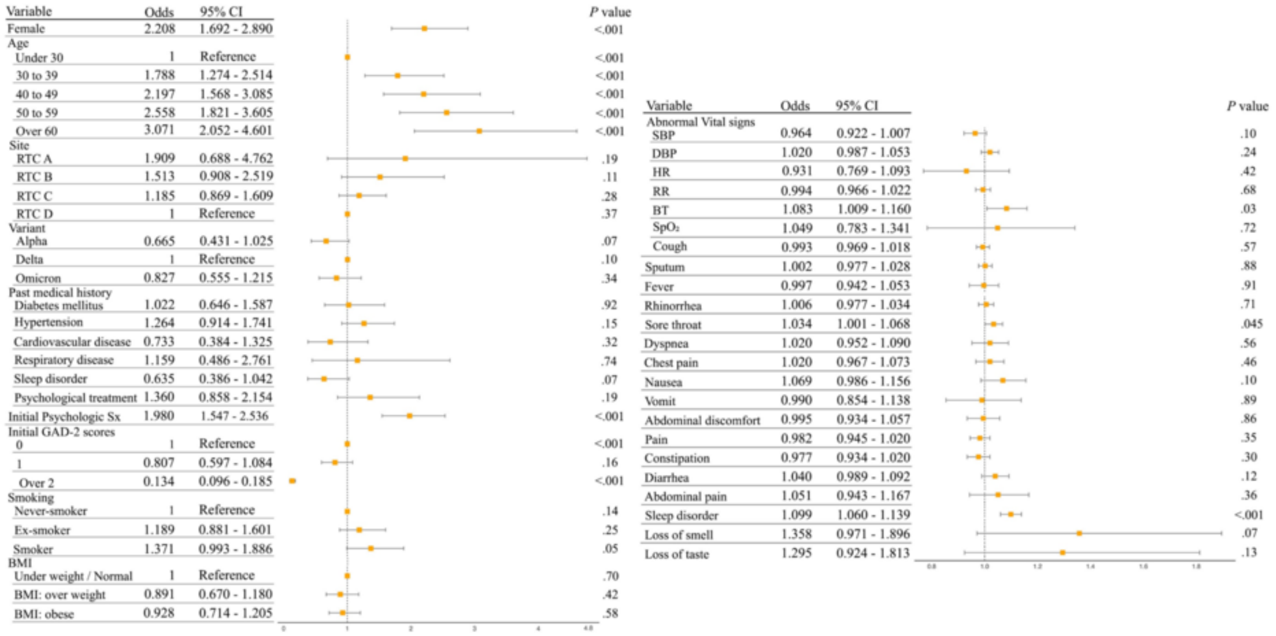
Association of Acute Signs and Symptoms of COVID-19 and Exacerbation of Anxiety

A total of 523 patients presented exacerbation of anxiety. Among abnormal vital signs, abnormal BT was associated with exacerbation of anxiety (OR 1.08, 95% CI 1.01-1.16). Among acute COVID-19 symptoms, the presence of sleep disorders and sore throat were associated with exacerbation of anxiety (sleep disorders: OR 1.1, 95% CI 1.06-1.14; sore throat: OR 1.03, 95% CI 1.00-1.07). Women showed higher odds of exacerbation of anxiety than men (OR 2.21, 95% CI 1.69-2.88) and higher odds of exacerbation of anxiety with increased age

(>60 years; OR 3.07, 95% CI 2.05-4.60). Presence of initial psychological symptoms was associated with the exacerbation of anxiety (OR 1.98, 95% CI 1.54-2.53). The higher patients' GAD-2 scores at admission indicated lower odds of exacerbation of anxiety (OR 0.13, 95% CI 0.10-0.19). Figure 3 illustrates the ORs from the regression models adjusted for patients' clinical characteristics.

BT: body temperature; DBP: diastolic blood pressure; HR: heart rate; PHQ-2: 2-item Patient Health Questionnaire; RR: respiratory rate; RTC: residential treatment center; SBP: systolic blood pressure; SpO_2: saturation of percutaneous oxygen.



Discussion

Principal Findings

To the best of our knowledge, this study is the first to explore the association between acute signs and symptoms of COVID-19 and the exacerbation of depression and anxiety in patients with clinically mild COVID-19 [13-15]. Among sociodemographic features, we found that female sex and older age affected the likelihood of exacerbation of depression and anxiety in patients with clinically mild COVID-19, which is consistent with previous studies [23-26]. In addition, RTC A, located in Daegu and Gyeongbuk province, where patients in the early phase of COVID-19 with social stigma were admitted, was found to be highly associated with exacerbation of anxiety.

The most common acute COVID-19 symptoms are cough, sputum, rhinorrhea, sore throat, and loss of smell and taste. The proportion of these symptoms was ~40%-65%, which was relatively lower than that reported in previous studies on acute and persistent symptoms in nonhospitalized patients with COVID-19 [11]. This may reflect the results of triage, which incorporates multiple symptoms in accordance with the hospitalization policy of the Korea Disease Control and Prevention Agency. The types of acute COVID-19 symptoms most commonly complained of were consistent with those reported in previous studies in that fever, cough, myalgia, and fatigue were described as common symptoms of COVID-19 [9,10] and loss of smell and taste as prevalent and relatively discriminative symptoms of COVID-19 [27-29]. Sputum production has been regarded as a less common symptom of early COVID-19 [30,31] but was reported as one of the most common symptoms in this study. The reason for the high proportion of sputum production seems to be that study participants included patients infected with the omicron variant of SARS-CoV-2 whose complains of sputum symptoms were relatively high [32].

Among acute COVID-19 symptoms, patients who experienced sleep disorder symptoms more frequently during quarantine showed higher odds of exacerbation of depression (*P*<.001) and anxiety (*P*<.001) than those who did not. Sleep disorders are a core symptom of depression and anxiety, and this study shows a strong association between them, which is consistent with those reported in previous studies [33-35]. We also found that those who had experienced sore throat more frequently during quarantine had an elevated risk of anxiety symptoms (*P*<.05). The more the patient experiences sore throat, which is one of the representative upper respiratory symptoms of COVID-19 infection with the omicron variant, the higher the risk of exacerbation of anxiety, which means that early active intervention for mental health may be necessary. We expected that other similarly frequently reported acute symptoms such as cough, sputum production, rhinorrhea, and loss of smell and taste would also be associated with exacerbation of depression and anxiety, but this correlation was not found. Although it is difficult to generalize the results of this study, the association between physical symptoms and depression and anxiety is well known, and it is also well known that depression and anxiety accompany somatic symptoms. Thus, in the acute phase within 1 week of COVID-19 infection, health care providers should examine both physical and mental health during the treatment course of patients with acute COVID-19.

On the contrary, the vital signs of COVID-19 were stable, with a small proportion of patients presenting abnormal ranges during quarantine at the RTC. These results indicate that most patients admitted to the RTC had clinically mild conditions and did not require inpatient treatment. Patients who presented abnormal SpO_2 during quarantine demonstrated higher odds of exacerbation of depression ($P<.05$) than those who did not. In addition, patients who had an abnormal BT during quarantine demonstrated higher odds of exacerbation of anxiety ($P<.05$). It is important to note that patients who often had unstable vital signs during quarantine showed the possibility of exacerbation to depression and anxiety due to exposure.

As anticipated, patients who had experienced psychological symptoms at admission had higher odds of exacerbation of depression ($P<.001$) and anxiety ($P<.001$) than those who did not. Meanwhile, the PHQ-2 and GAD-2 scores measured at admission showed that lower the score, higher the association between exacerbation of both depression ($P<.001$) and anxiety ($P<.001$). In addition, patients who had received previous psychological treatment were less likely to experience exacerbation of depression ($P<.001$). The group that received psychological treatment might have had a higher PHQ-2 or GAD-2 score at admission. Thus, these results can be interpreted as follows: higher the PHQ-2 or GAD-2 score at admission, narrower the range of scores that can be exacerbated.

The novelty of this study is the use of both contactless RPM systems and screening scales. First, data were obtained through a contactless RPM system for patients with COVID-19. More than 80% of patients with COVID-19 had clinically mild conditions, and these patients were quarantined at home or RTCs, not medical institutions, and monitored with a contactless RPM system. The establishment of a contactless RPM system for patients with clinically mild conditions who do not require intensive care unit care has been gradually attempted in various studies [36-38], and the SNUH has also established a contactless RPM system [18]. The data analyzed in this study were also the results of establishing the system at 4 RTCs operated by the SNUH.

Second, the results of this study provide supporting evidence that depression and anxiety can be assessed by the PHQ-2 and GAD-2, which are useful and efficient scales for patients with COVID-19 quarantined at home. As the prevalence of mood disorders has increased after the onset of the COVID-19 pandemic [4-7], concerns about individuals' mental health are growing. Patients with COVID-19 who are self-isolated at home or at an RTC might be in a clinically mild condition and are not fully aware of the need for mental health assessment. Since they are not hospitalized and have limited access to medical personnel, it is necessary to assess the mental health of patients using a readily accessible simple convenient tool. In that sense, the PHQ-2 and GAD-2, which have already been validated as having high sensitivity and specificity as the PHQ-9 and GAD-7, may be regarded as useful screeners and efficient tools for monitoring treatment progress and outcomes in primary medical settings [21,39-43]. Furthermore, the results from this study suggest the importance of considering further interventions that might mitigate the exacerbation of depression and anxiety associated with acute signs and symptoms during the post–COVID-19 condition [15].

Limitations

This study is not without its limitations. First, this was a retrospective observational study; therefore, causal relationships cannot be inferred, and further analysis of additional data such as socioeconomic factors, not collected in the hospital information system at the SNUH, was not possible. Second, the data analyzed were retrieved from a single tertiary hospital operating 4 RTCs of different sizes in accordance with government regulations. The possibility of influence or correlation with various unmeasured variables such as, but not limited to, lack of social interactions, financial loss, and vaccination status may limit the generalizability of our findings. Third, sample bias was possible as patients with missing data were excluded. Fourth, there were no follow-up longitudinal data after discharge from the RTC. Thus, it was not possible to explore the associations between COVID-19–related acute signs and symptoms and the exacerbation of depression and anxiety, considering the acute and chronic periods in response to post–COVID-19 condition. Fifth, there may be a social desirability bias as patients self-reported their signs and symptoms and were not objectified by the caregivers. Lastly, while the mean quarantine period of participants was approximately 7 days, the PHQ-2 and GAD-2 measures depression and anxiety symptoms over the last 2 weeks. These timeline issues should be considered when interpreting the results. Further, other tools may be used in future studies.

Conclusions

This study explored the association between acute signs and symptoms of COVID-19 and the exacerbation of depression and anxiety in patients with clinically mild COVID-19 who were admitted at RTCs. Among the acute signs and symptoms of COVID-19, exacerbation of depressive symptoms was associated with an abnormal SpO_2 (OR 1.27, 95% CI 1.00-1.62) and sleep disorder (OR 0.60, 95% CI 0.36-0.98). Exacerbation of anxiety symptoms was associated with an abnormal BT (OR 1.08, 95% CI 1.01-1.16), sleep disorder (OR 1.1, 95% CI 1.06-1.14), and sore throat (OR 1.03, 95% CI 1.00-1.07). As anticipated, patients who had experienced initial psychological symptoms at admission were more likely to experience depression (OR 1.91, 95% CI 1.52-2.41) and anxiety (OR 1.08, 95% CI 1.01-1.16) than those who did not. Meanwhile, the PHQ-2 and GAD-2 scores measured at admission showed that lower the score, higher the possibility of exacerbation of both depression (OR 0.15, 95% CI 0.11-0.22) and anxiety (OR 0.13, 95% CI 0.10-0.19). Our results suggest the importance of considering further interventions that might mitigate the exacerbation of depression and anxiety in patients with an abnormal SpO_2, abnormal BT, sore throat, and sleep disorders or those with initial psychological symptoms. In addition, we propose the use of the PHQ-2 and GAD-2, which are short and efficient scales, in the assessment of mental health for patients with clinically mild COVID-19 who are quarantined at home.

Acknowledgments

This work was supported by an Institute of Information & Communications Technology Planning & Evaluation grant funded by the Korean government (2021-0-00312: Development of Non-Face-to-face Patient Infection Activity Prediction and Protection Management SW Technology at Home and Community Treatment Centers for Effective Response to Infectious Disease).

Data Availability

The data sets generated or analyzed during this study are not publicly available in accordance with the hospital's regulations, adhering to the National Privacy Act and relevant guidelines. However, they may be available from the corresponding author on reasonable request after review and approval of the institutional review board and the institutional data steering committee.

Authors' Contributions

SS, YSB, and EKC conceptualized the study and reviewed and edited the manuscript. SS, SHK, and YSB developed the study methodology and drafted the manuscript. SS, SHK, CL, YK, and YSB carried out the formal analysis. EKC supervised the study and acquired funding for the study. All authors reviewed the results and approved the final version of the manuscript. YSB and EKC contributed equally to this work as the corresponding author.

Abstract

Background: Highly effective COVID-19 vaccines are available and free of charge in the United States. With adequate coverage, their use may help return life back to normal and reduce COVID-19–related hospitalization and death. Many barriers to widespread inoculation have prevented herd immunity, including vaccine hesitancy, lack of vaccine knowledge, and misinformation. The Ad Council and COVID Collaborative have been conducting one of the largest nationwide targeted campaigns ("It's Up to You") to communicate vaccine information and encourage timely vaccination across the United States. More than 300 major brands, digital and print media companies, and community-based organizations support the campaigns to reach distinct audiences.

Objective: The goal of this study was to use aggregated mobility data to assess the effectiveness of the campaign on COVID-19 vaccine uptake.

Methods: Campaign exposure data were collected from the Cuebiq advertising impact measurement platform consisting of about 17 million opted-in and deidentified mobile devices across the country. A Bayesian spatiotemporal hierarchical model was developed to assess campaign effectiveness through estimating the association between county-level campaign exposure and vaccination rates reported by the Centers for Disease Control and Prevention. To minimize potential bias in exposure to the campaign, the model included several control variables (eg, age, race or ethnicity, income, and political affiliation). We also incorporated conditional autoregressive residual models to account for apparent spatiotemporal autocorrelation.

Results: The data set covers a panel of 3104 counties from 48 states and the District of Columbia during a period of 22 weeks (March 29 to August 29, 2021). Officially launched in February 2021, the campaign reached about 3% of the anonymous devices on the Cuebiq platform by the end of March, which was the start of the study period. That exposure rate gradually declined to slightly above 1% in August 2021, effectively ending the study period. Results from the Bayesian hierarchical model indicate a statistically significant positive association between campaign exposure and vaccine uptake at the county level. A campaign that reaches everyone would boost the vaccination rate by 2.2% (95% uncertainty interval: 2.0%-2.4%) on a weekly basis, compared to the baseline case of no campaign.

Conclusions: The "It's Up to You" campaign is effective in promoting COVID-19 vaccine uptake, suggesting that a nationwide targeted mass media campaign with multisectoral collaborations could be an impactful health communication strategy to improve progress against this and future pandemics. Methodologically, the results also show that location intelligence and mobile phone–based monitoring platforms can be effective in measuring impact of large-scale digital campaigns in near real time.

Introduction

The COVID-19 pandemic has impacted every country in the world, and the United States was hit particularly hard. As of February 2022, more than 900,000 people had died in the United States after contracting the virus [1]. Several highly effective vaccines have been developed and authorized for emergency use by Food and Drug Administration [2,3]. In sharp contrast to the early days of the pandemic in the United States, there are fewer structural barriers that could interfere with vaccine coverage. However, attitudinal barriers remain prevalent [4]. According to a national poll conducted by the COVID Collaborative, although nearly 90% of Americans recognize the effectiveness of vaccines, only about a third plan to get vaccinated themselves [5]; and other surveys revealed similar patterns [6,7]. This mistrust is more prevalent among racial and ethnic minority communities. A nationwide poll found that only 14% of Black Americans and 34% of Latinx Americans trust the safety of the vaccines [8]. The massive distrust among racial and ethnic minority communities is the result, according to various analyses, of generational trauma and continued mixed messages about the pandemic and vaccines [9]. Latinx and African American communities have been disproportionately affected by the COVID-19 pandemic [10-12]. This needs to be addressed immediately since enhancing access and uptake of the COVID-19 vaccine among those most at risk is critical to control the epidemic, reduce the emergence of new variants, and promote health equity.

Similar hesitancy has been documented with nearly all vaccines [9,10]. Vaccine hesitancy is a multifactorial phenomenon, and therefore, requires multifaceted strategies. An effective and comprehensive campaign should be part of a national vaccination plan. Many states began dealing with vaccine hesitancy early in vaccine rollout, particularly in selected areas and among certain racial and ethnic groups. Information campaigns were developed to provide science-based information and culturally appropriate resources, either through existing medical networks or communication firms [11]. Some states also built or used partnerships with faith-based leaders and trusted community organizations to reach critical populations and increase vaccine acceptance among minority communities [11]. There are also other forms of media campaigns, primarily focusing on certain groups or areas [12].

At the national level, the Ad Council and the COVID Collaborative launched a nationwide vaccine education campaign called “It’s Up to You” in February 2021 [13]. As one of the largest public health efforts in US history, the campaign aims to educate the American public and build confidence in vaccines by communicating vaccine messages informed by the best science. In coordination with over 300 major brands, digital and print media companies, community-based organizations, medical experts, the Ad Council has been rolling out public service announcements across airwaves, publications, and social media. The public service announcements provide facts and correct information, answer questions, and preempt false narratives through platforms that the target groups regularly visit. To bridge the racial and ethnic gap in vaccine knowledge, the campaign particularly targets racial and ethnic minority communities with contents customized for distinct cultural and historical background. Campaign materials are available in 7 languages (English, Spanish, Simplified Chinese, Korean, Russian, Haitian Creole, and Vietnamese) on the campaign website. Interested readers are referred to Ad Council and the campaign website for more information about the campaign design and delivery.

As of September 19, 2021, the campaign received US $168 million in media support and related publicity and achieved 80 million engagements with messages via social and search [13]. Historically, the use of media campaigns to communicate public health knowledge and promote positive behaviors has shown varying degrees of effectiveness [14-16]. Without a systematic assessment, implementers lose the opportunity to identify potential gaps in campaign design and make strategic changes to message content and dissemination strategy. Therefore, our study aims to evaluate the effectiveness of this national campaign in promoting vaccine uptake, which could be used to inform the design and evaluation of other large-scale behavior change interventions.

Methods

Exposure Data

Monitoring the exposure to mass media campaigns is challenging due to the dynamic nature of the campaign rollout and massive coverage. Traditional monitoring approaches include surveys, interviews, and cohort studies [17,18]. However, the relatively slow turnaround makes the approaches more suitable for a retrospective evaluation but less able to generate timely and actionable feedback.

Emerging geospatial technologies present an opportunity for frequent and rapid data collection. We collect aggregated exposure data through Cuebiq’s privacy-preserving geospatial data and analytics platform. Cuebiq partners with over 100 location-centric smartphone apps, providing a path for users to opt in and provide informed consent for their anonymized and aggregated data to be used for research purposes. In addition to its General Data Protection Regulation and California Consumer Privacy Act–compliant data collection practices, Cuebiq applies additional privacy protections beyond simple anonymization to prevent the reidentification of individual users.

To measure campaign exposure, a digital breadcrumb known as a pixel is attached to creative media assets served through multiple advertisement media, including web, mobile, and in-app browsing. Cuebiq then generates impressions data and matches those impressions with its own panel of users in a privacy-preserving manner. Measurement data are accessed by researchers via the Cuebiq Workbench platform, an auditable sandbox environment that allows access for the querying of data and generation of aggregate, privacy-preserving outputs. The sandbox enables the creation of aggregate data at county levels, without the ability or need to create individual-level outputs.

The Cuebiq platform collects exposure information in a nearly continuous manner for each individual device. The exposure is then summarized by a binary indicator for each device, denoting whether or not it is exposed to the campaign. Finally, for each county, we calculate the number of exposed devices, the number of unexposed devices, and the exposure rate (ie, the proportion of exposed devices among all monitored devices) on a weekly basis. As described above, the "It's Up to You" campaign uses both digital and print media to deliver the materials. Our exposure data only measure the exposure to digital contents.

The final analytical data set covers 3104 counties in 48 states and the District of Columbia. Hawaii and Alaska are excluded because the spatial model requires counties to have geographically adjacent neighbors. Ad Council campaigns and Cuebiq's measurement campaign were launched in late February 2021, but the campaign did not reach national coverage until about one month later. Campaign activities and related exposures wound down rapidly after August. To avoid potential selection bias in early campaign rollout, our analyses only used data between March 29 and August 29, 2021. The panel's width and length are adequate for us to include complex model components, such as the spatiotemporal correlation structure.

Outcome Data

The outcome measure, vaccination rate, comes from Centers for Disease Control and Prevention's COVID Data Tracker, which provides county-level vaccination rates on a daily basis. To remain consistent with the exposure measures described above, weekly averages are taken at the county level.

Other Control Variables

Several socioeconomic and demographic indicators have been shown to influence vaccine uptake. This study explored the following: age (percentage of people 85 years or older); race and ethnicity (percentage of non-Hispanic White population); political affiliation (percentage of people who voted for democrats in the 2020 presidential election); income (median household income). The inclusion of covariates is based on literature review, data availability, and model diagnoses.

Statistical Model

Bayesian hierarchical mixed-effects models are used to estimate the correlation between exposure and outcome measures at the county level. As an important feature of infectious diseases, county-level pandemic measures exhibit spatial autocorrelation [19]. Nearer counties are more similar than distant counties in terms of COVID-19 pandemic and vaccination. We will account for the spatial autocorrelation in the regression. However, the residual may still display spatial autocorrelation, which violates a key regression modeling assumption. Similarly, panel data typically display temporal autocorrelation. Therefore, our model includes a conditional autoregressive (CAR) component to account for the spatiotemporal autocorrection in the data. Essentially, the CAR component supplements the main effects model with a set of spatiotemporally autocorrelated random effects [20].

Our final model can be formally expressed as follows:

Here, where $c=1,2,\ldots,c$ indexes counties; Y_{ct} denotes the vaccination rate (weekly and not cumulative) in week t in county c; X_{ct} denotes regressors in week t in county c. Of note, some variables may be time invariant; β denotes a column vector of regression slopes.

A key model component is ψ_{ct}, which induces the spatiotemporal autocorrelation for county-level measures after accounting for the covariate effects. In particular, we use a first-order autoregressive process where correlation is ρ^w, $\rho\in(0,1)$ for Us that are w time units apart. Of particular interest is the spatial model that allows the U_{ct} to be correlated with correlation depending on a distance metric. As for the first-order autoregressive time-series model, spatial models induce correlation among the U_{ct} for a fixed t.

County coordinates are used to compute Euclidean distances. With relatively few nearby counties, a parameter model will estimate nearby correlations based on correlations between distant counties (an extrapolation). There are several model forms, including (powered) exponential, Gaussian, Spherical, Matern, and CAR models [21]. Due to the large number of contiguous counties in our data set, the CAR model worked well and was included in our analyses.

The model was fitted in R using the CARBayesST package [22]. The final results are extracted from 10,000 samples after discarding 10,000 burn-ins and thinning by 10 to reduce potential sample autocorrelation.

Ethical Considerations

Study data are anonymous and deidentified, and the study did not constitute human subjects. Therefore, ethical approval was not required for this study.

Results

The campaign was launched in February 2021, starting with a small number of counties in the first few weeks. It reached national coverage in week 13 (March 29 to April 4, 2021), when about 99% (3058/3104) of counties in the Cuebiq platform detected exposure to the campaign. Campaign activities started winding down quickly from week 34 (August 23-29, 2021). As a result, this study covered a period of 22 weeks. Cuebiq continued monitoring a panel of about 17 million mobile devices (Figure 1). The panel remained stable during this period, ensuring the temporal comparability of the observed metrics.

Since this is not a randomized controlled trial, it is important to assess the potential selection issues in the data. Selection could have occurred in two stages. First, certain areas and groups may be overrepresented in the Cuebiq platform. This may be caused by different smartphone penetration rates by state and county. Second, the dissemination of Ad Council campaigns may be disproportionally concentrated in certain areas and groups. To assess the severity of selection, we plotted Cuebiq coverage rate and campaign exposure rate against race, income, and political affiliation at the county level (Figure 2). The Cuebiq coverage is higher in counties with a larger percentage of non-Hispanic White population. Campaign exposure rate has a similar correlation with race. A similar correlation is observed for household income. Richer counties tend to be overrepresented in the Cuebiq platform and get more exposure to the campaigns than poorer counties. For political affiliation, more democratic counties appear to be less represented in the Cuebiq platform, and there is not a strong pattern between campaign exposure and political affiliation. In sum, there may be potential selection issues in both Cuebiq platform coverage and campaign exposure. We will minimize the bias through accounting for these factors in the regression model.

The overall proportion of Cuebiq-enrolled devices exposed to the Ad Council campaigns started at 3.17% in the first week of the study period and gradually declined to 1.28% by the end of August 2021. A large number of channels were used to disseminate the campaign messages. Top channels in terms of exposure include The Trade Desk, Q Digital, Buzzfeed, Pandora, and Red Ventures.

During the study period, the national vaccination rate increased from 16.4% to 47.2%, but the progress began slowing down (Figure 3) [23]. Overall, the weekly vaccination rate peaked in week 15 when 3.34% of Americans completed full vaccination that week; it dropped below 1% in later weeks. The box plots in Figure 3 illustrate the substantial heterogeneity in weekly vaccination rates across counties.

Temporal autocorrelation in weekly vaccination rate is evident. Figure 4 illustrates the strong geographic clustering or spatial correlation in weekly vaccination rates. That spatial correlation may not fully be explained by the 3 variables in the model.

All indicators included in the Bayesian hierarchical model vary greatly across the 3104 counties analyzed in the study. The average percentage of the population aged 85 years and older is 2.3% (SD 0.01%) with a minimum of 0.0% and a maximum of 8.0% (Table 1). The ranges of the percentage of non-Hispanic White population and the percentage who voted for democrats are much wider at 5.1%-99.8% and 3.1%-82.1%, respectively. The poorest county earns an average of 36.5 thousand US dollars per household, while the richest county earns 243.8 thousand.

Table 2 presents our main results from the Bayesian hierarchical model with a spatiotemporally correlated residual structure. The coefficient for the exposure rate is 2.2 (95% uncertainty interval: 2.0-2.4). The effectiveness is impressive; exposing everyone in the county to the campaign may boost the vaccination uptake by 2.2% on a weekly basis. This effectiveness size is substantial, given the slow weekly vaccination rate of less than 1% at the end of the study period. It is worth noting that the effectiveness was assessed based on observed data. The exact magnitude of the effectiveness will likely change when the overall vaccination rates grow substantially higher in the future.

All factors in the model also have statistically significant impacts on vaccine uptake. Proportions of older population (≥85 years), non-Hispanic White population, democratic affiliation, and household income are all positively associated with vaccine rollout. This is consistent with findings from previous studies.

Figure 1. Number of opted-in, deidentified devices (in million) monitored by the Cuebiq platform and the percentage exposed to the Ad Council Campaign.

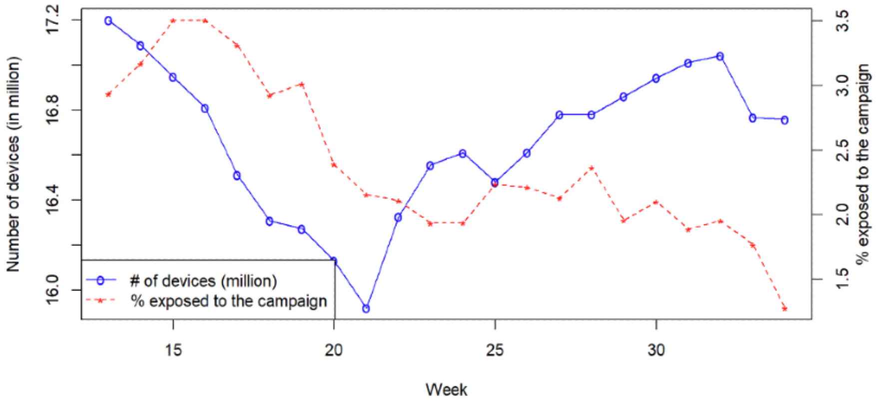

Figure 2. Cuebiq coverage and campaign exposure rate versus race, household income, and political affiliation during the first week of the study period. (A) Cuebiq coverage vs race; (B) Campaign exposure vs race; (C) Cuebiq coverage vs household income; (D) Campaign exposure vs household income; (E) Cuebiq coverage vs political affiliation; (F) Campaign exposure vs political affiliation.

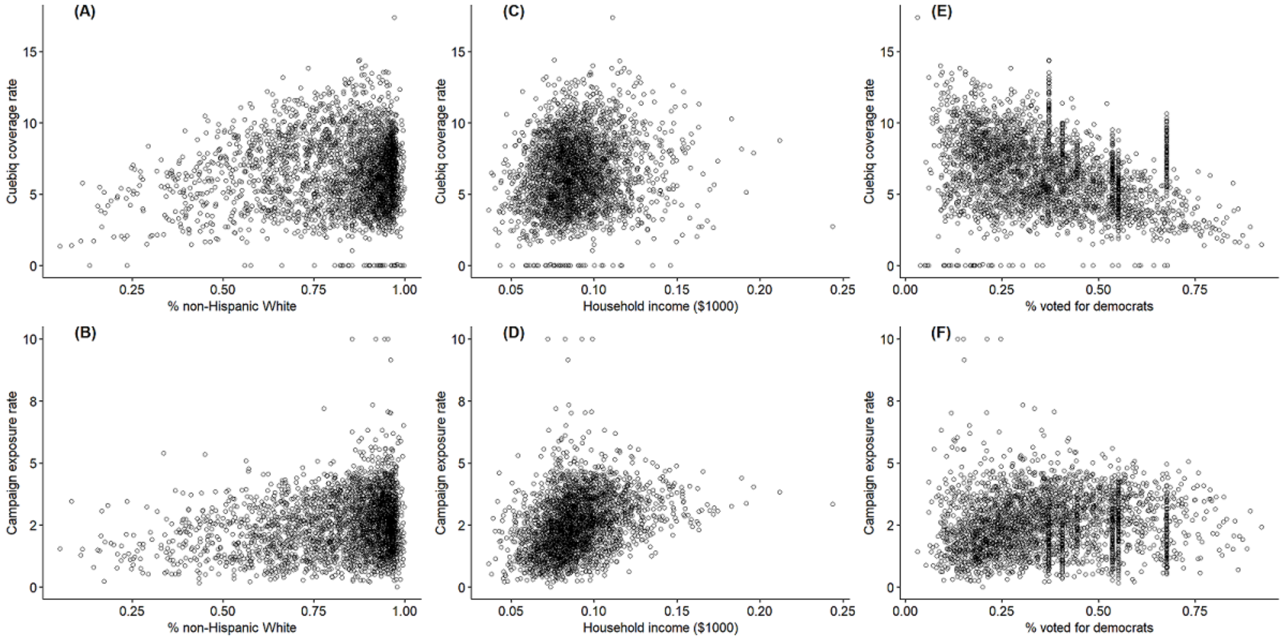

Figure 3. Distribution of county-level Centers for Disease Control and Prevention–reported weekly vaccination rate by week.

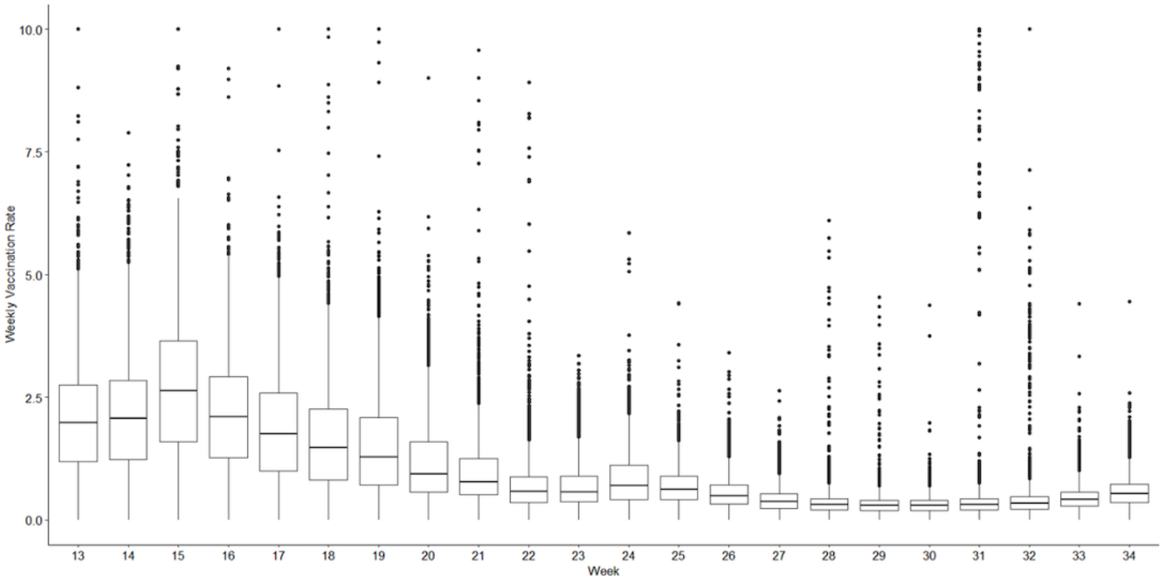

Figure 4. Exposure to the campaign and weekly vaccination rate by county during the first and last weeks of the study period. (A) Exposure rate (number of devices exposed to the campaign or total number of devices) to the campaign during the first week of the study period (week 13 or March 29 to April 4, 2021); (B) weekly vaccination rate during the first week of the study period; (C) exposure rate to the campaign during the last week of the study period (week 34 or August 12-29, 2021); (D) weekly vaccination rate during the last week of the study period.

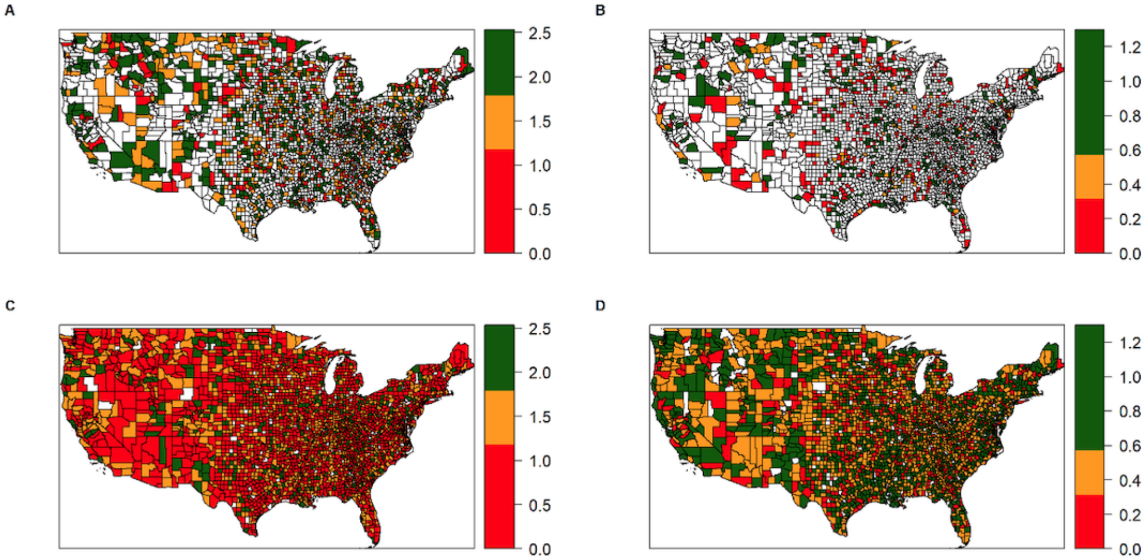

Table 1. Summary statistics of control variables for the 3104 counties in the study.

Variable	Mean (SD)	Min	Max
Population aged ≥85 years (%)	2.3 (0.01)	0.0	8.0
Non-Hispanic White (%)	83.3 (0.16)	5.1	99.8
Voted for democrats (%)	36.9 (0.17)	3.1	82.1
Household income (US $1000)	89.2 (20.0)	36.5	243.8

Table 2. Results from the Bayesian hierarchical model. Weekly data collected from 3104 counties during March 29 to August 29, 2021 (22 weeks); 95% uncertainty intervals were calculated from the posterior distributions.

Variable	Mean	95% uncertainty interval
Exposed to the campaign (%)	0.022	0.02 to 0.024
Population aged ≥85 years (%)	0.031	0.021 to 0.042
Non-Hispanic White (%)	0.004	0.003 to 0.004
Voted for democrats (%)	0.014	0.013 to 0.014
Median household income (US $1000)	0.058	0.054 to 0.062
Intercept	–0.005	–0.005 to –0.004

Discussion

The study is one of the first rigorous evaluations of the “It’s Up to You” campaign, the largest effort in promoting COVID-19 vaccine awareness and uptake in the United States. We used Cuebiq’s nationwide location intelligence platform to monitor campaign exposure and then estimated its association with vaccine uptake data tracked by US Centers for Disease Control and Prevention. Results from the Bayesian hierarchical model support the effectiveness of the campaign in promoting vaccine uptake.

Under Operation Warp Speed, the COVID-19 vaccine research and development achieved great success at unprecedented scale and speed, thanks to the coordinated effort from governments, pharmaceutical companies, and other stakeholders [24]. The US Food and Drug Administration granted Emergency Use Authorization to 2 highly effective COVID-19 vaccines in late 2020. Since then, barriers to achieving herd immunity have shifted from medical to social.

On May 25, 2021, the United States marked the milestone of inoculating half of the adults in the country. Vaccinating the remaining population will be harder. Even before the milestone, vaccinations had been plateauing, and the official data had been chronicling a decreasing daily vaccination rate. Research and expert consensus suggest that as high as 80%-90% of the total population needs to be vaccinated to achieve herd immunity after considering recent factors, such as more contagious variants [25]. Given the high prevalence of vaccine hesitancy and uneven distribution across regions and populations, convincing the hesitant groups to get inoculated is necessary.

Overall, the already vaccinated population is better informed, less vaccine hesitant and skeptical, and more eager to be vaccinated than the remaining unvaccinated group. As the country approaches the vaccination rate required for herd immunity, vaccine resistance is also becoming more prominent in the remaining unvaccinated population. Reaching herd immunity requires vaccinating a significant proportion of the resistant population in addition to vaccinating all nonresistant populations. Thus, effective messaging campaigns are urgently needed. The root causes of vaccine hesitancy, such as fear, mistrust, and misconceptions, need to be addressed through targeted communication strategies.

The study has several limitations. First, the campaign was not designed to be a randomized control trial. People (or devices) were not randomly chosen to be exposed to the campaign messages. However, it is unlikely that there were systematic self-selection biases, given the passive nature of campaign exposure. Second, vaccine uptake requires a complex decision-making process that involves a potentially large number of factors. Due to limited data availability, our model may have missed some important variables that affect vaccine uptake. Third, as a county-level ecological analysis, it is challenging to make a causal inference. Lastly, the Cuebiq platform only monitors exposure to digital campaigns. Exposure to traditional media (eg, print publication, billboards, and posters) is not captured in the study.

Despite the limitations, the study is among the first efforts to evaluate the nation’s largest public health campaign. We built a fully validated model and established a statistically significant association between campaign exposure and vaccine uptake at the county level. The sizable effectiveness suggests that Ad Council is a sound investment of public and private resources. Given the low exposure and slow vaccination rate as of the end of the study period, expanding the messaging campaign may help accelerate vaccination progress.

The United States is no outlier when it comes to vaccine hesitancy, which was reported for nearly every vaccine and named one of the top ten threats to global health by the World Health Organization [26]. Misinformation about vaccines and antivax messages are global concerns. For example, a factor for Israel’s successful vaccination rollout is its multiprolonged educational campaigns that provide information, allay fears, and overcome hesitancy [27]. The successful implementation of the “It is Up to You” campaign and the documented effects in promoting vaccine uptake may generate valuable experience for other countries facing similar challenges.

Data Availability

Cuebiq data are available upon request from the Cuebiq Data for Good Program. All other data used in the study are publicly available from respective sources.

Authors' Contributions

QL conceptualized the study, developed the models, visualized the results, and wrote the manuscript. JCP and ARE extracted the data from the Cuebiq platform. AL, CY, and BL secured funding. All authors reviewed and revised the manuscript.

Abstract

Background: The COVID-19 pandemic had many unprecedented secondary outcomes resulting in various mental health issues leading to substance use as a coping behavior. The extent of changes in substance use in a US sample by nativity has not been previously described.

Objective: This study aimed to design a web-based survey to assess the social distancing and isolation issues exacerbated by the COVID-19 pandemic to describe substance use as a coping behavior by comparing substance use changes before and during the pandemic.

Methods: A comprehensive 116-item survey was designed to understand the impact of COVID-19 and social distancing on physical and psychosocial mental health and chronic diseases. Approximately 10,000 web-based surveys were distributed by Qualtrics LLC between May 13, 2021, and January 09, 2022, across the United States (ie, continental United States, Hawaii, Alaska, and territories) to adults aged ≥18 years. We oversampled low-income and rural adults among non-Hispanic White, non-Hispanic Black, Hispanic or Latino, and foreign-born participants. Of the 5938 surveys returned, 5413 (91.16%) surveys were used after proprietary expert review fraud detection (Qualtrics) and detailed assessments of the completion rate and the timing to complete the survey. Participant demographics, substance use coping behaviors, and substance use before and during the pandemic are described by the overall US resident sample, followed by US-born and foreign-born self-reports. Substance use included the use of tobacco, e-cigarettes or nicotine vapes, alcohol, marijuana, and other illicit substances. Marginal homogeneity based on the Stuart-Maxwell test was used to assess changes in self-reported substance use before and during the pandemic.

Results: The sample mostly included White (2182/5413, 40.31%) and women participants (3369/5406, 62.32%) who identified as straight or heterosexual (4805/5406, 88.88%), reported making ≥US $75,000 (1405/5355, 26.23%), and had vocational or technical training (1746/5404, 32.31%). Similarities were observed between the US-born and the foreign-born participants on increased alcohol consumption: from no alcohol consumption before the pandemic to consuming alcohol once to several times a month and from once to several times per week to every day to several times per day. Although significant changes were observed from no prior alcohol use to some level of increased use, the opposite was also observed and was more pronounced among foreign-born participants. That is, there was a 5.1% overall change in some level of alcohol use before the pandemic to no alcohol use during the pandemic among foreign-born individuals, compared with a 4.3% change among US-born individuals.

Conclusions: To better prepare for the inadvertent effects of public health policies meant to protect individuals, we must understand the mental health burdens that can precipitate into substance use coping mechanisms that not only have a deleterious effect on physical and mental health but also exacerbate morbidity and mortality in a disease like COVID-19.

KEYWORDS

substance use; COVID-19; US nativity

Introduction

Background

The COVID-19 pandemic, as of March 2022, has >456 million recorded cases and 6 million reported deaths worldwide [1]. Although COVID-19 is caused by SARS-CoV-2, increased morbidity and mortality are associated with multiple direct and indirect social, physiological, and environmental factors [2,3]. There were, however, indirect health effects of the pandemic that affected mental health [4] and exacerbated maladaptive coping mechanisms such as substance use [5,6].

Coping strategies provide the ability to manage external and internal demands, given an individual's resources [7]. When demands are exceeded owing to high levels of physiological and psychological stress, as observed during the COVID-19 pandemic, it can lead to the adoption of maladaptive coping behaviors [8,9]. As such, mental health issues were exacerbated by multiple social and environmental stressors, social distancing, and isolation during the COVID-19 pandemic that in turn affected coping mechanisms leading to changes in substance use patterns [10,11].

Statistics for June 2020, when compared with 2019, as reported by the Centers for Disease Control and Prevention [5], show that 13% of US adults aged ≥18 years started or increased substance use to cope with stress from the COVID-19 pandemic. Reports of increased use were found for both licit and illicit substances [12,13] such as alcohol [14] and opioids [15], respectively. There were also mixed findings regarding the use of substances such as tobacco [16-18] and marijuana [19] as well as their respective methods of use through vaping [13,20,21]. Moreover, using licit and illicit substances can cause increased morbidity and mortality, especially when considering the physiological effects of COVID-19, in addition to worsening mental health [5].

The effects of social distancing and isolation early in the pandemic were compounded by multiple issues associated with access to health, mental health, and related telehealth services [22]. Multiple deficits and barriers to mental health services, especially among underserved and underrepresented communities, precipitated health care access and treatment disparities [6,10,23]. These deficits and barriers were then exacerbated by the COVID-19 pandemic and may have led to substance use as a prevalent coping mechanism during a period when substance treatment options were already limited [10,22,23]. Nonetheless, studies on substance use as a coping strategy during the COVID-19 pandemic are limited.

Objectives

Further research is needed to understand the multiple and varying sociodemographic and socioeconomic factors to fill this gap. In addition, there is a critical need to include both US-born and foreign-born individuals in substance use research during the COVID-19 pandemic as these studies are still limited. A limited number of studies have reported mixed findings, that is, increased and decreased substance use during the pandemic [24,25]. Nevertheless, the psychological effects of substance use may be detrimental and synergize disparities among racial and ethnic foreign-born minorities [24,26,27]. As such, our purpose was to describe substance use as a coping mechanism to COVID-19–induced social distancing and isolation by comparing substance use before and during the pandemic by US-born and foreign-born individuals.

Methods

Overview

Our study *Understanding the Impact of the Novel Coronavirus (COVID-19) and Social Distancing on Physical and Psychosocial (Mental) Health and Chronic Diseases* created a comprehensive 116-item web-based survey that was nationally distributed in the United States. The survey modules included (1) general health status; (2) COVID-19 symptoms, testing, and prevention; (3) chronic illness management; (4) social distancing; (5) mental health; (6) pandemic economic impact; (7) discrimination; and (8) sociodemographics.

The target population comprised adults aged ≥18 years residing in the United States. The US resident sample included both US-born and foreign-born participants. Qualtrics LLC was contracted to facilitate the recruitment and distribution of the web-based survey to both US-born and foreign-born racial and ethnic groups. The US-born racial and ethnic groups included Hispanic or Latino, White, Black, Asian, American Indian and Alaskan Native, and Native Hawaiian and Pacific Islander participants. Foreign-born racial and ethnic groups included African, Middle Eastern, Hispanic or Latino, and Asian participants. Qualtrics then used proprietary consumer panels to randomly sample White participants that matched demographic characteristics with other racial and ethnic groups. We oversampled adults with low income (<US $25,000 annual household income) who resided in rural areas (self-reported and cross-referenced with zip codes already collected by Qualtrics) among non-Hispanic White, non-Hispanic Black, Hispanic, and foreign-born participants. The survey was available only in English.

A total of 10,000 surveys were distributed between May 13, 2021, and January 09, 2022. The initial surveys received by Qualtrics were assessed via expert review fraud detection to prevent multiple submissions and detect "bots" to protect the integrity of the data. After the assessment, 5938 surveys were received by the research team from Qualtrics. Information Management Services, Inc, a research support firm that provides analytic services, was given the task to clean and manage the deidentified survey data.

To improve study integrity, initial data cleaning by the Information Management Services included flagging surveys based on the completion rate and the timing to complete the survey. Participants were flagged and removed from the analysis if they completed <80% of the survey based on 102 questions after accounting for skip pattern items or took <5 minutes to complete the survey. In total, 125 surveys were removed at this stage, giving us 5813. Our study ended with a total of 5413 surveys based on the completed responses in the social distancing module of the *Understanding the Impact of the Novel Coronavirus (COVID-19) and Social Distancing on Physical and Psychosocial (Mental) Health and Chronic Diseases* survey. The survey can be requested from the principal investigator, Faustine Williams, PhD, MPH, MS, from the National Institute on Minority Health and Health Disparities of the National Institutes of Health (NIH) in Bethesda, Maryland.

Ethical Considerations

Qualtrics recruited study participants, and web-based informed consent was provided before the survey. Participants were asked to participate in a voluntary research study titled *Understanding the Impact of the Novel Coronavirus (COVID-19) and Social Distancing on Physical and Psychosocial (Mental) Health and Chronic Diseases* conducted by Faustine Williams. If they chose to participate in the study, they were assured that their responses would be kept confidential. Participants were reminded that the study was voluntary; as such, they could change their minds at any time after starting the survey and opt out with no fear of repercussions. Participants could skip any questions that they did not want to answer. All answers were kept confidential, and Qualtrics assured the participants that no personal identifiers would be shared with the National Institute on Minority Health and Health Disparities research team. Participants were to receive an incentive of a US $10 gift card after the completion of their survey, which would take approximately 30 minutes of their time. At the end of the survey, participants were also asked if they would be interested in participating in another follow-up survey. Then, Qualtrics would follow-up with those who responded that they were interested. Participants were provided the contact information of the principal investigator (Faustine Williams) as well as the phone number of the NIH Institutional Review Board.

The research protocol for this study was reviewed by the NIH, Intramural Research Program Institutional Review Board, Human Research Protection Program, and Office of Human Subjects Research Protections and received an exemption on December 23, 2020 (IRB#000308). The NIH, Intramural Research Program Institutional Review Board, Human Research Protection Program, and Office of Human Subjects Research Protections determined that our protocol did not involve human participants and was excluded from the institutional review board review.

Descriptors

Sociodemographic Variables

All sociodemographic items were self-reported and allowed for either the selection of multiple categories or provided a free response if they selected a blank or other category. Nativity was categorized by country of birth as either US born or foreign born. US-born nativity was based on respondents' self-reported births in the 48 contiguous states, Washington, the District of Columbia, Alaska, Hawaii, and other US territories such as Puerto Rico. Foreign-born nativity was based on respondents' self-reported births occurring in another country outside the United States based on the US birth classification. Racial and ethnic categories included selecting ≥1 of the following options: White, Black or African American, Asian, American Indian or Alaskan Native, Hawaiian or Pacific Islander, African, Middle Eastern, and multiracial or multiethnic. If respondents selected ≥2 racial or ethnic groups, they were classified as multiracial and multiethnic. Gender categories included men, women, nonbinary, transgender people, and others. Sexual orientation included straight or heterosexual, lesbian, gay, bisexual, and other. The lesbian and gay categories were combined. Age was self-reported starting from 18 to ≥85 years. Age categories were then constructed as follows: 18 to 35 years, 36 to 55 years, and 56 to ≥85 years. Annual household income was reported as <US $25,000, US $25,000 to US $34,999, US $35,000 to US $49,999, US $50,000 to US $74,999, and US ≥$75,000. Educational attainment was categorized by self-reported highest schooling that included (1) less than high school or General Language Development (ie, did not attend school; elementary education, 6 years or less; more than elementary to junior high school; or some high school), (2) high school diploma or General Language Development, (3) some college or vocational or technical schooling, (4) bachelor's degree, and (5) master's degree or above (ie, master's degree or doctoral, professional, or postgraduate degree). Employment status was assessed using multiple survey items. Current employment (ie, employed, self-employed, unpaid or voluntary work, apprenticeship or vocational training, disabled, caretaker or looking after family or home, in school, retired, or unemployed) and if considered an essential worker (ie, no or yes). Unemployed or nontraditional work was categorized as being disabled, a caretaker or looking after family or home, in school, retired, or unemployed. Nonessential workers were categorized as not considered an essential worker and employed, self-employed, unpaid or voluntary work, or apprenticeship or vocational training. Essential workers were categorized as being considered an essential worker and employed, self-employed, unpaid or voluntary work, or apprenticeship or vocational training.

Substance Use

Coping behaviors for social distancing and isolation during the COVID-19 pandemic were assessed by asking questions regarding substance use in the social distancing module of the survey. Questions specific to exclusively using the following substances to cope were used: cigarettes or vaping, increased alcohol use, marijuana use, and illicit substance use. To assess cases of substance use during the pandemic, we asked "During the past month, how often did you" (1) smoke cigarettes or other tobacco products for tobacco use, (2) smoke e-cigarettes or other nicotine vaping products, (3) have a drink containing alcohol for alcohol use, (4) use marijuana, and (5) use illicit drugs. Illicit drugs were defined as other substances that were not previously listed (ie, tobacco, nicotine, alcohol, or marijuana) and could include but not be limited to opiates, hallucinogens, cocaine, or amphetamines. A follow-up control question was used for each aforementioned question category that asked, "Compared to before the pandemic, this is or was... .” Responses to each question had the following levels: not at all, once during the month, several times a month, once a week, several times a week, almost every day or every day, and several times a day. Responses were collapsed to (1) not at all, (2) once to several times per month, (3) once to several times per week, and (4) every day to several times per day.

Analytic Procedure

Descriptive statistics of survey sample sociodemographics and substance use behaviors during the COVID-19 pandemic were assessed by the nativity of respondents, that is, US born and foreign born. Descriptives for the overall survey sample before and during the pandemic were assessed, followed by a more detailed assessment by nativity. A Stuart-Maxwell test was used to examine whether substance use before the COVID-19 pandemic was equal to substance use during the pandemic among survey respondents. If significant differences were found in substance use, we tested for differences based on participant self-reported nativity. The Stuart-Maxwell test is an ideal nonparametric test to examine asymptotic symmetry and marginal homogeneity on matched-pair controls (ie, before the COVID-19 pandemic) and cases (ie, during the COVID-19 pandemic) with various discrete levels of substance use (ie, not at all, once several times per month, once to several times per week, and every day to several times per day). All analytical procedures were conducted using Stata/MP (version 16.1; StataCorp LLC). All analytical files are available upon reasonable request.

Results

Overview

The overall sample was primarily racially and ethnically White, Black or African American, and Hispanic or Latin. Most of the participants self-reported as women (3369/5406, 62.32%); were straight or heterosexual (4805/5406, 88.88%); had a household annual income of US ≥$75,000 (1405/5355, 26.23%); had some college, vocational, or technical training (1746/5404, 32.31%); and were unemployed or participated in nontraditional work (2401/5405, 44.42%). The age of the sample was between 18 and 35 years (1839/5119, 35.92%) and 36 and 55 years (1971/5119, 38.5%). The sample self-reported primarily using the following substances in the following order based on proportion: marijuana use (109/5404, 2.02%), increased alcohol use (87/5404, 1.61%), e-cigarette or nicotine vape (83/5404, 1.54%), and illicit substance use (24/5404, 0.44%). A more detailed breakdown of the sociodemographic profiles and substance use by nativity is shown in Table 1.

Table 2 describes substance use before and during the COVID-19 pandemic for the overall sample. Most of the participants who reported substance use before the COVID-19 pandemic used tobacco every day to several times per day (940/5130, 18.32%), e-cigarettes or nicotine vapes once to several times per month (366/5130, 7.13%), alcohol once to several times per month (1563/5130, 30.47%), marijuana every day to several times per day (471/5130, 9.18%), and other illicit substances once to several times per month (225/5130, 4.38%). During the COVID-19 pandemic, the same participants used tobacco every day to several times per day (664/3802, 17.46%), e-cigarettes or nicotine vapes once to several times per week (269/3802, 7.07%), alcohol once to several times per month (1051/3802, 27.64%), marijuana every day to several times per day (336/3802, 8.84%), and other illicit substances once to several times per week (148/3802, 3.89%).

In Table 3, we describe substance use before and during the COVID-19 pandemic by US-born and foreign-born individuals. If reporting substance use before the COVID-19 pandemic, the US-born sample primarily reported use of tobacco every day to several times per day (846/3903, 21.68%), e-cigarettes or nicotine vapes once to several times per week (298/3889, 7.66%), alcohol once to several times per month (1207/3903, 30.92%), marijuana every day to several times per day (420/3873, 10.84%), and other illicit substances once to several times per week (196/3887, 5.04%). The same US-born sample during the COVID-19 pandemic, if reporting substance use, used tobacco every day to several times per day (600/2912, 20.60%), e-cigarettes or nicotine vapes once to several times per week (231/2899, 7.97%), alcohol once to several times per month (812/2921, 27.80%), marijuana every day to several times per day (300/2901, 10.34%), and other illicit substances once to several times per week (131/2896, 4.52%).

The foreign-born sample’s substance use before the COVID-19 pandemic indicated tobacco use every day to several times per day (94/1179, 7.97%), e-cigarettes or nicotine vapes once to several times per month (75/1176, 6.38%), alcohol once to several times per month (356/1187, 29.99%), marijuana once to several times per month (62/1170, 5.3%), and other illicit substances once to several times per month (44/1180, 3.73%). The same foreign-born sample during the COVID-19 pandemic, if reporting substance use, used tobacco every day to several times per day (67/860, 7.79%), e-cigarettes or nicotine vapes once to several times per week (39/857, 4.55%), alcohol once to several times per month (242/860, 28.14%), marijuana once to several times per month (41/855, 4.79%), and other illicit substances once to several times per month (24/852, 2.82%).

Differences in Substance Use Before and During the COVID-19 Pandemic

Using the Stuart-Maxwell test of asymptotic symmetry and marginal homogeneity, we found significant differences in alcohol use in the overall sample (Table 4). In Table 5, we see that the largest contribution to χ^2 symmetry (χ^2_3=20.2) was owing to differences in no alcohol use before the COVID-19 pandemic to once to several times per month during the COVID-19 pandemic (ie, a 1.71% change) and once to several times per month before the COVID-19 pandemic to not at all during the COVID-19 pandemic (ie, a 3.37% change). The second largest contribution (χ^2_3=15.6) was observed with alcohol use once to several times per week before the COVID-19 pandemic to every day to several times per day during the COVID-19 pandemic (ie, a 2.25% change) and every day to several times per day before the COVID-19 pandemic to once to several times per week during to the COVID-19 pandemic (ie, a 1.07% change). All other substance use changes reported before and during the pandemic were not significant but can be found in Multimedia Appendix 1.

Then, we assessed differences in substance use before and during the pandemic by nativity and found them to be significantly different between US-born and foreign-born individuals (Table 5). Among the US-born participants, the largest contribution to the symmetry χ^2 (χ^2_3=13.3) was owing to differences in no alcohol use before the COVID-19 pandemic to once to several times per month during the COVID-19 pandemic (ie, a 1.77% change) and once to several times per month before the COVID-19 pandemic to not at all during the COVID-19 pandemic (ie, a 3.28% change). The second largest contribution among US-born participants (χ^2_3=13.2) was in alcohol use once to several times per week before the COVID-19 pandemic to every day to several times per day during the COVID-19 pandemic (ie, a 2.22% change) and every day to several times per day before the COVID-19 pandemic to once to several times per week during to the COVID-19 pandemic (ie, a 1.00% change). See Table 6 for more detail.

As seen in Table 7 among foreign-born participants, the largest contribution to the symmetry χ^2 (χ^2_3=7.4) was owing to differences in no prior alcohol use before the COVID-19 pandemic to once to several times per month during the COVID-19 pandemic (ie, a 1.5% change) and once to several times per month before the COVID-19 pandemic to not at all during the COVID-19 pandemic (ie, a 3.7% change). The second largest χ^2 contribution was alcohol use once to several times per month to every day to several times a day (χ^2_3=3.8). Of the 843 respondents, 23 (2.7%) shifted from alcohol use once to several times per month before the pandemic to every day to several times per day during the pandemic, compared with 18 (2.1%) who shifted from alcohol use every day to several times per day before the COVID-19 pandemic to once to several times per month during the COVID-19 pandemic. The third largest contribution (χ^2_3=2.6) was in alcohol use once to several times per week before the COVID-19 pandemic to every day to several times per day during the COVID-19 pandemic (ie, a 2.4% change) and every day to several times per day before the COVID-19 pandemic to once to several times per week during the COVID-19 pandemic (ie, a 1.3% change). Refer to Table 5 for all *the* χ^2 contributions to symmetry.

Table 4. Alcohol use before the COVID-19 pandemic compared with during the pandemic[a].

Before the COVID-19 pandemic	During the COVID-19 pandemic				
	Not at all, n (Δ%)	Once to several times per month, n (Δ%)	Once to several times per week, n (Δ%)	Every day to several times per day, n (Δ%)	Total
Not at all	1432 (N/A[b])	64 (1.71)	22 (0.59)	4 (0.11)	1522
Once to several times per month	126 (3.37)	826 (N/A)	136 (3.64)	15 (0.40)	1103
Once to several times per week	29 (0.77)	127 (3.40)	611 (N/A)	84 (2.25)	851
Every day to several times per day	12 (0.32)	21 (0.56)	40 (1.07)	182 (N/A)	255
Total	1599 (N/A)	1038 (N/A)	809 (N/A)	285 (N/A)	3731

[a] Symmetry (asymptotic) was based on χ^2_6=42.1 and $P\leq.001$; marginal homogeneity was based on the Stuart-Maxwell test (χ^2_3=30.0; $P\leq.001$).

Discussion

Principal Findings

We assessed changes in the use of combustible tobacco, e-cigarette and nicotine vape, alcohol, marijuana, and other illicit substances. Although use of alcohol was found to have significant changes before and during the pandemic in our overall sample, we did not observe significant changes in the use of tobacco, e-cigarette and nicotine vape, marijuana, or other illicit substances (Multimedia Appendix 1). Then, we examined alcohol use changes by comparing US-born and foreign-born participants and found significant changes in each group. The χ^2 contributions to symmetry indicated that the largest contributors to significant changes in substance use before and during the COVID-19 pandemic were similar for the overall sample in the United States and the US-born sample. Similarities were observed across US-born and foreign-born samples; however, changes in increased alcohol use among these groups were observed on (1) no alcohol use before the pandemic to using alcohol once to several times a month and (2) once to several times per week to every day to several times per day. Increases in alcohol use may indicate maladaptive coping with the effects of social distancing and isolation [8,9]. The increase from weekly alcohol use to daily use indicates increased physiological and psychological risk as well as a risk of developing possible alcohol use disorders [28].

Although we found that significant changes were observed from no prior alcohol use to some level of increased use, we also observed the opposite in both the US-born and foreign-born groups. The decrease in alcohol use was slightly more pronounced among foreign-born participants. That is, there was a 5.1% overall change in some level of alcohol use before the pandemic to no alcohol use during the pandemic among foreign-born participants, compared with a 4.3% change among US-born participants. In our findings, the largest shift was not associated with increased alcohol use but with decreased alcohol use. This decrease in substance use may also be indicative of isolation [26].

Comparison With Prior Work

The use of both licit and illicit substances can have deleterious effects not only on mental health but also on physiological health and physical functioning, as well as damage organ systems that can increase morbidity and mortality from COVID-19 [29]. First, given our findings, the synergistic effects of isolation and alcohol use must be considered. Although participants may use alcohol to cope with the deleterious effects of isolation and psychological distress caused by the COVID-19 pandemic, the use of substances in themselves has been reported to be maladaptive [9,26]. One could argue that the use of alcohol has social connotations, whereas others would argue that substance use creates isolation owing to its taboo in the social context [26]. In the context of our findings, the increase from weekly alcohol use to daily use may be interpreted as increased personal use, not during social gatherings, given the context of social distancing practices. Conversely, decreases in alcohol use may also be tracked to the social nature of general alcohol consumption that the pandemic disrupted [30,31].

When specifically seeking to understand the differences in alcohol use between US-born and foreign-born participants during the COVID-19 pandemic, the available studies were limited. Overall, when foreign-born immigrants were assessed for substance use during the pandemic, they reported less substance use when compared with their US-born counterparts [24,26,27]. Our findings parallel what the limited studies have found, yet we did find that changes in decreased alcohol use were higher in foreign-born individuals compared with US-born individuals, that is, from once to several times per month to not at all during the pandemic.

Nevertheless, decreased alcohol use may be observed in our sample owing to a wide range of socioeconomic status factors such as low income and unemployment and environmental factors such as access and scarcity [32]. This may also be an artifact of our oversampling of lower socioeconomic status groups. Regardless, more information is needed to assess the deleterious effects on physical and mental health based on the frequency and number of drinks consumed as well as the level of risk of developing possible alcohol use disorders.

Our findings at this stage may indicate small percentage changes but may reveal the ideal point of intervention to mitigate the effect of use disorders. Moreover, we must acknowledge the synergetic effects of mental health and physiological health, especially in the context of COVID-19. As such, the extremes of general alcohol consumption and use disorders must continue to be monitored not only for concomitant health effects, such as alcohol-associated liver disease and mortality [28,29], but also to better understand the social and environmental effects of the COVID-19 pandemic and the policies that affect changes in alcohol use [33]. Future research should focus on polysubstance, mental health, coping behaviors, and prior substance use to identify the groups most at risk and design the most appropriate intervention strategies.

Limitations

Our study had some limitations. First, although the survey was anonymous, the possibility of bias in recall and responses must be considered. There is a possible recall bias from self-reports, as we asked about behaviors before COVID-19 owing to the data collection starting in May 2021 and ending in January 2022. This may be magnified by asking sensitive questions concerning substance use behaviors before and during the pandemic, increasing the response bias. Second, the data were obtained from a cross-sectional survey that provided a descriptive analysis of substance use change in a large US sample. However, this sample is not representative of the United States. Moreover, because this was a cross-sectional sample, we could not discern causality or temporal directionality. The data and descriptive analysis provided a solid foundation for further examination and identification of substance use patterns across a diverse US sample.

Conclusions

Pandemics are predicted to increase in frequency in the near future. To better prepare for the indirect effects of public health policies meant to protect the health of individuals, we must also prepare for their indirect effects on mental health and related coping mechanisms. Substance use affects both physical and mental health and will therefore require a multimodal approach to efficiently and effectively address and intervene on the deleterious effects, especially for underserved and underrepresented communities.

Abstract

Background: Mobile health (mHealth) apps are rapidly emerging technologies in China due to strictly controlled medical needs during the COVID-19 pandemic while continuing essential services for chronic diseases. However, there have been no large-scale, systematic efforts to evaluate relevant apps.

Objective: We aim to provide a landscape of mHealth apps in China by describing and comparing digital health concerns before and after the COVID-19 outbreak, including mHealth app data flow and user experience, and analyze the impact of COVID-19 on mHealth apps.

Methods: We conducted a semilongitudinal survey of 1593 mHealth apps to study the app data flow and clarify usage changes and influencing factors. We selected mHealth apps in app markets, web pages from the Baidu search engine, the 2018 top 100 hospitals with internet hospitals, and online shopping sites with apps that connect to smart devices. For user experience, we recruited residents from a community in southeastern China from October 2019 to November 2019 (before the outbreak) and from June 2020 to August 2020 (after the outbreak) comparing the attention of the population to apps. We also examined associations between app characteristics, functions, and outcomes at specific quantiles of distribution in download changes using quantile regression models.

Results: Rehabilitation medical support was the top-ranked functionality, with a median 1.44 million downloads per app prepandemic and a median 2.74 million downloads per app postpandemic. Among the top 10 functions postpandemic, 4 were related to maternal and child health: pregnancy preparation (ranked second; fold change 4.13), women's health (ranked fifth; fold change 5.16), pregnancy (ranked sixth; fold change 5.78), and parenting (ranked tenth; fold change 4.03). Quantile regression models showed that rehabilitation (P_{75}, P_{90}), pregnancy preparation (P_{90}), bodybuilding (P_{50}, P_{90}), and vaccination (P_{75}) were positively associated with an increase in downloads after the outbreak. In the user experience survey, the attention given to health information (prepandemic: 249/375, 66.4%; postpandemic: 146/178, 82.0%; P=.006) steadily increased after the outbreak.

Conclusions: mHealth apps are an effective health care approach gaining in popularity among the Chinese population following the COVID-19 outbreak. This research provides direction for subsequent mHealth app development and promotion in the postepidemic era, supporting medical model reformation in China as a reference, which may provide new avenues for designing and evaluating indirect public health interventions such as health education and health promotion.

Introduction

Background

In the wake of the COVID-19 outbreak, digital health technologies to assist medical service systems and people [1], such as telemedicine, have moved from a convenience to a demand [2-5]. Mobile health (mHealth) apps are a novel platform that uses mobile devices to acquire data across wellness and disease diagnosis, prevention, and management [6,7].

Before the COVID-19 outbreak, several studies investigated the characteristics of apps in China; these studies focused on only specific health domains, such as disease management, women's health, and sports, instead of elaborating on the overall mHealth app situation [8-11]. However, in the context of COVID-19, the development of mHealth apps has become a hot topic [12]. Only a few studies have investigated the mHealth app market status, focusing on the assessment of functional distribution but without refined classifications of mHealth apps and lacking information integrity [13]. Therefore, the classifications for mHealth apps have not been elaborated, and detailed descriptive research on mHealth apps is lacking.

After the outbreak, apps directly related to COVID-19 that were used to track high-risk groups and assist in diagnosis were the most studied [14-16]. One study provided an overview and classifications of mHealth apps currently available on the market to combat COVID-19, based on differences in basic functions and purpose [17]. However, in the face of the significant challenges posed by the pandemic, app types other than those related to COVID-19 were also considered valuable tools, such as easing the burden on hospitals, providing access to reliable information, tracking individuals' symptoms and mental health, and discovering new predictors [18]. Previous studies have shown that mHealth apps can improve people's life needs (such as fertility), which promote their use [19]. However, the development trends for many types of mHealth apps have been complicated due to the pandemic, which requires attention.

At the same time, unlike other countries, China implemented normalized pandemic prevention and control and rarely used contact tracing apps in a personal form; thus, the apps developed directly as a result of the pandemic were not the focus of this research. There was a spike in the volume of phone calls asking medical questions after the outbreak with a great increase in online demand in China [17]. The unbalanced allocation of health resources between the east and west, due to the vast size of China, also led to the demand for telemedicine. During the COVID-19 pandemic, a multimodal telemedicine network in Sichuan Province in Western China was activated immediately, which was demonstrated to be feasible, acceptable, and effective [20]. Moreover, due to the unique national conditions of the 1-child policy and the aging population, changes in mHealth app fields before and after the outbreak are different from those in other countries [21,22]. Therefore, mHealth apps, as emerging tools, that focus on changes in various health functions before and after the outbreak are worth studying in China and could be important for prevention, diagnosis, treatment, and management decisions for future public health emergencies.

However, it is presently unclear what mHealth app characteristics, if any, have been influenced and appropriately deployed in the pre and postpandemic periods.

Objectives

Here, we conducted a nationwide study of mHealth apps in China. The aim of this study was (1) to describe and compare digital health concerns before and after the COVID-19 outbreak, including mHealth app data flow and user experience, and (2) to analyze the impact of COVID-19 on mHealth apps.

Methods

Data Acquisition

Before the COVID-19 outbreak, we conducted a comprehensive electronic search of 4 sources up to October 25, 2019: (1) apps on leaderboards of health-related categories in the 6 largest app markets in China, including the top 50 on the Huawei Android Market (Huawei Technologies Co Ltd; Shenzhen, China), top 50 on the OPPO Android Market (Oppo Electronics Co Ltd; Dongguan, Guangdong, China), top 100 on the Vivo Android Market (Vivo Co Ltd; Dongguan, Guangdong, China), top 50 on the Tencent Android Market (Tencent Holdings Limited; Shenzhen, China), top 100 on the 360 Android Market (Qihoo 360 Technology Co Ltd; Beijing, China), and top 100 on the Apple iTunes store for China (Apple; Cupertino, CA) [23]; (2) the mHealth apps on the first 20 web pages of the Baidu search engine, which is the largest search engine in China; (3) apps that can connect to smart devices from the 4 large online shopping sites (Tmall, JD, Pinduoduo, and Suning); and (4) apps affiliated with internet hospitals on the list of the top 100 Chinese hospitals in 2018. The exclusion criteria were (1) duplicated apps, (2) app descriptions irrelevant to health, (3) apps not available in the Chinese language, (4) apps that were not available for download through the official Android and Apple app stores or the Baidu search engine, and (5) apps that could not be opened or used due to technical problems. Apps with patient and clinician versions were evaluated as different items. Search terms, sample quantities, and data collection times for each source are provided in Table S1 in Multimedia Appendix 1.

We collected 4 types of data: (1) basic app characteristics from the description interface, including the size of apps, number of app downloads, and target users; (2) app developers' information from the largest commercial inquiry platform, the Tianyancha website [24], including transaction amount, registered capital, number of staff, operating status, establishment date, and geographic location; (3) app permission listing data from the permission interface; and (4) app functions from app trials, except for apps only open to internal users. As the iOS App Store does not display the number of downloads, we replaced total downloads in iOS with the number of reviews and used statements of "downloads" in the following paragraphs. If an app existed on multiple platforms, the total number of app downloads was calculated as the sum of app downloads from all platforms. The app trial included at least two investigators who downloaded selected applications and independently identified application functionality according to a clear functional definition by using iPhones and Android phones. See Table S2 in Multimedia Appendix 1 for details on function definitions.

Following the outbreak, the same mHealth apps were investigated a second time in April 2021 as semilongitudinal samples with download data, and we determined whether COVID-19 content had been added. A download change was defined as the difference between post and prepandemic downloads.

User Experience Survey

We recruited residents through a community health checkup program to explore the user experience with mHealth apps among a large community of more than 20,000 people with a balanced age distribution in southeastern China. We used an offline questionnaire to survey 400 participants from October 2019 to November 2019 before the COVID-19 outbreak and 200 participants from June 2020 to August 2020 after the outbreak. A total of 553 (553/600, 92.2%) participants completed the survey: 375 (375/400, 93.8%) before the outbreak and 178 (178/200, 89.0%) after the outbreak. A predesigned, structured questionnaire was provided to potential participants in the waiting areas of the medical examination center in this community. The questionnaire was designed to collect information on participants' attention to health information, various aspects of mHealth technology usage, willingness to consume mHealth technology, and health status and demographic characteristics. Trained research assistants who were fluent in Chinese administered the questionnaire and provided verbal instructions about how to complete them.

Ethical Considerations

Before taking the survey, informed consent was obtained from each participant. This study was approved by the Biomedical Research Ethics Committee of Fujian Medical University (2018 number 11). All procedures were performed using the relevant guidelines and regulations.

Data Analysis

A descriptive analysis was conducted for mHealth app characteristics, developers, permission, functions, and user experiences in China. Data are presented using frequencies and percentages, bar charts, statistical maps, Venn diagrams, and heat maps. Continuous variables are presented as the mean and SD or the median and IQR, while categorical variables are presented as the frequency and percentage. Mann-Whitney *U* tests or chi-square tests were used to assess differences among variables.

We also compared the post and prepandemic app downloads of each category using paired *t* tests. To account for multiple comparisons, we calculated a Bonferroni-corrected *P* value criterion of .05/28. Therefore, $P<1.79\times10^{-3}$ was considered statistically significant.

Quantile regression (QR) models were used to explore the relationship between modeling covariates and quartiles of the outcome variable of interest [25]. Because of the wide range and non-normal distribution of download changes, we used QR models to examine associations between app characteristics, functions, and outcomes at specific quantiles of distribution in download changes. This analysis does not make assumptions about the residual distribution and is more robust to outliers in the outcome [26]. Unlike an ordinary linear regression model, which models the mean of only 1 dependent variable, QR examines the effect of covariates at different points of the conditional distribution of the response variable and gives more comprehensive results. QR models provided a more detailed view of associations of app characteristics, functions, and outcomes with download changes. We obtained estimates and plotted them at the following quantiles: 10th, 25th, 50th (median), 75th, and 90th. In the QR analysis, significance was assessed at the 10% level.

All analyses were prespecified and performed using SPSS 25.0 (IBM Corp; Armonk, NY) and Stata version 13 (StataCorp; College Station, TX).

Results

App Characteristics

A total of 1593 mHealth apps were included in the analysis (see Figure 1). During the COVID-19 pandemic, various app downloads showed an overall upward trend (change in median: 61,561), and approximately 10% (182/1593, 11.4%) of the apps had functions or content added for COVID-19 (see Table 1). Figures 2 and 3 show the target users and geographic distribution of the apps. Target users included healthy people (921/1593, 57.8%), patients (513/1593, 32.2%), and health care professionals (393/1593, 24.7%). The geographical distribution of mHealth app developers included in the study was concentrated in megacities (ie, Beijing, Shanghai, Guangzhou) and southeast China (coastal areas with a developed economy; see Figure 3). Additional permission requests were found in app markets (see Table S3 in Multimedia Appendix 1).

Figure 2. Sankey diagram of flow direction in apps. The width of the colored boxes and their connecting gray bands are directly proportional to the frequency of apps from every data source (left side) and flow quantities of these apps to the attributable user communities (right side). Hcps: health care professionals.

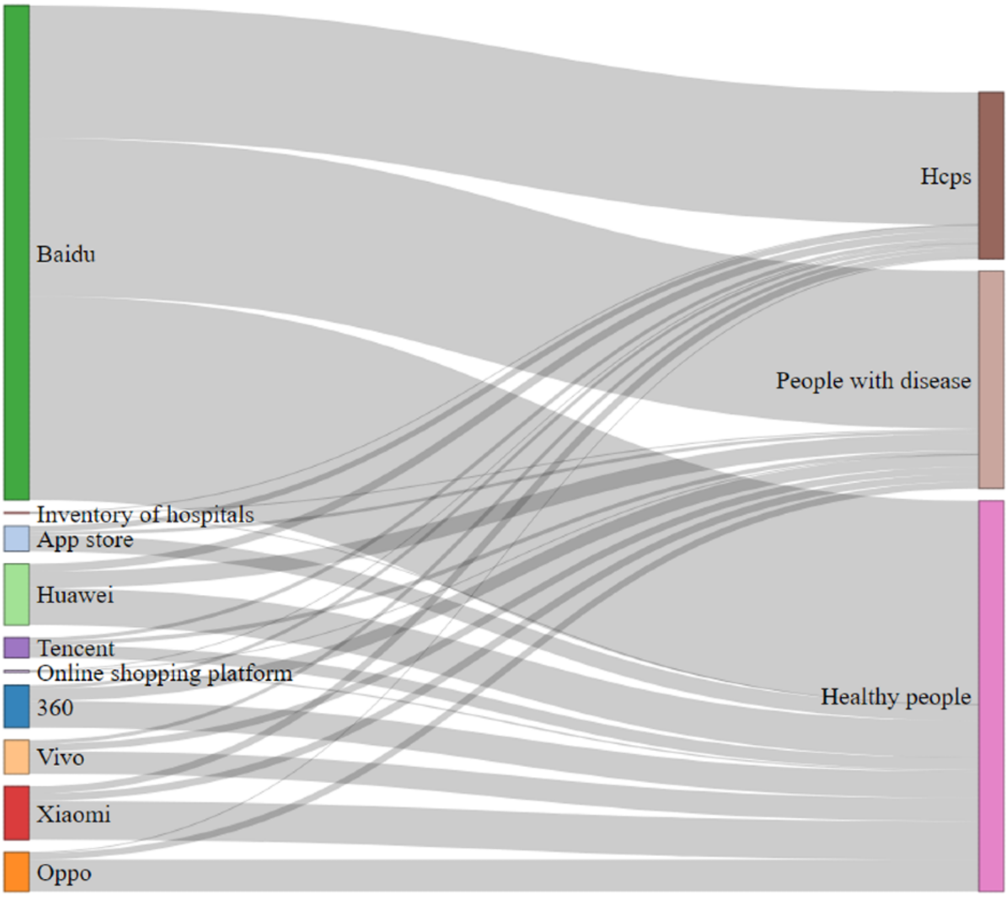

Figure 3. (A) Geographical distribution and (B) distribution of the time of establishment of mobile health (mHealth) app developers in China. There is another developer in Canada.

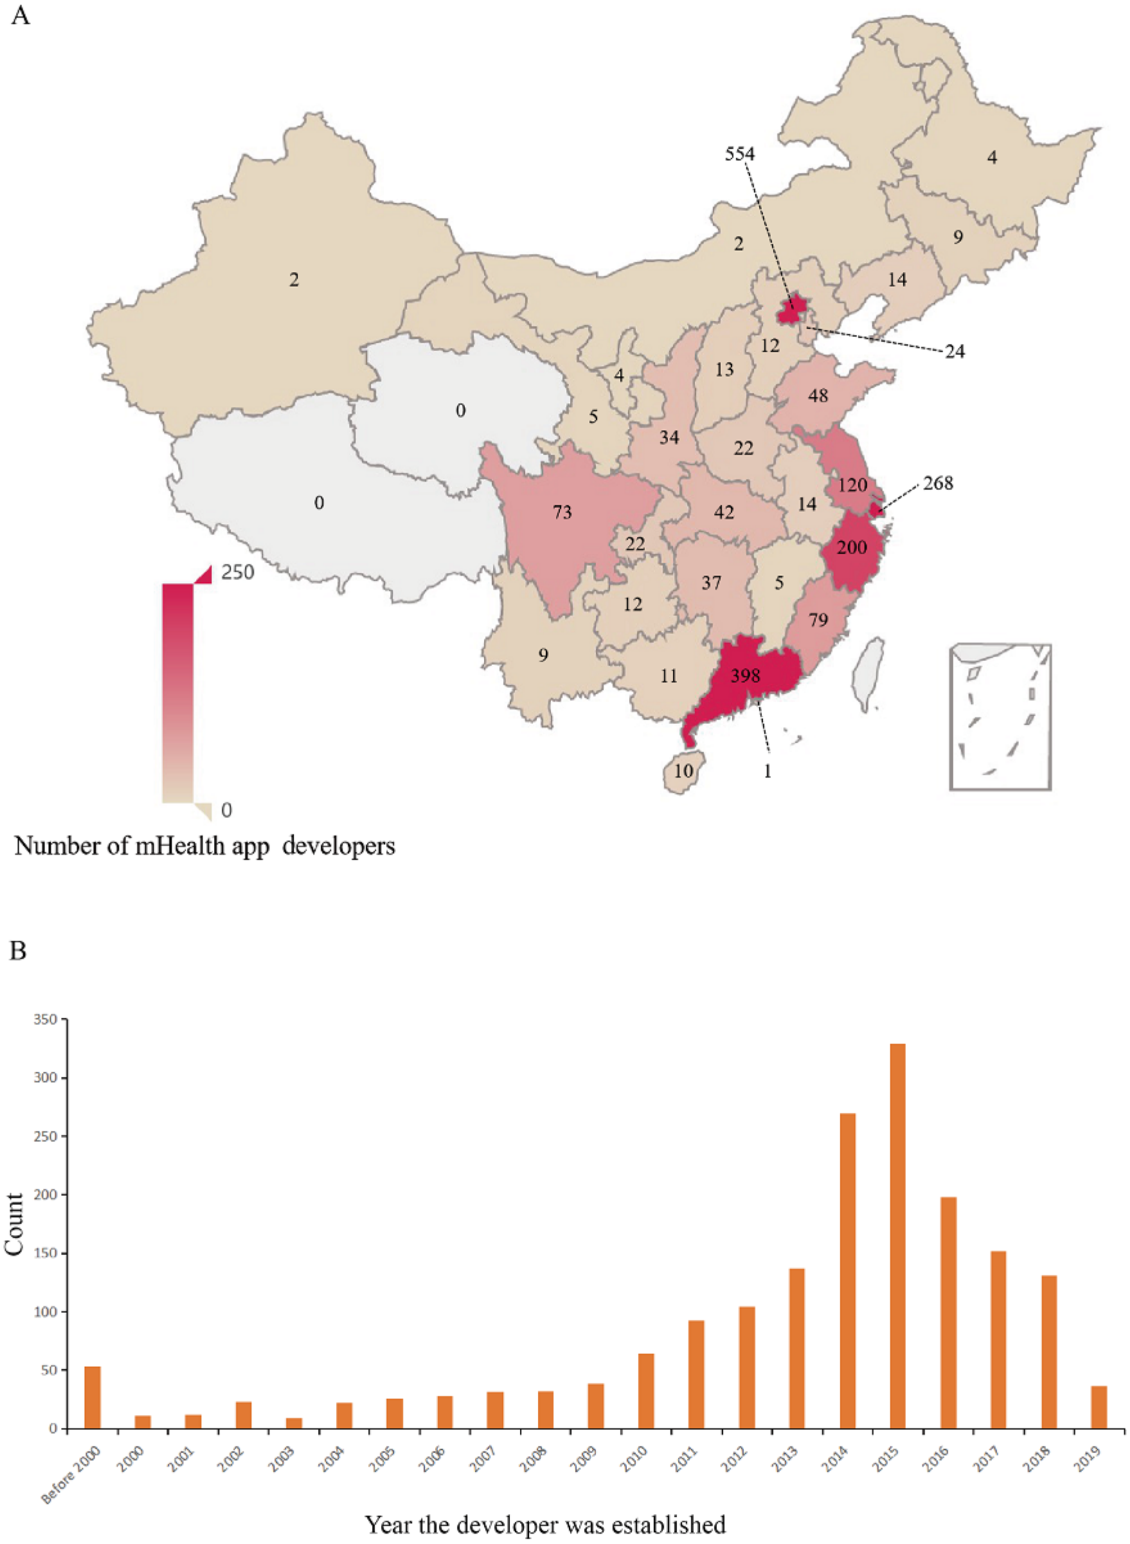

Of the 1593 mHealth apps, 1285 (80.7%) apps had full functionality available to conduct the app trial, including apps for health management (1248/1593, 78.3%) and apps for medical support (697/1593, 43.8%). The frequency of each function available in Chinese mHealth apps is shown in Figure 4. Figure 5 shows the associations between the 5 app classifications, with the circles scaled to the number of apps in each app classification. The rating concepts for these 5 different classifications in app trials are available in Table S4 in Multimedia Appendix 1 [27].

Figure 4. For each classification of mobile health (mHealth) apps in China: (A) frequency of app functions for 5 classifications; (B) ranking of the frequency of app functions is displayed on a color scale ranging from green (lowest charge rates) to orange, yellow, and red (highest charge rates).

Comparison of Download Changes in Apps With Different Functions Between Pre and Postpandemic

Overall upward trends in app downloads during the pandemic were driven by some key app functions (see Figures 6 and 7). Rehabilitation (prepandemic median 1,437,500; postpandemic median 2,741,890; *P*<.001) and pregnancy preparation (prepandemic median 480,520; postpandemic median 1,982,490; *P*<.001) were the most often used functions, with statistically significant differences between pre and postpandemic. The 9 most important drivers for increasing downloads were divided into 2 categories. Three functions related to children and maternal health were observed: women's health (fold change 5.16), pregnancy (fold change 5.78), and parenting (fold change 4.03). Increased downloads of these apps (women’s health, *P*<.001; pregnancy, *P*<.001; parenting, *P*<.001) were also observed between pre and postpandemic. The other 6 most popular functions regarding treatment needs and maintenance were treatment (fold change 5.31), plastic surgery (fold change 8.77), drug use (fold change 5.92), patient information management (fold change 5.06), nutrition (fold change 8.79), and Chinese medicine (fold change 10.04). Vaccination, which was most relevant to COVID-19, saw a large spike in download rates, with an increase of 6.26 times (absolute change in mean: 7,233,800) postpandemic compared with prepandemic.

The 6 functions that decreased in ranking the most in the postpandemic period were health education, genetic screening, medical service purchases, drug purchases, inquiries, and physiological testing via mobile phone; 4 additional functions that declined after the COVID-19 outbreak included medical examination, medical community, patient management, and disease management. Bodybuilding, which was closely related to outdoor activities, also declined in ranking, with an increase of only 2.71 times prepandemic rates, but its absolute change in mean was 28,247,800. All these functions with declining rankings were growing, albeit at lower speeds relative to high-ranking functions. For example, the increase in drug purchases was 2.05 times (absolute change in mean: 7,388,400) the prepandemic rate, and patient management downloads were 4.98 times (absolute change in mean: 3,039,900) the prepandemic rate.

Figure 6. The number of occurrences of each function (ie, function frequency) in the 1593 mobile health (mHealth) apps with multiple functions in China.

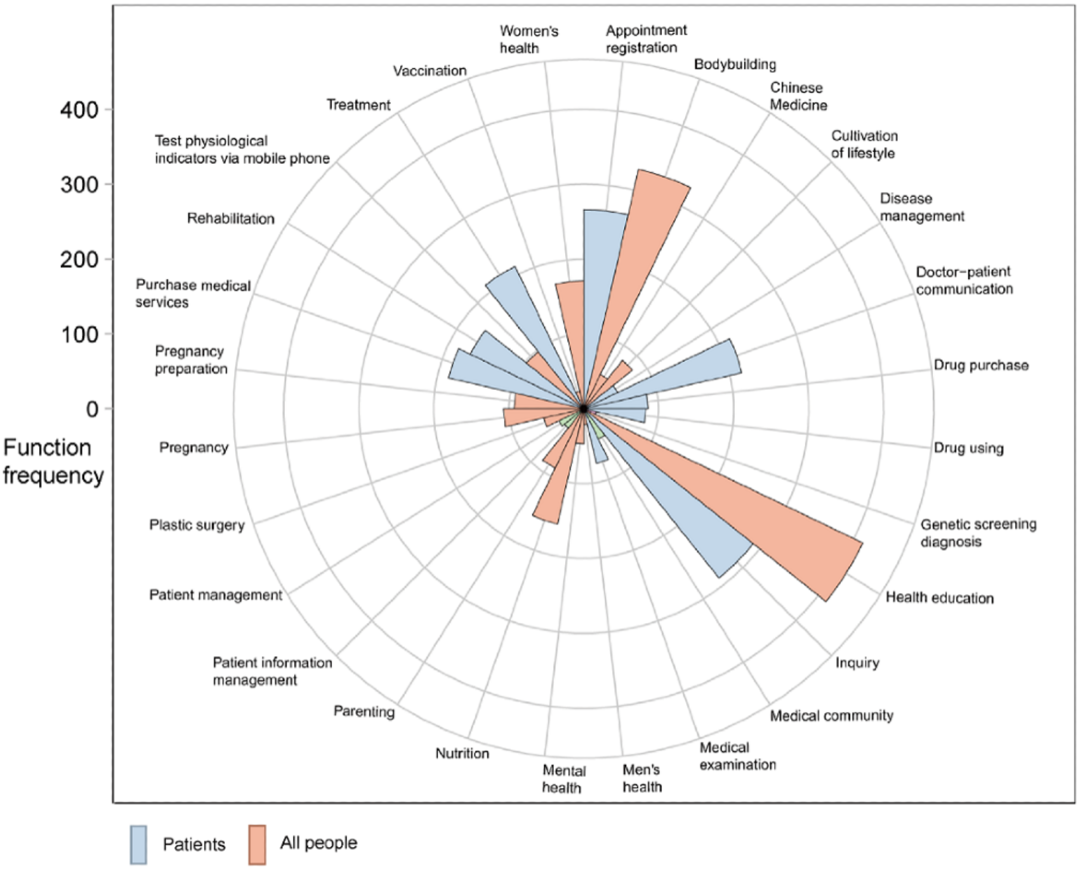

Figure 7. Leading functions of mobile health (mHealth) apps in the pre and postpandemic periods in China, connected by lines between the periods to show increased (solid line) or decreased (dashed line) ranking, while bold number indicate significant changes between the periods as determined using paired *t* tests with Bonferroni-corrected *P* values <1.79x10^{-3}. Fold change in median of the number of app downloads=(Medpost-Medpre)/Medpre. Absolute change in mean of the number of app downloads=∑(npost-npre)/n.

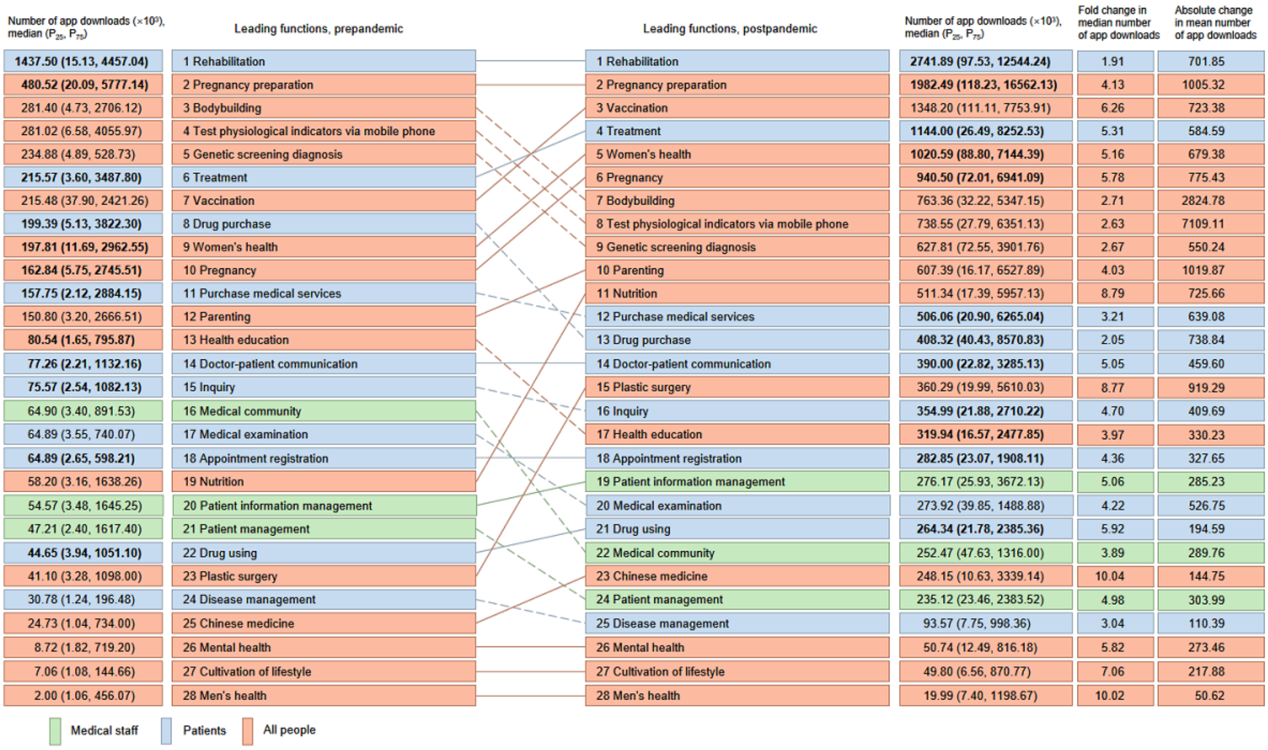

Number of app downloads (×10³), median (P_{25}, P_{75})	Leading functions, prepandemic	Leading functions, postpandemic	Number of app downloads (×10³), median (P_{25}, P_{75})	Fold change in median number of app downloads	Absolute change in mean number of app downloads

Relationship Between App Characteristics and Download Changes

Based on the QR analysis, a positive effect for adding COVID-19 function and content on apps (P_{10}: *P*=.001; P_{50}: *P*=.01; P_{75}: *P*=.009; P_{90}: *P*=.01) was observed across download changes in most quantiles, with the largest effect at the 90th quantile (see Table 2, Figure 8, and Multimedia Appendix 2). Positive effects of the size of apps on download changes were also observed at high quantiles (P_{75}: *P*=.03; P_{90}: *P*=.002). Other characteristics of the QR are shown in Table 2.

Table 2. Quantile regression coefficients of app characteristics for changes in downloads.

Relationship Between App Functions and Download Changes

We found that 4 of 28 functions, including rehabilitation (P_{75}: *P*=.003; P_{90}: *P*=.02), pregnancy preparation (P_{90}: *P*=.09), bodybuilding (P_{50}: *P*=.07; P_{90}: *P*=.08), and vaccination (P_{75}: *P*=.06), were positively associated with download changes, mainly in the higher quantiles (see Table 3, Figure 9, and Multimedia Appendix 3). Health education (P_{75}: *P*=.09; P_{90}: *P*=.09), drug use (P_{90}: *P*=.08), cultivation of lifestyle (P_{25}: *P*=.02; P_{50}: *P*=.06; P_{75}: *P*=.07), men's health (P_{90}: *P*=.07), and disease management (P_{75}: *P*=.03) had negative correlations with download changes. Other functions in the QR are shown in Table S5 in Multimedia Appendix 1.

User Experience

No significant difference was found in the sex (*P*=.41) or mean age (*P*=.52) of the participants. The attention given to health information (prepandemic: 249/375, 66.4%; postpandemic: 146/178, 82.0%; *P*=.006) and the percentage of people owning smartphones (prepandemic: 186/375, 49.7%; postpandemic: 108/178, 60.7%; *P*=.02) steadily increased after the outbreak (see Table 4). The vast majority of individuals (prepandemic: 129/141, 92.1%; postpandemic: 89/90, 98.9%) used social networks (eg, WeChat) to obtain health information online. Furthermore, the ratio of internet hospital use rose dramatically (prepandemic: 6/375, 1.6%; post-pandemic: 23/178, 12.9%; *P*<.001). Other characteristics of the user experience analysis are shown in Table 4.

Table 4. Population use of mobile health (mHealth) apps in the pre and postpandemic periods.

Characteristics	Before the outbreak (n=375)	After the outbreak (n=178)	*P* value

Discussion

Principal Findings

Our study demonstrates that the usage and population utilization of mHealth applications increased after the COVID-19 outbreak. As a powerful tool for providing health care services, functions closely related to the pandemic, including rehabilitation, treatment, drug use, and vaccination, were positively associated with changes in app downloads. The high growth of app use related to maternal and child health, including pregnancy preparation and women's health, shows the potentially increased desire for family among the Chinese population in the postpandemic era. Moreover, the user experience and high use of health management apps also reflect great attention to self-care. Overall, mHealth apps assist with health improvement against the background of normalized pandemic control and may improve fertility.

COVID-19–Related Apps

The usage of COVID-19 pandemic-related apps, such as vaccination, increased in rank. Furthermore, adding pandemic-related functions positively correlated with increased downloads. The likely reason behind this rise was that apps inherently related to the pandemic can easily capture the attention of the public as a means of obtaining information. Some apps with larger user groups may also add COVID-19 modules to respond to normalized pandemic prevention and control policies [14].

Medical Support Apps

Unprecedented large-scale quarantine measures and shortages of medical resources have made telemedicine care an important and real demand during the pandemic [28]. In our research, rehabilitation, including apps for long-term care or chronic disease management, was the most widely used function before and after the outbreak, overcoming the interruption of personal health care services caused by COVID-19. mHealth apps are used for many rehabilitation purposes [25]**.** One study showed that effective rehabilitation apps helped patients increase their health and happiness index during the pandemic period [29]. Furthermore, the use of mHealth apps can help improve adherence to treatment [30]. Use of apps with functions for rehabilitation, treatment, and drug use increased significantly after the outbreak, providing stable medical services to reduce the negative impact of home isolation. China's emerging internet model provides the basis for remote pharmacy services [31], assisting patients who cannot always go to the pharmacy. At the same time, personalized medical plans are also an important part of precision medicine [32]. The city of Taizhou, China, had a successful experience using telemedicine to prevent and treat COVID-19 [33]. Consequently, mHealth apps are an effective medical tool in the context of COVID-19.

Health Management Apps

Most apps were designed for health management by all people, mainly focusing on bodybuilding and nutrition. In our research, app flow and user experience surveys both showed that the rankings of most functions related to health management were rising, which reflects great attention to self-care postpandemic.

It is interesting that there was increased use of maternal and child health apps, including pregnancy preparation, women's health, pregnancy, and parenting, after the outbreak, showing potentially increased desire for fertility among the Chinese population.

One study concluded that the pandemic is affecting people's desire to become parents, which was consistent with our results [34]. Another previous study conducted a cross-sectional survey of 285 apps to analyze the current situation of maternity apps in Italy, finding that high-quality, targeted, and effective apps for pregnancy and postnatal health care had relevant implications in terms of maternal and newborn health prevention and promotion [35]. mHealth apps have the potential to be used extensively in improving maternal well-being [36]. The high growth of maternal and child health-related apps such as pregnancy preparation and women's health in our study coincides with this. Before the pandemic, the progression of population aging, decline of women in the childbearing period, and increase in high-risk pregnancies had led to the continuous decline in China's fertility rate [21]. Women have suffered significant reproductive health disruption since the beginning of the COVID-19 pandemic [37,38], which may have aggravated the decline in fertility [39]. However, with long-term home isolation and 2-child and 3-child policies proposed by the government, people are giving more attention to family matters, including pregnancy preparation and raising children, which may slow the decline in fertility to a certain extent. Therefore, maternal and child health apps can effectively assist health management and fill the vacancy of in-person perinatal health care services [40], despite interrupted pregnancy checkups [39]. It has been suggested that a model of health management combined with continuous care using the WeChat platform can significantly improve patients' postoperative medication compliance and quality of life by requiring them to complete their rehabilitation tasks in the WeChat group, which is worth applying and promoting [41]. In China, pregnant women are accustomed to using WeChat groups recommended by hospitals to discuss pregnancy health information and may promote apps in it, which may be a way to increase app usage.

For bodybuilding apps, this function had positive changes in downloads during the COVID-19 pandemic. One study found that the keyword "mHealth" was closely associated with "physical activity" and "ehealth" in the last 2 decades of research on digital health behavior change technologies [42]. Closed gyms and restricted outdoor activities during the pandemic reduced physical activity levels; however, the use of physical activity apps may counteract the decline in exercise [43].

Many kinds of apps attempted to provide health education, which was the most widely available function in our study. Although this function declined during the pandemic and had negative changes in downloads, the population's attention to health information increased. The probable cause behind this phenomenon is that new media platforms in China, such as WeChat and Weibo, have been vigorously promoted as important means for pandemic-related health information dissemination, which may decrease interest in acquiring apps when the information is readily available on these platforms. The high levels of knowledge of the Chinese public about COVID-19 prevention mainly comes from WeChat [44]. This is consistent with the results of our study that people use WeChat most often to obtain health information.

The COVID-19 pandemic has caused health anxiety at the population level. Digital intervention by mHealth apps is suitable for alleviating such sociopsychological consequences [45]. However, it may be because of the vigorous development of the psychological counseling hotline project in China during the pandemic that mental health apps were not of great concern. Furthermore, a study that conducted a systematic assessment of self-guided cognitive behavioral therapy (CBT)–based apps concluded that only a few self-guided CBT-based apps offer comprehensive CBT programs or suicide risk management resources, which may also be one of the reasons for not getting much attention [46].

Willingness to Use mHealth Apps

Consistent with the report of the rapid increase in older adult internet users during the COVID-19 pandemic in China, we found that people over 50 years old paid more attention to mHealth apps after the outbreak [47-50]. In conjunction with the increased interest of older adults in the mHealth space, the results of a previous study suggested that person-centered mHealth apps can be used to create mHealth solutions with positive outcomes for older adults [51]**.** Coupled with the higher probability of chronic diseases or other conditions, older individuals should be a primary and adaptable group for mHealth apps [52]. However, the digital divide makes optimizing mHealth apps among older individuals difficult [53]. The Chinese people strongly support public health measures proposed due to COVID-19, which makes it possible to develop the ability to use smart devices, reduce the digital divide, and provide QR codes for pass certificates [54]. It is worth noting that a larger software file size was positively associated with download changes, indicating that excessive software size has little effect on the willingness to use the software. Having the right function is what users are most concerned about, and the causal relationship needs to be further studied [55].

Limitations

Our study should be considered in the context of important limitations. First, this study excluded apps that were used internally by medical staff because we could not log in as an internal account holder; this dilutes the results of mHealth apps designed for health care professionals. However, our research focused on apps for patients and healthy people rather than internal apps. Future work will be conducted with apps used internally in medical care. Second, the absence of newly emerging apps made it impossible to provide an overview of the mHealth market after the COVID-19 outbreak. Therefore, we compared the changes in downloads during the pre and postpandemic periods to explore the relationship between various types of apps and the pandemic. Third, as a semilongitudinal survey, this study measured exposure and outcome, and it was difficult to derive causal relationships from the analysis; thus, we only made assumptions based on the status quo.

Strengths

The study has practical implications and applications. This study is the first to investigate the relationship between COVID-19 and population-level utilization of mHealth apps through a semilongitudinal study of app markets' data and a field questionnaire, combined with the results of both the web-based survey and the population user experience survey. As China is one of the few countries to adopt more active public health prevention and control measures, this study, which involves a multilevel and broad research scope, can provide strong data support for future comparative studies between different countries and regions. In the user experience survey, we explored the changing attitudes of the population toward digital health technology, suggesting that there is a good development environment for mHealth apps in the postpandemic era. This study, with consistent definitions of variables and processes, allowed the investigators to consistently classify mHealth apps and ensure data integrity, underpinning its strength. Our research clarified the relationship between various types of apps and usage changes by conducting investigations in the pre and postpandemic periods. We believe our results provide a good reference for the subsequent development of future mHealth apps. In addition to the increasing number of COVID-19–related apps prompted by pandemic policies, app developers should be aware that maternal, child, and self-care management are app functions about which the population is concerned.

Perspective

mHealth apps utilize information and telecommunications technology to transfer medical information for diagnosis, therapy, and education and played a significant role following the COVID-19 outbreak. The pandemic made people aware of the value of mHealth in promoting universal health coverage, which promotes stronger management of self-care. Against the backdrop of an increased desire to raise a family among the Chinese population in the postpandemic era, maternal and child health apps, as a health education tool, promote a healthy lifestyle for women's self-management in the antenatal and postpartum periods. Further research is needed to understand the users' requirements for these apps, which will influence their adoption. The explicit design of apps is another potential factor that can facilitate or hinder user engagement and requires further investigation.

Conclusion

mHealth apps are an effective approach to providing health care in the context of COVID-19. This study clarifies the increasing usage of different apps during the pre and postpandemic periods, showing greater attention to self-care and the Chinese population's increasing desire to raise a family. Moreover, our research provides direction for subsequent mHealth app development and promotion in the postepidemic era, supporting medical model reformation in China as a reference. This may provide new avenues for designing and evaluating indirect public health interventions such as health education and health promotion. Further research is needed to investigate the functions in each kind of app, which will contribute to the personalized development and specific improvement measures of mHealth apps as a health promotion strategy.

Acknowledgments

We thank the study participants. Abstract

Background: While many studies evaluated the reliability of digital mobility metrics as a proxy of SARS-CoV-2 transmission potential, none examined the relationship between dining-out behavior and the superspreading potential of COVID-19.

Objective: We employed the mobility proxy of dining out in eateries to examine this association in Hong Kong with COVID-19 outbreaks highly characterized by superspreading events.

Methods: We retrieved the illness onset date and contact-tracing history of all laboratory-confirmed cases of COVID-19 from February 16, 2020, to April 30, 2021. We estimated the time-varying reproduction number (R_t) and dispersion parameter (k), a measure of superspreading potential, and related them to the mobility proxy of dining out in eateries. We compared the relative contribution to the superspreading potential with other common proxies derived by Google LLC and Apple Inc.

Results: A total of 6391 clusters involving 8375 cases were used in the estimation. A high correlation between dining-out mobility and superspreading potential was observed. Compared to other mobility proxies derived by Google and Apple, the mobility of dining-out behavior explained the highest variability of k (ΔR-sq=9.7%, 95% credible interval: 5.7% to 13.2%) and R_t (ΔR-sq=15.7%, 95% credible interval: 13.6% to 17.7%).

Conclusions: We demonstrated that there was a strong link between dining-out behaviors and the superspreading potential of COVID-19. The methodological innovation suggests a further development using digital mobility proxies of dining-out patterns to generate early warnings of superspreading events.

Introduction

The COVID-19 pandemic has caused nearly 300 million confirmed cases and over 5 million attributable deaths worldwide during 2020-2021. As human mobility is a key driver of SARS-CoV-2 transmission [1], nonpharmaceutical interventions (NPI) aimed at reducing human movements and contacts, including travel restrictions, case detection, isolation, quarantine of close contacts, and social distancing, have been effective in flattening incidence curves and protecting the health care system from being overwhelmed [2]. Of the human activities, indoor dining at eateries exposes people to a high SARS-CoV-2 infection risk, especially since mask mandate does not apply in those occasions. Several investigations have shown that permitting on-premises dining was associated with increased risk of COVID-19 infections [3,4].

In the current pandemic, digital data encoding human mobility information have been highly leveraged for purposes of assessing risk of infectious disease transmission, quantifying the effectiveness and compliance of NPI, and enabling early detection early detection of cases to prompt timely interventions. To facilitate the control of the COVID-19 pandemic, several multinational companies with GPS-related services released their mobility data, such as the community mobility reports from Google LLC [5], mobility trends report from Apple Inc [6], and the COVID-19 mobility data network from Meta Data for Good program [7]. There are some more fine-grained digital proxies applied to construct the COVID-19 mobility networks, which entailed hourly movements to specific points of interest, including restaurants [8,9].

As a densely populated metropolitan, Hong Kong was vulnerable to considerable COVID-19 outbreak risk and has kept community transmissions at a containable level through case detection and isolation, intense contact tracing, and quarantine in the early phases of the pandemic [10,11]. However, the superspreading events (SSE), where a large number of secondary cases were generated by a few primary cases, presented challenges for the effectiveness of these measures. Previous studies indicated that approximately 20% of cases seeded 80% of all local transmissions in the first and second wave of COVID-19 epidemics [12,13]. Similar observations were also reported in other Asia-Pacific settings such as South Korea [14]. The government has rolled out different levels of measures to prevent transmissions by restricting capacity, limiting the number of diners per table, and shortening the dine-in hours. Eateries were found to be settings where major clusters with SSE occurred, even though corresponding restriction measures such as social distancing and limited dine-in hours were in place [15,16].

Many studies assessed the reliability of different digital mobility metrics as a proxy of the SARS-CoV-2 transmission [17-21]. For example, Kurita et al [19] demonstrated that Apple mobility data were useful for the short-term prediction of COVID-19 transmissibility. Nevertheless, to our knowledge, none have examined the relationship between the trend of dining-out behaviors and the superspreading potential of COVID-19. A good understanding of the relationship is essential for informing and evaluating the effectiveness of NPI. In this work, we aim to examine the association between the trend of dining-out behaviors and disease transmissibility in Hong Kong, a setting with COVID-19 outbreaks characterized by SSE.

Methods

Epidemiological Data

Surveillance data on local COVID-19 cases were provided by the Centre for Health Protection, Department of Health of the Government of the Hong Kong Special Administrative Region. All COVID-19 infections were confirmed by testing with polymerase chain reaction. We retrieved the illness onset date and contact-tracing history of the confirmed cases. Based on the contact history, we reconstructed the transmission clusters, defined as a number of cases with the same source of infection (ie, a primary case) or epidemiologically linked [22]. Cases without source cases that did not have epidemiological linkage with other confirmed cases were defined as sporadic cases (ie, cases with untraceable contacts). A sporadic case was considered as a cluster equal to one. The study period was from February 16, 2020, to April 30, 2021, when the third wave of transmissions was brought under control.

Digital Mobility Proxy of Dining-Out Patterns

A web crawler was developed to retrieve user comments from OpenRice, the most commonly used restaurant catalog for people to search and provide feedback in Hong Kong. The website covers restaurant information and user comments for more than 28,000 eateries and is open for public access without a log-in requirement. We obtained the daily total number of comments as a proxy of dining out in eateries from February 16, 2020, to April 30, 2021. The daily counts were normalized using the baseline means of total comments between November 1 and December 31, 2018.

Other Digital Mobility Proxies

We obtained anonymized and aggregated human mobility data released by Google and Apple during the COVID-19 pandemic by locations and transport modes [5,6]. The Google COVID-19 community mobility reports included the daily change of visitor numbers to 6 locations (ie, retail and recreation, grocery and pharmacy, parks, transit stations, workplaces, and residential) compared to the median value in baseline days (from January 3, 2020, to February 6, 2020). The commuting information was collected through GPS linked with the Google Maps app. Similarly, mobility data from Apple mobility trends were also obtained, which reports on the daily ratio of trip numbers to the baseline (January 13, 2020). The data sets were generated from users' devices connected to the Apple Maps service for directions and were categorized by driving and walking.

Estimation of the Time-Varying Reproduction Number

Following Cori et al [23], we estimated the time-varying reproduction number (R_t) over the study period. In this approach, the daily number of cases by illness onset date was modeled through a branching process, where the incidence at time t (ie, I_t) is Poisson distributed with the mean given by , where ω_s is the discretized probability distribution of the serial interval. Epidemiologically, a serial interval approximated the infectiousness of a COVID-19 case at time s after the symptom onset. We assumed the mean and SD of the serial interval during the study period to be 6.5 and 4.1 days, respectively, based on a previous study conducted in Hong Kong [24]. As the empirical serial interval estimates may be biased due to the sampling and selection bias within the contact-tracing data collected during an ongoing epidemic [25], we also tested another assumption of serial interval distribution (mean 4.6, SD 4.9 days) estimated from a modeling study that corrected for such bias [26] as a sensitivity analysis. We only considered cases that acquired the infection locally in the estimation. The R_t was estimated by fitting the time-series data to the Poisson distributions in a sliding window process, assuming the R_t remained constant within each window.

Estimation of Superspreading Potential

Given the stochastic effect of transmissions, the transmission dynamics can be described by an offspring distribution (ie, the distribution of the number of secondary cases generated by the primary case). Following Lloyd et al [27], we assumed a negative-binomial offspring distribution, which was parametrized by a reproduction number and a dispersion parameter (*k*). When *k* is sufficiently low (ie, less than 1), SSE are more likely to occur. Applying the branching process theory, *k* could be estimated by fitting the transmission cluster data to a cluster size distribution [28], which describes the probability of clusters with a size of *z* seeded by *u* primary cases. We only included transmission clusters that were initiated by local cases. For an ongoing epidemic, the clusters' sizes are likely to grow after the time of estimation. To this end, we also considered right censoring in the cluster size distributions [22,28,29]. Thus, the likelihood function is:

Here, Pr(.) is the probability mass function of the cluster size distribution assuming a negative binomial offspring distribution following previous studies [22]. The term *c* is an indicator of censoring, where *c*=0 if the cluster is censored and *c*=1 if the cluster is considered as self-limited. A cluster is censored if it has new confirmed cases within 11 days before the day of estimation [22]. We determined the time-varying *k* during the study period in a sliding window process.

The window length was fixed at 30 days, which could cover 4 transmission generations based on the upper bound of the estimated generation interval of COVID-19 [30]. Within each window period, we estimated *k* using the Markov chain Monte Carlo method. Gamma distribution and half-normal distribution were used as prior distributions for R_t and *k*, respectively. For each Markov chain Monte Carlo chain, we obtained 10,000 thinned posterior samples from 500,000 iterations.

Associations Between Mobility Proxies and Transmission Dynamics

Time series of the mobility proxies were smoothed by a 7-day rolling average. The Pearson correlation coefficients (*r*) between the mobility proxies and R_t, and between the mobility proxies and *k*, were computed, respectively. The R-square was determined to quantify the proportion of variance explained by a mobility proxy using linear regression. A full regression model was built including all the mobility proxies. R_t and *k* were log-transformed and negative log-transformed in the regression models, respectively. To quantify the relative contribution of a specific mobility proxy in predicting the R_t or *k*, we determined the difference in *R*-squares (ΔR-sq) between a full model and the model without the proxy [31]. We calculated the means and 95% credible intervals (CrIs) for the estimates by sampling 10,000 times from the posterior distributions of the estimates; 3 and 7 days of lags were tested to examine the lag effects of mobility on the outcomes of disease transmissibility ensuring the robustness of the study findings.

The analysis was conducted in R statistical software (version 4.0.3; The R Foundation). The programming code is available upon request.

Ethics Approval

Ethics approval was obtained from the Survey and Behavioral Research Ethics Committee, The Chinese University of Hong Kong (SBRE-20-581). Because this study was a modeling analysis using secondary data with no personal information, the requirement for obtaining informed consent was waived.

Results

The relationship between and among social distancing policies, disease transmission dynamics, and the mobility proxies from February 16, 2020, to April 30, 2021, is illustrated in Figure 1 and Figure 2. The estimated R_t decreased from 1.94 (95% CrI 1.63 to 2.29) to 0.17 (95% CrI 0.07 to 0.34), from 2.88 (95% CrI 2.59 to 3.20) to 0.59 (95% CrI 0.55 to 0.63), and from 1.63 (95% CrI 1.29 to 2.01) to 0.72 (95% CrI 0.66 to 0.78) at 3 intervention phases, respectively.

A total of 6391 clusters involving 8375 cases were reported during the study period. Among the identified clusters, there were 4527 clusters with a size equal to 1 (ie, sporadic cases). The distribution of the number of secondary cases generated by the primary cases for the whole study period is showed in Multimedia Appendix 1. Of the 7194 linked cases, 1096 (15.23%) cases generated at least 2 secondary cases, and 1 case even initiated a transmission cluster composing 394 cases. The cluster data were used to estimate *k*, which was negative log-transformed, so the larger the value, the higher the superspreading potential. At the 3 intervention phases, the negative-log *k* decreased from 3.49 (95% CrI 3.12 to 3.83) to 2.34 (95% CrI –0.70 to 3.30), from 3.02 (95% CrI 2.63 to 3.37) to 0.69 (95% CrI 0.28 to 1.06), and from 2.51 (95% CrI 1.61 to 3.17) to 0.68 (95% CrI 0.09 to 1.19), respectively (Figure 2).

Similar decreasing trends were observed for the mobility proxies (Figure 2 and Table 1). A high correlation between dining-out behavior and *k* was observed (*r*=0.46, 95% CrI 0.32 to 0.56). While several other mobility proxies were also highly correlated with *k*, including visiting retail and recreation (*r*=0.41, 95% CrI 0.24 to 0.54), parks (*r*=0.36, 95% CrI 0.17 to 0.51), and workplaces (*r*=0.37, 95% CrI 0.24 to 0.46), mobility proxies of transit stations, driving, and walking had a weaker correlation with *k* (*r*<0.15). Correlations between mobility proxies and R_t were generally weaker. Only the mobility of dining-out behavior in eateries (*r*=0.16, 95% CrI 0.14 to 0.18) and workplace (*r*=0.13, 95% CrI 0.10 to 0.16) maintained a larger correlation with R_t.

The mobility proxies could explain a higher percent of variability of *k* than that of R_t. In the full model, including all the mobility proxies, the *R*-squares were 54.3% (95% CrI 30.3% to 75.2%) and 23.7% (95% CrI 21.5% to 25.9%) for regressing *k* and R_t, respectively. We used ΔR-sq to quantify how much of the variabilities of the k and R_t were explained by each of the mobility proxies (Figure 3 and Table 1). Among the proxies, the mobility of dining-out behavior explained the most of variability of k (ΔR-sq=9.7%, 95% CrI 5.7% to 13.2%) and R_t (ΔR-sq=15.7%, 95% CrI 13.6% to 17.7%). Other mobility proxies result in a mean ΔR-sq of less than 5% when regressing k. For R_t, the proxies of driving and transit stations had a ΔR-sq of 7.8% (95% CrI 6.3% to 9.3%) and 3.3% (95% CrI 2.3% to 4.5%), respectively. Other mobility proxies had the mean ΔR-sq<3% when regressing R_t.

We examined the effects of 3-day and 7-day lags of mobility proxies on k and R_t (Multimedia Appendix 2). In general, dining-out behavior still explained the highest variance of the outcomes. The ΔR-sq of a 3-day lag of the metric was 7.8% (95% CrI 4.2% to 11.4%) and 13.1% (95% CrI 11.1% to 15.2%) for k and R_t, respectively, whereas that of a 7-day lag of the metric was 4.1% (95% CrI 2.1% to 6.8%) and 11.7% (95% CrI 9.9% to 13.7%) for k and R_t, respectively. The changes in ΔR-sq for other mobility proxies were also not apparent when their lag effects were considered. Apart from that, a change of the assumed serial interval (mean 4.6, SD 4.9 days) only resulted in a minor change in the ΔR-sq for R_t with the primary findings remaining unaffected (Multimedia Appendix 3).

Figure 1. Number of reported cases and estimated time-varying reproduction number (Rt) in Hong Kong from February 16, 2020, to April 30, 2021. The number of reported cases is indicated by the gray bars (left axis), and the posterior median estimate of Rt is indicated by the red line, with shading indicating the 95% credible interval (right axis). The purple shaded areas show the intervention phases at different periods. Phase 1: A table of restaurants was limited to 4 people, and 6 types of premises must close from 6 PM from March 28, 2020, and bars must close from 6 PM from April 3, 2020. The measures started to be relaxed from May 5, 2020 (left); Phase 2: Restaurant dine-in services at night were banned, and no more than 2 persons may be seated together at 1 table in restaurants since July 13, 2020. The measures started to be relaxed since August 28, 2020 (middle). Phase 3: Business hours of restaurants, bars, and clubs were shortened; the number of people allowed to be seated together at 1 table was reduced; and the number of people participating in any 1 banquet in catering premises would be limited to 40 since November 16, 2020. Dine-in services at restaurants from 6 PM to 5 AM of the next day were banned, and the number of people participating in a banquet was further limited to 20 since December 10, 2020. The measures started to be relaxed since February 18, 2021 (right).

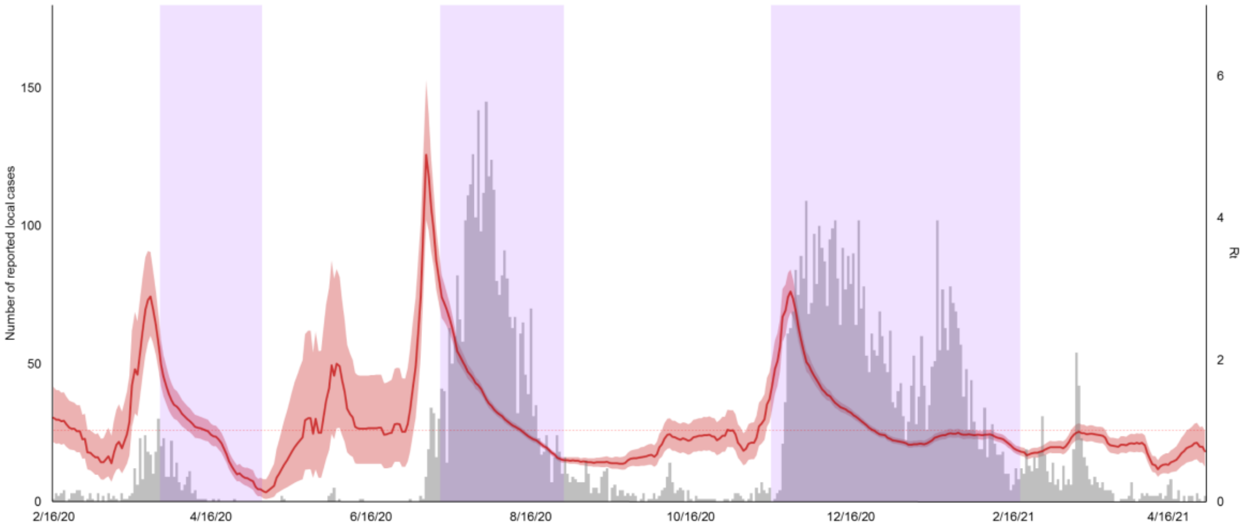

Figure 2. Negative logarithm of dispersion parameter (k) and mobility proxies. A. The negative logarithm of *k* is indicated by the blue line, with shading indicating the 95% credible interval (left axis), and the normalized counts of dining-out mobility is indicated by the orange line (right axis). B. The Google Mobility Index by types. C. The Apple Mobility Index by types.

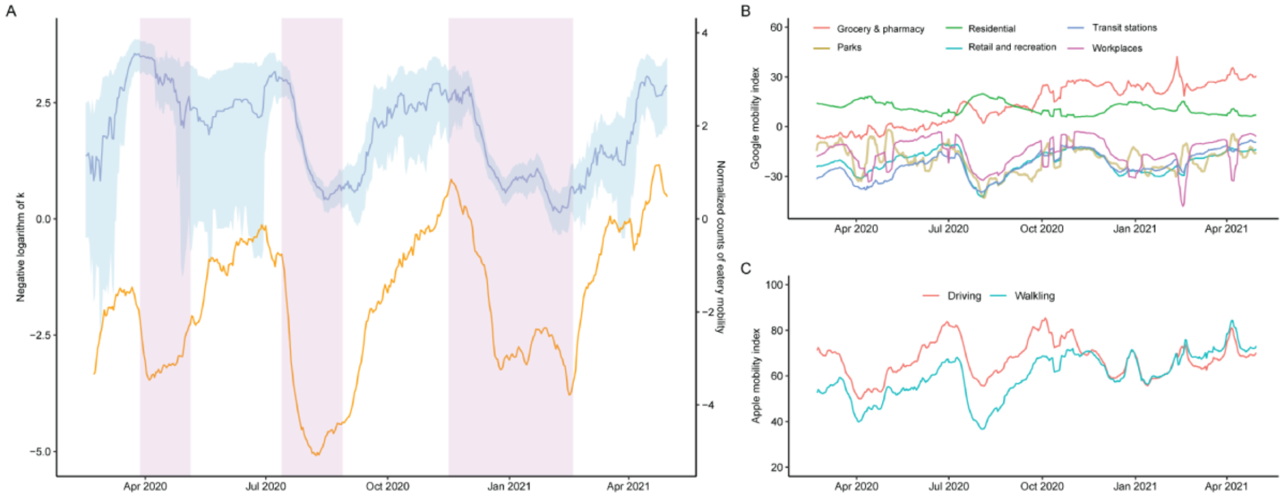

Table 1. Associations between mobility proxies and transmission dynamics[a].

Mobility proxies	R_t [b]		k [c]	
	r [d]	ΔR-sq[e] (%)	r	ΔR-sq (%)
Dining-out behavior	0.16 (0.14 to 0.18)	15.7 (13.6 to 17.7)	0.46 (0.32 to 0.56)	9.7 (5.7 to 13.2)
Retail and recreation	0.00 (–0.02 to 0.02)	0.8 (0.4 to 1.4)	0.41 (0.24 to 0.54)	3.7 (1.0 to 7.3)
Grocery and pharmacy	–0.01 (–0.04 to 0.03)	2.4 (1.5 to 3.5)	–0.23 (–0.36 to –0.04	1.3 (0.0 to 4.1)
Parks	–0.10 (–0.12 to –0.08)	0.8 (0.3 to 1.4)	0.36 (0.17 to 0.51)	0.4 (0.0 to 1.6)
Transit stations	0.02 (–0.01 to 0.04)	3.3 (2.3 to 4.5)	0.16 (0.06 to 0.24)	0.7 (0.0 to 2.3)
Workplaces	0.13 (0.10 to 0.16)	1.3 (0.8 to 1.9)	0.37 (0.24 to 0.46)	0.1 (0.0 to 0.5)
Residential	–0.03 (–0.05 to –0.01)	0.1 (0.0 to 0.2)	–0.21 (–0.29 to –0.11)	1.0 (0.2 to 2.0)
Driving	0.02 (0.00 to 0.05)	7.8 (6.3 to 9.3)	0.11 (–0.01 to 0.22)	0.4 (0.0 to 1.8)
Walking	–0.05 (–0.08 to –0.03)	0.0 (0.0 to 0.1)	0.01 (–0.08 to 0.08)	2.7 (1.0 to 4.7)

[a] The results were presented using means and 95% credible intervals of the estimates from the posterior distributions. Proxy of dining-out behavior was retrieved from OpenRice. Proxies of retail and recreation, grocery and pharmacy, parks, transit stations, workplaces, and residential were retrieved from Google COVID-19 community mobility reports. Proxies of driving and walking were retrieved from Apple mobility trends.

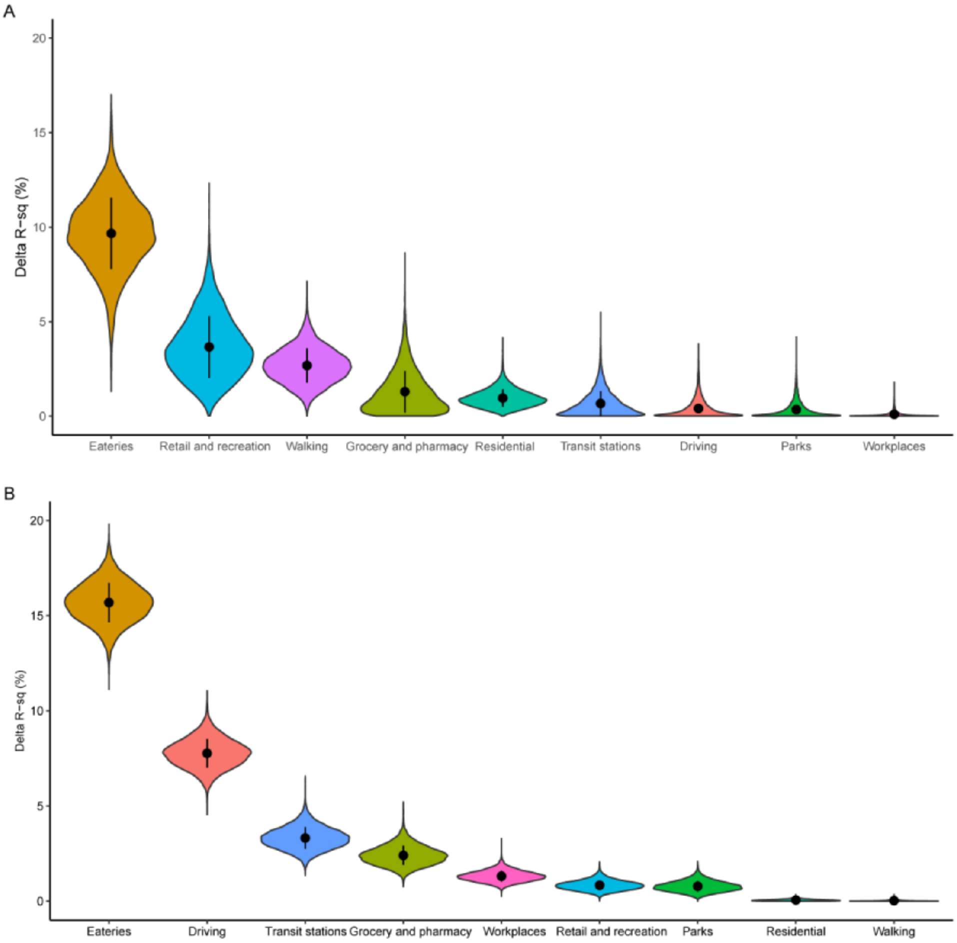
[b] R_t: time-varying reproduction number.

[c] k: dispersion parameter of superspreading potential.

[d] r: Pearson correlation coefficient.

[e] ΔR-sq: difference in *R*-squares between a full model and the model without the proxy.

Figure 3. Relative contributions of the mobility proxies in predicting dispersion parameter (k) and time-varying reproduction number (*R*t). A, B: The relative contributions of each of the mobility proxies, including eateries, retail and recreation, grocery and pharmacy, parks, transit stations, workplaces, residential, driving, and walking, in predicting (A) *k* and (B) *R*t were quantified by the differences in *R*-squares (ΔR-sq). The black dot indicates the mean estimate of ΔR-sq interpolated with an SD.



Discussion

Principal Findings

Digital data on human mobility play an important role in tracking public compliance with NPI as well as monitoring infectious disease dynamics. While many studies evaluated the reliability of different digital mobility metrics as a proxy of the SARS-CoV-2 transmission [17-21], none have examined the relationship between the trend of dining-out behaviors and the superspreading potential of COVID-19. In this study, we evaluated the reliability of dining-out activities at eateries as a proxy for SARS-CoV-2 transmission risk in Hong Kong with outbreak highly characterized by SSE. According to our results, dining out activities were associated with the change in disease transmissibility as well as the superspreading potential of COVID-19. This finding is consistent with the fact that eatery venues were high-risk settings for frequent virus exposure and superspreading, as they tend to be indoors, populated, and without the mandate of mask wearing, having the highest proportion of COVID-19 infection counts than other places [32,33]. According to the COVID-19 spread pattern in Hong Kong, as characterized by previous research, eateries had a higher outbreak potential of unlinked cases than other settings and accounted for the second highest number of linked transmissions after the households [15,16], as dining-out activities gather individuals that are not socially connected in adjacent and common areas of the restaurant, widening the dispersion of infected persons and subsequently sustaining case clusters propagated across different settings. Similar to our results, the county-level COVID-19 growth in the United States increased from 1.1% to 1.2% when dining-out restrictions were removed, and a 55% decline in new COVID-19 cases was found after imposing bans on indoor on-premises dining [3,4].

During the COVID-19 epidemic, Hong Kong did not impose any stringent measures on eatery settings (eg, compulsory banning of indoor dining and closures of eatery venues), which has been adopted in a number of countries such as the United Kingdom and Singapore, before the availability of COVID-19 vaccines [34,35]. Nevertheless, as demonstrated in this study, less stringent measures such as shortening the business hours and restricting the capacity of eateries were still able to decrease the related mobility as well as the superspreading potential, particularly in the second and the third intervention phases. The finding supports the effectiveness of these measures, even though the related effect on transmission has been questioned [36]. However, we cannot factor in the effects of other social distancing measures implemented, although by including other mobility proxies in our analyses, we have adjusted for some secular effects from the other measures.

Of the mobility proxies, mobile device data including the community mobility reports from Google LLC and mobility trend reports from Apple Inc have been well studied as proxies for changes in human activities and SARS-CoV-2 transmissibility [17-19]. For instance, a Japanese investigation demonstrated that Apple mobility data were reliable for a short-term prediction of COVID-19 transmission [19], whereas an Italian investigation showed the changes in transmissibility of SARS-CoV-2 were associated with both social distancing measures and Google mobility [18]. While the studies assured the reliability of these metrics, we showed that dining-out behavior had a greater contribution to the COVID-19 transmissibility compared with the digital proxies generated by Google and Apple, likely because their data are not specific to eateries. Nevertheless, our analysis showed that the movement metrics including driving and transit stations still accounted for a certain proportion of variability of the community transmission. This observation echoes a previous study in Hong Kong using digital transactions in public transport and social mixing data to forecast the COVID-19 epidemics [20]. Similar movement metrics provided by Baidu Huiyan were also well demonstrated as useful data to improve the temporal and spatial resolution of COVID-19 transmissions [20,21].

In this study, estimating superspreading potential required comprehensive data of rapid contact tracing. In the Omicron epidemic, public health resources for conventional contact tracing were overwhelmed in Hong Kong due to a rapid and huge surge in infections. With insufficient data on case linkages, the superspreading potential cannot be determined during the Omicron period. It suggests a need for novel digital tools for contact tracing, for example, by app-based tools that can notify users instantaneously when their contacts are confirmed positive [37,38]. The deployment of app-based tools at a population level not only improves the timeliness of tracing but also avoids the recall bias in contact tracing. While digital contact tracing is common in many places [39], residents in Hong Kong were skeptical of this type of app due to ethical and privacy concerns [40]. As long as the digital data are available with a large population coverage and adequate compliance, they could be incorporated in our analytical framework that requires comprehensive contact tracing data.

With the comprehensive information of rapid contact tracing before an Omicron outbreak in Hong Kong, the major strength of this study is the capability of using the corresponding data for the estimation of time-varying superspreading potential, which were unlikely to be available in other settings without intense contact tracing during the COVID-19 pandemic. In addition, while a majority of studies related the mobility proxies to reproduction numbers [17,19], our study is the first investigation that linked the mobility pattern to disease superspreading, especially for the COVID-19 transmission, which was found to be highly heterogeneous [12-14,28,41].

Limitations

Nonetheless, this study had several limitations. First, individual-level data on demographics, duration of indoor dining, and the number of people dining together were not available, thus lowering the resolution of transmission risk imposed on the individual in an eatery. Still, the aggregated information provided a simple, inexpensive, and readily available data source for informing decisions for pandemic control and predicting the superspreading potential. Second, dining-out behavior may be different by geographic locations given the differential distributions of eateries. Due to a lack of the geographic information of the mobility proxies, the modeling analysis was unable to account the spatial variation, and the study findings may thus suffer from bias. Third, our study did not intend to develop a forecast model given limited mobility and social mixing data [20]. We expect that an increased coverage of app-based tools would offer high-resolution data for further development of a prediction model. Fourth, a single data source of proxy for the dining-out behavior was used for this study. While OpenRice was the most common web page for commenting and rating different eateries, we were unable to include diners who preferred using other web page or apps such as Facebook.

Conclusion

In conclusion, we demonstrated that there was a strong link between dining-out behaviors and the superspreading potential of COVID-19, and the metric was more reliable than other common mobility data derived by Google and Apple Inc. The findings suggest that the mobility proxy of dining-out behavior is able to help health officials for monitoring the public compliance of social distancing measures as well as the cluster outbreak potential. For example, officials could adjust the intensity of social distancing measures (eg, restriction of the maximum number of seats in a restaurant and mandatory closure of eateries) based on the disease transmissibility inferred by the mobility proxies. In addition, our methodological innovation recommends a further development of using digital mobility proxies of dining-out patterns to generate early warnings of SSE, thereby assisting in resource planning on corresponding measures.

Acknowledgments

We would like to thank Hospital Authority and Department of Health, Hong Kong Government, for providing the data for this study, and HyperLab for developing the web crawler. Abstract

Background: The pan-European VACCELERATE network aims to implement the first transnational harmonized and sustainable vaccine trial Volunteer Registry, being a single entry point for potential volunteers of large-scale vaccine trials across Europe. This work exhibits a set of harmonized vaccine trial–related educational and promotional tools for the general public, designed and disseminated by the pan-European VACCELERATE network.

Objective: This study primarily aimed to design and develop a standard toolkit to increase positive attitudes and access to trustworthy information for better access and increased recruitment to vaccine trials for the public. More specifically, the produced tools are focused on inclusiveness and equity, and are targeting different population groups, including underserved ones, as potential volunteers for the VACCELERATE Volunteer Registry (older individuals, migrants, children, and adolescents). The promotional and educational material is aligned with the main objectives of the Volunteer Registry to increase public literacy and awareness regarding vaccine-related clinical research or trials and trial participation, including informed consent and legal issues, side effects, and frequently asked questions regarding vaccine trial design.

Methods: Tools were developed per the aims and principles of the VACCELERATE project, focusing on trial inclusiveness and equity, and are adjusted to local country-wise requirements to improve public health communication. The produced tools are selected based on the cognitive theory, inclusiveness, and equity of differently aged and underrepresented groups, and standardized material from several official trustworthy sources (eg, COVID-19 Vaccines Global Access; the European Centre for Disease Prevention and Control; the European Patients' Academy on Therapeutic Innovation; Gavi, the Vaccine Alliance; and the World Health Organization). A team of multidisciplinary specialists (infectious diseases, vaccine research, medicine, and education) edited and reviewed the subtitles and scripts of the educational videos, extended brochures, interactive cards, and puzzles. Graphic designers selected the color palette, audio settings, and dubbing for the video story-tales and implemented QR codes.

Results: This study presents the first set of harmonized promotional and educational materials and tools (ie, educational cards, educational and promotional videos, extended brochures, flyers, posters, and puzzles) for vaccine clinical research (eg, COVID-19 vaccines). These tools inform the public about possible benefits and disadvantages of trial participation and build confidence among participants about the safety and efficacy of COVID-19 vaccines and the health care system. This material has been translated into several languages and is intended to be freely and easily accessible to facilitate dissemination among VACCELERATE network participant countries and the European and global scientific, industrial, and public community.

Conclusions: The produced material could help fill knowledge gaps of health care personnel, providing the appropriate future patient education for vaccine trials, and tackling vaccine hesitancy and parents' concerns for potential participation of children in vaccine trials.

(JMIR Public Health Surveill 2023;9:e44491) doi:10.2196/44491

KEYWORDS

vaccine trials; volunteer registry; educational material; promotional material; patient education; health communication; health promotion; public health; COVID-19; coronavirus; SARS-CoV-2; pandemic; vaccine; vaccination; hesitancy; campaign; misinformation

Introduction

VACCELERATE [1] is an independent, innovative, and transparent Pan-European academic network with the aim of harmonizing multinational vaccine trial initiatives and conducting capacity mapping of vaccine clinical trials sites and laboratories with standardized methods and protocols across Europe. The network identifies and provides access to state-of-the-art vaccine trial sites to accelerate the development of vaccines and recruit volunteers for vaccine trials through the VACCELERATE Volunteer Registry [2].

The main goal of the VACCELERATE Volunteer Registry [2] is to establish the first transnational harmonized trial participation platform serving as single entry point for the European region. The VACCELERATE Volunteer Registry [2], under the mandate of the European Union’s Health Emergency Preparedness and Response Authority (HERA) [3], provides a sustainable platform source for the recruitment of potential volunteers for clinical studies for the current COVID-19 pandemic and future epidemics.

According to the literature, one of the main challenges of a volunteer registry is the registration of a large number of potential trial participants with great diversity [4,5] and dedication in order to be able to recruit and match suitable candidates for the selected clinical trial. Therefore, a great amount of effort is spent looking for strategies to improve communication [6] and convince [7] potential volunteers to take part in vaccine trials.

The enrollment of volunteers in vaccine trials is also influenced by factors such as complacency, conspiracy theories [8] on social media regarding COVID-19, convenience and confidence (the “Three Cs” model of vaccine hesitancy) [7,9], disinformation [10], fake news [11], fear [12], and increasing level of health misinformation [13-15]. The latter leads to an infodemic [16] of misleading information with immediate effects on public health, refusal, and vaccine hesitancy [9] for participation in clinical trials [17,18]. It should be noted that health misinformation is responsible for increased fear and lack of trust, which are major factors for enrollment also in cancer clinical trials [19-21]. Recently, Luís et al [22] reported that there is a lack of public information about COVID-19 vaccine trials among several population groups (eg, minorities and underrepresented populations or individuals), while the available tools for trial participation were also sparse.

The main purpose of this study is the design and development of a standardized toolkit based on the Social Cognitive Theory [23,24] to increase positive attitudes, access to trustworthy information for better access and increased recruitment to vaccine trials. Our secondary objective is to foster engagement of the community through the VACCELERATE Volunteer Registry and smart technology for participating in forthcoming clinical trials [25-28]. The VACCELERATE toolkit has been translated into several languages and is freely and easily accessible to facilitate dissemination among the participating countries of the VACCELERATE Consortium [1].

Methods

The development of the VACCELERATE educational and promotional tools included the following steps: (1) conceptualization of the idea and context based on the selected educational aims and objectives; (2) selection of targeted population groups (eg, older individuals, children, adolescents, and minorities); (3) prioritization of trustworthy sources and websites for seeking information about COVID-19 vaccine trials for the developed materials; (4) performing graphical design (eg, visualization, audio, product, print, and animation design); and (5) acquisition of a digital object identifier (DOI) for each produced material from a DOI registration agency. More details on the developed tools are presented in the *Results* section.

The context of the educational and promotional tools was created and reviewed by a group of experts in the field of infectious diseases and vaccine and pedagogical research. Two graphic designers developed and selected the appropriate color palette and audio (music, speaker voice, and dubbing) for the video story-tales and they adapted the produced material into an efficient pedagogical, attractive, and eye-catching way. The developed tools were (1) icons related to the COVID-19 pandemic (eg, use of a face mask, syringe, microscope, vaccine, handwashing, virus, etc); (2) different versions of logotypes for the VACCELERATE project; (3) typefaces; (4) samples of fonts with different sizes; (5) color palettes (primary and secondary colors); (6) imagery templates and guidelines for social media (eg, Twitter and Instagram); (7) human characters (ie, medical staff, minorities, and older individuals) as prototypes for any future VACCELERATE promotional and or educational material. Special attention was also paid to foster inclusiveness among the characters (different age groups, different ethic and other minority groups, citizens with disabilities, migrants, etc). The provided tools also include QR codes with a URL. The selected URL can be a website (as shown on the VACCELERATE website [29]) or selected animation videos from trustworthy sources of information (eg, COVID-19 Vaccines Global Access [ie, COVAX]; the European Centre for Disease Prevention and Control; the European Patients’ Academy on Therapeutic Innovation; the European Vaccine Initiative; Gavi, the Vaccine Alliance; the United Nations International Children's Emergency Fund; and the World Health Organization).

In addition, the produced puzzles test memory in a team-based manner and help develop hand-eye coordination.

Finally, the developed tools have been designed in a such a way that can be adjusted in accordance with local country-wise requirements and requirements to build confidence among participants about the safety and efficacy of COVID-19 vaccines and the health care system, which is a key parameter to improve recruitment among minority communities.

Results

VACCELERATE Flyers

The flyers (see Multimedia Appendix 1) provide the appropriate amount of information to the public regarding the registration process and the VACCELERATE Volunteer Registry in general. The flyers are A3-sized (29.7×43.18 cm) and include a short description of the VACCELERATE Volunteer Registry objectives and volunteer selection process. In addition, they contain the appropriate contact details (email ID) and link (along with a QR code) for registration in the Volunteer Registry [30]. The registration link directs the interested volunteer to a brief survey (which takes 5-10 minutes to complete) that collects comprehensive information required for clinical trials. The flyer invites all citizens to register, including those with prior COVID-19 vaccination, with specific questions regarding COVID-19 infection, and the invitations to eligible volunteers for future vaccine trials will be sent out by the Coordination Office of VACCELERATE (University Hospital Cologne, Cologne, Germany). Finally, the flyers have been translated into 9 languages (Cypriot Greek, English, French, German, Greek, Hebrew, Italian, Portuguese, and Spanish).

VACCELERATE Posters

The developed posters (see Multimedia Appendix 1) are A0-sized (84.1×118.9 cm) and depict human characters (ie, medical staff, minorities, and older individuals, among others) and a QR code including a URL for the VACCELERATE Volunteer Registry website [30], as well as catchy slogans such as “Be the missing piece” and “Together we can tackle the COVID-19 pandemic.” Finally, the posters have been translated into 7 languages, namely English, French, German, Greek, Hebrew, Italian, and Spanish, in collaboration with individual partners and national coordinators of the VACCELERATE Consortium. The promotion of the VACCELERATE Volunteer Registry for participating in COVID-19 vaccine trials could be achieved by affixing these prototype posters to a wall at sites or in buildings with high visibility (eg, hospitals, universities, malls, and public buildings).

VACCELERATE Extended Brochure (Booklet)

The extended VACCELERATE brochure (see Multimedia Appendix 1) comprises valuable information regarding the VACCELERATE Volunteer Registry, such as “What is the VACCELERATE Network,” the mission and objectives, the current promotion activities, the importance of registration, and a description of the registration process. The brochure also contains key information for the volunteers, such as the possibility to withdraw their registration at any time. Finally, the extended brochure also includes a QR code that directs the interested reader to the VACCELERATE Volunteer Registry website [30] after scanning it with a smart device.

VACCELERATE Interactive Educational Cards

The educational cards enhance general knowledge and address the misinformation about COVID-19 vaccines, vaccine trials, and COVID-19 vaccination, as well as voluntary trial participation of children and adults. Each set of educational cards represents an educational aim and comprises a specific number of cards and target groups, as shown in Table 1.

The interactive educational cards (Multimedia Appendix 1) have been prepared with the help of 2 graphic designers and under the guidance of a pediatrician and several VACCELERATE participants. The educational cards include a QR code with a URL for promoting educational material on the one side and additional text script and characters on the other. The URL can be a website (eg, the one showed on the VACCELERATE website [29]) or selected videos from trustworthy sources (eg, COVID-19 Vaccines Global Access [ie, COVAX]; the European Centre for Disease Prevention and Control; the European Patients’ Academy on Therapeutic Innovation; the European Vaccine Initiative; Gavi, the Vaccine Alliance; the United Nations International Children's Emergency Fund; and the World Health Organization) and produced animation videos from VACCELERATE.

Table 1. Characteristics of interactive educational cards.

Set	Cards, n	Target group	Aim
1	25	Individuals aged >12 years	Increase literacy about vaccine trials, trial registries, participation in vaccine trials, and participant procedures in trials
2	10	Individuals aged ≥12 years	Increase literacy about COVID-19 vaccination and messenger RNA vaccines
3	7	Individuals aged ≥12 years	Increase literacy about vaccine manufacturing, the vaccine approval process, safety monitoring, and awareness against vaccine misinformation
4	4	All individuals irrespective of age	Improve awareness and information about the VACCELERATE Volunteer Registry
5	12	All individuals irrespective of age	Increase literacy about COVID-19 vaccination, expand awareness for COVID-19 vaccine equity, and utilitarianism

VACCELERATE Puzzles

The VACCELERATE puzzles (Multimedia Appendix 1) were developed using graphic techniques under the guidance of the VACCELERATE participants, including a pediatrician, with focus on younger children (aged <12 years) in order to raise their awareness of clinical trials, vaccines, and participation in trials and to promote inclusiveness. The link to the produced puzzles is provided in Multimedia Appendix 1.

One of the developed puzzles comprises 25 pieces and depicts a variety of human characters (ie, medical staff, minorities, older individuals, and children, among others) obtained from the VACCELERATE toolkit, including the appropriate link to the VACCELERATE Volunteer Registry [30]. The concept herein is to include as many human characters as possible to highlight the importance of inclusiveness and diversity in vaccine trials, especially for underserved population groups such as racial and ethnic minorities and older individuals.

The other 2 smaller puzzles (8 pieces each) were developed to familiarize children with symbols and icons related to the COVID-19 pandemic, as well as to understand and recognize the effectiveness of vaccines in minimizing the risk of infection and harmful effects of COVID-19.

VACCELERATE Animation Videos

Educational Videos (Adult and Pediatric)

The first produced educational video (see Multimedia Appendix 1) was mainly focused on adults and designed using advanced animation techniques, appropriate subtitles based on a storyboard and educational aims, and audio settings (eg, music and a speaker voice). In addition, the video included the following sections: (1) highlight and increase information regarding clinical trials and their necessity and usefulness for public health (eg, good clinical practices, vaccine trial phases and monitoring, and applied safety protocols); (2) the contribution of volunteers (ie, citizens, patient advocacy groups, and underserved populations) to this effort for capacity mapping and building of registries; and (3) volunteer safety, benefits, and any potential risks during a clinical trial.

The second educational video (see Multimedia Appendix 1) was mainly aimed at children and adolescents. Special attention was given to contain informative animations while delivering the learning aim and keeping each video segment short. The produced video included the following sections: (1) provide information about the significance of vaccine trials; (2) share knowledge and information about the high value of vaccination as the most powerful “weapon” to prevent morbidity and mortality associated with infectious diseases; (3) acknowledge the advancements in technology and safety procedures, which have contributed significantly to the development, evaluation, approval, and monitoring of safe and effective vaccines; and (4) highlight the contribution and importance of pediatric volunteers in vaccine clinical trials and ensure their safety and the benefits and risks of participating in clinical trials.

Promotional Video

The promotional video (see Multimedia Appendix 1) presents short, recorded videos by the VACCELERATE work package leaders and the National Coordinator’s pictures to promote, inform, and describe the VACCELERATE Volunteer Registry through specific text scripts. The aim of the video is the inclusiveness and representation of all participating European Union countries and European Union–associated countries of the VACCELERATE Consortium. Currently, we have active representation from 17 countries (Austria, Belgium, Cyprus, Czech Republic, Germany, Greece, Ireland, Israel, Italy, Hungary, Lithuania, the Netherlands, Norway, Portugal, Spain, Sweden, and Turkey) in the VACCELERATE Volunteer Registry.

Discussion

Principal Findings

This paper presents the first set of harmonized promotional and educational tools of the VACCELERATE Volunteer Registry [2]. The produced material, based on the selected population group, includes flyers, posters, interactive educational cards, puzzles, and animation videos. The tools can be downloaded from the official website of VACCELERATE [29] and appropriate references, based on their own DOIs. It should be noted that the provided educational material can be adopted to the user needs and may also be used as base-prototypes for further improvement and production of related tools.

To ensure high rates of vaccination in populations [31] and a large number of participants in vaccine trials, it is necessary to ensure effective, targeted, and trustworthy educational and promotional tools regarding vaccines and vaccine trials, guaranteeing high diversity and inclusiveness in vaccine trials without underrepresentation of minorities.

The developed standardized toolkit is one example of information from trustful sources that can be used against health misinformation and disinformation, lack of trust, fear, and fake news. Furthermore, it can be also used to increase literacy and understanding of the importance of vaccine clinical trials in the general population as part of an emergency preparedness plan.

In addition, the promotional and educational material will be able to bridge the gap in public information (eg, communication approach, target audiences, and type of media produced) regarding COVID-19 vaccine trials, which is covered in only 2.51% of the collected media and only in 4 languages (English, French, German, and Czech) [22]. Another challenge is using visual material and stories in order to inform children about the procedures, importance of, and volunteer participation in vaccine trials and about vaccination.

Limitations

The impact and assessment of the promotional and educational material are beyond the scope of this study. Nevertheless, we are currently in the process of evaluating them for vaccine trials during this year by another expert group (WP4) of the VACCELERATE Consortium.

Conclusions

Communicating with trustworthy information to the public, related to public health issues and vaccine research or trials, constitutes the most important preventive strategy against infectious diseases and threats of future emerging infection diseases.

Future initiatives could involve further improvement of the dissemination process for the developed tools in order to increase the number of volunteer registrations and in particular among population groups, which remain underrepresented in vaccine trials. Another initiative could be the design of an innovative video game [31,32] targeting training and educational material for vaccine clinical trials, addressing vaccine hesitancy and refusal.

Other prospective initiatives could be the conduct of studies based on citizen science methods (eg, community-based participatory action research [28]) for vaccine research [25-27,33] and future epidemics by engaging community members and service providers as partners in the research process and providing them the appropriate educational tools for tackling current and future public health issues. Such actions will eventually contribute to reduce the knowledge gaps and hesitancy regarding participation in vaccine trials in the general population.

Acknowledgments

This project has received funding from the European Union’s Horizon 2020 research and innovation program (grant agreement 101037867; VACCELERATE). The produced educational and promotional tools were developed as part of the VACCELERATE Consortium. For further information, please refer to the official website of the VACCELERATE network [29].

The research leading to these results was conducted as part of the VACCELERATE consortium. For further information please refer to [29].

Data Availability

All data generated or analyzed during this study are included in this published article and its supplementary information file (Multimedia Appendix 1).

Conflicts of Interest

JS-G has received speaker honoraria from Gilead and Pfizer. The rest of the authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

Abstract

Background: Contact tracing is a fundamental intervention in public health. When systematically applied, it enables the breaking of chains of transmission, which is important for controlling COVID-19 transmission. In theoretically perfect contact tracing, all new cases should occur among quarantined individuals, and an epidemic should vanish. However, the availability of resources influences the capacity to perform contact tracing. Therefore, it is necessary to estimate its effectiveness threshold. We propose that this effectiveness threshold may be indirectly estimated using the ratio of COVID-19 cases arising from quarantined high-risk contacts, where higher ratios indicate better control and, under a threshold, contact tracing may fail and other restrictions become necessary.

Objective: This study assessed the ratio of COVID-19 cases in high-risk contacts quarantined through contact tracing and its potential use as an ancillary pandemic control indicator.

Methods: We built a 6-compartment epidemiological model to emulate COVID-19 infection flow according to publicly available data from Portuguese authorities. Our model extended the usual susceptible-exposed-infected-recovered model by adding a compartment Q with individuals in mandated quarantine who could develop infection or return to the susceptible pool and a compartment P with individuals protected from infection because of vaccination. To model infection dynamics, data on SARS-CoV-2 infection risk (IR), time until infection, and vaccine efficacy were collected. Estimation was needed for vaccine data to reflect the timing of inoculation and booster efficacy. In total, 2 simulations were built: one adjusting for the presence and absence of variants or vaccination and another maximizing IR in quarantined individuals. Both simulations were based on a set of 100 unique parameterizations. The daily ratio of infected cases arising from high-risk contacts (q estimate) was calculated. A theoretical effectiveness threshold of contact tracing was defined for 14-day average q estimates based on the classification of

COVID-19 daily cases according to the pandemic phases and was compared with the timing of population lockdowns in Portugal. A sensitivity analysis was performed to understand the relationship between different parameter values and the threshold obtained.

Results: An inverse relationship was found between the *q* estimate and daily cases in both simulations (correlations >0.70). The theoretical effectiveness thresholds for both simulations attained an alert phase positive predictive value of >70% and could have anticipated the need for additional measures in at least 4 days for the second and fourth lockdowns. Sensitivity analysis showed that only the IR and booster dose efficacy at inoculation significantly affected the *q* estimates.

Conclusions: We demonstrated the impact of applying an effectiveness threshold for contact tracing on decision-making. Although only theoretical thresholds could be provided, their relationship with the number of confirmed cases and the prediction of pandemic phases shows the role as an indirect indicator of the efficacy of contact tracing.

Introduction

Background

Contact tracing is a fundamental activity in public health and is the process of identifying, triaging, and monitoring individuals exposed to a communicable disease to prevent secondary transmission [1]. When systematically applied, contact tracing leads to the breaking of transmission chains, and its valuable role in controlling COVID-19 transmission is widely recognized in the context of low transmission and active community transmission [2]. It is also acknowledged that the earlier the identification of infection cases and individuals to trace, the higher the likelihood of the pandemic situation being controlled even in instances where contact identification is incomplete [1,3,4].

In Portugal, contact tracing and the imposing of quarantine measures are tasks specific to public health units [5]. The capacity of local public health units to perform contact tracing is constrained by the availability of technological and workforce resources [3]. Several simulation studies have demonstrated that contact tracing could only be effective if a combination of high adherence to quarantine measures, minor delays from symptom onset to isolation of cases, and an increased number of contacts traced occurred [3,6-8].

Such conditions were more likely to be verified in moments with a lower number of confirmed cases (ie, corresponding to the troughs of the epidemic curve) [9]. Moreover, the initial Portuguese guidelines for tackling the pandemic predicted that contact tracing efforts would be abandoned when the pandemic entered a community transmission phase [10]. Therefore, it should be deemed necessary to estimate a threshold beyond which contact tracing and potential individual quarantine measures cease to be effective in breaking infection chains and, consequently, diminishing SARS-CoV-2 infection rates in the community [11]. This information may be used as a decision-making support tool for imposing generalized population containment measures and offers important lessons concerning population control of viral infections with characteristics similar to those of SARS-CoV-2 [12].

The effectiveness of contact tracing as a mechanism for breaking transmission chains occurs because of the quarantine of contacts of confirmed infected cases. Should these contacts develop the disease, they will not transmit it to other community members [1]. Thus, the hypothetical identification of all contacts of all SARS-CoV-2–infected individuals would necessarily lead to the breaking of all transmission chains. In other words, in a scenario where all the contacts of all infection cases were identified, new infection cases would only occur in those contacts. Hence, the effectiveness threshold of a contact tracing and quarantine strategy could be derived from the proportion of infection cases that arise in contacts of confirmed cases.

Hence, the effectiveness threshold of contact tracing is the point at which its utility as a health intervention that includes quarantine in controlling and breaking transmission chains is defined. The proportions of confirmed cases from quarantined individuals above this threshold could be indicative of effective contact tracing, and the pandemic combat strategy could rely mainly on this intervention. In contrast, proportions below the threshold could indicate that contact tracing is not effective and that further interventions may be necessary to stop transmission.

The proportions of confirmed cases from quarantined individuals lower than the effectiveness threshold may have occurred at different stages throughout the pandemic, mainly in periods of case surges, situations in which there was a need to implement more restrictive measures (namely, general or selective confinements). Imposing confinements has been demonstrated to affect pandemic control regarding case numbers, hospital admissions, and deaths because of COVID-19 when implemented at least 14 days before the peak of a case surge [13,14]. In Portugal, the decision to impose a population lockdown was primarily based on the 14-day incidence rate; the transmissibility rate (Rt); and, more recently, the critical care bed occupancy rate [15].

Despite the public availability of several global databases on COVID-19, especially concerning the number of new cases, deaths, tests performed, and vaccination data, there is no information on the number of infected cases coming from individuals identified as high-risk contacts through contact tracing. Furthermore, data on quarantined individuals are scarce. Portuguese data were until recently an exception in that the Directorate-General of Health (DGS) reported in a daily bulletin on COVID-19 the number of high-risk contacts identified, defined as individuals in quarantine by mandate from health authorities [16]. The Data Science for Social Good (DSSG) initiative developed a data repository [17] for COVID-19 in which it gathered, compiled, and curated the data made public by the DGS in these bulletins.

Infection dynamics and the effectiveness of contact tracing are not only influenced by the vaccinated population (for which the DSSG also kept curated data). They may also be affected by the prevalence of different SARS-CoV-2 variants at different points in time. The European Centre for Disease Prevention and Control keeps a data repository on the prevalence of different variants in Europe reported through The European Surveillance System in an open-access database [18].

Objectives

The aim of this study was to identify the ratio of COVID-19 cases that occurred in individuals in quarantine mandated by health authorities and the potential use of this ratio as a proof of concept of an indicator for assessing pandemic control in parallel with other established criteria such as the transmissibility index (Rt) and incidence.

Methods

Study Design

In this study, we collected data on COVID-19 for Portugal and built an expanded structure to a susceptible-exposed-infected -recovered (SEIR) compartmental model to emulate the pandemic. All compartment data came from collected data except for those of protected individuals. The purpose of the model was to estimate the daily number of quarantined individuals who became infected and the daily number of susceptible and vaccinated individuals who were quarantined as data regarding those values were lacking.

We input different values for each known strain of SARS-CoV-2 (infection risk [IR] and time until infection and until the end of quarantine) and immunity from vaccination and ran the model for 690 days. Consequently, we estimated the daily ratio of cases arising from daily quarantined individuals (*q* estimate) using the number of daily confirmed cases as the denominator. We measured the correlation between this *q* estimate and data from confirmed cases.

According to the epidemic case curve, we defined 3 pandemic phases in the Portuguese data: interpandemic phase, alert phase, and pandemic phase. As a proof of concept, we estimated the best hypothetical cutoff for our *q* estimates to distinguish the interpandemic and alert phases and compared that theoretical cutoff with the timing of population confinement measures. Finally, we performed a 2-part sensitivity analysis. Initially, we ran a multiple linear regression on the thresholds that each set of parameters conveyed to assess how each parameter would change the threshold value. In addition, we fixed the maximum and minimum values for each parameter and measured the correlation with the main simulation results and threshold values obtained by changing all other parameters.

Table 1 includes all model inputs, values, and sources of each input. We also describe the only 2 outputs of the model, namely, the number of daily quarantined individuals who develop infection and the theoretical *q* estimate.

The compartment transition dynamics were in accordance with the following equations (note that only equations 1 and 3 were estimated, corresponding to compartments S and E, for which real data were not available. All other compartment data were directly collected from official reports [17]):

$$S' = \kappa Q + \rho P - (\phi + \psi + \varepsilon)S \quad \textbf{(1)}$$

$$Q' = \phi S + \chi P - (\gamma + \kappa + \varsigma)Q \quad \textbf{(2)}$$

$$E' = I - \gamma Q \quad \textbf{(3)}$$

$$I' = \gamma Q + \iota E - \pi I \quad \textbf{(4)}$$

$$R = \pi I \quad \textbf{(5)}$$

Table 1. Data sources and model inputs and outputs.

Parameter	Value	Source
Susceptible (S)	Base case: 10 million	Estimated
Protected through vaccination (P)	P (Protection) × V	Estimated
Quarantined (Q)	Base case: 0	DSSG[a] [17]
Exposed not traced (E)	Base case: 0	Estimated
Infected (I)	Base case: 2	DSSG [17]
Recovered from infection (R)	Base case: 0	DSSG [17]
Vaccinated (V)	Base case: 0	DSSG [17]
Inoculation vaccine efficacy (Ve_0)	10%-60% (uniform distribution)	Hall et al [19] and Polack et al [20]
Maximum vaccine efficacy (Ve_{max})	Ve_0-95% (uniform distribution)	Hall et al [19] and Polack et al [20]
Waned vaccine efficacy (Ve_{waned})	$(Ve_0 + Ve_{max})/2$	Estimated
Inoculation booster dose efficacy (Be_0)	Ve_{waned}-80%	Estimated
Maximum booster dose efficacy (Be_{max})	Be_0-95%	Estimated
Waned booster dose efficacy (Be_{waned})	$(Be_0 + Be_{max})/2$	Estimated
Time until maximum efficacy (Δte_{max})	15 d	Hall et al [19] and Polack et al [20]
Time until waned efficacy (Δte_{waned})	180 d	Hall et al [19]
Variant prevalence	Base case: other=100%; alpha, beta, gamma, delta, and omicron=0%	ECDC[b] [18]
Maximum time until γ ($\Delta t\gamma_{max}$)	2-14 days (uniform distribution)	DGS[c] [5,21] and Wu et al [22]
Average time until γ ($\Delta t\gamma_{mean}$)	2-$\Delta t\gamma_{max}$ days (uniform distribution)	DGS [5,21] and Wu et al [22]
Maximum time until κ and ς ($\Delta t\kappa\varsigma_{max}$)	2-14 days (uniform distribution)	Estimated
Average time until κ and ς ($\Delta t\kappa\varsigma_{mean}$)	2-$\Delta t\kappa\varsigma_{max}$ days (uniform distribution)	Estimated
IR[d] simulation A	10%-50% (uniform distribution)	ECDC [1], Karumanagoundar et al [23], and Tang et al [24]
IR simulation B	0.1%-2.5%	Calibration
Quarantined infected	γQ	Estimated
Ratio of cases from quarantined (*q*)	$\gamma Q/(\gamma Q + \iota E)$	Estimated

[d] IR: infection risk.

Data Collection

The sources of data are described in full in Table 1. The primary data source to meet this study's aim was the DSSG COVID-19 data repository [17]. The data included the number of confirmed cases, daily new cases, people under surveillance, people fully vaccinated, and individuals with vaccine booster doses (using any of the vaccines available in Portugal) between the first confirmed case of COVID-19 in Portugal (March 2, 2020) and January 20, 2022. Open-access data from The European Surveillance System regarding the weekly prevalence of SARS-CoV-2 variants were also collected through the European Centre for Disease Prevention and Control open repository [18] for the same period. In the absence of specific data on the number of cases of COVID-19 among high-risk contacts, we built a simulation model to calculate the ratio of daily cases from those contacts using the available data.

Epidemiological Compartmental Model

Data were inserted into an epidemiological model based on compartmental models already applied to COVID-19 and other epidemiological contexts [25,26]. Several expanded models to an SEIR model have been attempted, including either one or more quarantine compartments and one or more protected individuals through vaccination [27]. In addition, the concept of high-risk exposure and exposed individuals (frequently included in compartment E) did not entirely comprise the DGS definition of high-risk contact in that, in all models, an exposed individual could not return to being susceptible [28]. Furthermore, in most models, a quarantined individual could have come from being susceptible and either return to being susceptible or progress to being infected [29]. Other quarantine definitions, different from the idea of prophylactic isolation, came from infected individuals [30].

Moreover, 2 transitions have not been reported in the reviewed literature on expanded SEIR models, namely, the direct transition between compartments S and I and the transition between vaccinated or protected compartments and quarantine or exposure compartments. As our model needed to comprise these transitions, several differences from already published models had to be introduced. To keep with the base SEIR structure, compartment E included only individuals who would progress to compartment I without previous contact tracing. The model was extended with compartments Q and P. Figure 1 illustrates the compartmental model used and the transitions between compartments and subcompartments.

Compartment S (susceptible) is the initial compartment of the model (ie, the starting point for all individuals). From compartment S, individuals can progress to compartments P, Q, and E.

Compartment P (protected) refers to the group of individuals who are immune to SARS-CoV-2 infection because of vaccination. Although the main effect of vaccines is protection against severe disease and not protection against infection [20], short-term efficacy in infection prevention has been proven [19]. This preventive effect is considerably reduced 6 months after the date of inoculation. When classified as high-risk contacts through contact tracing, individuals in this compartment could be quarantined regardless of their vaccination status in line with Portuguese norms that only lifted these compulsory measures for fully vaccinated individuals on January 10, 2022 [5].

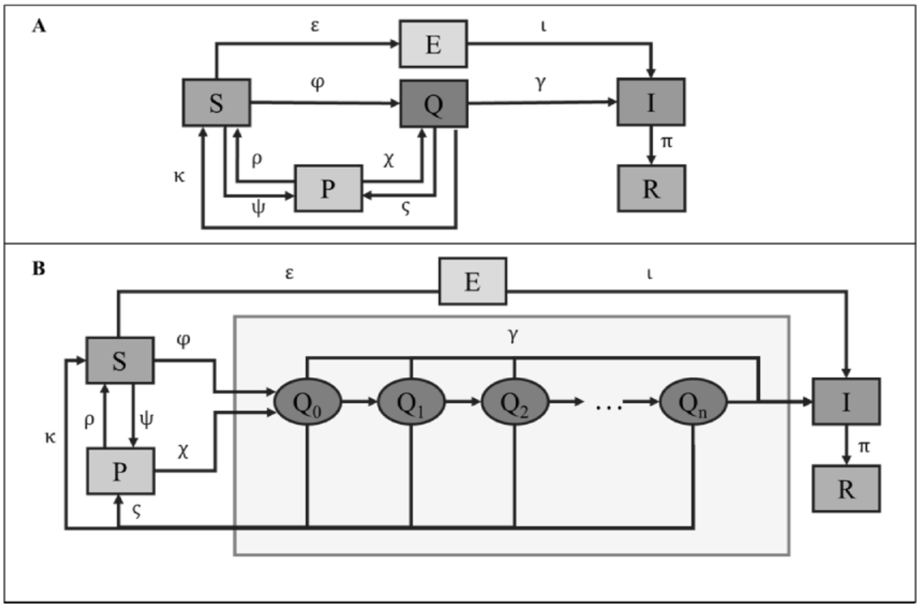
Compartment Q (quarantined or exposed with tracing) includes all high-risk contacts of SARS-CoV-2–infected individuals for whom quarantine was mandated by a public health authority according to norms and guidelines [5] and the definition by the Portuguese DGS as “individuals under surveillance” applicable at each moment. Individuals in this compartment could return to compartment S. This compartment is further divided into subcompartments, each representing a day in which an individual stayed in the exposed compartment. Thus, the transitions ϕ and κ, χ and ς, and γ are the pooled transitions from each subcompartment inside compartment Q and compartments S, P, and I, respectively.

Compartment E (exposed without tracing) includes exposed individuals who will develop COVID-19 and have not been traced by health authorities. Compartment I consists of all the confirmed cases of SARS-CoV-2 infection.

Compartment R (recovered) includes all individuals who recovered from infection. Compartment R is the terminal compartment as the model is not circular. This is because an individual previously infected with COVID-19 cannot be considered a high-risk contact before 180 days have passed from the date of infection or when not presenting symptoms suggesting SARS-CoV-2 infection [21]. In other words, until the natural immunity gained from infection fades, there can be no transition between the recovered (R) and exposed (E) or quarantined (Q) compartments. When such immunity wanes, the individual should return to compartment S. However, and assuming a large enough number of individuals in compartment S (equal to or greater than the total number of confirmed cases in the analysis period), there is no need to consider transitions between compartments R and S—even in case of reinfection, each new case of COVID-19 can be regarded as a case from a different individual.

The daily ratio of cases arising from individuals in quarantine mandated by health authorities was given by the quotient of the daily transitions between compartments Q and I (represented by γ) and the daily total confirmed cases.

Figure 1. Compartmental model without subcompartments (A) and with subcompartments (B). E: individuals exposed to SARS-CoV-2 who will develop COVID-19 and have not been traced by health authorities; I: infected individuals; P: subset of susceptible individuals protected from SARS-CoV-2 infection through vaccination; Q: quarantined individuals; Q0, Q1, Q2,..., Qn: subcompartments of the quarantine compartment (each number represents the number of days since exposure); R: recovered individuals; S: susceptible individuals.



Parameterization and Transitions

The compartmental model was run for 690 days (from March 2, 2020, to January 20, 2022). The data collected populated compartments Q, I, and R daily. In the absence of data for compartment S, an initial value of 10 million individuals was assumed, which is a frequently used approximation for the Portuguese population. This value ensured that the model was not circular and obviated the need to consider the possibility of reinfection. Data on compartments P and E were calculated, and expected values for other parameters were defined within each simulation run (Table 1).

Regarding daily transitions between compartments and subcompartments, the model was built in 3 steps: transitions from subcompartments inside Q (step 1), S-E-I transitions (step 2), and S-Q and P-Q transitions (step 3). Despite the existence of data for all compartments and some model parameters, owing to a lack of data in each of these steps regarding the actual number of individuals that transition in each iteration of the model, some parameters were input by defining expected values for the parameters that govern those transitions. Only those parameters were estimated (Table 1).

In step 1, Q-S, Q-P, and Q-I transitions are the sums of the number of individuals who each day (represented by each subcompartment) transition to compartments S, P, or I, respectively. Each day, transitions from each subcompartment are governed by the probabilities of staying in compartment Q (transition to the following subcompartment Q_{i+1}), making the transition γ to compartment I, or returning to compartment S or P (transitions κ and ς). The probabilities of transition of each subcompartment were defined according to the IR of a high-risk contact of a confirmed COVID-19 case and to the mean and maximum periods an individual remains exposed until the person either develops the infection or is considered susceptible again. Any of these 5 parameters can vary with the viral variant to which the individuals were exposed and with the quarantine period. Therefore, in the context of the described model, the probability of transitioning from any subcompartment to compartment S, P, or I is given by the sum of the product of the transition probability of each specific variant and the number of individuals exposed to that variant. Step 1 is concluded after calculating the ratio of new daily cases of infection that came from compartment Q (resulting from transition γ) to the total number of new daily cases (*q* estimate).

Steps 2 and 3 aim to keep the model closed (a necessary condition for using compartmental models), allowing the model to simulate the following day. The number of individuals that follow the ε and ι transitions in step 2 is given by the difference between the number of new daily infections and the number of individuals in transition γ. The ϕ and χ transitions in step 3 are calculated as the difference between the number of exposed individuals (high-risk contacts) on the following simulation day and the number of individuals inside compartment Q after steps 1 and 2. The value of this transition corresponds to the number of individuals inside subcompartment Q_0 at the beginning of step 1 on the following simulation day.

Finally, compartment P was defined according to 5 parameters, namely, vaccine efficacy after inoculation, maximum efficacy, and efficacy after a waning period as well as the elapsed time between vaccination and maximum efficacy and between maximum efficacy and waned efficacy. This compartment was calculated as the product of the probability of each vaccinated individual being protected from SARS-CoV-2 infection and the number of vaccinated individuals.

Assumptions of the Simulation

To operationalize the proposed model, several assumptions were made, namely regarding the transitions involving compartments Q and P.

A Markov chain Monte Carlo simulation defined the transitions between the Q subcompartments. Consequently, to compute the transitions between subcompartments, a series of steps were taken (Textbox 1).

Regarding compartment P, and particularly vaccine efficacy, a constant rate was assumed between two events: (1) efficacy after inoculation and maximum efficacy and (2) maximum efficacy and waned efficacy. Hence, vaccinated individuals were probabilistically placed in compartment P each day according to the time elapsed since inoculation. After defining new values for booster efficacy, the same procedure was replicated for individuals with booster doses. Individuals in compartment P could transition to compartment Q, but their IR was set at 0. Individuals in compartments S and P would transition to compartment Q according to the ratio between those compartments.

Owing to the inherent variability in the timing of contact tracing and imposing quarantine, it is impossible to accurately define certain parameters in the model for each variant of SARS-CoV-2 and each vaccine. Therefore, we decided to simulate a set of different parameterizations for these parameters. For each variant, the maximum time elapsed for the transition to compartments I and S was assumed to range from 2 to 14 days. The mean time for these transitions ranged from 2 days to the maximum time previously set for each variant. IR was set to range from 10% to 50% [1,23,24], and we considered 6 different variants, namely, “alpha,” “beta,” “gamma,” “delta,” “omicron,” and “others” (according to collected data). We assumed that the weekly prevalence of each variant [18] was equal to the prevalence on each day of that week, and individuals in the ϕ transition would be distributed to each variant according to that prevalence.

Regarding vaccination, we defined an efficacy between 10% and 60% after inoculation and a maximum efficacy of up to 95% [19,20]. We assumed a waned efficacy as the mean value between both efficacies. Booster vaccines had an assumed efficacy between the waned efficacy previously defined and 80% after inoculation and a maximum efficacy of up to 95%. A period of 15 days until maximum vaccine efficacy, and a period of 180 days until waned efficacy were assumed [19,20]. Individuals from compartment P entered the model as exposed to variant “others” with an IR set at 0%—in other words, they were set to follow the Poisson distribution estimated for returning to compartments S and P for the variant “others.”

Textbox 1. Steps taken to compute the transitions between subcompartments.

- To calculate the different transition probabilities, we assumed that everyone who transitions to compartment Q has a predetermined probability of becoming infected, called infection risk (IR). IR is specific to each variant.
- For each variant included, 2 different Poisson distributions were applied to the individuals who would become infected and those who would return to compartments S and P. Each distribution had a maximum and mean time until transition.
- From the combined transition probabilities of each distribution and according to the IR, a transition table was constructed, including the pooled transition probabilities from each subcompartment to the following subcompartment, to compartments S and P, and to compartment I.
- A Monte Carlo simulation was then applied to this transition table. Therefore, on each simulation day, an individual in a subcompartment of the Q compartment transitions probabilistically to the following subcompartment, to compartments S and P, or to compartment I.

Description of the Simulations

In total, 2 different simulations were performed, approaching the objective in 2 different ways. Table 2 summarizes the main characteristics and differences between the simulations. We first defined that each simulation should have a run time of ≤9 hours. An iteration of the model was tested on a computer with an Intel64 Family 6 Model 126 Stepping 5 GenuineIntel processor with a maximum clock frequency of 1498.0 MHz with 4 physical cores, 8 logical cores, and 15.60 GB of RAM using the operating system Windows 10.0.19041. With this hardware and software combination, the response time (time taken from start to end of the process) for this iteration was 10 seconds [31].

Simulation A aimed to be as approximate as possible to what we could expect in real life by accounting for the potential influence of variants and vaccination. However, it assumed that the risk of infection was fixed for all variants at the beginning of the simulation. For this simulation, 100 parameterizations were established, and these were quadrupled to reflect the presence and absence of the influence of variants and vaccination. Each parameterization was iterated 100 times, totaling 40,000 model iterations with an estimated run time of 8 hours and 20 minutes.

Simulation B ignored the presence of different variants (we assumed that all cases came from the variant “others”) and estimated the maximum value of IR for which the model kept the q estimate at <1. However, as in simulation A, the risk of infection in exposed individuals was fixed for each parameterization and did not fluctuate throughout each iteration. This simulation used the same set of 100 parameters used in simulation A, doubled to account for the presence or absence of vaccination. The IR started at 100% with each iteration interrupted, and this value was reset and diminished by 0.1 percentage points every time the daily q estimate was >1. We assumed that this approach might lead, in extremis, to circa 1000 iterations of each parameterization. Although mostly incomplete because of the described procedure to calibrate the IR, this number of iterations would lead model B to take 20 times longer to run than model A. Therefore, the research team opted to conduct only 10 iterations of each parameterization, which, jointly with half of the total parameterizations of simulation A, kept the estimated simulation running time at 8 hours and 20 minutes.

Table 2. Main characteristics of the implemented simulations.

	Simulation A	Simulation B
Used information on vaccines	Yes	Yes
Used information on variants	Yes	No
Number of different parameterizations, n	400 (100 × 4)	200 (100 × 2)
Ceiling value for the ratio of cases (*q* estimate)	No	Yes
Parameters included fixed infection risk	Yes	Yes
Number of iterations per parameterization, n	100	Approximately 1000
Total model iterations, n	40,000	200,000
Estimated run time	8 h and 20 min	8 h and 20 min

Data Analysis

The parameters' characteristics were aggregated in means and medians and described for each simulation. For each simulation, the distribution of the ratio of daily cases resulting from the γ transition (*q* estimate) for each parameterization was combined into a single distribution according to the methodology implemented by Hill [32]. We also combined the results of each simulation into a single distribution according to the presence or absence of both vaccination and different variants in the model when applicable. Although the *q* estimate intended to represent the proportion of cases arising from high-risk contacts, certain parameter combinations yielded values of the *q* estimate of >1 (Textbox 2).

Since other COVID-19 measures for lockdown were presented in a 14-day moving average, we applied a 14-day moving average to the daily *q* estimate for each simulation and to the gathered data on daily cases. The Spearman correlation was calculated between the 14-day *q* estimate and the 14-day average number of cases.

Local maxima for 14-day data on confirmed infected cases were computed, and local minima immediately before and after the computed local maxima were maintained. By using an adaptation of the method used by Vázquez-Seisdedos et al [33] and applied by Gianquintieri et al [34] to data on COVID-19 cases, we determined the inflection point of the case curve that occurs between the local minimum and the local maximum. This inflection point corresponds to the beginning of a pandemic phase. Each pandemic phase was defined, in the context of this study, as the interval between an inflection point and the following local minimum, which had a local maximum between them.

It was assumed that, by definition, a contact tracing effectiveness threshold would have to be surpassed during a pandemic phase. Specifically, the value of the effectiveness threshold would have to occur in an alert phase, defined as the critical period between the wave's inflection point and up until 14 days before the day when the peak number of cases was registered. In addition, it was assumed that contact tracing as a main strategy for pandemic combat was reset after the end of each pandemic phase (ie, local minimum after case peak) and the model entered an interpandemic phase. For this reason, an effectiveness threshold was calculated considering the interpandemic and alert phases. In other words, we included the entire period analyzed except for periods between the end of an alert phase and the end of each pandemic phase. The data between a local minimum and the next inflection point (interpandemic phase) were considered as controls for determining the threshold. As there was a more considerable period of control data than the period in the alert phase, we oversampled the test data. This classification into interpandemic, alert, and pandemic phases was loosely based on the World Health Organization pandemic phases for influenza [35].

This threshold estimation from the *q* estimates was a theoretical demonstration of the impact of applying the same procedure to the actual proportion of cases arising from high-risk contacts in anticipation of the need for populational lockdown measures that were ultimately imposed.

Effectiveness threshold values were estimated for each simulation using a receiver operating characteristic model applying the Youden method. The sensitivity, specificity, and positive predictive value (PPV) were calculated for the theoretical effectiveness threshold. Sensitivity represented the proportion of days in the alert phase in which the *q* estimate was below the effectiveness threshold. Specificity represented the proportion of days in the interpandemic phase in which the *q* estimate was above the effectiveness threshold. The PPV was the quotient of the number of alert phase days in which the *q* estimate was below the effectiveness threshold and the number of days in which the *q* estimate was below the effectiveness threshold.

Finally, we implemented a 2-part sensitivity analysis. First, we estimated a hypothetical threshold for each of the different parameterizations used (both in simulations A and B) and ran a multiple linear regression with the estimated thresholds as the dependent variable. We included 10% increases in IR of a high-risk contact of a confirmed COVID-19 case and mean and maximum periods during which an individual remains quarantined until they either develop the infection or are considered susceptible in days, for each strain, and 10% increases in maximum and waned efficacies for complete vaccination and booster doses as independent variables. The second part consisted of fixing the maximum and minimum values for parameters included in simulation B (all but those related to virus variants) and estimating both the thresholds obtained and the Spearman correlation coefficients with the results of simulation B. We presented the range of thresholds and correlations obtained.

The adapted compartmental model was constructed, the simulations were run, and the data were analyzed using the statistical computing and graphics software R (version 4.0.2; R Foundation for Statistical Computing) in the integrated development environment RStudio (version 2022.07.1+554; Posit). Packages *zoo* (version 1.8-10), *pROC* (version 1.18.0), and *unbalanced* (version 2.1) were used. The 95% CIs were calculated for all punctual estimates.

Textbox 2. Scenarios for different q estimates.

- The *q* estimate derived from the constructed models represents the ratio between the daily expected number of cases arising from quarantined high-risk contacts and the total number of daily cases. Several parameterizations might lead to different numbers of expected cases resulting from applying the modeled transitions to the real number of quarantined individuals.
- Simplifying the presented model to a single-day transition (all quarantined individuals must progress to being infected or return to being susceptible or protected), if on any given day 100 individuals were in compartment Q and the total number of new cases was 20 and…:
  - ...the infection risk (IR) was defined as 10%, the q estimate would be 0.5 (10% × 100/20). In other words, we would expect half the cases to come from quarantined individuals.
  - ...the IR was defined as 20%, the q estimate would be 1.0 (20% × 100/20). In other words, we would expect all cases to come from quarantined individuals.
  - ...the IR was defined as 30%, the q estimate would be 1.5 (30% × 100/20). In other words, we would expect more cases from quarantined individuals than the total number of new cases.
- Therefore, the *q* estimate determined by this model is not a proportion as *q* estimates of >1 are possible within the constructed model (see the Discussion section).

Ethical Considerations

Our study used publicly available aggregated secondary data with no characteristics that allowed for individual identification. Therefore, the research team considered that there were no relevant data protection and privacy issues to report.

Results

Descriptive Analysis of the Parameterizations

The characteristics of the parameterizations used in the model and for each simulation are described in Table 3. The median of the maximum transition periods ($\Delta t\gamma_{max}/\Delta t\kappa\varsigma_{max}$) was 8 days (IQR 6 for the γ transition and IQR 7 for the κ and ς transitions) and 4 days for the average transition periods ($\Delta t\gamma_{mean}/\Delta t\kappa\varsigma_{mean}$; IQR 4). The main difference between the simulations is in the IR, with an average of 28.9% (SD 13.6%) verified in simulation A, which is much higher than that of 0.8% (SD 0.5%) for simulation B.

Table 3. Descriptive analysis of simulation parameters.

	Simulation A	Simulation B
Variants		
$\Delta t\gamma_{max}$[a] (d), median (IQR)	8 (6)	8 (6)
$\Delta t\gamma_{mean}$[b] (d), median (IQR)	4 (4)	4 (4)
$\Delta t\kappa\varsigma_{max}$[c] (d), median (IQR)	8 (7)	9 (7)
$\Delta t\kappa\varsigma_{mean}$[d] (d), median (IQR)	4 (4)	4 (4)
IR[e] (%), mean (SD)	28.9 (13.6)	0.8 (0.5)
Complete vaccination (%), mean (SD)		
Ve_0[f]	33.7 (16.3)	33.7 (16.3)
Ve_{max}[g]	64.8 (21.8)	64.8 (21.8)
Ve_{waned}[h]	49.2 (14.9)	49.2 (14.9)
Booster doses (%), mean (SD)		
Be_0[i]	65.1 (14.0)	65.1 (14.0)
Be_{max}[j]	80.1 (12.3)	80.1 (12.3)
Be_{waned}[k]	49.2 (14.9)	49.2 (14.9)

Descriptive Analysis of the Simulations

The daily value of the *q* estimate is plotted in Figures 2-5 for simulations A and B. This estimate exceeded the value of 1 at some moments in simulation A, indicating that, according to the model's parameters, it would be expected that more infection cases resulting from quarantined individuals had occurred than the total number of new cases of COVID-19 reported for those specific days (Textbox 2).

An inverse relationship between the values of the *q* estimate and the total number of new cases of COVID-19 is ascertainable through analysis of Figures 2 and 4. Indeed, simulation A presented a correlation of −0.71 (95% CI −0.74 to −0.67), and simulation B showed a correlation of −0.76 (95% CI −0.79 to −0.73).

Despite the different procedures underlying the 2 simulations (A and B), the maximum *q* estimate in both simulations was reached on day 161. After that, the same *q* estimate never reached >50% of that maximum value.

The analysis of all iteration results according to the presence or absence of different variants and vaccination's protective effect (Figures 3 and 5) shows the considerable overlap between the curves in either simulation A or B.

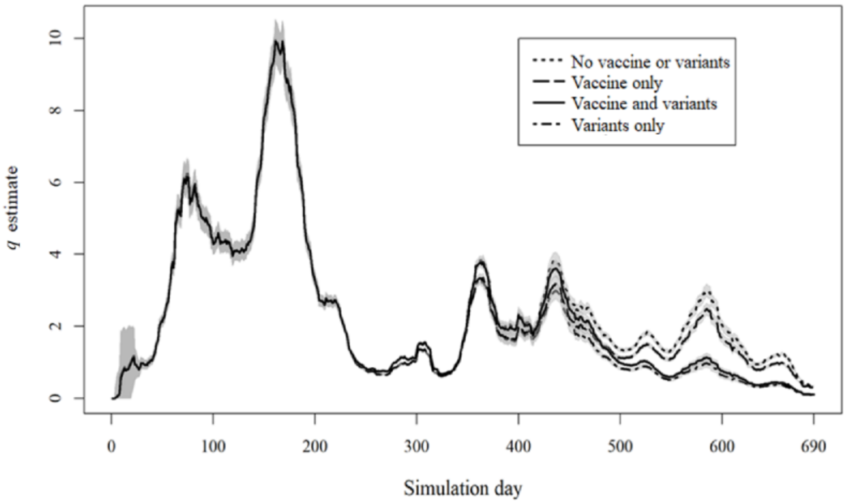

Figure 4. Results of simulation B in comparison with the daily total number of new COVID-19 cases at scale.

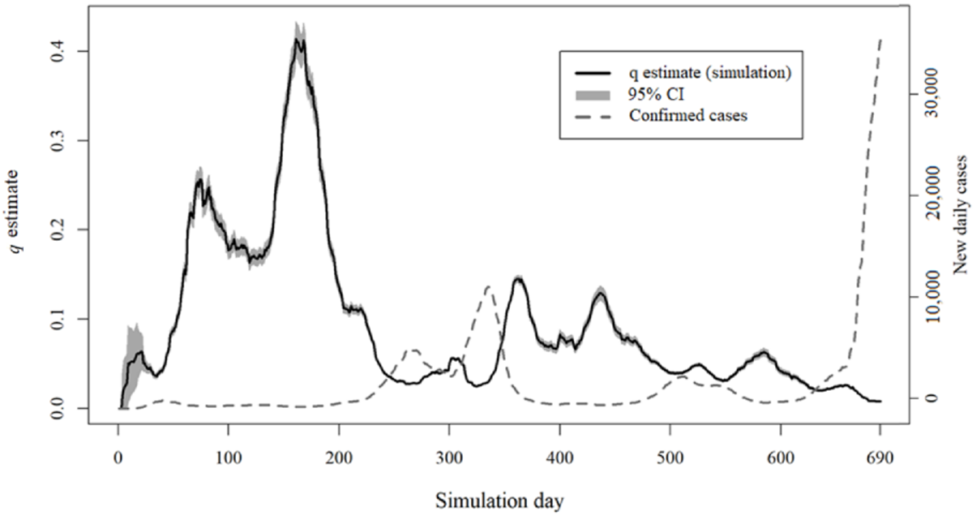

Figure 5. Results of simulation B separated according to the inclusion or exclusion of vaccines.

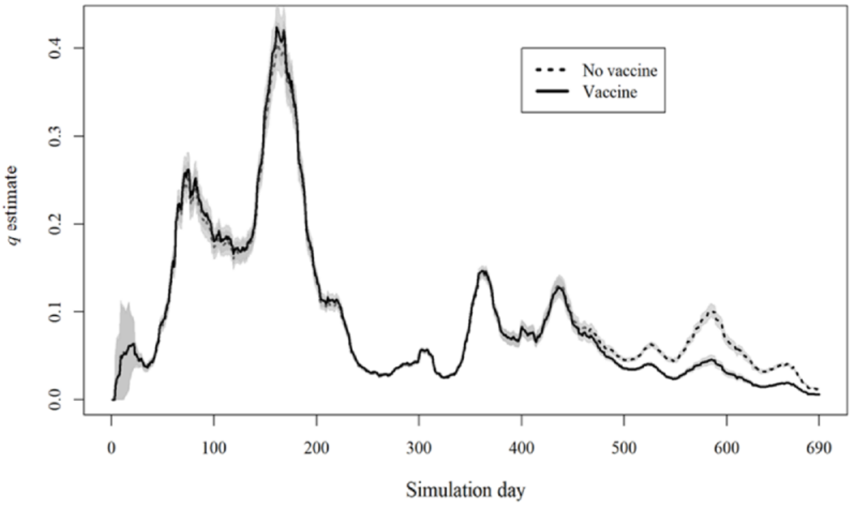

Defining the Effectiveness Threshold

Figure 6 shows the distribution of the number of daily cases throughout the 690 days included in the compartmental model, including the local maxima; local minima; inflection points; and pandemic, alert, and interpandemic phases. Case peaks occurred on days 40, 264, 335, and 511 of the study period. We also considered that, on day 690 (end of the study period), we were at a new peak because of the number of cases. The inflection points for each of the 5 peaks identified show that alert phases occurred between days 18 and 26 for the first pandemic phase, between days 220 and 250 for the second pandemic phase, between days 310 and 321 for the third pandemic phase, between days 470 and 497 for the fourth pandemic phase, and between days 660 and 676 for the fifth and final pandemic phase. The period included in calculating the effectiveness threshold encompassed 403 days (between days 1 and 26, days 82 and 250, days 302 and 321, days 400 and 497, and days 588 and 676 in accordance with each of the 5 pandemic phases). Table 4 shows the testing periods of the theoretical thresholds derived from both models and the classification of those periods in the alert (test-positive) and interpandemic (test-negative) phases.

For simulation A, we observed that the value of the *q* estimate that would most likely define the theoretical effectiveness threshold of contact tracing would be 1.93, with 85.7% (258/301; 95% CI 82.1%-89.7%) of alert phase days in which the *q* estimate was below the effectiveness threshold (ie, sensitivity), 66.1% (199/301; 95% CI 60.5%-71.1%) of interpandemic phase days in which the *q* estimate was above the effectiveness threshold (ie, specificity), and a proportion of alert days among days with the *q* estimate below the effectiveness threshold (ie, PPV) of 71.7% (258/360; 95% CI 68.4%-75.1%). For simulation B, the hypothetical effectiveness threshold was 0.07, with 87% (262/301; 95% CI 83.4%-90.7%) sensitivity, 66.8% (201/301; 95% CI 61.5%-72.1%) specificity, and a 72.5% (262/362; 95% CI 69.2%-75.9%) PPV.

In Portugal, population lockdowns were imposed during all pandemic phases except the fifth one [36]. In the model days, lockdowns occurred on days 18, 236, 313, and 488. Both simulations would, by default, start below the effectiveness threshold from day 1 in the model until the first pandemic phase. Unsurprisingly, by day 18, both would still stay below the effectiveness threshold. Neither of the simulations' *q* estimates went above threshold levels between the second and third pandemic phases, which may indicate that this hypothetical estimate could be used as an argument against lifting lockdown measures, thus avoiding an interpandemic phase of just 8 days. Both models kept *q* estimates below the effectiveness threshold after the fourth pandemic phase. For the 2 remaining pandemic phases (second and fourth), simulation A broke the threshold within the respective alert phases 7 and 17 days before the actual lockdowns (days 229 and 471), and simulation B broke the threshold 4 and 16 days before the actual lockdowns (days 232 and 472).

Figure 6. Daily COVID-19 case number evolution with identification of wave peaks and periods included in the effectiveness threshold for contact tracing. Vertical dotted lines represent the imposing of population lockdown measures by Portuguese authorities in each pandemic phase during the period of analysis.

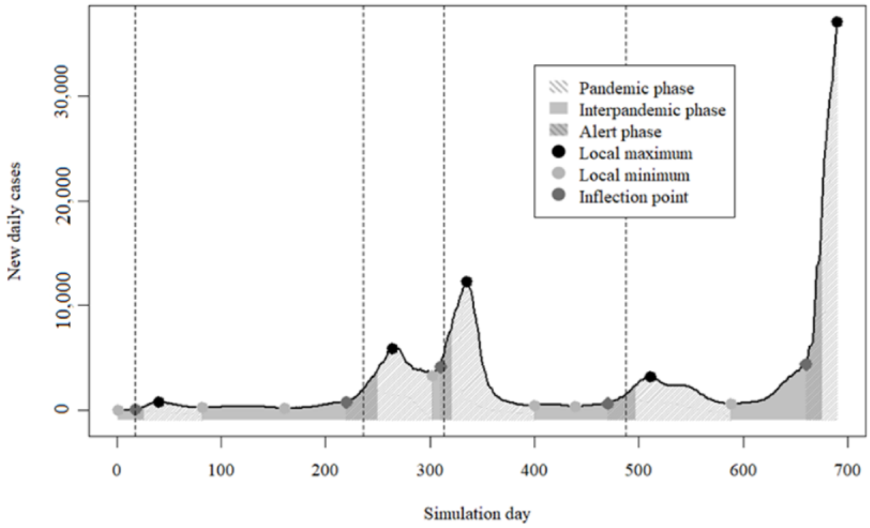

Table 4. Testing periods for theoretical effectiveness threshold.

Days	Phase	Classification
1-17	Interpandemic	Negative
18-26	Alert	Positive
82-219	Interpandemic	Negative
220-250	Alert	Positive
302-309	Interpandemic	Negative
310-321	Alert	Positive
400-469	Interpandemic	Negative
470-497	Alert	Positive
588-659	Interpandemic	Negative
660-676	Alert	Positive

Sensitivity Analysis

Tables 5 and 6 show the results of the sensitivity analysis. On the basis of the multiple linear regression results (Table 5), a 10% increase in IR for each variant was associated with an increase in the estimated threshold value of at least 0.01. The influence was maximal for the variant “other” (β=.52; *P*<.001). The influence on the result of the model for the remaining variant parameters was inconsistent, with some parameters leading to an increase in the hypothetical threshold for a certain variant and the same parameter leading to a decrease in the estimated threshold for other variants. Of these parameters, maximal and mean times until κ and ς for variant “other” were negatively related to the estimated threshold (β=−.10 and *P*<.001, and β=−.08 and *P*=.02, respectively), as were the mean times until κ and ς for the alpha and delta variants (β=−.08 and *P*=.04, and β=−.08 and *P*=.048, respectively). In contrast, an increase in the mean time until κ and ς for the omicron variant was related to an increased threshold (β=.08; *P*=.02). Regarding vaccination, only an increase in efficacy at inoculation for booster doses was negatively related to the estimated threshold (β=−.11; *P*=.02). All other vaccine efficacies did not present a significant relationship with the threshold attained.

Regarding the correlation and threshold analyses (Table 6), we obtained a minimum correlation coefficient of 0.87 and a maximum correlation coefficient of 0.99. Threshold values were highly variable except for those resulting from IR and when vaccine efficacy at inoculation (Ve_0) was set to 60%, where the ratio between the maximum and minimum thresholds was <20. This result corroborates the results obtained in the multiple linear regression regarding the impact of IR on the threshold estimates and, consequently, on *q* estimates.

Discussion

Principal Findings

In this study, we developed a compartmental model to describe the relationship among the official data on COVID-19 for Portugal, namely regarding the DGS definition of quarantined individuals. The main aim of this study was to estimate the daily ratio of cases that occurred in individuals in imposed quarantine through contact tracing (*q* estimate). Despite being a compartmental model, only transitions to and from compartment Q (quarantined individuals) were modeled. Daily data regarding all the other transitions and daily data on all compartments except compartments S (susceptible) and E (exposed individuals not traced) were already available and, therefore, not processed.

To the best of our knowledge, this study is the first attempt to use COVID-19 contact tracing data to define the infection dynamics of SARS-CoV-2. The main reason for this might be that the DGS was, as far as the authors are aware, the only national health authority with public data regarding individuals under quarantine systematically imposed by health authorities.

We obtained *q* estimates for 2 different simulations, both grounded on published evidence and some degree of parameter estimation. Simulation A was intended to reflect the presence of multiple strains with different infectious characteristics, whereas simulation B was intended to calibrate the IR of SARS-CoV-2 in quarantined individuals. The *q* estimates obtained by the 2 simulations were highly negatively correlated with the number of confirmed daily cases of COVID-19, which shows that a diminishing ratio of cases from quarantined individuals indirectly indicates the waning effectiveness of contact tracing. Assuming that we have proven this concept, it may indicate epidemiological contexts in which contact tracing as an epidemic combat measure would be insufficient, thus prompting the need to consider implementing complementary pandemic combat measures that result in further social restrictions, namely, general lockdowns.

To demonstrate the impact of applying this theoretical *q* estimate, we tried to establish, for each simulation, a hypothetical effectiveness threshold for contact tracing and relate it to the key moment for implementing general lockdowns, either by defining the phases of the pandemic and estimating a PPV (ie, the quotient of the number of alert phase days in which the *q* estimate was below the effectiveness threshold and the number of days in which the *q* estimate was below the effectiveness threshold) of each simulation or by comparing with actual lockdown measures in Portugal. We found a PPV of >70% for both simulations, and an anticipation of at least 4 days in the second and fourth lockdowns was the result of the theoretical simulations used for decision-making.

In addition, a sensitivity analysis of the parameters used to model compartment Q transitions showed that only the IR for any strain and the vaccine efficacy at booster dose inoculation did significantly affect the *q* estimates. Despite having a residual influence, the parameters input do not allow for a direct interpretation of the value of the *q* estimate, especially in simulation A as this simulation at times obtained values of >1. The scenarios where this situation could occur in our model were explained in Textbox 2. The main reasons for these estimates are more likely related to an overestimated IR in compartment Q and may include misclassification of low-risk exposures as high-risk exposures (eg, in schools when the first guidelines initially considered all same-class students as high-risk contacts regardless of mask or social distancing measures implemented [37]), delayed diagnosis, or different timing for testing in quarantined individuals (such as changes in guidelines for testing in the beginning, middle, or end of imposed quarantine [5,21,38]) and different isolation timing (some individuals might only be traced near the end of their period of isolation, which in turn leads to a reduced time in compartment Q not controlled by our model design).

Therefore, our study should be regarded as a demonstration of the application of an effectiveness threshold for contact tracing as a measure of pandemic control. Consequently, the *q* estimates and effectiveness thresholds derived from both simulations are hypothetical values but likely to be highly correlated with the true proportion of cases from quarantined individuals, as shown by our sensitivity analysis.

We deem it necessary to draw attention to the importance of open data and data sharing as a way to catalyze research and accelerate innovation and development that shortens the time between the detection of potentially epidemic pathogens and the development of appropriate containment and mitigation measures [39,40]. The advantages of data sharing will only be fully attained if data are reported on an everyday basis of definitions and procedures. This factor was not observed during the COVID-19 pandemic. This research team expects that this lesson, too, can be derived from this pandemic and that, consequently, definitions and procedures will be adapted in conformity [41].

Limitations

The main limitation of our study arises from implementing a compartmental model and simulation methods to estimate transitions between compartments, potentially leading to results that only partially reflect reality as it occurred at each moment of the period analyzed. Furthermore, it is not possible to exclude the influence that the implementation of confinement measures or other measures implemented during each pandemic wave may have had on the proportion of new cases from exposed individuals. However, the impact of considering different parameterizations of variants or vaccination efficacy, demonstrated by the visual overlap between the results of the different simulations as well as the conducted sensitivity analysis, strengthens the potential robustness of the results and the model.

In addition, the parameters chosen include other limitations as they are based on data collected in studies that were run under controlled conditions [42]. Most of those studies also focused on the disease's transmission dynamics [22], analyzing mainly those persons who developed the disease and the time that elapsed until infection. Therefore, we lacked estimates of the duration of epidemiological surveillance for exposed individuals who did not develop the infection. To mitigate this limitation, we assumed that this time would be similar to the time required for individuals to develop the disease.

Few studies have compared the risk of infection per virus variant throughout the quarantine period. Therefore, although we acknowledge that some variants might have been more transmissible than others, it did not allow us to determine whether this variable translated only to a higher IR or a lower time until the transition between exposed and infected (or any other hypotheses, for that matter). To mitigate the impact of this limitation, different values for parameters (which assumed that all variants could have variable IR and time to infection) had the potential to depict variant differences concerning the degree of contagion and infection. The residual impact of different variants, except for their respective IRs, on the simulation results may attenuate this limitation.

It is not possible to exclude the hypothesis that the effect of implementation of confinement measures (or other measures implemented during each pandemic phase) on the ratio of new cases from quarantined individuals may have led the model to present *q* estimates that were different from those expected without such measures. Thus, the definition of a value for the ratio of cases of quarantined individuals that could work as a threshold for lifting those more restrictive measures or restarting contact tracing as the primary pandemic combat strategy is beyond the scope of this study. This “lift measures threshold” could define the moment where the influence of confinement measures stopped manifesting. In our model, we assume that the contact tracing strategy is maintained throughout the simulation period and only use data from the interpandemic and alert phases to define the hypothetical effectiveness threshold.

Finally, given the format in which the data were collected, the analysis could be conducted only at the national level. This lack of data granularity demanded an implicit assumption that any change in the number of cases or individuals under quarantine imposed by health authorities affects national, regional, and local levels simultaneously and proportionally. Greater data detail, both geographical and sectorial, would potentially allow for determining effectiveness thresholds—and the consequent implementation of pandemic containment measures—at those differentiated levels, with a more apparent effort-benefit ratio that could be better understood and better accepted by the population. This would most likely result in higher population adherence to containment measures and finer-tuned control of both the sanitary and socioeconomic impacts of the pandemic.

Future Work

As we have stated, this work is a starting point for using data on high-risk contacts of COVID-19 cases to define transmission dynamics of SARS-CoV-2, which could lead to further studies addressing the aforementioned limitations and discussions of alternative hypotheses and perspectives left unexplored in this study. An immediate suggestion could be the case of a scenario in which the variation in IR for compartment Q occurs within each iteration. Such dynamic IR should reflect the implementation of pandemic combat measures that have been proven to change the IR (namely, large-scale testing [11], scaling up of contact tracing [1], and population lockdowns [13,14]). Caution should be taken when applying this dynamic IR to these models to tackle *q* estimates of >1. Such an approach, without accounting for other measures, would lead to a maximization of IR in quarantined individuals, which would mean that, in pandemic phases in which cases are expected to occur mostly in non–contact-traced individuals, we would contrarily have a maximization of the *q* estimate.

Another scenario to tackle in future work—perhaps also resorting to simulation methods—would be to investigate what would happen should contact tracing come to a halt and what would be the impact of fully transferring resources allocated to this public health task to other activities regarding epidemiological dynamics and the pandemic’s impact on a country’s sanitary and economic dimensions.

As mentioned previously, the theoretical definition of contact tracing effectiveness thresholds that would allow for the relief of restrictive measures is beyond the scope of this work. Nonetheless, it might be equally valuable to define thresholds for restrictive measure relief as it could be helpful for communication by public officials during pandemic scenarios as well as to balance the scales between the implicit health-economy dichotomy that so often arose in narratives with global reach. There is also a relevant economic component to this work as it is intertwined with the efficiency of these pandemic control measures and their direct and indirect impacts on countries’ health and economy. This work might be very helpful in drawing lessons that better enable us to adapt our society to events such as pandemics.

Finally, and from a health economics standpoint, it would be interesting to understand how the population perceives contact tracing as an instrument used by health authorities to contain pandemics and what the perception would be, for example, in terms of adherence to pandemic control measures should contact tracing cease.

Conclusions

Our work provides important information for policy and decision makers, namely in terms of epidemiology and pandemic/crisis management, as well as for public health professionals. It also constitutes a relevant source of information and an objective acknowledgment of the importance of contact tracing, which was widely used worldwide in all stages of the COVID-19 pandemic.

Concretely, this study, although using secondary data, allowed us to (1) provide a proof concept for using estimates of an effectiveness threshold for contact tracing as a primary measure of pandemic containment and (2) consider the potential use of this effectiveness threshold as a decision variable for imposing more restrictive measures, namely, lockdowns, along with indicators that were used to assess the pandemic situation (such as the transmissibility indexes and case incidence). Our results are consistent with this last possibility and, notwithstanding the presented limitations, reveal a path that, we hope, deserves further exploration.

Acknowledgments

This paper was based on the scientific efforts of the research team developed upon the execution of the research protocol that won the first edition of the Scholarship Award Amélia Leitão, promoted by the Portuguese National Association of Public Health Doctors and Pfizer Laboratories. This work would have been impossible without the generous contribution of Data Science for Social Good in compiling and curating the data reported in PDF format by the Directorate-General of Health. This is our way to give back to the community as part of the benefits we received through them.

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author upon reasonable request. The code we developed and on which these simulations are based is available on a GitHub repository [43].

Abstract

Background: The community environment plays a vital role in the health of older adults. During the COVID-19 epidemic, older adults, who were considered the most impacted and most vulnerable social group, were confined to their homes during the implementation of management and control measures for the epidemic. In such situations, older adults may have to contend with a lack of resources and experience anxiety. Therefore, identifying the environmental factors that are beneficial for their physical and mental health is critical.

Objective: This study aimed to assess the association between community cohesion and the physical and mental health of older adults and to identify the related community services and environmental factors that may promote community cohesion.

Methods: This community-based cross-sectional study was designed during the COVID-19 epidemic. A multistage sampling method was applied to this study. A total of 2036 participants aged ≥60 years were sampled from 27 locations in China. Data were collected through face-to-face interviews. The neighborhood cohesion instrument consisting of scales on 3 dimensions was used to assess community cohesion. Self-efficacy and life satisfaction, cognitive function and depression, and community services and environmental factors were also measured using standard instruments. Statistical analyses were restricted to 99.07% (2017/2036) of the participants. Separate logistic regression analysis was conducted to assess the association among community cohesion and physical and mental health factors, related community services, and environmental factors among older adults.

Results: The results showed that high levels of community cohesion were associated with good self-perceived health status and life satisfaction (odds ratio [OR] 1.27, 95% CI 1.01-1.59 and OR 1.20, 95% CI 1.15-1.27, respectively) and high levels of self-efficacy and psychological resilience (OR 1.09, 95% CI 1.05-1.13 and OR 1.05, 95% CI 1.03-1.06, respectively). The length of stay in the community and the level of physical activity were positively associated with community cohesion scores, whereas the education level was negatively associated with community cohesion scores (*P*=.009). Community cohesion was also associated with low levels of depression and high levels of cognitive function. Community cohesion was significantly associated with community services and environmental factors on 4 dimensions. High levels of community cohesion were associated with transportation services and rehabilitation equipment rental services as well as high levels of satisfaction with community physicians' technical expertise and community waste disposal (OR 3.14, 95% CI 1.87-5.28; OR 3.62, 95% CI 2.38-5.52; OR 1.37, 95% CI 1.08-1.73; and OR 1.23, 95% CI 1.01-1.50, respectively).

Conclusions: Community cohesion was found to be associated with the physical and mental health of older adults. Our research suggests that enhancing community services and environmental resources may be an effective strategy to increase community cohesion during major infectious disease epidemics.

community cohesion; physical and mental health; community services; environmental resources; COVID-19 epidemic; older adults

Introduction

Background

Older adults become more vulnerable to mental diseases and environmental challenges as their age increases [1]. The community environment plays a vital role in their health, especially their mental health, as they age [2]. They usually wish to remain living in the community as long as possible, but their health status may deteriorate during the last stage of their lives to the point where they can no longer live alone. Therefore, the World Health Organization suggests the provision of a familiar environment and an emotional bond to support *aging in place* to enable older adults to live in their community independently and comfortably by experiencing a sense of attachment, connectedness, security, and identity [3-5].

During the COVID-19 pandemic, older adults were considered the most impacted and vulnerable social group because they had a high risk of being infected by SARS-CoV-2 and dying [6]. Several epidemic prevention and control measures had changed to a large extent the way of living they were accustomed to and seriously interfered with their access to public resources. During the initial stage of the pandemic, they were alone and unattended at home; thus, they could not purchase masks and obtain any information on disease prevalence; they also felt anxious, helpless, and scared [7-9]. Some studies showed that the deterioration in physical functioning and the reduction in social contact may have caused many older adults to experience poor mental health [10,11]. During COVID-19–related lockdowns imposed by the authorities, older adults were cut off from the outside world, which also hindered them from receiving social support [12]. In such circumstances, older adults can experience serious physical and mental health consequences, and, as a result, they become more dependent on community services and environment resources.

The Importance of Community Cohesion

Community cohesion, which is an important element of the community, includes 3 essential dimensions. It involves social relations, identification with the geographical unit, and orientation toward the common good [13]. Individual-level community cohesion is assessed in a geographically bounded neighborhood; this is known as the community or neighborhood cohesion assessment. In recent years, interest in the study of community cohesion has escalated, probably because of the sharp increase in older populations. A study suggested that community cohesion is an important factor that affects physical and psychological health outcomes among older adults [14]. Many studies have shown that community cohesion may positively influence both friendship and well-being, which act as buffers against serious psychological distress among older adults [15-17]. A lack of community cohesion is associated with depression, loneliness, suicidal ideation, and poor mental health [18-20]. Community cohesion is also an important protective factor for preventing posttraumatic stress disorder symptoms when older adults experience negative events and disasters [21]. Clinical and epidemiological studies have found a lack of community cohesion to be associated with disability, hypertension, myocardial infarction, stroke, and mortality [22-25]. Empirical studies have confirmed that low levels of community cohesion can accelerate epigenetic aging, and high levels of community cohesion can reduce the risks of diseases associated with genetic risk factors [26,27].

The COVID-19 pandemic has had an enormous and long-lasting negative impact on the physical and mental health of older adults worldwide. However, the unprecedented COVID-19 outbreak and special prevention and control measures have resulted in a limited number of studies being conducted on the association of community cohesion with the physical and mental health of older adults. We found several similar studies on the relationship between community cohesion and mental health, but these studies have a small sample size, resulting in low statistical power [28,29]. In addition, the difficulty in data collection during the COVID-19 pandemic resulted in only a single study (with a lack of theoretical models) being conducted on the association of community cohesion with the mental health of older adults. A multiscale evaluation study on the complex impact of the COVID-19 pandemic on the physical and mental health of older adults has not yet been conducted. To our knowledge, no research has assessed community cohesion factors, such as community services and community resources, that affected the physical and mental health of older adults and the possible community public strategies that could have been used to improve their physical and mental health during the COVID-19 pandemic while at the emergency prevention and control stage. Through this research, we expected to collect considerable amounts of community resources information as well as physical and mental health measurement data so that we could fully explore the effects of community cohesion on the physical and mental health of older adults at the individual, community, and social levels during the COVID-19 pandemic based on the social-ecological model and investigate the complex relationship among community cohesion, community services, environmental resources, and the physical and mental health of older adults and the potential interaction mechanism.

We hypothesized that a good community environment and satisfactory health service facilities can improve community cohesion and enhance community residents' perception of social support and self-efficacy in the effective use of community services and environmental resources. This study aimed to explore the effects of community cohesion on the physical and mental health of older adults living in a community during the COVID-19 epidemic, identify the association between community cohesion and perceived social support and self-efficacy, and clarify and define the community services and environmental factors that may promote community cohesion.

Methods

Study Design

A cross-sectional study was conducted among community-dwelling older adults to assess the related factors of community cohesion and the association between community cohesion and the physical and mental health of older adults during the COVID-19 pandemic. This study was supported by a big data–driven community mental health management model as well as an accessibility evaluation of health-related resource projects. Two community-based surveys that aimed to assess health status and accessibility of community health services among older adults living in the community were conducted to discover the main psychological and mental health challenges and explore ways to promote community health based on the theory of social ecology.

Participants

A total of 2036 community residents were selected through a multistage sampling design according to comprehensive geographic location attributes and fully considering the regional aging degree. Sampling was performed at 27 locations in 4 provinces in China from July 15, 2020, to August 31, 2022. All participants were aged ≥60 years. Participants with severe physical dysfunction and mental disorders who would not have been able to complete the questionnaire were not eligible to participate in this study.

Ethics Approval and Participation

The study was approved by the institutional review board at the School of Public Health, Zhejiang University (ZGL2020-010), and it was performed in accordance with the principles of the Declaration of Helsinki. All participants provided written informed consent; the secondary analysis was allowed without additional consent. All data were anonymous and kept confidential to protect the privacy of participants. This study was required to pay ≥CN¥40 (US $5.8) to each participant.

Data Collection

Well-trained investigators conducted face-to-face interviews with all participants in the presence of family members or in the community. Before the formal survey, community administrators made a home visit or telephone call to older adults living in the community. The community administrators briefly explained the basic situation and recruitment requirements for the project to the older adults and asked them whether they would participate in the survey. Participants who agreed were then scheduled to take the survey. On the day of the survey, the investigator explained the purpose, content, method, and other information regarding the survey to the eligible participants. Subsequently, the investigator received the participants' informed consent. Most of the participants (1835/2036, 90.13%) completed the interview in 50-60 minutes. The questionnaires consisted of 16 parts and included 578 items. The main contents included the following information: demographic characteristics; behavioral habits and general health status; community services and environmental resources; community cohesion; social support and psychological resilience; self-efficacy; neurocognition and social cognition; and assessment of depression, personality disorder, and activities of daily living.

The following general characteristics of the participants were collected: age, sex, education level, individual monthly income, marital status, physical activity level, and dietary habit. Community services and environmental resources were assessed in terms of 4 dimensions: community service facilities, medical resources, nursing resources, and welfare resources. Smoking status was examined using the question *Do you smoke?* If the response was yes, the question *What kind of cigarette do you smoke?* was asked, followed by the question *How many cigarettes do you smoke in a day?* Smoking history and age of starting smoking were also included in the questions. Physical activity status was examined using the question *Do you regularly participate in sports, such as hiking, jogging, playing ball, or swimming?* If the response was yes, details regarding time spent and frequency of participation in physical activity were obtained. Sleep was assessed using the following questions: *How many hours of actual sleep did you have per night during the past month?* and *When do you usually go to bed and get up?* Regarding daily living habits, participants were asked the following questions: *Do you eat at regular times every day? Do you have the habit of drinking tea?* and *Do you have a mobile phone?* Self-perceived health status was assessed using the question *Would you say your health is very good, good, fair, poor, or very poor?* Individuals with chronic diseases were identified using the question *Have you ever been diagnosed with chronic diseases by a doctor?* A total of 28 chronic diseases were included in the options.

Public service facilities in the community were assessed by using the questions *Does your community provide a meal service? Are activity centers for older adults available near your community?* and *Are you satisfied with the clearing and disposal of garbage?* The answer options were *Yes* and *No*. Community medical service resources were assessed using the questions *How far is your home from the nearest medical institution?* and *Does your community provide a family doctor contract service?* Nursing resources were assessed using the questions *Does your community provide day care services?* and *Does your community provide nursing care for patients with severe chronic disease?* The questions used to determine welfare resources included *Does your community organize regular outdoor activities for older adults?* and *Does your community provide transportation services?*

Measurements

Community Cohesion

The neighborhood cohesion instrument was applied to assess community cohesion using 18 items [30]. The neighborhood cohesion instrument consists of scales on 3 dimensions to measure the synthesis of community cohesion concepts. The 3 items—*Overall, I am very attracted to living in this neighborhood*; *Given the opportunity, I would like to move out of this neighborhood*; and *I rarely have neighbors come over to my house to visit*—measure attraction to the neighborhood.

Six items, including *If I needed advice about something I could go to someone in my neighborhood*, *I borrow things and exchange favors with my neighbors*, and *I rarely have neighbors come over to my house to visit*, measure the degree of neighboring. Nine items, including *I feel like I belong to this neighborhood*, *I think I agree with most people in my neighborhood about what is important in life*, and *I feel loyal to the people in my neighborhood*, measure the psychological sense of community. The response options for each item are (1) strongly agree, (2) agree, (3) neither agree nor disagree, (4) disagree, and (5) strongly disagree based on a 5-point Likert scale. The estimated Cronbach α coefficients range from .86 to .95.

Other Measurements

The general self-efficacy scale was used to measure the level of self-efficacy [31]. The general self-efficacy scale consists of 10 items with a total score ranging from 10 to 40 points; the higher the score, the higher the level of self-efficacy. The Chinese version of the Older American Resources and Services (OARS) scale was used to assess the level of social support [32]. The OARS scale consists of 3 dimensions: social interaction, family support, and interpersonal relations. High OARS scores indicate high levels of social support. The Chinese version of the 21-item Dementia Assessment Sheet for Community-Based Integrated Care System (DASC-21) was used to assess individual cognitive functions [33]. A score of ≥27 points suggests possible dementia, and a high score is recognized as indicative of a low level of cognitive function. The Eysenck Personality Questionnaire-Revised Short Scale was used to assess the personality characteristics of participants [34]. Community services and environmental resources included 44 items. However, the item *Help with using the toilet* was removed, given that participants with severe physical dysfunction were not eligible to participate in the study [35].

Statistical Analysis

The data obtained from participants with complete questionnaires (N=2017) were used for statistical analysis. Descriptive statistics were used to report the general characteristics of participants. Frequencies and percentages were computed for the variables.

The means and SDs of community cohesion scores were calculated using participant characteristics. A 2-tailed *t* test was used to compare the mean values between 2 groups, and 1-factor ANOVA was used to compare multiple groups. We conducted a normality test and a variance homogeneity test before performing the *t* test and 1-factor ANOVA.

Three separate logistic regression analyses were conducted to evaluate the association between community cohesion and physical and mental health factors by area (urban vs rural). Community cohesion scores were treated as a binary dependent variable and added to the logistic regression model. Self-perceived health and life satisfaction, cognitive function and depression, and self-efficacy and psychological resilience were added as independent variables to the 3 logistic regression models. Age, sex, marital status, education level, individual monthly income, physical activity level, and dietary habit were adjusted in all models, and the Eysenck Personality Questionnaire-Revised Short Scale scores for psychological factors were also controlled.

Binary logistic regression analysis was used to assess the association between community cohesion and self-perceived social support. The scores of the 3 dimensions for social support and the total scores were added to the logistic regression model. The association of community cohesion with community environmental factors was assessed on 3 dimensions—attraction to neighborhood, degree of neighboring, and psychological sense of community—using binary logistic regression analysis. The total community cohesion score, which was divided into 2 categories, was used as a dependent variable to establish the logistic regression model. For each logistic regression model, we used the stepwise regression method to select the variables. A variable has a power of 80% at a significance level of .05 for univariate analyses that can be added to the logistic regression model. The community cohesion scores among different levels of community services and environmental resources were calculated, and a radar map was drawn.

The association among community cohesion and self-efficacy, social support, cognitive function, community services and environmental resources, and physical and mental health was evaluated through mediating and moderating effect tests based on step-by-step general linear regression model. Statistical significance was set at $P<.05$ for the 2-tailed test. All data analyses were performed using SAS for Windows (version 9.4; SAS Institute Inc).

Results

Participant Characteristics

The general characteristics of participants by sex are shown in Table 1. Of the 2017 participants, 855 (42.39%) were aged ≥70 years, 771 (38.22%) were male, and 1246 (61.77%) were female. A total of 20.48% (413/2017) of the participants reported that they had completed ≥13 years of education. In terms of marital status, 9.5% (73/771) of the male participants and 23.43% (292/1246) of the female participants were unmarried. Overall, 72.93% (1471/2017) of the participants self-reported that they had ≥1 chronic diseases. More than half of the participants (1108/2017, 54.93%) had lived in their community for ≥30 years.

Table 1. Characteristics of study participants by sex (N=2017).

Variable categories	Male participants (n=771), n (%)	Female participants (n=1246), n (%)
Age (years)		
<70	399 (51.8)	763 (61.23)
≥70	372 (48.2)	483 (38.76)

No	192 (24.9)	354 (28.41)
Years lived in the community		
<30	299 (38.8)	610 (48.96)
≥30	472 (61.2)	636 (51.04)

Community Cohesion Scores Based on Participant Characteristics

Table 2 shows the means and SDs of community cohesion scores based on the characteristics of the participants. According to the logistic regression analysis, education level was negatively associated with the community cohesion score: the lower the education level, the higher the community cohesion score. In addition, we used a generalized linear regression model, and we observed a strong statistically significant linear trend (*P*<.001). Participants' self-reported levels of physical activity were positively associated with community cohesion scores (*P*=.003). The community cohesion scores were higher (*P*<.001) when individuals lived in the community longer.

Table 2. The means and SDs of community cohesion scores by participant characteristics.

Variable categories	Values, mean (SD)	*P* value
Age (years)		.39
<70	68.4 (9.5)	
≥70	69.1 (8.3)	
Sex		.01
Male	67.3 (8.2)	
Female	69.3 (9.2)	
Years of education		<.001
0-6	71.6 (9.3)	
7-9	70.5 (8.2)	
10-12	68.1 (9.6)

Community Cohesion–Related Physical and Mental Health Status

The evaluation of community cohesion–related physical and mental health status by area (urban vs rural) is presented in Table 3. The logistic regression analysis showed that high levels of community cohesion were positively associated with life satisfaction, psychological resilience, levels of self-efficacy, and self-perceived health status (odds ratio [OR] 1.21, 95% CI 1.14-1.28; OR 1.05, 95% CI 1.03-1.07; OR 1.11, 95% CI 1.06-1.16; and OR 1.36, 95% CI 1.04-1.78, respectively, in urban areas; and OR 1.15, 95% CI 1.03-1.28; OR 1.07, 95% CI 1.02-1.11; OR 1.02, 95% CI 1.01-1.07; and OR 1.14, 95% CI 0.90-1.83, respectively, in rural areas). High levels of community cohesion were associated with good levels of cognitive function and low levels of depression, and community cohesion was negatively associated with cognitive function and depression scores (OR 0.92, 95% CI 0.87-0.98 and OR 0.80, 95% CI 0.71-0.90, respectively, in urban areas; and OR 0.88, 95% CI 0.79-0.91 and OR 0.92, 95% CI 0.90-0.99, respectively, in rural areas).

Table 3. Community cohesion–related physical and mental health factors by logistic regression analysis.

Variables	Multivariable adjusted odds ratio (95% CI)	*P* value
Urban areas		
Life satisfaction	1.21 (1.14-1.28)	<.001
Cognitive function	0.92 (0.87-0.98)	<.001
Depression	0.80 (0.71-0.90)	<.001
Self-efficacy	1.11 (1.06-1.16)	.002
Psychological resilience	1.05 (1.03-1.07)	<.001
Self-perceived health	1.36 (1.04-1.78)	.03
Rural areas		
Life satisfaction	1.15 (1.03-1.28)	<.001
Cognitive function	0.88 (0.79-0.91)	.02
Depression	0.92 (0.90-0.99)	.04
Self-efficacy	1.02 (1.01-1.07)	.05
Psychological resilience	1.07 (1.02-1.11)	.02
Self-perceived health	1.14 (0.90-1.83)	.06

Association Between Community Cohesion and Self-perceived Social Support

Table 4 shows a positive association between community cohesion and self-perceived social support after education level, dietary habit, age, sex, marital status, physical activity level, and individual monthly income were adjusted (OR 1.27, 95% CI 1.15-1.40; *P*<.001). Community cohesion was significantly associated with the 3 dimensions of social support: social interaction, family support, and interpersonal relations (OR 1.39, 95% CI 1.18-1.65; OR 1.34, 95% CI 1.05-1.72; and OR 1.31, 95% CI 1.13-1.52, respectively).

Table 4. The association between community cohesion and self-perceived social support.

Variables	Multivariable adjusted odds ratio (95% CI)	*P* value
Total scores of social support	1.27 (1.15-1.40)	<.001
Social interaction	1.39 (1.18-1.65)	<.001
Family support	1.34 (1.05-1.72)	.02
Interpersonal relations	1.31 (1.13-1.52)	<.001
Education level	0.72 (0.56-0.92)	.009
Dietary habit	0.85 (0.57-1.27)	.41
Sex	1.15 (0.70-1.89)	.59
Age	1.02 (0.98-1.06)	.32
Marital status	0.63 (0.33-1.19)	.16
Physical activity	1.06 (0.63-1.80)	.83
Individual monthly income	0.84 (0.63-1.11)	.21

Association Between Community Cohesion and Community Services and Environmental Factors

The community cohesion scores from different dimensions associated with community services and environmental factors by logistic regression analysis are shown in Table 5. In model 1, attraction to neighborhood was significantly associated with levels of satisfaction with community physicians' attitude, rehabilitation equipment rental services, caregiver guidance, and community waste disposal (OR 1.55, 95% CI 1.18-2.05; OR 3.91, 95% CI 2.39-6.37; OR 1.85, 95% CI 1.08-3.17; and OR 1.37, 95% CI 1.10-1.71, respectively). In model 2, the degree of neighboring was associated with re-employment assistance, rehabilitation equipment rental services, and levels of satisfaction with community physicians' technical expertise (OR 2.49, 95% CI 1.49-4.18; OR 1.63, 95% CI 1.10-2.42; and OR 1.24, 95% CI 1.01-1.53, respectively). In model 3, psychological sense of community was associated with transportation services, rehabilitation equipment rental services, and health assessment (OR 2.96, 95% CI 1.78-4.92; OR 3.55, 95% CI 2.34-5.39; and OR 2.27, 95% CI 1.28-4.04, respectively). In model 4, the overall levels of community cohesion were associated with transportation services and rehabilitation equipment rental services as well as levels of satisfaction with community physicians' technical expertise and community waste disposal (OR 3.14, 95% CI 1.87-5.28; OR 3.62, 95% CI 2.38-5.52; OR 1.37, 95% CI 1.08-1.73; and OR 1.23, 95% CI 1.01-1.50, respectively).

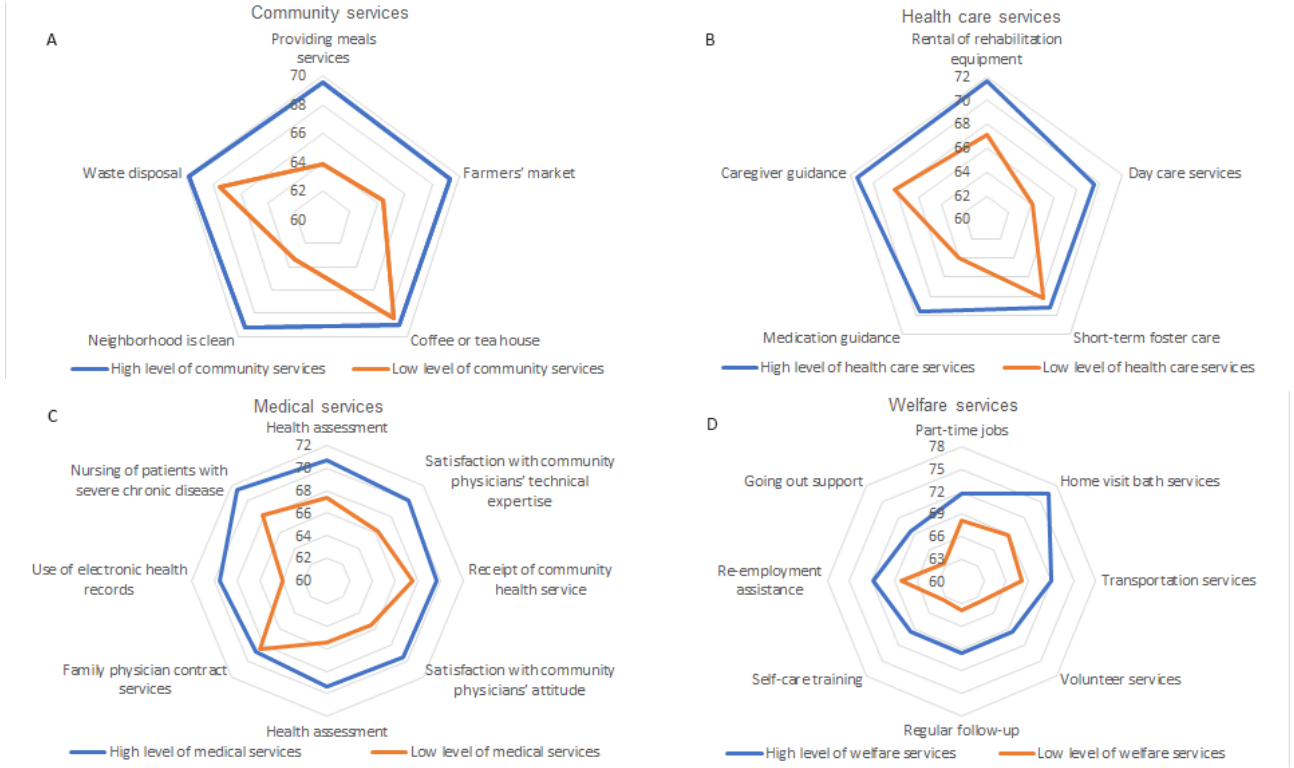
The mean scores of community cohesion from the 4 dimensions of community services and environmental resources are shown in Figure 1. In the community services environment, provision of meals, use of farmers' markets, and neighborhood showed high community cohesion scores (Figure 1A). In health care services, high community cohesion scores were observed in the following services: day care service, medication guidance, rehabilitation equipment rental services, and caregiver guidance (Figure 1B). In medical services, health assessment, satisfaction with community physicians' attitude, receipt of community health service, satisfaction with community physicians' technical expertise, nursing of patients with severe chronic disease, and use of electronic health records showed high community cohesion scores (Figure 1C). In welfare services, home visit bath service, transportation service, volunteer service, regular follow-ups, self-care training, re-employment assistance, going out support, and part-time jobs were associated with high community cohesion scores (Figure 1D).

Table 5. The odds ratios of community environment and other factors related to community cohesion by logistic regression model.

Variables	Multivariable adjusted odds ratio (95% CI)	*P* value
Model 1 (attraction to neighborhood)		
Levels of satisfaction with community physicians' attitude	1.55 (1.18-2.05)	.001
Levels of satisfaction with community waste disposal	1.37 (1.10-1.71)	.005
Rehabilitation equipment rental services	3.91 (2.39-6.37)	<.001
Caregiver guidance	1.85 (1.08-3.17)	.03
Depression scores	0.85 (0.76-0.94)	.001
EPQ-RSS[a] scores	1.09 (1.03-1.16)	.004
Model 2 (degree of neighboring)		
Levels of satisfaction with community physicians' technical expertise	1.24 (1.01-1.53)	.049
Rehabilitation equipment rental services	1.63 (1.10-2.42)	.02
Re-employment assistance	2.49 (1.49-4.18)	<.001
Depression scores	0.90 (0.82-0.99)	.04
Age	0.96 (0.94-0.98)	.006
Model 3 (psychological sense of community)		
Rehabilitation equipment rental services	3.55 (2.34-5.39)	.005
Transportation services	2.96 (1.78-4.92)	<.001
Health assessment	2.27 (1.28-4.04)	<.001
Depression scores	0.86 (0.77-0.96)	.005
EPQ-RSS scores	1.07 (1.01-1.13)	.03
Model 4 (total model)		
Levels of satisfaction with community physicians' technical expertise	1.37 (1.08-1.73)	.008
Levels of satisfaction with community waste disposal	1.23 (1.01-1.50)	.048
Rehabilitation equipment rental services	3.62 (2.38-5.52)	<.001
Transportation services	3.14 (1.87-5.28)	<.001
Depression scores	0.84 (0.75-0.93)	.001
EPQ-RSS scores	1.09 (1.04-1.16)	.001
Self-efficacy scores	1.05 (1.02-1.08)	.004

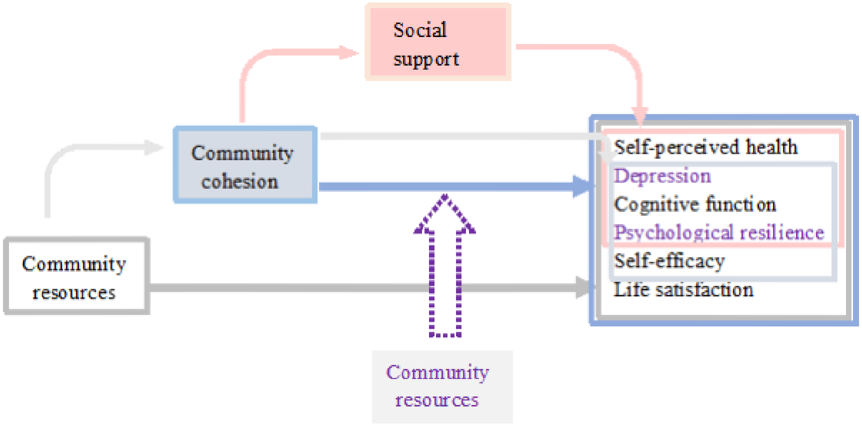
[a] EPQ-RSS: Eysenck Personality Questionnaire-Revised Short Scale.

Figure 1. Mean community cohesion scores. (A) Community cohesion scores for public services. (B) Community cohesion scores for health care services. (C) Community cohesion scores for medical services. (D) Community cohesion scores for welfare services.



The results of the association among community cohesion and self-efficacy, social support, cognitive function, community services and environmental resources, and physical and mental health are shown in Figure 2. Community cohesion, community resources, and social support were directly associated with physical and mental health. Community cohesion was associated with physical and mental health (self-perceived health, depression, cognitive function, and psychological resilience), which may be partially mediated by social support. Community resources were associated with physical and mental health (depression, cognitive function, psychological resilience, and self-efficacy), which may be partially mediated by community cohesion. In addition, the association between community cohesion and psychological resilience and depression may be moderated by community resources.

Figure 2. The association among community cohesion and social support, community resources, and physical and mental health of older adults.



Discussion

Principal Findings

In this study, we found that community cohesion had an important effect on the physical and mental health of older adults during the COVID-19 pandemic. Moreover, high levels of community cohesion were associated with good self-perceived health status and high life satisfaction. Participants who reported high levels of community cohesion stated that they had high levels of self-efficacy, psychological resilience, and self-perceived social support. Community cohesion was positively associated with transportation and rehabilitation equipment rental services as well as levels of satisfaction with community physicians' technical expertise and community waste disposal.

Some studies have reported the beneficial effects of community cohesion on the mental health of older adults; however, studies on the association between community cohesion and physical and mental health during the COVID-19 pandemic, especially studies on community services and environment factors that can improve community cohesion during major infectious disease epidemics, are limited [36,37]. The COVID-19 pandemic has brought about major changes in the daily lives and environment of older adults. Social support from children and relatives was unavailable because of COVID-19–related restrictions, regular visits to medical facilities were banned, and public transportation was inaccessible because they could not operate intelligent public transportation apps on their mobile phones. As they could not acquire and show health codes, as a result, they will be refused public transportation, which would lead them to feel more panicked and helpless. The restrictions on the use of public resources also caused them to become more dependent on the community. However, the implementation of COVID-19 prevention and control measures increased the interaction between the older adults and community staff, and this proved to be of considerable help to the older adults. Free testing to assess the prevalence of COVID-19 in the community made them feel safer. The community became a big presence in their lives. These pieces of evidence from the field supported our findings.

Studies have shown that rural areas have more neighborhood networks than urban areas [38], but community cohesion for health benefits between urban and rural areas demonstrates no difference among the general population. Our study showed that, during the COVID-19 pandemic, there were no differences between individuals with high levels of community cohesion association and good levels of physical and mental health in different areas (urban vs rural). However, the association between community cohesion and self-perceived health was inconsequential in rural areas. The prevalence of COVID-19 has resulted in the return of people to their community, which supports the observation on the effects of community cohesion on the physical and mental health of older adults during the COVID-19 pandemic. Our results showed that high levels of community cohesion were associated with high levels of self-perceived health status and life satisfaction. However, older adults were highly anxious about their health, and their lives were grossly circumscribed. During the pandemic, because family and social support for older adults was hindered, they became emotionally dependent on their community, and the rising levels of community cohesion enabled them to experience a high level of social support. Several studies have suggested that community cohesion can be viewed as a pattern of social support, which might affect individual mental health through enhancing mutual trust and emotional support as well as reducing stress levels [39].

Community cohesion can be linked to individual health benefits, but the underlying mechanism is still not fully understood. Studies have suggested that community cohesion enhances subjective well-being by promoting positive emotions and purpose in life, which acts as a barrier to psychopathology factors, resulting in better physical health and longevity [40-42]. Community cohesion can strengthen collective advocacy for resources, which promotes the dissemination of health-related information and increases awareness of chronic disease [43]. However, there is limited quantitative research on the association between community cohesion and physical and mental health among older adults during the COVID-19 pandemic. Our results showed that high levels of community cohesion were associated with low levels of depression and high levels of psychological resilience and cognitive function. This result can be easily explained by qualitative observation. During the pandemic, community prevention and control measures resulted in increased communication between individuals and community staff. There was also an increase in the exchange of information among neighbors on disease prevalence and prevention. In these circumstances, community cohesion and individual sense of security were enhanced, promoting the spread of health-related information and improving the recognition for diseases among older adults. A study has reported on the association between community cohesion and the use of preventive health services [44]. The study suggested that high levels of community cohesion could be positively associated with an increase in the use of influenza vaccine and cholesterol tests for community individuals through 4 hypothesized mechanisms: increasing the diffusion of information, providing emotional support, advocating for environmental resources, and maintaining healthy behaviors through informal social control.

There is growing interest in studying the effects of the environment on health and health-related outcomes, such as identifying the environmental resources and community services that may enhance community cohesion. In this study, we found that transportation and rehabilitation equipment rental services as well as levels of satisfaction with community physicians' technical expertise and community waste disposal were positively associated with community cohesion. These factors are extremely important for improving community cohesion. During the pandemic, operating intelligent public transportation apps on their mobile phones was a huge barrier for older adults when taking public transport. Being confined to the home for long periods and the restrictions on going out led to difficulties in physical functioning, which increased the use of, and demand for, transportation and rehabilitation equipment rental services among older adults. The COVID-19 outbreak made older adults more dependent on community physicians. A high level of technical expertise demonstrated by community physicians can make older adults living in the community feel safe and reduce their fear of disease. At the initial stage of the pandemic, normal garbage disposal was also disrupted. The normalization of community garbage disposal and the clean and tidy community environment once again made the community attractive to older adults. These factors directly or indirectly affected the physical and mental health of older adults during the COVID-19 pandemic.

The main strength of this study is that it was based on the use of big data platforms to study the mental health of older adults during the COVID-19 pandemic. We collected complete data, which enabled us to consider more indicators of mental health measurement and community cohesion–related factors for the analysis and control of many potential confounding factors. The large amount of data also ensured the reliability of the study results. This study included ≥10 mental health measurement instruments and identified the association between community cohesion and the physical and mental health of older adults at the individual, community, and social levels based on the social-ecological model. Using moderation and mediation analysis, this study further revealed community cohesion to be a potential interaction mechanism linking social support, self-efficacy, environmental resources, and the physical and mental health of older adults. This study also identified specific community services and environmental factors that can increase community cohesion and that can be considered when designing public health policies to deal with major infectious disease pandemics. Furthermore, when the COVID-19 pandemic initially broke out in China, the country's public health administration and disease control departments implemented a series of unprecedented prevention and control measures, including a *dynamic clearing* epidemic prevention policy and home isolation. This provided us with a rare opportunity to study the effects of community cohesion on the physical and mental health of older adults.

Study Limitations

Our study includes several limitations. First, the causality could not be determined, given that this study adopted a cross-sectional design. However, the associations between community cohesion and community services and environmental factors were observed through relatively large sample sizes, and the inference was based on some previous studies. Second, all participants in this study were older adults. During the first stage of the study, the face-to-face interviews took approximately 45 minutes to complete. Each participant was compensated with CN¥40 (US $5.8), based on local research payment standards and as required by the ethics committee. After the items to be investigated were added, the survey time was extended to approximately 60 minutes, and participants were offered higher remuneration accordingly. It is possible that the compensation offered could have led prospective participants to deceive the researchers regarding their eligibility, and the information they provided could have been biased [45]. Third and last, the study was conducted during the COVID-19 pandemic. We selected the participants according to the inclusion and exclusion criteria; however, we excluded some older adults with severe physical dysfunction and mental disorders, which could have resulted in potential exclusion bias.

Conclusions

We obtained important evidence on the effects of community services and environmental factors on community cohesion during the COVID-19 pandemic. We found that community cohesion is substantially positively associated with transportation and rehabilitation equipment rental services as well as high levels of satisfaction with community physicians' technical expertise and community waste disposal. Community cohesion is also directly or indirectly associated with the physical and mental health of older adults. Our research suggests that enhancing community services and environmental resources is an effective strategy to increase community cohesion during major infectious disease epidemics. Improving community cohesion will also help to promote the physical and mental health of older adults.

Abstract

Background: Prior to the development of effective vaccines against SARS-CoV-2, masking and social distancing emerged as important strategies for infection control. Locations across the United States required or recommended face coverings where distancing was not possible, but it is unclear to what extent people complied with these policies.

Objective: This study provides descriptive information about adherence to public health policies pertaining to mask wearing and social distancing and examines differences in adherence to these policies among different population groups in the District of Columbia and 8 US states.

Methods: This study was part of a national systematic observational study using a validated research protocol for recording adherence to correct mask wearing and maintaining social distance (6 feet/1.83 meters) from other individuals. Data were collected from December 2020 to August 2021 by research team members who stationed themselves in outdoor areas with high pedestrian traffic, observed individuals crossing their paths, and collected data on whether individuals' masks were present (visible or not visible) or worn (correctly, incorrectly, not at all) and whether social distance was maintained if other individuals were present. Observational data were entered electronically into Google Forms and were exported in Excel format for analysis. All data analyses were conducted using SPSS. Information on local COVID-19 protection policies (eg, mask wearing requirements) was obtained by examining city and state health department websites for the locations where data were being collected.

Results: At the time these data were collected, most locations in our study required (5937/10,308, 57.6%) or recommended (4207/10,308, 40.8%) masking. Despite this, more than 30% of our sample were unmasked (2889/10136, 28.5%) or masked incorrectly (636/10136, 6.3%). Masking policy was significantly related to correct masking with locations that required or recommended masking (66% correct masking vs 28/164, 17.1% in locations that did not require masking, $P<.001$). Participants who maintained social distance from others were more likely to be correctly masked than those who were not ($P<.001$). Adherence to masking policy by location was significant ($P<.001$); however, this was driven by 100% compliance in Georgia, which did not require masks at any point during the data collection period. When the same analysis was conducted for compliance with mask requirements and recommendations, there was no significant difference by location. Overall adherence to masking policies was 66.9%

Conclusions: Despite a clear relationship between mask policies and masking behavior, one-third of our sample was nonadherent to those policies, and approximately 23% of our sample did not have any mask, either on or visible. This may speak to the confusion surrounding "risk" and protective behaviors, as well as pandemic fatigue. These results underscore the importance of clear public health communication, particularly given variations in public health policies across states and localities.

COVID-19; mask adherence; social distancing; public health; health policy; public health mandates

Introduction

Since the novel COVID-19 pandemic became known in January 2020, the United States has experienced over 103 million cases and over 1.1 million deaths (cumulative as of February 25, 2023) [1]. From the beginning of the pandemic, certain communities have been shown to be disproportionately affected by COVID-19; a recent systematic review of disparities in COVID-19 infections, hospitalizations, and deaths showed that African Americans/Blacks and Hispanic/Latinx populations had disproportionately higher rates of SARS-CoV-2 infection, hospitalization, and COVID-19–related mortality compared with non-Hispanic/Latinx White populations [2]. Other data show that older age and presence of health comorbidities—including presence of obesity and diabetes, cardiovascular disease, and chronic kidney disease—are associated with higher risk of COVID-19 morbidity and mortality [3].

Although the development and widespread dissemination of effective vaccines to prevent COVID-19 infection have helped to reduce infection rates, voluntary uptake of the vaccine has been slower than expected. National surveillance data show that, although 81.1% of the total US population—including 92% of adults over the age of 18 years—have had at least 1 dose of the SARS-CoV-2 vaccine, only 69.2% completed the primary series and only 16% have received an updated bivalent booster dose [4]. Nonetheless, vaccine uptake, combined with continued preventive behaviors (ie, mask wearing and social distancing), remain the most effective ways to minimize infection and transmission risk [5-9].

The importance of mask wearing continues to be an effective way to protect against infection against COVID-19 and other respiratory infections. There have been numerous studies of the effectiveness of mask wearing against SARS-CoV-2 infection. For example, in a cross-sectional, web-based study of US-based individuals, Rader et al [10] found that a reported 10% increase in mask wearing was associated with more than a 3-fold increase in infection control and that communities with high reported mask wearing and social distancing had the highest predicted probability of transmission control. In another study from Japan that surveyed close contacts of SARS-CoV-2–infected patients, Sugimura et al [11] found that the individuals who indicated that they did not wear face masks were infected at a higher rate than mask wearers (16.4% compared with 7.1%). A comprehensive narrative review published in 2021 by Howard et al [12] found support for the effectiveness of public mask wearing, stating that "...public mask wearing is most effective at reducing spread of the virus when compliance is high...in conjunction with existing hygiene, distancing, and contact tracing strategies." They further recommended that "public officials and governments strongly encourage the use of widespread face masks in public, including the use of appropriate regulation" [12]. The importance of continued masking is underscored by the presence of highly transmissible variants such as the Omicron variants, which, combined, accounted for 93.8% of infections in the United States (as of February 25, 2023) [13] and are contagious even among those who are fully vaccinated and boosted.

The issue of regulation—such as the enforcement of vaccine and mask wearing mandates—for the protection of public health has historically been and continues to be contentious [14]. In the way the COVID-19 pandemic unfolded in the United States, general vaccine hesitancy, politicization of governmental mandates, and the politicization of the pandemic itself served to hamper timely uptake and adherence to public health recommendations for mask wearing at a time when infections were rapidly spreading and vaccines had not yet become available. The politicization of the pandemic and mask wearing by conservative governmental leaders was particularly noteworthy; in the absence of a national mask wearing mandate, individual states implemented legislation requiring the wearing of face masks in public. In August 2020, while the epidemic was sweeping through the United States, 34 states and the District of Columbia had mask mandates, while 16 states—each of which had a Republican governor—did not [14]. A study that examined adherence to state-level masking policies and SARS-CoV-2 infection rates in those states at around this same time period in 2020 found that 93% of the states that had no mask wearing policies for the general public reported high COVID-19 rates, whereas none of the 8 states that had at least 75% adherence to masking policies reported high infection rates [15].

The effectiveness of a public health mandate to protect against disease spread may also be dependent on the level of mobilization of people in and and out of the community. For example, efforts to prevent SARS-CoV-2 infection and transmission in metropolitan regions may be especially tricky given the movement of people into and out of cities and their surrounding suburban areas, and Black and Indigenous People of Color (BIPOC) communities may have elevated levels of vulnerability to COVID-19 because of their participation in sectors of the workforce that are deemed essential. For example, the pandemic picture in the Washington, DC, region—which includes the District of Columbia and immediate surrounding jurisdictions in Maryland and Virginia—mirrors that of the rest of the nation in terms of its impact on disproportionately affected populations [16-18]. Because of its location between Maryland and Virginia, the District has very fluid boundaries and experiences a significant amount of population migration to and from these states as people enter and exit the District for employment, commerce, and tourism. As a result, the level of infection risk for SARS-CoV-2 in the District may be affected by factors in its neighboring jurisdictions, including the R0 (basic reproduction number), rate of vaccination uptake, and levels of social and community vulnerability that might increase SARS-CoV-2 infection risk. For these reasons, adherence to preventive behaviors in urban centers is of paramount importance.

Although there are data about the adherence to these preventive behaviors for other locations in the country, little is known about the levels of adherence to these behaviors in the metropolitan Washington, DC area and how this region compares with other metropolitan centers. The purpose of this paper was to provide descriptive information about adherence to mask wearing and social distancing in the District of Columbia and 8 other US states and to examine differences in adherence among different population groups within these locations.

Methods

This study was conducted by the George Washington University team that was part of the larger, national-level Systematic Observation of Mask Adherence and Distancing (SOMAD) study [19]. Although the methodological details pertaining to this study are provided elsewhere [20], we will also explain them in the following sections to provide clarity about the study procedures.

Student Researcher Training

The research team included 13 student researchers who were trained by the SOMAD principal investigator (via Zoom meeting) on the study protocol [21] and data collection procedures. The student researchers spent approximately 1 week practicing the data collection procedures to ensure comfort with and ability to adhere to the study protocol. Issues that arose during the "practice data collection" sessions were discussed with our university's faculty team leaders to ensure that study procedures were clear and that data collection practices were adherent with the master SOMAD protocol. Student researchers were advised that, although it may be difficult to ascertain exact ages, genders, and race/ethnicity of persons observed, they should use their best judgment based on the way the person is presenting.

Data Collection Methods

Our study was conducted from December 1, 2020, to August 1, 2021. During this time, the university was operating virtually, so student researchers were attending classes and research team meetings from their home locations. Student researchers chose places close to home as their observation sites. Although most data were collected in the metropolitan Washington, DC area (which includes parts of Maryland and Northern Virginia), we did have team members who were collecting data in other states. As such, in addition to data from the metropolitan Washington, DC area, data were collected from Georgia, Missouri, Arizona, California, Nevada, and Illinois.

As these data were collected prior to the wider availability of COVID-19 vaccines, all observation locations were outdoors and in high pedestrian traffic areas, such as parks, multi-use paths and trails (eg, walking, running, and biking trails), city intersections, and shopping areas that had outdoor pedestrian walkways and spaces. Student researchers wore masks and maintained social distance from others while collecting data to protect themselves from infection risk.

Per the SOMAD protocol [21], the student researcher (acting as the observer) selected a specific spot for data collection. As individuals passed by that spot, the student researcher recorded the characteristics of that person, entered those data into the online data collection form, and then continued to observe and enter data for the next person who passed by. If persons were walking in groups, student researchers would assess the general characteristics of 4 persons within each group (in order to retain as much detailed information as possible) and enter those data into the online form for each person.

Data were collected for a minimum of 2 hours per week, with 1 observation session occurring on a weekday and 1 session occurring on a weekend. Both observation sessions occurred at the same time of day to ensure comparability between weekdays and weekends. Data were collected using the national SOMAD team's online data collection form. Data were then cleaned by the national team's statistician and returned to our university team for analyses.

Measures

Data were collected pertaining to a variety of characteristics related to the outdoor space where data collection occurred and the persons being observed. These variables are described in the following sections.

Location and Setting Variables

At the start of each observation session, the student researcher recorded the date, time, city, address, and zip code in which the observation was occurring. Additionally, student researchers recorded the type of location where the observation was occurring (eg, commercial street, neighborhood park, trail) and, if applicable, the official name of the location (eg, the specific name of the park or trail). Student researchers also noted if the location had a masking policy and whether there was sufficient space in the location for social distancing, which is defined as being able to maintain 6 feet or 1.83 meters from another person.

Demographic Variables

With regard to the persons being observed, it was understood that it is often difficult to ascertain with certainty the demographic characteristics of individuals simply by looking at physical characteristics. Such judgments may be made even more difficult if individuals are wearing face coverings. Nonetheless, student researchers were asked to do the best they could to ascertain the approximate age, gender, and race/ethnicity of the persons being observed. Options for age group included infant or toddler (0-2 years of age), child (3-12 years of age), adolescent or teen (13-19 years of age), adult (20-59 years of age), and older adult (60 years of age and older). With regard to gender and race/ethnicity, student researchers were asked to note the gender (male, female, unable to judge) and apparent race/ethnicity (White, Black/African American, Asian, Latinx, unable to determine) of each observed individual.

Additionally, as these observations were occurring in outdoor spaces, student researchers were asked to record the physical activity levels of the individuals. Individuals could be categorized as being sedentary (eg, sitting, laying down, or being carried in the case of a child), moderately active (eg, walking or biking slowly), or vigorously active (eg, running, biking, climbing). Similarly, individuals using modes of transportation were recorded as being either "on wheels" (ie, being on a bicycle or skateboard or in a wheelchair or stroller) or "not on wheels" (ie, being on foot).

COVID-19 Protective Practices

Student researchers collected data on the adherence to COVID-19 protective practices of mask wearing and social distancing. For mask wearing, individuals were noted as having their masks on correctly (ie, covering the nose and mouth), wearing their masks incorrectly (eg, mask covering mouth but not nose or vice versa), having visible masks present but not on their face (eg, masks in hand, dangling from an ear, or being worn under the chin), or having no face covering at all. With regard to social distancing, student researchers recorded if observed individuals were traveling alone or in a group (defined as 2 or more people together) and whether individuals (including those traveling in groups) were maintaining social distance from others.

Policy Variables

In addition to the notation about masking policies of specific locations where observations occurred, we collected data pertaining to state and local masking and social distancing policies through examination of city and state health department websites for the locations where data were being collected.

Analyses

Observational data were entered electronically into Google Forms and were then exported in Excel format for analysis. Univariate and bivariate analyses were conducted to obtain descriptive information about the observational sample. Pearson's chi-square analyses were used to test for significant associations between study variables. All data analyses were conducted using SPSS version 24.

Ethical Considerations

Prior to engaging in data collection, the study protocol was submitted to the George Washington University's Institutional Review Board for review. A waiver of informed consent was requested due to (1) the nature of the study being purely observational and not requiring personal interaction with prospective participants (ie, those persons being observed) and (2) the fact that no protected personally identifying information or protected health data were collected from individuals who were observed as part of the study. Because no personally identifying information were collected, all data from persons observed were anonymous and analyzed in aggregate. Finally, as these data were collected without involving interpersonal interaction, individuals whose behaviors were observed as part of this study were not offered compensation. Based on these aspects of the study, the George Washington University Institutional Review Board determined that this study constituted minimal risk to research participants and therefore was exempt from review (IRB# NCR213396).

Results

Sample Demographics

The findings presented here represent data collected between November 29, 2020, and August 1, 2021, in multiple locations across 8 states and the District of Columbia. The geographic locations of our study sites in the United States are shown in Figure 1. In addition to geographic location, we have provided the daily average of new COVID-19 cases in each location (using data from the New York Times COVID-19 Tracker) [22] in order to demonstrate how the pandemic was affecting each state or, where more specific data were available, each city at the approximate date when data collection started.

Demographic data about the individuals observed are presented in Table 1. A total of 10,308 observations were collected. The sample was relatively evenly split between persons observed to be male and persons observed to be female (4539/10,081, 45% vs 5542/10,081, 55%), with most persons observed being adults between the ages of 20 years and 59 years (7490/10,118, 74%), of White or Black race (5271/10,308, 51.1% and 2623/10,308, 25.4% respectively), and of non-Latinx ethnicity (8928/9822, 90.9%). Of the observations, 47% (4836/10,291) were collected in the metropolitan Washington, DC area, and 38% (3942/10,291) came from 3 sites in the metropolitan Atlanta area in Georgia. Most data collection locations had policies requiring (5937/10,308, 57.6%) or recommending (4207/10,308, 40.8%) masking in outdoor locations.

[d] n=10,118.

[e] Observations marked as unknown have been combined with missing.

[f] n=9822.

[g] n=10,291.

Adherence to COVID-19 Preventive Behaviors

Regarding adherence to social distancing, the sample was almost evenly split between those correctly social distancing (maintaining a distance between persons of >6 feet/1.83 meters; 5185/10,113, 51.3%) and those incorrectly social distancing (standing <6 feet//1.83 meters from others; 4928/10,113, 48.7%). Approximately 65% (6611/10,136, 65.2%) of participants observed were wearing masks correctly (ie, fully covering the nose and mouth), while another 23.2% (2353/10,136) were not wearing masks at all. These data are shown in Table 2.

When examining correlates of correct masking behavior, several interesting findings emerged. These data are presented in Table 3. Persons who were correctly masked were more likely to be those observed as female (3828/5538, 69.1%; $\chi^2_1=74.8$, $P<.001$), of Asian race (793/1033, 76.8%; $\chi^2_2=129.6$, $P<.001$), and aged 60 years or older (790/1172, 67.4%; $\chi^2_4=206.7$, $P<.001$). Those correctly masked were also more likely to be adherent to social distancing guidelines (3556/5180, 68.6%; $\chi^2_1=55.7$, $P<.001$).

Correct masking behavior was more likely to be observed outside of the metropolitan Washington, DC area compared with within the metropolitan Washington, DC area (3585/5401, 66.4% vs 3018/4718, 64%; $\chi^2_1=6.4$, $P=.01$) and in locations with required or recommended outdoor masking policies (3796/5791, 65.5% and 2787/4181, 66.7%, respectively; $\chi^2_2=171.7$, $P<.001$). We further examined potential differences in adherence to masking policy by state or region, focusing on the 4 states and regions for which we had the most data: the metropolitan Washington, DC area; Georgia; Nevada; and Illinois. These data are presented in Table 4. In the time during which these data were collected, the metropolitan Washington, DC area; Illinois; and Nevada had policies that mandated masking in both indoor and outdoor locations, while Georgia did not have a mask mandate in place. However, despite the absence of a state-level mask mandate, the businesses in Georgia where those data were collected did require or recommend that customers entering those indoor spaces wear masks. When we examined masking behavior and adherence to state policies where masking was mandated, we found that, overall, there was significant adherence to masking policies ($\chi^2_3=1584.1$, $P<.001$), and the significance was largely driven by Georgia's 100% adherence to a state policy that did not require masking. We then examined masking behavior and adherence to policies where masking was either mandated (eg, state policy) or required or recommended (eg, business policies in GA). When combining these 2 conditions, we found that, although overall levels of masking adherence were close to 66%, the comparison was no longer statistically significant ($\chi^2_3=3.2$, $P=.37$).

Table 2. COVID-19 preventive behaviors among the study sample (n=10,308).

Variable	Results[a], n (%)
Social distancing behavior[b]	
Correctly social distancing	5185 (51.3)
Incorrectly social distancing	4928 (48.7)
Masking behavior[c,d]	
Mask on	6611 (65.2)
Mask partially on (eg, worn below nose)	636 (6.3)
Mask visible	536 (5.3)
No mask	2353 (23.2)

[a] The total sample sizes for the variables may not match due to missing data.

[b] n=10,113.

[c] Categories are mutually exclusive.

[d] n=10,136.

Table 3. Correlates of correct masking behavior (n=10,136).

Variable	Correct masking, n (%)	Incorrect or no masking, n (%)	χ^2 (*df*)	*P* value
Location[a]			6.4 (1)	.01
Metropolitan Washington, DC area	3018 (64)	1700 (36)

Discussion

Principal Findings

Our data show that, in a sample that included observations from 8 states and the District of Columbia, individuals who were observed to be female, older than 60 years, and of Asian race were more likely to be correctly adherent to public health guidelines in terms of the correct utilization of face masks when outdoors in public spaces. Moreover, we found that those who had engaged in correct masking behavior were also more likely to be adherent to social distancing guidelines. The findings from this study support the findings from the other SOMAD studies that also observed higher levels of adherence to correct mask usage among female individuals and persons of older age, as well as persons of Asian ancestry [20,23].

Comparisons With Prior Work

It is of interest to note that, while most of the data collection sites had policies in place that either required or recommended masking outdoors, we found that approximately 23% of the sample were not wearing masks at the time they were observed. This may be due to the perception—which is supported by epidemiological data—that SARS-CoV-2 transmission risk is significantly lower in outdoor spaces [24]. To that point, we did find a 66% adherence to state or local masking policies. This finding supports the results of another national-level systematic observation study that found that mask mandates result in a 3-fold increase in adherence to mask wearing [25]. Additionally, our finding showed that local policies—such as those implemented by private businesses in Georgia requiring or recommending mask wearing by their customers even though there was no mask mandate in place at the state level—may be influential in prompting preventive behaviors even in broader environmental and legislative contexts where such behaviors are not deemed important. Together, these findings support the idea that policies promoting or mandating public health protective behaviors can be useful in helping states and localities mitigate the impact of disease spread. It is likely that future observational studies of indoor mask wearing may show different levels of adherence to ongoing recommendations pertaining to social distancing and mask wearing, particularly in light of rising rates of vaccination among the general population, changing state and local policies pertaining to indoor mask usage, and waning rates of infection in the general population.

Limitations

There are several significant limitations of this research that should be noted. As mentioned previously, all data collected were observational. Because most participants were masked, it may have been more difficult than it would be under normal circumstances to ascertain persons' race, ethnicity, sex, and age. Similarly, because of the diversity of people observed and general difficulties in guessing people's ages, race/ethnicity, and gender, there is likely some amount of error in our data pertaining to our participants' demographic characteristics. This lack of precision is a limitation of the data collection procedures. Also, because data collectors were frequently observing individuals as they moved through spaces (eg, crossing a street or walking on a sidewalk), it may be possible that observers were unable to clearly determine individuals' demographic characteristics or mask usage. This may have contributed to misclassification of individuals into demographic and behavioral adherence categories.

Conclusions

Despite these limitations, we were able to collect a substantial amount of data from a variety of locations across the country, thereby providing a representative picture of COVID-19 preventive behaviors in a diverse population. These data provide some significant takeaways that can inform public health practice as the world moves into the third year of addressing the COVID-19 pandemic. The first of these points is that, despite significant gains in vaccination uptake, there is still a need for adherence to COVID-19 preventive behaviors, particularly in places (eg, rural communities) and among populations (eg, communities of color) where disparities in vaccine access and uptake exist and where the presence of significant health comorbidities increase risk of severe disease if persons do become infected. Similarly, with the continued emergence of new SARS-CoV-2 variants, maintaining high levels of adherence to protective behaviors will be critical to preventing further surges in the numbers of COVID-19 cases, including both new and breakthrough infections. As the pandemic becomes endemic and more normalized, maintaining adherence to preventive behaviors is challenging, as the presence of effective vaccines may cause the public to believe that the pandemic is over or that preventive behaviors are no longer relevant. Future research should focus on developing more innovative ways to promote continued adherence to masking and social distancing guidance where necessary and appropriate, with particular attention to how to mitigate "pandemic fatigue" [26].

Our findings also highlight the importance of clear and effective public health communication regarding the need for adherence to preventive behaviors other than or in addition to vaccination. This is particularly necessary considering variations in state and local adherence with federal guidance, as well as the abundance of misinformation about COVID-19 that continues to circulate in the news media and on social media. A recent Kaiser Family Foundation report found that, in a sample of 1519 adults 18 years of age and older sampled through random digit dialing, approximately 78% indicated that they believed or were unsure about at least one false statement about the COVID-19 pandemic or about vaccination that they had seen in the news media [27]. Future research should focus not only on improving the health messages that are disseminated to the public about COVID-19 and disease prevention but also on improving health literacy among the general population so that individuals are better able to determine the veracity of information they hear through the news media so that they can more easily spot "fake news" about the pandemic. Moreover, given the continued evolution of highly transmissible and contagious SARS-CoV-2 variants, it is critical that public health campaigns effectively communicate the continued benefit of protective behaviors such as vaccination, masking, and distancing as strategies to reduce the morbidity and mortality associated with the COVID-19 pandemic.

Acknowledgments

The study team would like to thank Dr. Deborah Cohen and the National Systematic Observation of Mask Adherence and Distancing (SOMAD) Research Team for giving us the opportunity to be a part of this study. We would also like to acknowledge the contributions to this research made by the SOMAD@GW team of "citizen scientist" data collectors: Rhiana Brennan, Jackie Carlton, Gabby Carmichael, Giulia Folli, Tsion Gashaw, Agnes Halm-Lutterodt, Misaal Irfan, Catherine Jones, Nicole Joseph, Hannah Latif, Elizabeth Mendoza-Tirado, Zena Osman, and Lizzie Zinn.

Data Availability

The data sets generated or analyzed during the current study are available from the corresponding author (MSR) on reasonable request. Data requests for the national SOMAD study should be made to Dr. Deborah A Cohen (Deborah.A.Cohen@kp.org).

Abstract

Background: Studying patients’ social needs is critical to the understanding of health conditions and disparities, and to inform strategies for improving health outcomes. Studies have shown that people of color, low-income families, and those with lower educational attainment experience greater hardships related to social needs. The COVID-19 pandemic represents an event that severely impacted people’s social needs. This pandemic was declared by the World Health Organization on March 11, 2020, and contributed to food and housing insecurity, while highlighting weaknesses in the health care system surrounding access to care. To combat these issues, legislators implemented unique policies and procedures to help alleviate worsening social needs throughout the pandemic, which had not previously been exerted to this degree. We believe that improvements related to COVID-19 legislature and policy have positively impacted people’s social needs in Kansas and Missouri, United States. In particular, Wyandotte County is of interest as it suffers greatly from issues related to social needs that many of these COVID-19–related policies aimed to improve.

Objective: The research objective of this study was to evaluate the change in social needs before and after the COVID-19 pandemic declaration based on responses to a survey from The University of Kansas Health System (TUKHS). We further aimed to compare the social needs of respondents from Wyandotte County from those of respondents in other counties in the Kansas City metropolitan area.

Methods: Social needs survey data from 2016 to 2022 were collected from a 12-question patient-administered survey distributed by TUKHS during a patient visit. This provided a longitudinal data set with 248,582 observations, which was narrowed down into a paired-response data set for 50,441 individuals who had provided at least one response before and after March 11, 2020. These data were then bucketed by county into Cass (Missouri), Clay (Missouri), Jackson (Missouri), Johnson (Kansas), Leavenworth (Kansas), Platte (Missouri), Wyandotte (Kansas), and Other counties, creating groupings with at least 1000 responses in each category. A pre-post composite score was calculated for each individual by adding their coded responses (yes=1, no=0) across the 12 questions. The Stuart-Maxwell marginal homogeneity test was used to compare the pre and post composite scores across all counties. Additionally, McNemar tests were performed to compare responses before and after March 11, 2020, for each of the 12 questions across all counties. Finally, McNemar tests were performed for questions 1, 7, 8, 9, and 10 for each of the bucketed counties. Significance was assessed at $P<.05$ for all tests.

Results: The Stuart-Maxwell test for marginal homogeneity was significant ($P<.001$), indicating that respondents were overall less likely to identify an unmet social need after the COVID-19 pandemic. McNemar tests for individual questions indicated that after the COVID-19 pandemic, respondents across all counties were less likely to identify unmet social needs related to food availability (odds ratio [OR]=0.4073, *P*<.001), home utilities (OR=0.4538, *P*<.001), housing (OR=0.7143, *P*<.001), safety among cohabitants (OR=0.6148, *P*<.001), safety in their residential location (OR=0.6172, *P*<.001), child care (OR=0.7410, *P*<0.01), health care access (OR=0.3895, *P*<.001), medication adherence (OR=0.5449, *P*<.001), health care adherence (OR=0.6378, *P*<.001), and health care literacy (0.8729, *P*=.02), and were also less likely to request help with these unmet needs (OR=0.7368, *P*<.001) compared with prepandemic responses. Responses from individual counties were consistent with the overall results for the most part. Notably, no individual county demonstrated a significant reduction in social needs relating to a lack of companionship.

Conclusions: Post-COVID-19 responses showed improvement across almost all social needs–related questions, indicating that the federal policy response possibly had a positive impact on social needs across the populations of Kansas and western Missouri. Some counties were impacted more than others and positive outcomes were not limited to urban counties. The availability of resources, safety net services, access to health care, and educational opportunities could play a role in this change. Future research should focus on improving survey response rates from rural counties to increase their sample size, and to evaluate other explanatory variables such as food pantry access, educational status, employment opportunities, and access to community resources. Government policies should be an area of focused research as they may affect the social needs and health of the individuals considered in this analysis.

Introduction

When people think of health care, facilities such as hospitals, primary care clinics, and other direct health care services typically come to mind. The direct services provided by health care professionals at these institutions are generally considered to constitute the health care system in its entirety. However, this is only one piece of the health care system. An individual's social needs outside of health care facilities also directly impact their health, and are important in understanding the causes of many health conditions and health disparities and in determining the actions society should take to improve overall health [1]. For example, obesity is influenced by the consumption of foods with poor nutritive value, a decrease in physical activity, and many other factors, which in turn lead to negative long-term health impacts [2,3].

One area of scientific research focuses on the neighborhood effect, which involves the interaction of social and environmental factors and how these interactions impact housing, crime, and violence [2]. The Robert Wood Johnson Foundation formed the Commission to Build a Healthier America, a nonpartisan group focused on improving public health outcomes for vulnerable populations, and released a report in 2014 comparing average life expectancy by county demonstrating wide variations in outcomes based on race/ethnicity, gender, income, and other factors [2,4]. A geospatial analysis showed that children with asthma residing in certain hotspot counties considered to be underserved have higher social vulnerabilities and are associated with longer hospital stay durations [5]. Another study found that social risk factors were associated with persistent functional disability caused by juvenile idiopathic arthritis [6].

Among the 105 counties in Kansas, United States, Wyandotte County is ranked 102nd according to county health rankings [7]. Wyandotte County residents are very diverse, with a distribution of 24.4% African American and 26.9% Latino [8]. Despite having one of the largest populations in the state (165,265 people), Wyandotte County is ranked among the lowest 25% of counties in Kansas regarding health outcomes and health factors [7]. Among adults, Wyandotte has a smoking rate of 20%, an obesity rate of 40%, a physical inactivity rate of 39%, and an uninsured rate of 17% compared to state averages of 17%, 36%, 26%, and 11%, respectively. Such vulnerable populations have been disproportionately impacted by the COVID-19 pandemic, creating the added burdens of stress and family challenges, both of which have impacted mental well-being [9].

The COVID-19 pandemic, declared by the World Health Organization on March 11, 2020, created challenges not only for the public health system but also for children and families suffering from housing and food insecurity [10]. COVID-19 had a different impact on each population group. For example, children experienced an increase in food insecurity due to the rising costs of food and reduced access to in-person school lunches [10]. In addition, people of color have experienced higher rates of COVID-19 infections, fatalities, and lower vaccination rates [11]. A lack of access to health care has been shown to cause food insecurity as health complications lead to or exacerbate the issue [12]. Lower-income households purchased shelf-stable processed foods and were more reliant on these types of foods than fresh food [13].

Income and education are other significant contributors to food insecurity, with lower-income families and those with lower educational attainment experiencing greater levels of insecurity [14]. Both income and education were also found to be major factors contributing to food security in Arkansas, which is one of the most food-insecure states in the United States [14]. Moreover, the COVID-19 pandemic exacerbated food insecurity for groups such as unemployed students [15,16].

During the first surge of the pandemic, an interview conducted with 20 nurses indicated that nearly every patient they were serving was a person of color, especially individuals of Hispanic ethnicity, who constituted a majority of the COVID-19 patients [17]. Many patients were suffering from untreated comorbidities, especially cases of diabetes and hypertension, that made patients more susceptible to the more serious outcomes associated with COVID-19 [17]. Some nurses also described cultural differences; for example, many Hispanic patients would not seek treatment when they began experiencing symptoms, and only sought medical attention when they became seriously ill at which time they were admitted directly to the intensive care unit (ICU) [17].

Differences in geographic location, income, education, and employment could explain a large amount of the disparity in vaccination coverage between Hispanic and white populations [18,19]. Models developed by Williams et al [20] indicated that health insurance in particular accounted for a 0.9 percentage-point disparity, and if the Hispanic population had a 13 percentage-point higher health insurance coverage to match that of white respondents, their predicted vaccination coverage would be an additional 1% higher. Their findings suggested that lack of insurance, unfamiliarity with the health care system, and not knowing that vaccines are provided free of charge may explain part of the vaccination coverage difference between these groups [20]. Compared with individuals identifying as white, minority groups such as Black, Asian, and Native American populations were more likely to have higher rates of ICU admissions, hospitalizations, and deaths when adjusted for age [21]. Research studies differ on the exact level of disparity; however, some minority groups experienced hospitalization rates that were nearly 9-times higher and infection rates that were 27-times higher than those of white individuals [21-23]. Based on data collected during the pandemic, life expectancy projections indicate that individuals of all races will experience a decreased life expectancy; however, Black and Latino individuals are expected to lose 2 and 3 years of life expectancy, respectively [24].

Social needs have a serious impact on a patient's access to care and vulnerability to the COVID-19 virus; this causes disparities in health outcomes between counties within the United States. Access to healthy food, health care services, and willingness to accept COVID-19 vaccines play a significant role in population health outcomes. To help minimize the impact of COVID-19, the United States implemented several policies. Moratoriums on evictions were implemented nationwide [25,26], meal plans for children and vulnerable populations were expanded [27], and stimulus funds were made available to nearly all citizens. These policies may have prevented many families from suffering dire consequences associated with business closures and COVID-19–related medical expenses. These programs aimed to help alleviate the elevated social needs issues across the nation.

Despite the vast amount of research aimed at examining the effects of COVID-19 on human health in the United States, very little research has been conducted to examine the outcomes associated with funds provided to households to combat food insecurity, the moratorium implemented to prevent evictions, and other federal policies on the population. This is an important gap in the literature that should be addressed as socials impacts could play an important role in directing federal policy during the next pandemic.

With this in mind, the research question we set out to address is whether there is a significant difference in social needs before and after the COVID-19 pandemic declaration. Additionally, we wanted to explore how the social needs of individuals compare across counties. A notable county of interest is Wyandotte County, Kansas. Compared to other counties in the Kansas City metropolitan area, Wyandotte has a high poverty rate of 16.9%, a large minority population, and a high crime rate [28,29]. Therefore, we expected Wyandotte County to be impacted the most by COVID-19 and the resulting polices. If we can better understand how COVID-19 policies and programs have impacted individuals' social needs, we will gain a better understanding of how to address social needs from both legislative and individual perspectives.

Our study thus aimed to illustrate the differences in social needs between populations living in the different counties throughout the state of Kansas and western Missouri. These counties represent a combination of rural and urban counties throughout the two states; however, our research focuses primarily on the regions of Johnson (Kansas), Jackson (Missouri), and Wyandotte (Kansas), since these jurisdictions are urban/suburban, are located near one another geographically, and are part of the same metropolitan area. The socioeconomic factors are also quite different among these jurisdictions, which may be a cause of disparities in patient responses and experiences.

Methods

Study Design

We used a survey developed at The University of Kansas Health System (TUKHS), which is a modified version of the validated social needs survey built from the Health Leads Toolkit [30]. The updates were specific to the separation of personal violence from community violence as those resources may differ [31]. The survey responses are used by the 12 social workers at TUKHS who aid patients who answer "yes" to any of the social needs questions. The data were retrieved from TUKHS informatics data warehouse HERON (aka. i2b2). The data set consists of patient demographic information along with the social needs responses. R studio with R version 4.1.2 was used to perform the descriptive and statistical analyses [32].

Ethical Considerations

The study protocol was approved by the Institutional Review Board at the University of Kansas Medical Center (STUDY00148041).

Data Sources

The primary data element utilized for this study was the patient-administered social needs survey, which is completed by patients during their primary care visit at TUKHS. The survey included 12 questions related to social needs, which are listed in Textbox 1.

Textbox 1. Items of the social needs survey.

Question 1: In the last 12 months, did you ever eat less than you should because there wasn't enough? (Food)

Question 2: In the last 12 months, has your utility company shut off your service for not paying your bill? (Utility)

Question 3: Are you worried that in the next 2 months, you may not have stable housing? (Housing)

Question 4: Are you afraid you might be hurt in your home by someone you know? (Safe home)

Question 5: Are you afraid you might be hurt in your apartment building or neighborhood? (Safe area)

Question 6: Do problems getting child care make it difficult for you to work or study? (Child care)

Question 7: In the last 12 months, have you needed to see a doctor, but could not because of cost? (Health care access)

Question 8: In the last 12 months, did you skip medications to save money? (Medication)

Question 9: In the last 12 months, have you ever had to go without health care? (Skip health care)

Question 10: Do you have problems understanding what is told to you about your medical conditions? (Health literacy)

Question 11: Do you often feel that you lack companionship? (Support)

Question 12: If you answered YES to any questions above, would you like to discuss help? (Need help in general)

Data (responses to the survey) were abstracted from the electronic medical record along with the zip code, city, and county of the patient on January 4, 2022. After deidentification of the patient information, data from patients not in Kansas or western Missouri were removed. This provided a longitudinal data set with 248,582 observations (820 from 2017, 47,877 from 2018, 58,376 from 2019, 74,618 from 2020, and 66,891 from 2021) representing the catchment area of TUKHS. In addition to the survey questions, 2020 county population estimates were obtained from the May 2021 Annual Resident Population Estimates of the US Census Bureau; population division area deprivation index by zip code was obtained from the 2019 release for both Kansas and Missouri, and 2013 Rural-Urban Continuum Code (RUCC) classifications were obtained from the update on December 10, 2020. RUCC codes 1, 2, and 3 were classified as urban, and codes 4, 5, 6, 7, 8, 9, and 10 were classified as rural [33,34].

Data Analysis

For the pre-post COVID-19 analysis, the longitudinal data set was subset down to a paired-response data set for 50,441 individuals who had at least one response before March 11, 2020, and at least one response after. If an individual had multiple responses before the pandemic declaration, the response closest to March 11, 2020, was kept, and if an individual had multiple responses after, the most recent response was kept (ie, that closest to January 4, 2022). A contingency table and bar chart were constructed to explore the data responses. An overall pre-post composite score was calculated by adding the responses coded as yes=1 and no=0 across the 12 questions. The 3M Social Determinants of Health (SDoH) score in combination with individual metrics has been used to model health care utilization within a population; SDoH scores were highly impactful in these models when compared to the other variables [35]. Recent studies have proposed a similar approach, referring to these composite scores as polysocial risk scores or health indices [36,37]. A comprehensive risk score helps with a holistic approach to conduct statistical evaluation, addressing outliers or patients with enormous social needs. For example, patients with multiple social conditions would have a higher composite score compared with that of patients under relatively minimal social conditions such as a lack of child support. The composite score allows researchers to evaluate the impact of risk scores on patients' health outcomes [37].

A Stuart-Maxwell marginal homogeneity test was run to compare the pre and post composite scores (relative to the pandemic announcement on March 11, 2020) across all counties. McNemar tests were then run to evaluate whether there is a statistically significant difference for each question when compared to paired pre-post responses across all counties. County-level McNemar tests were performed for questions 1, 7, 8, 9, and 10 for the county groupings of Cass (Missouri), Clay (Missouri), Jackson (Missouri), Johnson (Kansas), Leavenworth (Kansas), Platte (Missouri), Wyandotte (Kansas), and Other.

Results

The most recent responses were divided into a subset and the data set was visualized to determine the number of respondents per county. Figure 1 shows that the majority of patients in the data set reside in the immediate surrounding counties of TUKHS. The number of patients by county was then divided by their corresponding 2020 census county population estimate to determine the percentage of the county captured. Figure 2 shows that when adjusting for county populations, most of the respondents in the data set were still based in the immediate surrounding counties of TUKHS. Because of the low percentage of counties not immediately near TUKHS, we decided to classify the respondents into the counties of Cass, Clay, Jackson, Johnson, Leavenworth, Platte, Wyandotte, and Other, which created groupings with at least 1000 responses in each.

The yes/no counts by group for the most recent responses are provided in Table 1, showing that Wyandotte County consistently had a higher proportion of "yes" responses when compared to the other counties. Table 1 also shows that the proportion of "yes" response was below 6% for the most recent responses, demonstrating the rarity of this response. The county buckets of Cass, Clay, Jackson, Johnson, Leavenworth, and Platte all had a "yes" response rate below 4%.

The Stuart-Maxwell test showed a significant (*P*<.001) difference in the composite scores between the pre and post responses. Unadjusted *P* values of the McNemar test for each of the questions across all counties showed significance at an α level of .05 for all the questions except question 11 (Support). However, it should be noted that statistical significance does not necessarily mean that a meaningful difference exists given the rarity in the event of a respondent answering "yes." This scenario is particularly apparent for questions 2 (Utility), 3 (Housing), 4 (Safe home), 5 (Safe area), and 6 (Child care). Therefore, questions 1 (Food), 7 (Health care access), 8 (Medication), 9 (Skip health care), and 12 (Need help in general) are the notable questions to consider further (Table 2).

Notable results from the county-level McNemar tests were related to questions 1, 7, 8, and 9 from Wyandotte County, which had a relatively high percentage of respondents who answered "yes" in the pre-COVID-19 category and subsequently answered "no" in the post-COVID-19 category. The unadjusted *P* values from the McNemar test were significant for these questions. When looking at the McNemar test results by county, significant reductions in respondents answering "yes" for question 1 were found in Clay, Jackson, Johnson, Wyandotte, and Other counties. Significant reductions in respondents answering "yes" for question 7 were found in Cass, Clay, Jackson, Johnson, Platte, Wyandotte, and Other counties. Significant reductions in respondents answering "yes" for question 8 were found in Cass, Clay, Jackson, Johnson, Platte, Wyandotte, and Other counties. Significant reductions in respondents answering "yes" for question 9 were found in Jackson, Johnson, and Wyandotte. Finally, no county buckets demonstrated a significant change in the response to question 10 (Table 2).

Discussion

Principal Findings

An interesting takeaway from the pre-post COVID-19 comparison is that the post-COVID-19 responses across the questions showed an improvement in social needs. Less respondents answered “yes” to the social needs questions in the post-COVID-19 survey period. At this point, we can only speculate on the reasons for this improvement. One possibility is that this was due to the government policies issued during the pandemic [38]. Across society, changes were made regarding economic relief, food availability, and the ability to evict tenants; thus, it is possible that these changes are directly impacting individuals’ social needs [39,40]. This trend was maintained when breaking down the analysis to the county level, notably in Wyandotte County. Based on the results, it is possible that Wyandotte County was affected by COVID-19 differently than Johnson County or Jackson County. It certainly appears that some of the responses to the social needs survey improved in the post-COVID-19 period to the greatest extent in Wyandotte County. Further investigation should be performed with respect to Wyandotte County to try and explain this observation. When looking at the most recent responses, Wyandotte County ranked higher in the proportion of “yes” responses to all questions except questions 4 and 11, and differences in outcomes were also significant when comparing all counties in the analysis.

Among the counties examined in this analysis, Johnson County and Jackson County have the two largest populations; however, Johnson County had the lowest affirmative response rate for nearly every question, while Jackson County had an affirmative response rate second only to that of Wyandotte County. This suggests that a county’s population is not proportional to the resources available for its residents to weather a pandemic-related storm and that large communities may have worse social needs outcomes than smaller communities. Similarly, both Johnson County and Jackson County are urban communities and yet their outcomes are strikingly different, suggesting that the urban/suburban population density may not be a factor in the social needs for a given population. The primary difference may lie in the socioeconomic factors associated with the various counties. Johnson County is a more socially affluent community with respect to nearly all metrics, with low unemployment rates, a strong social safety net, and good access to health care and educational opportunities. These factors should be considered in future research.

As observed in this study, the usage and expansion of assistance programs may lead to a reduction in social needs issues. Across the state of Kansas and in western Missouri, we found improvements in TUKHS survey responses after COVID-19 policies had been implemented. When broken down by county, it became clear that these programs impacted each county differently. As a society, we must better utilize assistance programs and policies that are in place and understand the different and unique needs of our diverse populations. Health and social workers should be well versed and keep their patients informed on programs that they are eligible for. These programs are not useful without public knowledge of their existence.

Limitations

This study has several important limitations that should be considered when implementing policy recommendations and determining future research. First, the data are limited only to patients of TUKHS, located in the Kansas City Metropolitan Statistical Area. Over 98% of the unique responses were from individuals residing in counties that are part of the metropolitan area and this population may not be representative of other counties within the states of Kansas or Missouri. Due to socioeconomic conditions prevalent in rural areas, such as high rates of poverty, unemployment, and lack of social services, patients located in these counties may not see similar rates of improvements in social needs following the COVID-19 pandemic declaration.

Second, due to the large sample size and unadjusted *P* values, even small differences in outcomes will be statistically significant, but these results are not necessarily practically significant. A determination should be made as to what level of improvement is considered *practically* significant before policy recommendations can be made using this analysis. In addition, the sample size is much smaller for rural counties (<2% of responses), which could skew the results, and larger sampling would potentially correct for the rural-urban disparity.

Third, the data set does not include uninsured patients. Although we do not have data on household income for the individuals that responded to this survey, the presence of insurance could be used as a proxy variable, whereas those with insurance have higher incomes than those who do not. Because this study only considered those with insurance, we can presume that these individuals are less likely to answer "yes" to the questions presented in the survey, which could underrepresent the baseline scores as well as the level of improvement.

Moreover, the economic and societal hardships brought about by COVID-19 could have changed public perceptions of social needs. What was once considered an issue before the pandemic may not have been considered an issue after. Perhaps a societal shift in the perception or willingness to share social needs accounts for our findings. Patients may be less likely to disclose their social needs to health care professionals now that they have seen the government willingly address them. Perhaps the social needs survey was distributed with less importance during the pandemic as COVID-19 screening surveys took priority during patient visits. Survey responses are a subjective measurement that can be impacted by self-reported biases, as each respondent has different thoughts, behaviors, and feelings in the context of social needs. Some of their social needs could be relative to their perception based on past encounters.

Due to the limitations of the data and disparities in the patient population, the generalizability of this study may be limited to populations in urban and suburban areas. However, despite the small sample size, significant differences were found when aggregate patient responses from rural counties were compared to the urban counties, and previous research on rural poverty and lack of health care in these areas suggest a larger sample will not likely change the results [41]. By contrast, additional data from rural patients may increase the disparity in these populations and confirm the differences we identified.

Policy Implications and Future Research

Further research should focus on certain counties, particularly those in rural areas to increase the number of patients from these areas. Since education has been identified as an important indicator of poverty and income, exploring educational programs in poor-performing counties could improve outcomes. Social workers and navigators play an important role in helping individuals access food pantries, educational opportunities, employment, and other resources that influence these outcomes; thus, further study should be directed toward outcomes associated with interactions that reduce barriers to care, and unit-level acuity metrics should be evaluated and reviewed frequently to understand the correlation between health outcomes and patient success rates in accessing these resources [42].

Finally, unlike the responses to many viruses that have spread throughout the world in recent decades, the United States took unprecedented steps to not only curtail the spread of COVID-19 but also to minimize the economic impact on the country and ensure the financial well-being of its people. Although it is unclear whether the country would implement similar policies in the event of a future pandemic, the impact of these policies should be thoroughly analyzed in the context of social needs outcomes, as they could be a significant reason why many individuals are not experiencing severe negative impacts.

Acknowledgments

We would like to extend our gratitude to Matthew S Mayo and Byron Gajewski for their constructive feedback on the manuscript.

Data Availability

Detailed data cannot be shared publicly to protect the privacy of individual participants. Information to support the findings of these analyses can be made available by contacting the corresponding author, who, upon reasonable request and understanding of the intended use of the data, will provide the requested information in a manner that continues to protect individual patient information.

Conflicts of Interest

None declared.

Abstract

Background: Mobility restriction was one of the primary measures used to restrain the spread of COVID-19 globally. Governments implemented and relaxed various mobility restriction measures in the absence of evidence for almost 3 years, which caused severe adverse outcomes in terms of health, society, and economy.

Objective: This study aimed to quantify the impact of mobility reduction on COVID-19 transmission according to mobility distance, location, and demographic factors in order to identify hotspots of transmission and guide public health policies.

Methods: Large volumes of anonymized aggregated mobile phone position data between January 1 and February 24, 2020, were collected for 9 megacities in the Greater Bay Area, China. A generalized linear model (GLM) was established to test the association between mobility volume (number of trips) and COVID-19 transmission. Subgroup analysis was also performed for sex, age, travel location, and travel distance. Statistical interaction terms were included in a variety of models that express different relations between involved variables.

Results: The GLM analysis demonstrated a significant association between the COVID-19 growth rate ratio (GR) and mobility volume. A stratification analysis revealed a higher effect of mobility volume on the COVID-19 GR among people aged 50-59 years (GR decrease of 13.17% per 10% reduction in mobility volume; *P*<.001) than among other age groups (GR decreases of 7.80%, 10.43%, 7.48%, 8.01%, and 10.43% for those aged ≤18, 19-29, 30-39, 40-49, and ≥60 years, respectively; *P*=.02 for the interaction). The impact of mobility reduction on COVID-19 transmission was higher for transit stations and shopping areas (instantaneous reproduction number [R_t] decreases of 0.67 and 0.53 per 10% reduction in mobility volume, respectively) than for workplaces, schools, recreation areas, and other locations (R_t decreases of 0.30, 0.37, 0.44, and 0.32, respectively; *P*=.02 for the interaction). The association between mobility volume reduction and COVID-19 transmission was lower with decreasing mobility distance as there was a significant interaction between mobility volume and mobility distance with regard to R_t (*P*<.001

for the interaction). Specifically, the percentage decreases in R_t per 10% reduction in mobility volume were 11.97% when mobility distance increased by 10% (Spring Festival), 6.74% when mobility distance remained unchanged, and 1.52% when mobility distance declined by 10%.

Conclusions: The association between mobility reduction and COVID-19 transmission significantly varied according to mobility distance, location, and age. The substantially higher impact of mobility volume on COVID-19 transmission for longer travel distance, certain age groups, and specific travel locations highlights the potential to optimize the effectiveness of mobility restriction strategies. The results from our study demonstrate the power of having a mobility network using mobile phone data for surveillance that can monitor movement at a detailed level to measure the potential impacts of future pandemics.

Introduction

Background

The COVID-19 pandemic had led to over 630 million infections and 6 million deaths worldwide by November 2022 [1]. Human mobility is critical to the transmission of airborne diseases. Reduction in human mobility was considered as one of the main tools to suppress and mitigate the pandemic, and has been applied widely and even repeatedly in multiple waves globally [2]. However, frequent mobility restrictions globally have caused unprecedented public health, social, and economic challenges. For example, mobility reduction was associated with indirect health outcomes, such as increased cerebrovascular excess deaths [3] and increased mental health issues [4]. Substantial economic and social burdens of lockdown measures were reflected in regions with different financial capacities [5]. The vaccine program may fail to help reach herd immunity, and easing mobility restrictions should be carefully considered against the risk of new outbreaks [6]. When variants with higher transmissibility circulate globally, mobility restriction could be one of the primary tools to control the pandemic. Therefore, it is important to determine how to optimize such mobility restriction measures to balance the indirect adverse outcomes in the society and economy, and the benefits of controlling transmission risk for COVID-19.

In almost 3 years of the COVID-19 pandemic, unprecedented efforts have been made to explore the association between human mobility and COVID-19 transmission [7]. Mobile-based mobility data can be used to assess mobility reduction and the effectiveness of social distancing for mitigating disease spread [8,9]. Most studies used mobility volume (ie, number of trips) for investigating the impact of mobility restriction policies on the transmission of COVID-19, but the correlation between reductions in mobility volume and COVID-19 transmission became weaker and even disappeared in the middle stage of the pandemic according to 2 studies in the United States [10,11]. Another study using the data of 52 countries indicated that the association between mobility volume and the reproduction number R changed over time [12]. After public health interventions were relaxed, the association between mobility and COVID-19 transmission decoupled in most countries. More detailed research is needed to better understand such a relation. Very few studies have explored the association between mobility distance and COVID-19 transmission [13], and it is unclear whether the weaker impact of mobility volume was influenced by a disproportional change in mobility distance. COVID-19 is known to exhibit age-related severity, and exposure rates are strongly dependent on age [14]. Similar mobility reductions among <18, 18-64, and ≥65 years age groups were reported in France [15], but it is unclear whether such reductions in various age groups have similar effects on COVID-19 transmission. Governments around the world have different policies for implementing and easing social distancing measures in various locations in the absence of evidence. These locations may have different transmission risks and social benefits [16]. It is critical to differentiate the impact of mobility reduction for various locations when making decisions to shut down specific locations. The impact of mobility reduction on COVID-19 transmission according to travel distance, location, and demographic factors is of great importance for understanding mobility restriction policies, but it has been poorly explored.

Objectives

In this study, we integrated anonymized geolocalized mobile phone data with census and demographic data in the Greater Bay Area of China. We aimed to analyze the impact of mobility reduction on COVID-19 transmission according to travel distance (long and short), location (workplaces, schools, recreation areas, shopping areas, transit stations, and other areas), age (≤18, 19-29, 30-39, 40-49, 50-59, and ≥60 years), and sex. The coverage rate of mobile phone use among the population aged 15-65 years was almost 100% [17]. This analysis could provide evidence to optimize mobility restriction policies for balancing the adverse outcomes of mobility reduction and the benefits of limiting community transmission of COVID-19.

Methods

Data Source

Mobility Data From the Greater Bay Area, China

Large volumes of anonymized aggregated mobile phone position data between January 1 and February 24, 2020, were collected for the 9 megacities of Guangzhou, Shenzhen, Foshan, Huizhou, Dongguan, Zhongshan, Zhaoqing, Zhuhai, and Jiangmen in Guangdong-Hong Kong-Macao Greater Bay Area, China. The Greater Bay Area is the most populated and largest urban area, and is 1 of the 4 largest bay areas in the world. Mobile phone data were provided by 1 of the 3 leading mobile phone service providers. Origin-destination matrices were constructed by computing the number of people that move between different locations on an hourly basis, as done previously [18]. The mobility volume was calculated as the number of trips between various locations. The mobility distance was determined by calculating the great circle distance between movement origins and destinations [19]. Aggregated sex- and age-specific daily mobility volumes were also obtained. Daily mobility volumes to various destinations (eg, workplaces, schools, recreation areas, shopping areas, transit stations, and other areas) were calculated by integrating the origin-destination matrices with the land use type of the trip destination (Table S1 in Multimedia Appendix 1). Official estimates of the total, sex-specific, and age-specific populations in the Greater Bay Area were retrieved from relevant government websites [20].

COVID-19 Transmission Data

Daily incidences of COVID-19 were obtained from official governmental reports in the Greater Bay Area, China [21]. Data on country-level estimates of the instantaneous reproduction number (R_t) were obtained from the EpiForecasts project by the London School of Hygiene & Tropical Medicine (London, UK) [22], which was calculated based on the daily number of COVID-19 infections by the European Centre for Disease Prevention and Control. The timings and details for public health interventions were taken as published on relevant government websites in the Greater Bay Area, China [23].

Ethics Approval

We used anonymized and aggregated mobile phone data at the population level without individual travel patterns for strict protection of personal privacy. All data were obtained in an anonymous format without personal identifying information. This study was approved by the Institutional Review Board of Shenzhen University, China (review number PN-202300030).

Statistical Analysis

The growth rate ratio (GR) of COVID-19 was computed as the average number of new cases per day over the previous 3 days to that over the previous 7 days. The static correlation and dynamic correlation between the GR and mobility volume were determined by Pearson correlation and rolling correlation. We tested the different day lags between the GR and mobility in the correlation analysis, as there may be a time lag between reported cases and true community infections. A generalized linear model (GLM) was established to test the association between mobility volume and COVID-19 transmission. Subgroup analysis was also performed for sex, age, travel location, and travel distance. The statistical interaction terms were included in a variety of models that express different relations between the involved variables. The R_t in Shenzhen by time for real transmission was estimated according to the likelihood-based estimation method [24].

An interaction analysis was performed by including the interaction terms of mobility volume ratio (VR) and distance ratio (DR) in the GLM analysis to determine whether the impact of mobility volume on COVID-19 transmission differs by mobility distance in the Greater Bay Area, China. The VR and DR were defined for each day (t), which quantified the change in mobility patterns and were similar to previous studies [25]. The baseline dates for the VR and DR were the normal days in 2020, which are here defined as the days before *Chunyun* (Spring Festival; January 1-10, 2020; Multimedia Appendix 1) for the Greater Bay Area, China. The VR is the sum of the total trips between various locations on a given day divided by the same measure on the baseline day, which reflects the change in the number of individual trips made to each area per day. VR_{it} was calculated as follows:

where V_{ij}^t represents the number of trips between areas i and j on day t, and t_0 represents the baseline measure. Using this function, VR values of 0, 0.5, and 1.0 indicate no trips, half the number of trips relative to baseline, and no change compared with baseline, respectively.

The DR represents the change in the distance of individual trips made to each area per day, relative to ordinary behavioral patterns (ie, before COVID-19), which was calculated as follows:

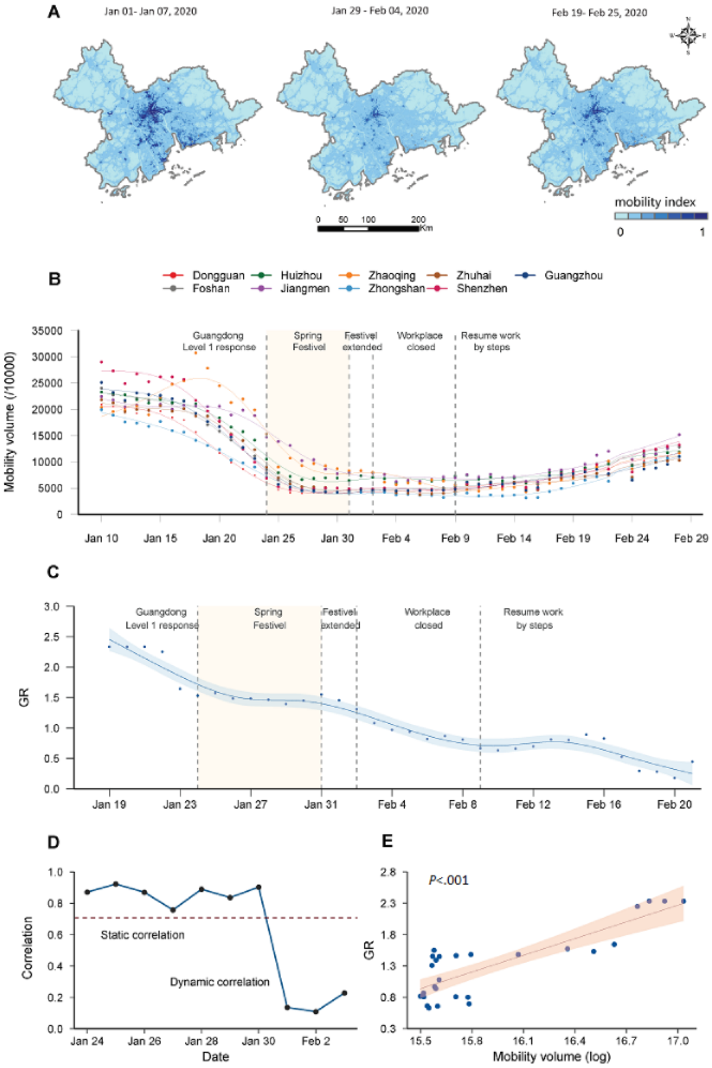
where D_{ij}^t represents the distance of trips between areas i and j on day t, and t_0 represents the baseline measure. DR values of 0, 0.5, and 1.0 indicate no trips, half of the mobility distance at baseline, and no change compared with baseline, respectively. Any value above 1 indicates that the mobility distance increased from baseline. The R_t ratio was defined as the R_t on a given day compared to the first R_t at the beginning of the study. ANOVA was used to evaluate the model with and without the interaction term. All statistical analyses were performed using R version 3.6.3 (R Foundation for Statistical Computing).

Results

The Effect of Mobility Volume on COVID-19 Transmission

The public health interventions in the Greater Bay Area, China during the study period are illustrated in Multimedia Appendix 2. The population mobility volume decreased by approximately 75%-85% and then was maintained at such a substantially low level for approximately 2 weeks in January 2020 in the Greater Bay Area, China (Figure 1A and 1B). The GR gradually decreased from 2.33 on January 19, 2020, to below 0.50 on February 20, 2020 (Figure 1C). The static correlation between the GR and mobility volume was 0.71 (*P*<.001; Figure 1D), considering the time lag of 2 days representing the highest correlation between the GR and mobility volume (Multimedia Appendix 3). The rolling correlation coefficients were >0.75 from January 24, 2020, to January 31, 2020 (all *P*<.01) but declined in February 2020. The GLM analysis demonstrated a significant association between the GR and mobility volume, with a 7.56% decrease in the GR per 10% reduction in mobility volume (95% CI 6.13%-9.00%; *P*<.001; Figure 1E).

Figure 1. Relationship between mobility volume and the GR in the Greater Bay Area, China. (A) Average mobility volume based on the mobile phone position data from January to February 2020 in the Greater Bay Area, China. (B) The change in mobility volume for 9 cities from January to February 2020 (the dots represent the observed data, and the plotted lines are smoothed by a generalized additive model). (C) The GR of COVID-19 from January to February 2020 (the line represents GLM fit to the data, and the shadow represents the 95% CI). (D) Correlation between mobility volume and the GR. (E) Association between mobility volume and the GR (the line represents GLM fit to the data, and the shadow represents the 95% CI). The dashed lines represent the main public health interventions. GLM: generalized linear model; GR: growth rate ratio.

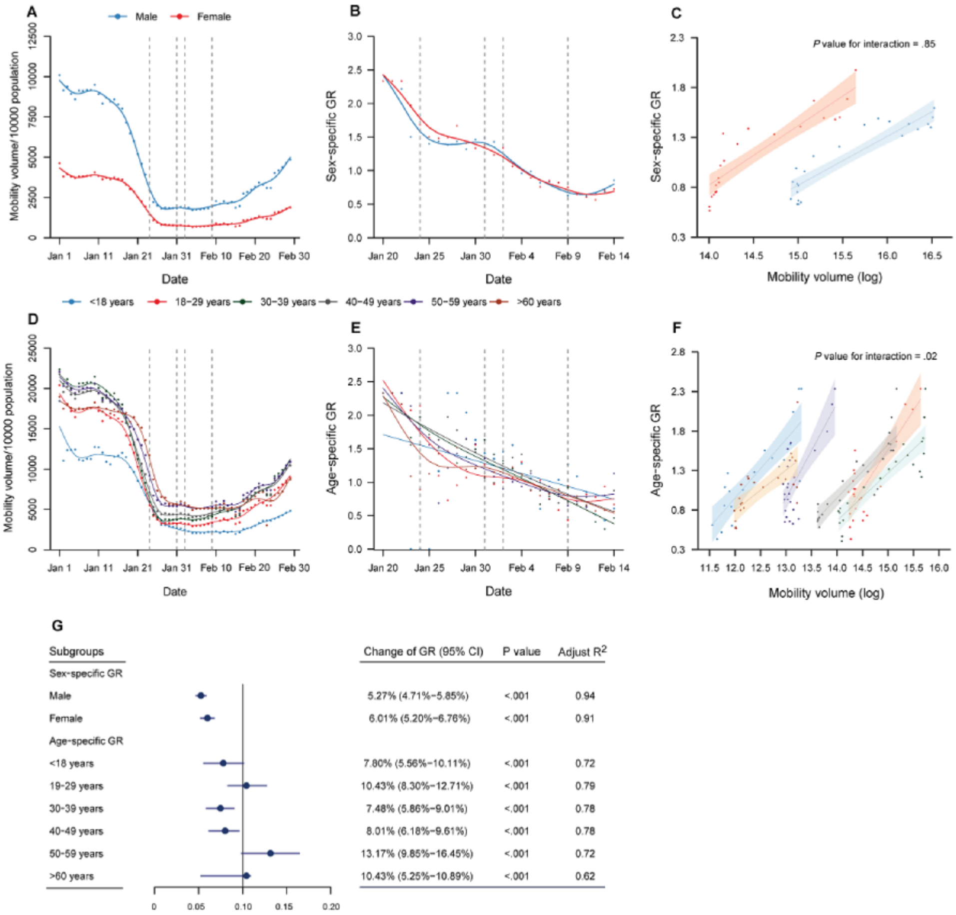


Demographic Disparities in the Impact of a Reduction in Mobility Volume on COVID-19 Transmission

We next investigated the impact of a reduction in mobility volume on COVID-19 transmission in various subgroups of sex and age. Although the mobility volume for females was less than that for males before, during, and after the COVID-19 pandemic (Figure 2A), a similar magnitude of decrease was observed (77.4% for females and 77.8% for males during the pandemic; Multimedia Appendix 4). The sex-specific GR declined with similar trends for both sexes (Figure 2B). The slopes of the association between the sex-specific mobility volume and sex-specific GR (Figure 2C and 2G) were similar in the GLM analysis for females and males.

Among different age groups, those aged 50-59 and ≥60 years exhibited the lowest levels of reduction in mobility volume of 72.9% and 67.0%, respectively, during the pandemic. The percentage reductions in mobility volume were 78.1%, 81.5%, 81.4%, and 77.7% for those aged ≤18, 19-29, 30-39, and 40-49 years, respectively (Figure 2D; Multimedia Appendix 4). The slopes of the association between the age-specific mobility volume and age-specific GR were significantly different among various age groups. The percentage decreases in the GR per 10% reduction in mobility volume were 7.80% for those aged ≤18 years (*P*<.001), 10.43% for those aged 19-29 years (*P*<.001), 7.48% for those aged 30-39 years (*P*<.001), 8.01% for those aged 40-49 years (*P*<.001), 13.17% for those aged 50-59 years (*P*<.001), and 10.43% for those aged ≥60 years (*P*<.001) (*P*=.02 for the interaction) (Figure 2F and 2G). The age group of 50-59 years had the highest slope in the GLM analysis for the age-specific GR and age-specific mobility volume.

Figure 2. Relationship between mobility volume and the GR by sex and age. (A) Time series of the daily average mobility volume and (B) the sex-specific GR for males and females. The dots represent the raw data, while the plotted lines are smoothed by a generalized additive model. (C) Relationship between the sex-specific GR and sex-specific mobility volume. The line represents GLM fit to the data, and the shadow represents the 95% CI. (D) Time series of the daily average mobility volume and (E) the age-specific GR for various age groups. The dots represent the raw data, while the plotted lines are smoothed by a generalized additive model. (F) Relationship between the age-specific GR and age-specific mobility volume. The line represents GLM fit to the data, and the shadow represents the 95% CI. The dashed lines represent the main public health interventions. (G) The change in the demographic-specific GR per 10% reduction in mobility volume. GLM: generalized linear model; GR: growth rate ratio.

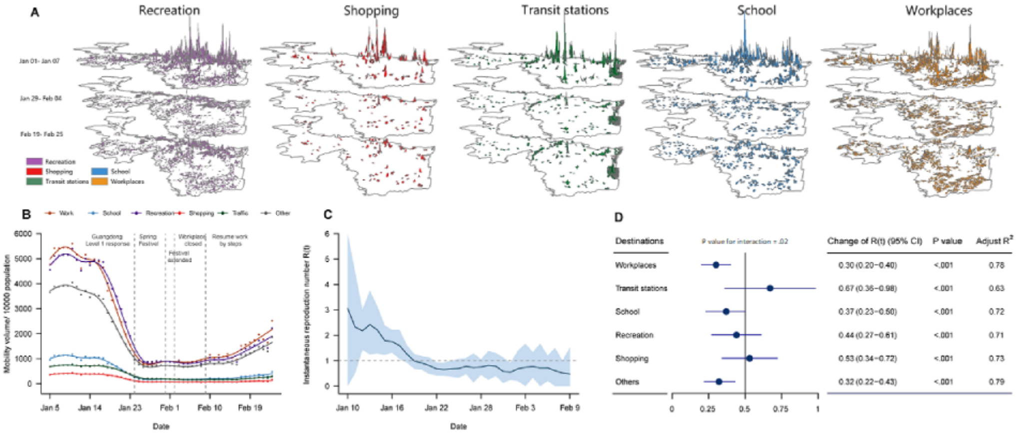


Subgroups	Change of GR (95% CI)	P value	Adjust R^2
Sex-specific GR			
Male	5.27% (4.71%–5.85%)	<.001	0.94
Female	6.01% (5.20%–6.76%)	<.001	0.91
Age-specific GR			
<18 years	7.80% (5.56%–10.11%)	<.001	0.72
19-29 years	10.43% (8.30%–12.71%)	<.001	0.79
30-39 years	7.48% (5.86%–9.01%)	<.001	0.78
40-49 years	8.01% (6.18%–9.61%)	<.001	0.78
50-59 years	13.17% (9.85%–16.45%)	<.001	0.72
>60 years	10.43% (5.25%–10.89%)	<.001	0.62

Location Disparities in the Impact of a Reduction in Mobility Volume on COVID-19 Transmission

The distribution of mobility volume at 6 types of locations at different time periods in the city of Shenzhen (one of the Greater Bay Area cities) is illustrated in Figure 3A. The mobility volume for workplaces was notably higher than other locations. The mobility volume at the 6 types of locations had declined during the pandemic, with average reductions of 83.8% for workplaces, 75.1% for transit stations, 83.5% for shopping areas, 82.9% for recreation areas, 83.7% for schools, and 81.8% for other locations (Figure 3B). The impact of mobility volume on the R_t was higher for the locations of transit stations and shopping areas, with the highest slope in the GLM analysis. The decreases in the R_t per 10% reduction in mobility volume were 0.67 for transit stations (*P*<.001), 0.53 for shopping areas (*P*<.001), 0.30 for workplaces (*P*<.001), 0.37 for schools (*P*<.001), 0.44 for recreation areas (*P*<.001), and 0.32 for other locations (*P*<.001) (*P*=.02 for the interaction; Figure 3D).

Figure 3. Relationship between mobility volume and COVID-19 transmission by various destinations. (A) The distribution of mobility volume for various destinations in the city of Shenzhen at different time periods in the Greater Bay Area, China (the peak of 3D bars represents the mobility volume in the given period), and (B) the time series of mobility volume at these destinations. (C) Time series of the instantaneous reproduction number (Rt) in Shenzhen. The shadow represents the 95% CI. (D) The change in the Rt per 10% reduction in mobility volume for a certain destination. Adjusted R^2 represents the goodness of fit for the models.

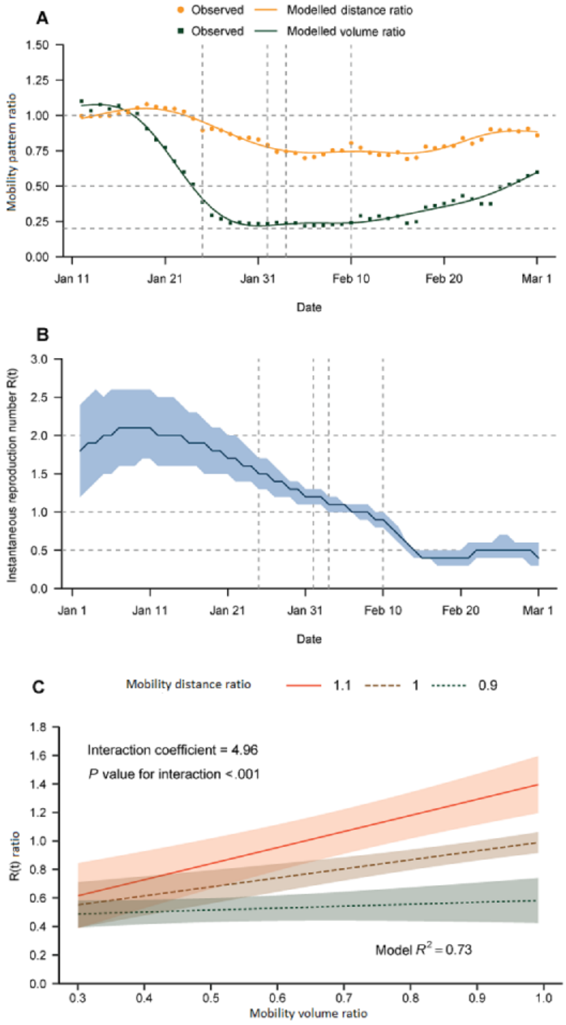


Mobility Distance Disparities in the Impact of a Reduction in Mobility Volume on COVID-19 Transmission

The change in mobility volume occurred earlier and was greater than the change in distance during the pandemic in the Greater Bay Area, China (Figure 4A). The population mobility volume had an average reduction of 76.1% in February compared with the baseline period of 2020 in the Greater Bay Area, China, and the mobility distance declined by an average of 18.6% (Figure 4A). The R_t had reduced to <1 by February 8, 2020, in China (Figure 4B). Exploratory analyses showed statistical evidence of an interaction between the VR and DR for the COVID-19 R_t ratio. In the analysis of Chinese cities, the impact of a reduction in mobility volume on the R_t was lower with a decreasing mobility distance. The percentage decreases in the R_t per 10% reduction in mobility volume were 11.97% when the average mobility distance increased by 10% compared with the baseline period, such as in the *Chunyun* period when people travelled longer distances in the Spring Festival (*P*<.001), 6.74% when the average mobility distance remained unchanged (*P*<.001), and 1.52% when the distance declined by 10% (*P*<.001) (*P*<.001 for the interaction; Figure 4C).

ANOVA showed that removing the interaction did significantly affect the fit of the model (*P*<.001). The R^2 for the model without an interaction was 0.65, which was lower than that for the model with an interaction (0.73 in the China model), increasing the variance of the dependent variable explained by the predictors. Finally, we validated the mobile phone mobility data for the Greater Bay Area, China by comparing it to Baidu mobility data for the whole country [26]. Here, the trend of mobility volume reduction was quite similar to the change in the mobility index from the Baidu Qianxi map (Multimedia Appendix 5).

Figure 4. Relationship between mobility volume and COVID-19 transmission by mobility distance. (A) Time series of the VR and DR in the Greater Bay Area, China. The dots represent the observed data, and the plotted lines are smoothed by a generalized additive model. (B) Time series of the instantaneous reproduction number (Rt) in the Greater Bay Area, China. The shadow represents the 95% CI. (C) Relationship between the VR and Rt ratio by different DRs in the Greater Bay Area, China. The line represents GLM fit to the data, and the shadow represents the 95% CI. DR: distance ratio; GLM: generalized linear model; VR: volume ratio.



Discussion

Principal Findings

In this study, we found that the impact of reductions in human mobility on COVID-19 transmission significantly varied by travel distance, location, and age. There was a significant positive interaction between mobility volume and mobility distance regarding COVID-19 transmission, with steeper slopes for the association (larger coefficient in the regression analysis) between mobility volume and COVID-19 transmission with increasing mobility distance. We found a significantly steeper slope for the association between the reduction in mobility volume and COVID-19 transmission among persons aged 50-59 years than among other age groups. Furthermore, the slope for the association was steeper for the locations of transit stations and shopping areas, compared with workplaces, schools, recreation areas, and other locations.

Our study indicated that the introduction of mobility restrictions in the Greater Bay Area, China led to a marked decrease in COVID-19 transmissibility. The time lag between mobility reduction and decline in the GR was estimated as 2 days at the very beginning of the pandemic in this area, which is shorter than the time of around 2 weeks in a similar study in the United States reported by Badr et al [11]. Our study also showed that the R_t in Shenzhen City, one of the megacities in this area, had declined from >3 to <1 within around 2 weeks, which means that the public health interventions in this area worked very fast. Therefore, the shorter time lag of 2 days between mobility reduction and change in the GR may be possible in the Greater Bay Area, China. The reduction in mobility volume with longer travel distances was associated with a greater reduction in COVID-19 transmission than shorter travel distances in our study. The decreasing correlations of mobility volume with COVID-19 transmission observed in our study were consistent with previous studies in the United States. Badr et al [11] found a strong correlation between mobility volume and COVID-19 case growth rates in the early stage of March to April 2020, but a strong linear association was absent after April 2020. Gatalo et al [10] also identified a strong correlation between March 27, 2020, and April 20, 2020, and only a weak correlation at later time periods (April 21, 2020, to May 24, 2020). The significant positive interaction between mobility volume and distance may provide a possible explanation for the time-driven relationship between mobility volume and COVID-19 transmission. The changes in mobility distance and volume are not necessarily synchronized. Our study indicated that there is an interaction, and changes in moving distance may affect the impact of mobility volume on COVID-19 transmission. This provides evidence for stricter restrictions in long-distance travel for better control of COVID-19 transmission. However, the different start times and levels of reduction in mobility volume and distance during the pandemic need to be further explored.

The mobility reduction was associated with a greater reduction in the GR for the age group of 50-59 years than the other age groups in our study. The slope of the association between mobility volume and the GR for those aged 50-59 years was steeper than that for the other age groups. Those aged 50-59 years showed lower mobility reduction than those aged ≤49 years, but were vulnerable to COVID-19 infection with a higher proportion of underlying chronic diseases compared with young people [27]. Those aged 50-59 years faced a higher risk of exposure to SARS-CoV-2 with more traveling for occupational and behavioral reasons compared with those aged ≥60 years [28]. These factors may provide possible explanations for the finding that most infections of COVID-19 in the initial wave in China were among those aged 50-59 years (22.4%) [29]. The highest proportion of COVID-19 cases was also among those aged 50-59 years during the initial wave from January to May 2020, but shifted toward younger people from June to August 2020 in the United States [30]. A similar age shift was observed in Europe, with the median age of patients with COVID-19 declining from 54 years at the beginning to 39 years in the later time periods [31]. Whether such an age shift is associated with a change in the mobility pattern for various age groups at the different stages of the pandemic needs further exploration. In addition, our data suggested that the declined magnitude of mobility volume and the effect of mobility volume on COVID-19 transmission were quite similar for both males and females, which is consistent with the conclusion of no sex variation for COVID-19 infections in China [32].

The mobility reduction for transit stations and shopping centers was associated with a greater reduction in COVID-19 transmission in the whole city compared with the findings for workplaces, schools, and recreation areas. The slopes for the association between mobility to transit stations and shopping centers and the R_t were steeper than the slopes for the association involving other locations. These high-contact environments are more crowded and therefore have a higher risk. However, the mobility reduction for transit stations was less than that for other locations. Many governments applied various policies for mobility restriction at specific locations, since there was not enough evidence available regarding which locations should be closed or which locations should remain open. Our study provides evidence that controlling mobility to a small number of locations could reduce transmission in the entire city. Therefore, location-specific mobility restrictions should be taken into consideration for precise interventions and reopening strategies with substantially lower economic costs [33].

Strengths and Limitations

Our results have public health and policy implications. First, we analyzed the relationship between mobility responses and COVID-19 transmission using mobility data of only a certain travel destination, travel distance, or demographic subgroup (age and sex groups) to gain more insightful knowledge. Our study provides evidence to identify hotspots of transmission and guide policy interventions for specific age groups or mobility patterns associated with higher risks of mobility-related COVID-19 transmission. Second, mobile phone data at fine spatial and temporal resolutions provide strong added value for explaining variations in COVID-19 transmission. The results from our study demonstrate the power of having mobility networks using mobile phone data that monitor movement at a detailed level across cities to measure the potential impacts of public health events. The network can be regularly updated and used to identify populations and travel characteristics at risk of adverse impacts during future pandemics or other crises. It is also suggested to set up a national mobility network that captures human mobility habits, which can form the basis for longitudinal studies.

It is important to note that our study has several limitations. First, we illustrated the detailed structural change in mobility patterns using mobile phone data from users in the Greater Bay Area, China, and these patterns may not be fully representative of other locations in China. However, the mobility change in the Greater Bay Area based on the mobile phone was quite similar to the change in the Baidu mobility index for the whole country, owing to nationally unified public health interventions. We believe that this analysis for the Greater Bay Area is an intuitive and representative estimate of the structural change in mobility patterns in China, but future extension of this analysis for the whole country should be further explored. Second, we focused on quantifying the relationship between mobility patterns and COVID-19 transmission; there is extensive evidence indicating that population-wide social distancing and other potential mitigating factors (eg, wearing face masks and washing hands) all contribute to achieving control of the COVID-19 pandemic [34,35]. Further studies are needed to evaluate the synergistic effect of other public health interventions along with mobility change in the environment confounded by climate, urban space, and other potential factors [36]. Third, our mobility estimates may also be biased toward the populations included in the mobile phone data, as the consumer location history feature is only available for smartphone users (young infants or very old people may be excluded from the data). However, despite these limitations, our fine-grained study facilitates a step toward using multiple data sets to capture population-level mobility patterns and provides important insights into the complex effects of mobility reduction for policymakers and future research.

Conclusions

The COVID-19 pandemic was the first time in human history that human mobility showed a large-scale decline after mobility restrictions to prevent and control the infectious disease. Our study demonstrated that the impact of reductions in human mobility on COVID-19 transmission was significantly modified by travel distance, travel location, and age. The higher impact of mobility reduction on COVID-19 transmission for longer distances, certain age groups, and specific locations highlights the potential to optimize mobility restriction policies to balance adverse health, society, and economic outcomes and the benefits of controlling the spread of COVID-19. It is of great significance to understand the impact of mobility reduction on the spread of infectious diseases in detail, and it provides evidence for the prevention and control of future pandemics.

Acknowledgments

We thank Mr Renzhe Xu for helpful suggestions, and Mr Juecheng Li and Ms Gongjian Wu for technical assistance. This work was supported by the National Key Research and Development (R&D) Program of China (grant number: 2018YFB2100704), Research on Prevention and Control of COVID-19 in the Guangdong Education Department (grant number: 2020KZDZX1171), Shenzhen Basic Research Fund (grant number: JCYJ20190808174209308), and National Natural Science Foundation of China (grant numbers: 42171400, 2021A1515011324, 82103945, and 71961137003). The funding body was not involved in the collection, analysis, or interpretation of the data, the writing of the article, or the decision to submit the manuscript for publication.

Data Availability

We purchased the mobile phone data (January to March 2020) from a service provider (China Unicom). Our data purchase agreement with China Unicom prohibits us from sharing the data with third parties, but interested parties can contact China Unicom to obtain the same data. We collated epidemiological data from publicly available data sources (government websites). All epidemiological information that was used has been documented in the article.

Authors' Contributions

YZ ran the study, analyzed and interpreted the data, wrote the paper, and obtained funding for the study. JX extracted the data, analyzed and interpreted the data, and obtained funding for the study. QL participated in discussions and obtained funding for the study. KY, Xiling W, Xiong W, DH, YY, BJC, EC, and ZD participated in discussions on the undertaking of the study. All authors reviewed the paper for content and approved the final report.

Conflicts of Interest

BJC has received honoraria from AstraZeneca, Fosun Pharma, GSK, Haleon, Moderna, Roche, and Sanofi Pasteur.

Abstract

Background: The ongoing COVID-19 pandemic has emphasized the necessity of a well-functioning surveillance system to detect and mitigate disease outbreaks. Traditional surveillance (TS) usually relies on health care providers and generally suffers from reporting lags that prevent immediate response plans. Participatory surveillance (PS), an innovative digital approach whereby individuals voluntarily monitor and report on their own health status via web-based surveys, has emerged in the past decade to complement traditional data collection approaches.

Objective: This study compared novel PS data on COVID-19 infection rates across 9 Brazilian cities with official TS data to examine the opportunities and challenges of using PS data, and the potential advantages of combining the 2 approaches.

Methods: The TS data for Brazil are publicly accessible on GitHub. The PS data were collected through the Brazil Sem Corona platform, a Colab platform. To gather information on an individual's health status, each participant was asked to fill out a daily questionnaire on symptoms and exposure in the Colab app.

Results: We found that high participation rates are key for PS data to adequately mirror TS infection rates. Where participation was high, we documented a significant trend correlation between lagged PS data and TS infection rates, suggesting that PS data could be used for early detection. In our data, forecasting models integrating both approaches increased accuracy up to 3% relative to a 14-day forecast model based exclusively on TS data. Furthermore, we showed that PS data captured a population that significantly differed from a traditional observation.

Conclusions: In the traditional system, the new recorded COVID-19 cases per day are aggregated based on positive laboratory-confirmed tests. In contrast, PS data show a significant share of reports categorized as potential COVID-19 cases that are not laboratory confirmed. Quantifying the economic value of PS system implementation remains difficult. However, scarce public funds and persisting constraints to the TS system provide motivation for a PS system, making it an important avenue for future research. The decision to set up a PS system requires careful evaluation of its expected benefits, relative to the costs of setting up platforms and incentivizing engagement to increase both coverage and consistent reporting over time. The ability to compute such economic tradeoffs might be key to have PS become a more integral part of policy toolkits moving forward. These results corroborate previous studies when it comes to the benefits of an integrated and comprehensive surveillance system, and shed light on its limitations and on the need for additional research to improve future implementations of PS platforms.

Introduction

The global COVID-19 pandemic in March 2020 has had unprecedented consequences around the world. It caused widespread illness and deaths, as well as worldwide economic, political, and social repercussions [1]. The occurrence of such an extraordinary event emphasizes the need for well-functioning disease surveillance systems to detect and monitor disease outbreaks and epidemics. Countries use disease monitoring systems to assess, predict, and mitigate infectious disease outbreaks [2,3]. Reliable and timely data are critical to protect populations and build the foundation for governments, policy makers, and officials to intervene and prevent widespread infections [4]. As such, developing and improving on existing surveillance methods remains a rapidly growing and emerging field [5].

Most current surveillance systems, listed here as traditional surveillance (TS) systems, rely largely on traditional health care institutions, such as clinics, hospitals, and laboratories, to systematically collect data from practitioners as a public health monitoring tool [2]. Health care providers send reports to public health officials with certain regional or national data aggregation. In a few cases (usually, only a small percentage), these reports are then confirmed by laboratory analysis. Reported cases are then accounted as official disease cases [6-8]. Since the data are sourced from different institutions, aggregation often involves several time lags throughout the chain of data collection, reducing the timeliness of measures and actions [4,9,10]. Moreover, the true burden of the disease is often underestimated. In industrialized countries, healthy adults with no previous conditions usually do not visit a doctor if their symptoms remain mild. In emerging countries, socioeconomically weak communities lack access or financial resources to seek medical aid and thus are overlooked by TS [11]. Over the last 2 decades, new digital disease surveillance approaches have emerged to supplement traditional data collection, such as participatory surveillance (PS). Participatory disease surveillance is understood as an approach that directly engages the public in providing health data. Individuals monitor and assess their own health status and are encouraged to submit self-reports through digital platforms using mobile apps, websites, and phone-based surveys via SMS text messages or automated calls (interactive voice response [IVR]) [12]. Any individual can register on the platform (if they live in a country where a PS platform is deployed) and participate on a voluntary basis. As such, digital crowdsourced data can be aggregated and analyzed in large numbers [13-15]. Users are asked to regularly complete a questionnaire aimed at gathering information about their current (lack of) symptoms, access to health care, risk exposure, and medications. In the case of COVID-19, the main difference compared to TS is the lack of laboratory-confirmed testing; positive cases are categorized as such only based on the reporting of certain symptoms, with a so-called syndromic surveillance approach. The added value of PS systems is that they can even reach individuals who do not engage with health care providers because of financial or cultural factors, because they live too remotely to have access to health care facilities, or because their symptoms are too mild to cause concern [12]. The rapid global increase in the use of mobile phones and wide access to the internet are largely responsible for the rise of such digital surveillance systems [3]. By integrating an additional subset of the population not covered by TS, the complementary data provide an additional layer of surveillance, potentially enabling more accurate detection of ongoing infections as well as anticipation of trend changes [13,14].

PS systems have so far proven to be accurate and reliable for influenza-like illness (ILI) surveillance [15,16]. Most recently, as testing capacities were exhausted across many countries in the context of the pandemic, PS systems were implemented to support traditional systems in monitoring and controlling COVID-19 infections [17,18]. So far, Brazil is the first and only Latin American country that has implemented a PS system on a large scale to carry out syndromic surveillance, specifically during the 2014 FIFA World Cup [19] and the 2016 Olympic Games [20]. Lately, a local Brazilian health authority has used a PS platform to complement the traditional system, with the goal of optimizing the targeting of test areas during the COVID-19 pandemic [17]. This PS system has been shown to be beneficial in identifying risk clusters for infections in this context; in particular, it was able to cover blind spots of the TS system, showcasing the potential to increase its sensitivity by complementing it with additional data, and to allocate scarce resources more efficiently by prioritizing certain areas for the distribution of test kits. Notably, in Europe and the United States, health agencies and governments are increasingly prone to using the innovative and digital PS approach as a complementary source of disease surveillance.

Low public funding and suboptimal resource allocation persist in the Brazilian health sector [21]. The limitations of the TS system stress the need to reduce the burden of diseases among vulnerable and socioeconomically weak communities. This motivates the study to examine the opportunities and challenges of a PS system in the context of COVID-19 case detection across 9 Brazilian cities. During 7 months of the global pandemic in 2020, several city-level governments implemented the *Brazil Sem Corona* PS platform to gather additional insights on the spread of the disease. *Brazil Sem Corona* was an initiative led by Colab in partnership with several local governments from Brazilian cities, with the purpose of leveraging PS data to complement TS systems in order to mitigate COVID-19 risk at the local level. For our analysis, we focused on 9 cities with the largest PS participation across Brazil. Our objective was to investigate the capability of PS data to approximately mirror traditional infection rates captured through TS, as well as the relevance of citizen participation for the identification of trends in COVID-19 cases. Furthermore, we investigated the potential benefits of combining the PS and TS systems for forecasting case trends. Among the benefits, we showed that the PS system captures a part of the population that is so far overseen by traditional sources.

Methods

Goal

In this work, the goal was to compare daily official COVID-19 infections at the municipality level with daily PS infection numbers.

TS Data

TS data for Brazil are publicly accessible on GitHub [22]. These data aggregate the official laboratory-confirmed daily new COVID-19 cases at the municipality level. Using the 2020 population size estimates for each city [23], we calculated the infection rate per 100,000 inhabitants as follows:

where *i* denotes the city and *t* denotes the day.

PS Data

PS data for this study were collected through the *Brazil Sem Corona* platform, a Colab participatory platform developed previously [24]. To gather information on an individual's health status, each participant was asked to fill out a daily questionnaire in the Colab app on symptoms as well as exposure. The app was available on the Apple Store as well as the Google Play Store. The list of symptoms was based on the COVID-19 case definition and contained the following: fever, cough, shortness of breath, runny nose, sore throat, headache, fatigue, nausea, rash, joint pain, chills, diarrhea, and loss of taste. Additionally, participants were asked to report about medication intake and whether they sought a health care facility for their symptoms. For this study, Colab subsequently provided access to the anonymized data set of *Brazil Sem Corona*.

Ethical Considerations

Before filling out the questionnaire, participants were asked to agree with an informed consent form in the registration phase. The form described the study and the purpose of the project, and provided information about how the data could be used by third parties for research analysis purposes. Access to the data and study was approved by the Colab Institutional Management Board. All methods were carried out in accordance with guidelines and regulations, including but not limited to the *Lei Geral da Proteção de Dados – LGPD*, the official regulation on data privacy and protection valid in Brazil. All collected study data were anonymous and deidentified. No compensation was provided to the participants. The data used in this study can be made available through a formal request to the Colab team.

Data Collection

The platform was set up online on March 20, 2020, right after the World Health Organization officially declared COVID-19 as a public health issue with pandemic implications on March 11, 2020 [25]. During the period following this official statement, Brazilian newspapers and magazines extensively advertised the *Brazil Sem Corona* platform, leading to an increase in self-report submissions [26-28].

The increase in the number of participants allowed the creation of a database of symptom-based reports that could be used for the analysis. Each report was categorized into one of the following categories: (1) no symptoms, (2) light symptoms, (3) suspected COVID-19 case, (4) severe suspected COVID-19 case, and (5) confirmed case. In order to be categorized as a suspected case, the user must report fever together with at least one other symptom. If along with these symptoms either medication intake is reported or a health care facility is sought, the report is labeled as severe suspected case [29]. Only those users reporting a positive laboratory COVID-19 test result were categorized as confirmed cases. All the suspected, severe suspected, and confirmed cases were then treated as *possible COVID-19 cases*, while light and no symptom cases were treated as *negative cases*. The inclusion of not only confirmed cases but also suspected cases is one of the key differences with respect to case counts performed in TS settings.

For each city in which data were collected, we aggregated the reports submitted for each day and calculated the daily infection rate:

where *i* denotes the city and *t* denotes the day.

Data sparsity and fluctuations were addressed by applying a simple but powerful tool called LOESS to the PS data. It fits smooth lines to empirical data using a nonparametric approach [30]. For all 9 cities, the smoothed PS and TS infection rates were then compared.

Pearson Correlation Calculation

To measure the statistical relationship between the 2 time series, we calculated the Pearson correlation (PC_t) coefficient for the original time series. Additionally, we used a 7-day and 14-day lagged PS series to calculate PC_{t-7} and PC_{t-14}. Finally, we determined the coefficients over a reduced 4-month observation period during which public engagement and participation rates were the largest.

Finally, we looked at the proportion among self-reported cases of confirmed cases and the percentage of confirmed cases seeking health care assistance.

Forecasting Models

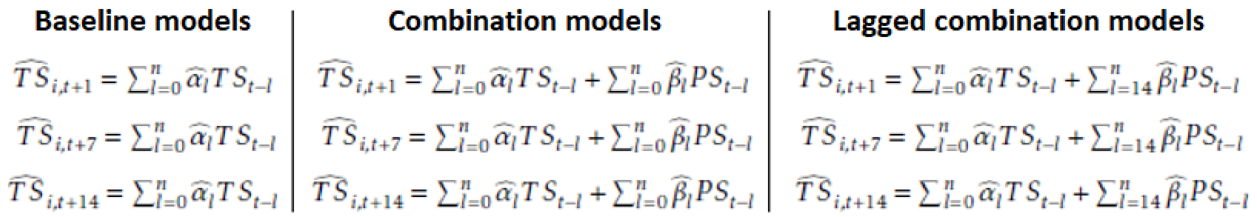
In order to further assess the added value of insights generated by PS systems, we used the PS data to inform 3 different forecasting models to predict incidence rates for COVID-19 with a time horizon varying between 1 and 3 weeks (Figure 1). TS data were used to generate a baseline model that represents the "ground truth" against which the forecasting models were compared.

Thus, the first model (further referred to as the *baseline model*) was a univariate model based on only TS data. The second and third models (referred to as the *combination model* and *lagged combination model*, respectively) were bivariate models integrating both TS and PS data. The third model also used a 14-day lag in the PS incidence rate series. For all 3 models, we used a linear autoregression function with *n* daily lagged components. For each city, the optimal number of independent variables was selected based on the Akaike Information Criterion (AIC) that estimates the prediction error and quality of statistical models. Thereby, the explained part of the variation was maximized while using only the lowest possible amount of time lag.

To evaluate the performance of the forecasting models, we calculated the root mean squared error (RMSE) and mean absolute error (MAE). The RMSE measures the difference between predicted and true values as follows:

The MAE measures the average of the absolute errors between predicted and true values as follows:

Figure 1. Model overview. stands for the estimation, whereas TS stands for the true value. By weighing n past components, 1-, 7-, and 14-day forecasts are estimated. The model parameters and are estimated based on a training subsample that contains the first 80% of the data. The out-of-sample forecasting accuracy is then calculated based on the remaining 20% of the data. Thus, the first 80% of the observation period is used to fit the models, while the remaining 20% is used to evaluate its performance. PS: participatory surveillance; TS: traditional surveillance.



Baseline models	Combination models	Lagged combination models
$\widehat{TS}_{i,t+1} = \sum_{l=0}^{n} \widehat{\alpha}_l TS_{t-l}$	$\widehat{TS}_{i,t+1} = \sum_{l=0}^{n} \widehat{\alpha}_l TS_{t-l} + \sum_{l=0}^{n} \widehat{\beta}_l PS_{t-l}$	$\widehat{TS}_{i,t+1} = \sum_{l=0}^{n} \widehat{\alpha}_l TS_{t-l} + \sum_{l=14}^{n} \widehat{\beta}_l PS_{t-l}$
$\widehat{TS}_{i,t+7} = \sum_{l=0}^{n} \widehat{\alpha}_l TS_{t-l}$	$\widehat{TS}_{i,t+7} = \sum_{l=0}^{n} \widehat{\alpha}_l TS_{t-l} + \sum_{l=0}^{n} \widehat{\beta}_l PS_{t-l}$	$\widehat{TS}_{i,t+7} = \sum_{l=0}^{n} \widehat{\alpha}_l TS_{t-l} + \sum_{l=14}^{n} \widehat{\beta}_l PS_{t-l}$
$\widehat{TS}_{i,t+14} = \sum_{l=0}^{n} \widehat{\alpha}_l TS_{t-l}$	$\widehat{TS}_{i,t+14} = \sum_{l=0}^{n} \widehat{\alpha}_l TS_{t-l} + \sum_{l=0}^{n} \widehat{\beta}_l PS_{t-l}$	$\widehat{TS}_{i,t+14} = \sum_{l=0}^{n} \widehat{\alpha}_l TS_{t-l} + \sum_{l=14}^{n} \widehat{\beta}_l PS_{t-l}$

Results

Reports were collected between March 20, 2020, and October 20, 2020. The analysis covered the whole 7-month observation period. Even though the platform was accessible all around Brazil, nearly 65% of the reports were submitted from 9 cities. Therefore, the study focused only on those cities with the largest number of submitted reports. People from Teresina, Caruaru, Santo Andre, Niteroi, Recife, Porto Alegre, Campinas, Sao Paulo, and Rio de Janeiro submitted an aggregated total of 83,005 reports (13,582 individuals).

To assess the importance of participation, we compared the capability of the PS data to mirror the infection rates reported by the TS systems implemented in the 9 cities. In Table 1, we present the 9 cities with the largest PS participation (the highest number of submitted reports across Brazil). As the population size varied between the cities, we additionally weighted the number of submitted reports by the population size displayed by the variable “number of reports by 100.” As participants could report several times throughout the observation period, there was a relatively large number of submitted reports compared with the number of participants. Even though São Paulo recorded a relatively large number of submitted reports, it was ranked only second to last due to its large population size. Teresina, Caruaru, and Santo André were ranked as the top 3 based on the variable “number of reports by 100.” The large participation in those 3 cities was not coincidental but rather driven by massive local media campaigns led by local officials [26-28]. Those social media campaigns seem to have impacted the participation behavior, underlining the government’s role. Additionally, we displayed the variable “share of zeros,” which captures the share of observation days on which no possible COVID-19 case was recorded on the platform within a city. This problem is often referred to as *zero inflation* (as the sample contains an excess of zeros) and is equivalent to censored data. Those numbers were negatively correlated with the level of engagement, as the cities at the bottom of the ranking displayed a striking share of zeros (as high as 96%).

As mentioned in the Methods section, every submitted report was categorized as either a negative COVID-19 case or suspected COVID-19 case based on the symptoms reported in the survey. In Figure 2, we show the TS and PS incidence rates over the entire 7-month observation period to compare differences in detected infection rates between the 2 surveillance methods. The 9 cities have been arranged according to the participation ranking (Table 1) from top left to bottom right. The top row displays the 3 cities with the largest community engagement (Teresina, Caruaru, and Santo André). Here, infections identified through PS and TS followed a relatively similar pattern, at least between March and August 2020. For most cities, the trend of detected cases diverged between the 2 methods toward the end of the observation period, which can be explained by the relatively low number of submitted reports over that interval. More details on the daily number of submitted reports can be found in Figure S1 in Multimedia Appendix 1. From the graphical analysis, it follows that the capability of the PS system to potentially point to the trend of infections seemed to decrease with low participation rates. This finding is supported by Table 2, which reports the Pearson correlation coefficients between the PS and TS time series within each city.

Table 2 confirms that the largest correlation between the 2 data sources was indeed noted for the cities with the largest participation rates (namely, Teresina, Caruaru, and Santo André). The Pearson correlation coefficients for those 3 cities were above 0.5, indicating a moderate to high positive correlation between the 2 data sources.

We next analyzed the participation behavior of individuals across all 9 cities. A significant share of 40%-50% of individuals participated only once throughout the observation period, while roughly 6%-13% were considered as frequent participants, with at least 15 submitted reports. Detailed numbers can be found in Table S1 in Multimedia Appendix 1.

In order to assess the effect of lag on the time series correlation, we also determined the Pearson correlation coefficients for the 3 key cities with the largest public engagement, using 7-day and 14-day lags in the PS data series. Table 3 shows the lagged Pearson correlations for the full observation period, while Table 4 presents the results for the reduced period from April 1 to July 31, 2020.

In Table 3, an increased correlation can only be found for Teresina, where the coefficient increased from 0.82 to 0.89 for the 14-day lag. For Caruaru and Santo André, the coefficients declined from 0.79 to 0.71 and from 0.56 to 0.45, respectively. However, the correlations for the 7-day lag remained at roughly the same level. While these results are ambiguous and rather weak, the picture appears clearer in Table 4.

In Table 4, the coefficients remain either constant or show an increase using 7-day and 14-day lags across all 3 cities. By removing the tails of the observation period, the focus was set on the months with the strongest engagement, as shown by the higher daily average of submitted reports in Table 4.

Table 5 presents the proportion of confirmed COVID-19 cases, proportion of cases for which health care assistance was sought, and proportion of cases involving medication intake among all submitted reports that were categorized as potential COVID-19 cases.

Table 1. Participation ranking for the 9 Brazilian cities under examination.

City	Number of reports	Number of reports per 100[a]	Number of participants	Share of zeros[b], %
Teresina	27,558	3.17	4449	7.0
Caruaru	10,279	2.81	1363	32.0
Santo Andre	14,207	1.97	2866	46.7
Niteroi	6757	1.31	897	62.9
Recife	3895	0.24	492	73.9
Porto Alegre	2779	0.19	336	96.1
Campinas	2006	0.17	307	92.9
Sao Paulo	12,453	0.10	2360	70.7
Rio de Janeiro	3071	0.05	734	74.6

[a] The ranking is based on the variable “number of reports per 100,” from the largest to the smallest. This variable shows the number of submitted reports per 100 inhabitants and is calculated as the number of submitted reports divided by population size times 100.

[b] The variable “share of zeros” shows the share of observation days on which no possible COVID-19 case was recorded within a city.

Figure 2. Daily PS and TS infection rates per city. The graphs are arranged according to the weighted participation from top left to bottom right. PS: participatory surveillance; TS: traditional surveillance.

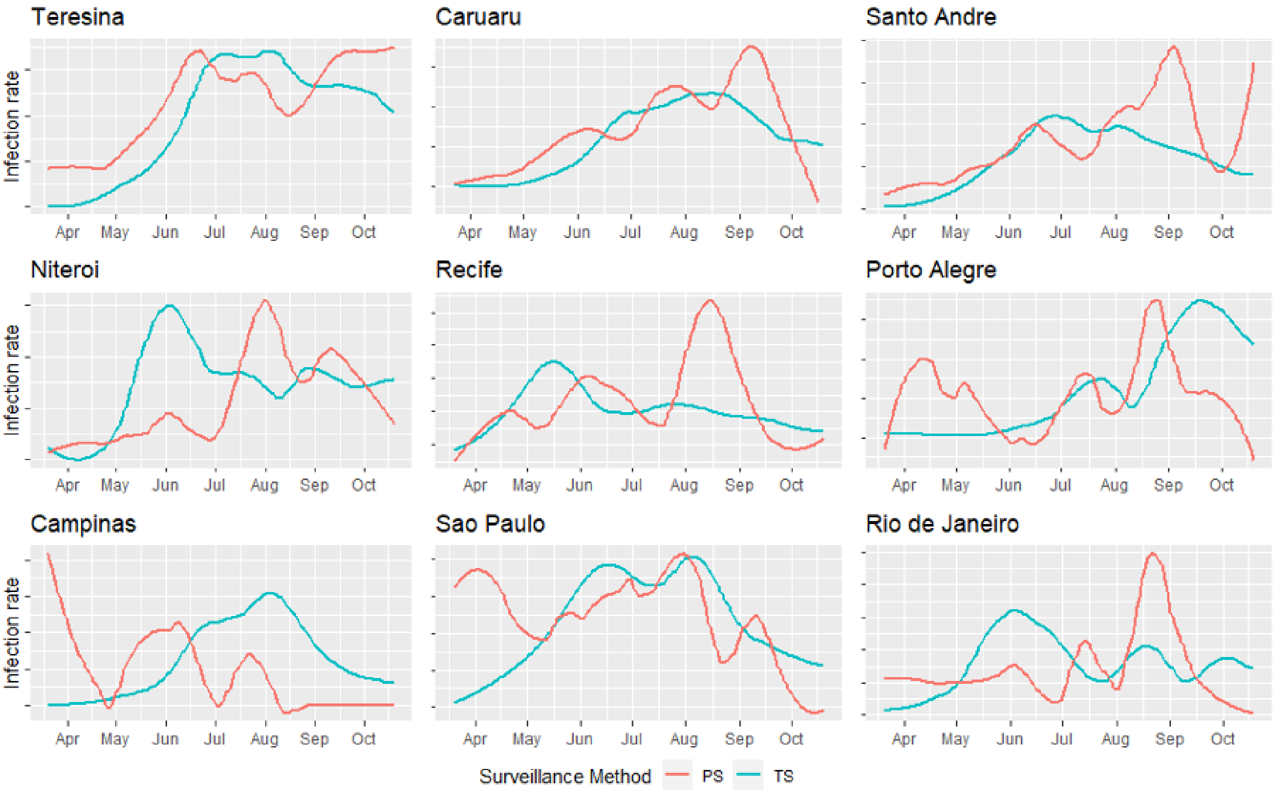


Table 2. Pearson correlations for each study city.

City[a]	Pearson correlation	*P* value
Teresina	0.82	<.001
Caruaru	0.79	<.001
Santo Andre	0.56	<.001
Niteroi	0.24	<.001
Recife	0.23	<.001
Porto Alegre	0.18	<.001
Campinas	−0.34	<.001
Sao Paulo	0.32	<.001
Rio de Janeiro	0.09	.19

[a] The cities are ranked according to population-weighted participation from the largest to the smallest.

Table 3. Lagged Pearson correlations for the full observation period (full 7-month period).

City	PC[a]	PC (7-day lag)	PC (14-day lag)	Average daily reports
Teresina	0.82	0.87	0.89	128
Caruaru	0.79	0.77	0.71	49
Santo Andre	0.56	0.56	0.45	66

[a] PC: Pearson correlation coefficient.

Table 4. Lagged Pearson correlations for the reduced observation period (April to July 2020).

City	PC[a]	PC (7-day lag)	PC (14-day lag)	Average daily reports
Teresina	0.86	0.91	0.93	193
Caruaru	0.85	0.85	0.88	76
Santo Andre	0.82	0.89	0.88	88

[a] PC: Pearson correlation coefficient.

Table 5. Characteristics of potential COVID-19 case reports.

Variable	Teresina (N=987), n (%)	Caruaru (N=356), n (%)	Santo Andre (N=189), n (%)
Confirmed cases	362 (36.7)	152 (42.7)	108 (57.1)
Cases seeking health care	270 (27.4)	112 (31.4)	65 (34.6)
Cases involving medication intake	495 (50.2)	185 (50.2)	110 (58.0)

Forecasting Models

For the 3 cities with an at least moderate (higher than 0.8) positive Pearson correlation coefficient, we compared the RMSEs and MAEs from the baseline model with those from the combination as well as lagged combination model (Tables 6-8). We show the results for 1-day, 7-day, and 14-day forecasts.

Even though improvements were only modest, there was a pattern that could be identified across all 3 cities. The combination model outperformed the baseline model for the 14-day forecast by up to 2.7%. The results for the 7-day forecast were ambiguous; while there were improvements of up to 4.1%, only 2 out of the 3 cities showed reduced RMSEs.

Table 6. Forecasting errors using different models for 1-day, 7-day, and 14-day forecasts in the city of Teresina.

Forecast period and model[a]	RMSE[b]	MAE[c]
1-day forecast		
Baseline model	0.0195	0.0133
Combination model	0.0198	0.0140
Lagged combination model	0.0193	0.0137
7-day forecast		
Baseline model	0.0410	0.0302
Combination model	0.0393	0.0281
Lagged combination model	0.0409	0.0310
14-day forecast		
Baseline model	0.0347	0.0245
Combination model	0.0338	0.0246
Lagged combination model	0.0340	0.0249

[a] The models used n=13 lagged components as independent variables.

[b] RMSE: root mean squared error.

[c] MAE: mean absolute error.

Table 7. Forecasting errors using different models for 1-day, 7-day, and 14-day forecasts in the city of Caruaru.

Forecast period and model[a]	RMSE[b]	MAE[c]
1-day forecast		
Baseline model	0.0214	0.0162
Combination model	0.0212	0.0160
Lagged combination model	0.0290	0.0220
7 -day forecast		
Baseline model	0.0316	0.0234
Combination model	0.0318	0.0237
Lagged combination model	0.0329	0.0244
14-day forecast		
Baseline model	0.0293	0.0190
Combination model	0.0288	0.0187
Lagged combination model	0.0292	0.0190

[a] The models used n=5 lagged components as independent variables.

[b] RMSE: root mean squared error.

[c] MAE: mean absolute error.

Table 8. Forecasting errors using different models for 1-day, 7-day, and 14-day forecasts in the city of Santo Andre.

Forecast period and model[a]	RMSE[b]	MAE[c]
1-day forecast		
Baseline model	0.0137	0.0094
Combination model	0.0236	0.0181
Lagged combination model	0.0203	0.0157
7 -day forecast		
Baseline model	0.0225	0.0169
Combination model	0.0219	0.0174
Lagged combination model	0.0321	0.0245
14-day forecast		
Baseline model	0.0292	0.0245
Combination model	0.0284	0.0236
Lagged combination model	0.0299	0.0251

[a] The models used n=14 lagged components as independent variables.

[b] RMSE: root mean squared error.

[c] MAE: mean absolute error.

Discussion

The goal of this study was to show how PS systems, already well established as a routine surveillance monitoring approach for ILI, can also complement and enhance TS systems for monitoring pandemic diseases such as COVID-19. The results showed that the validity of the approach strongly depends on the rate of participation among the general population.

We found that the PS infection rates from the 3 cities with the largest participation approximately mirrored the TS infection rates, even though the representativeness of the PS subpopulation was most likely biased in terms of sex and age. The 3 cities were able to engage a large group of individuals due to social media campaigns promoted by local officials and governments. The insights from the other cities were less reliable as the data were not able to represent the traditional infection rates due to low engagement and zero inflation. In Campinas, the city with the lowest total number of submitted reports, PS performed so poorly that its data displayed a *negative* correlation with TS data. With a total of only 2006 submitted reports over a period of 210 days (Table 1), a daily average of self-reports of just under 10 was observed, implying that the sample size was far too small. The same was true for the other cities at the low end of the ranking, with Pearson correlations below 0.25. The only exception was São Paulo, whose correlation was smaller than the correlations of the top 3 cities. Even though it was ranked as second to last regarding population-weighted participation, the total number of submitted reports for São Paulo was relatively large at 12,453 reports. This corresponded to an average of nearly 60 submissions per day, resulting in a Pearson correlation coefficient of 0.32. Overall, low participation is considered one of the main limitations for the capability of PS data to mirror traditional infection rates. Even though it is known for ILI that participation of 1%-2% is reasonable in epidemic periods, additional work is necessary to better estimate a reasonable cutoff for COVID-19.

A stronger correlation between the TS and lagged PS time series supports the theory of early trend detection, which is one goal pursued by PS. However, this was only conducted for 3 cities, which showed a strong positive PC_t above at least 0.5. It was found that toward the end of the observation period, only few people participated on the platform, such that around 80% of the reports were submitted within the period from April 1 to July 31, 2020.

The results from the forecasting analysis were also consistent with this conclusion. The errors for the 1-day ahead forecasts were generally smaller than the errors found in the 7-day and 14-day forecasts for all 3 cities. This is not surprising, as uncertainty rises with longer forecast horizons, and hence, the forecast accuracy of a model is lower. When looking at the 1-day forecasts, the baseline model seemed to outperform the combination model, at least for Teresina and Santo André. As mentioned before, uncertainty grows with longer horizons, which might explain the lack of value addition that comes from integrating PS data in a 1-day forecast. In Teresina, however, both the 7-day and 14-day forecasts from the combination and lagged combination models performed better than the baseline model, with slightly lower RMSEs. The combination model showed a 4.2% reduction in the RMSE for the 7-day horizon and a 2.6% reduction for the 14-day horizon, while the lagged combination model showed reductions of 0.2% and 2.1%, respectively. In Caruaru, the combination model performed slightly worse for the 7-day forecast relative to the baseline model, with a 0.5% increase in the RMSE, but an improvement was noted for the 14-day forecast, with a 1.7% reduction in the RMSE. Similar results were found for the lagged combination model, whereby the 7-day forecast showed a 4.1% increase in RMSE, while the 14-day forecast showed an improvement by 0.4%. The combination model applied on the data from Santo André again reduced the RMSEs for both the 7-day and 14-day forecasts by 2.8% and 2.7%, respectively. However, the lagged combination model was not able to improve the forecast for any of the applied horizons. This shows how complementing traditional disease surveillance systems may further increase the possibility for the early identification of outbreaks under the condition of sufficiently large participation. Slight improvements in the forecasting accuracy of up to 3% were identified for the models integrating data from both surveillance sources compared to the baseline model relying entirely on traditional data. Even if forecasting improvements are only weak, the detection of infections is improved as PS can cover an additional subset of the population that is overseen by the traditional system. The above findings contribute to a deeper understanding of the benefits of a complementary digital surveillance layer. They corroborate previous literature, emphasizing that the 2 approaches can be complements for timely health threat identification [3,14,16]. Even though some of the results indicate only small improvements in accuracy, the possibility of enhancing case detection through broader coverage cannot be neglected.

Some limitations related to the PS approach should be mentioned. Studies conducted in the United States and Western Europe suggest that the population subgroup captured by the *Brazil Sem Corona* PS system does not necessarily represent the general Brazilian population [31-33]. In previous PS data, female participants were significantly overrepresented compared to the general population. Besides that, age groups below 30 years and above 80 years were underrepresented. Moreover, the average participant most likely held a higher educational degree than the average population [34]. Furthermore, individuals living in bigger cities were more likely to participate, leading to clusters around more urban areas and information gaps in more remote regions. This is supported by the geocoordinates from the submitted reports on the *Brazil Sem Corona* platform, which indicate that a significant share of participants live in or around urban areas. Targeting the underrepresented population may prospectively improve the complementary benefit of the platform, particularly among those not seeking medical attention. Despite the biases found in the population covered by PS, studies highlight that PS systems that engage a sufficiently large group of participants can still adequately capture TS infection trends [33,35]. Ideally, PS tracks individuals throughout the season. Knowing that nearly half of the participants did not continue their engagement after the first report submission stresses the need for efforts to ensure more frequent participation in the future. Previous studies from the United States and Canada have found significant differences in participation across age groups, along with a 25% lower probability of frequent participation by women relative to men [33].

Another important aspect of complementing disease surveillance systems is the goal of early trend detection to identify disease outbreaks. Integrating multiple data sources not only aims at improving data insights and detecting more cases but also ideally leads to the detection of outbreaks at an earlier stage. The finding of greater coefficients in the lagged Pearson correlation indicates that the timeliness of the PS system helps in identifying slightly preceding trends. This supports the idea that a PS system, which engages a larger volunteer network, is more likely to depict infection trends, resulting in better data insights and, eventually, in earlier anticipation of trend changes. Recognizing outbreak patterns only slightly in advance might already have great benefits for health agencies when it comes to fighting pandemics. Improvements in 14-day forecasts allow health officials to respond more quickly and prioritize certain areas identified as more likely to suffer from rising infection numbers. This may be of particular importance for low-income countries or for regions that suffer from a considerable scarcity in health services. The PS system brings value by producing information that can be used to reduce uncertainty in allocation decisions. Furthermore, infection monitoring can be improved thanks to the geolocation information provided by PS data, which allows for a typically higher spatial resolution. Aside from preventing local transmissions, improvements in the surveillance system may result in externalities, such as lower infections in other regions [36].

We hypothesize that the severity of COVID-19 likely influenced individuals' motivation to engage in a voluntary surveillance system. Governments have adjusted their behavior during the ongoing pandemic and made significant efforts to improve the timeliness of traditional data reporting. Many countries, including Brazil, have overcome administrative burdens and were ultimately able to report daily new infections. As such, the timeliness that usually distinguishes a PS system from a TS system has most likely vanished. We see this as a reasonable explanation for why the magnitude of the results from the forecasting is weaker compared to the findings of previous studies conducted in the field of ILI [14,15]. Besides that, ILI tracking allows for data collection across several flu seasons, increasing the amount of available data and allowing for consistency checks across seasons, whereas the novelty of COVID-19 only allows for a single 7-month observation period in Brazil.

We emphasize the successful collaboration among governments, locals, and professionals when it comes to maximizing the use and gain of the *Brazil Sem Corona* platform. The 3 cities with extensive social media campaigns clearly demonstrated the capabilities of the PS system, under the condition of sufficient participation. Defining sufficient participation remains relevant for future research; so far, previous studies only highlighted the number of reports as a critical element and claimed the need to maintain sufficient coverage without setting a certain threshold [13,32,37]. Factors, such as population density, urbanization, and area size, most likely cause regional variations, making it significantly more difficult to determine a specific number that is generally valid.

The implementation of a proper surveillance system remains an important challenge in developing countries. While the PS system aims to address disparities in health outcomes, it currently reaches more urban regions and relatively more educated people. Therefore, voluntary crowdsourced information likely contains a population bias. Assessing the potential benefits for more rural communities remains open to future research in order to realize the system's full potential. Engaging and motivating a greater diversity of individuals remain key challenges that must be addressed in future PS platform implementations. Obstacles, such as lack of access to modern technologies, illiteracy, and simply lack of awareness of the benefits from participation, might hinder progress toward a more diverse reporting population.

Nearly half of the participants in Brazil submitted only a single report. This prevents monitoring the health status of individuals over a longer observation period, and as a result, reduces the insights that can be gained from PS systems. This stresses the need to evaluate incentives to induce more frequent participation. Additionally, in-depth research is needed to determine the reasons that lead to discontinuation of participation after the first submission. Addressing the above issues in future PS platform implementations is likely to lead to even greater benefits.

The unavailability of data on participants' sociodemographic characteristics in the *Brazil Sem Corona* platform prevents an important analysis of the representativeness of participants versus the general Brazilian population. Performing further tests and extending the method could confirm the validity of the results and deepen the insights. The forecasting models were kept rather simple on purpose, with only the TS and PS data as independent variables. Adding mobility data or contact tracing data, for instance, could improve accuracy, leading to a better understanding of transmission. There are further limitations to keep in mind, such as the impact of the criteria of categorization of a submitted report into either a *suspected COVID-19case* or a *negative case*, as this can influence the number of reports included in the case counts and the likelihood of false positives. Furthermore, the applied local regression ("LOESS") remains an approximation for smoothing the highly sparse data. Alternative smoothing techniques might produce different results, which could lead to divergent interpretations.

Public engagement remains a challenge. Future research needs to identify determinants of participation and proper incentives to induce larger coverage and higher diversity of participants. As the quality of data insights improves, PS benefits may further expand. Deeper insights allow for greater acceptance and credibility among governments and health authorities. Expanding collaboration among researchers, officials, and health authorities is needed to leverage data insights for timely response plans, which can ultimately lead to better health outcomes.

Abstract

Background: SARS-CoV-2 rapid antigen testing (RAT) could be a useful supplementary test to diagnose larger numbers of acute asymptomatic infections and alleviate the limitations of polymerase chain reaction testing. However, hesitancy to undergo SARS-CoV-2 RAT may compromise its implementation.

Objective: We aimed to understand the prevalence and correlates of hesitancy to undergo RAT among adults not infected with SARS-CoV-2 in mainland China.

Methods: A nationwide cross-sectional survey on hesitancy to undergo SARS-CoV-2 RAT was conducted among adults not infected with SARS-CoV-2 in mainland China between April 29, 2022, and May 10, 2022. Participants completed an online questionnaire that covered the following COVID-19–related factors: sociodemographic characteristics, experiences of COVID-19 restrictions and knowledge of COVID-19, and attitude toward COVID-19 and its screening. This study was a secondary analysis of data from the survey. We compared the characteristics of participants by hesitancy to undergo SARS-CoV-2 RAT. Thereafter, logistic regression with a sparse group minimax concave penalty was used to identify correlates of hesitancy to undergo RAT.

Results: We recruited 8856 individuals with diverse demographic, socioeconomic, and geographic characteristics in China. Eventually, 5388 participants (valid response rate of 60.84%; 52.32% [2819/5388] women; median age 32 years) were included in the analysis. Among the 5388 participants, 687 (12.75%) expressed hesitancy to undergo RAT and 4701 (87.25%) were willing to undergo RAT. Notably, those who were from the central region (adjusted odds ratio [aOR] 1.815, 95% CI 1.441-2.278) and those who received COVID-19 information from traditional media (aOR 1.544, 95% CI 1.279-1.863) were significantly more likely to report hesitancy to undergo RAT (both $P<.001$). However, those who were women (aOR 0.720, 95% CI 0.599-0.864), were older (aOR 0.982, 95% CI 0.969-0.995), had postgraduate education (aOR 0.612, 95% CI 0.435-0.858), had children (<6 years old) and elders (>60 years old) in the family (aOR 0.685, 95% CI 0.510-0.911), had better knowledge about COVID-19 (aOR 0.942, 95% CI 0.916-0.970), and had mental health disorders (aOR 0.795, 95% CI 0.646-0.975) were less likely to report hesitancy to undergo RAT.

Conclusions: Hesitancy to undergo SARS-CoV-2 RAT was low among individuals who were not yet infected with SARS-CoV-2. Efforts should be made to improve the awareness and acceptance of RAT among men, younger adults, individuals with a lower education or salary, families without children and elders, and individuals who access COVID-19 information via traditional media. In a reopening world, our study could inform the development of contextualized mass screening strategies in general and the scale-up of RAT in particular, which remains an indispensable option in emergency preparedness.

KEYWORDS

COVID-19; SARS-CoV-2; vaccine; hesitancy; rapid antigen testing; China

Introduction

Multiple variants of SARS-CoV-2 have occurred [1], of which the Omicron variant has spread swiftly across the world and has become the progressive strain globally [2-5]. During the period of the COVID-19 pandemic, policy makers from various countries and regions have been focusing on efforts to mitigate the pandemic's devastating impacts on public health, economy, and social development. COVID-19 vaccination and nonpharmaceutical interventions (NPIs) are expected to contain the pandemic to a large extent. Across the world, as of August 11, 2022, there were 34 COVID-19 vaccines that had been authorized for use [6]. In addition, many countries implemented NPIs, including face mask wearing, hand washing, and physical distancing, in response to the ongoing COVID-19 pandemic [7].

When the genetic sequence of SARS-CoV-2 was published in January 2020 [8], 3 types of diagnostic tests for COVID-19 were implemented, including polymerase chain reaction (PCR) testing, rapid antigen testing (RAT), and serology testing. While PCR testing and RAT could be used to diagnose an acute infection involving COVID-19, serology testing provides indirect evidence of infection 1-2 weeks after the onset of symptoms [9] and thus was not applied to large-scale screening in the early phase. PCR testing is highly sensitive and specific, and requires the support of laboratory facilities and highly trained staff. Its results become available in the time range of less than 2 hours to up to 7 days [10]. However, a delay of several days in receiving testing results is unacceptable for mass screening, as it may lead to missed diagnosis of many cases, which would cause secondary transmission. RAT, on the other hand, is a useful supplementary testing approach that detects viral proteins (eg, spike and nucleocapsid proteins) to diagnose larger numbers of acute asymptomatic SARS-CoV-2 infections, and it can overcome the limitations of PCR testing in the early phase of infection in mass screening. Of note, RAT requires minimal effort of medical personnel training and is much faster (within 15 minutes) at providing results [11,12]. Hence, RAT could confirm or exclude infection with SARS-CoV-2 at the individual level for case management or self-isolation, and at the population level for large-scale screening and emergency responses.

To tackle sporadic COVID-19 outbreaks, testing for large-scale screening should be one of the backbones of the response [13]. China has adopted the general strategy of "guarding against imported cases and preventing a resurgence of the outbreak at home" and the policy of "dynamic zero-COVID," which include large-scale screening in a timely manner [14]. Furthermore, in March 2022, China implemented RAT to successfully identify infected individuals in the early phase in Shanghai. RAT has been used at universities and other congregate settings in the United States [12]. Germany, France, and the United Kingdom have already adopted RAT in their own strategies [15]. RAT is very useful in surveillance and emergency responses; however, the public may lack knowledge of RAT, that is, when and how to undergo RAT, or may be hesitant to undergo the procedure. In the case of outbreaks of COVID-19, especially those involving the Omicron variant, optimization of strategies of RAT for individuals in order to exert a dramatic effect on COVID-19 spread should be carefully considered. To address the transition from a pandemic to an endemic, evidence-based optimization of diagnostic strategies should be considered in the global agenda. Many studies have assessed reasons for COVID-19 vaccination hesitancy [16,17]; however, research characterizing hesitancy and the factors influencing hesitancy to undergo RAT for COVID-19 is scarce. Our study aimed to understand the prevalence and correlates of hesitancy to undergo RAT for COVID-19 among adults uninfected with SARS-CoV-2 in mainland China. For the COVID-19 pandemic and outbreaks of novel infectious diseases, the findings of this study could inform the future decision-making of the scale-up of RAT.

Methods

Study Participants

We conducted a nationwide online cross-sectional survey on hesitancy to undergo RAT among mainland Chinese adults uninfected with SARS-CoV-2 between April 29, 2022, and May 10, 2022. Participants were recruited through WeChat, which is a popular social media platform in China with over 1 billion monthly active users [18]. An online, self-administered, anonymous questionnaire was developed via Wenjuanxing, an online survey platform.

Eligibility criteria were as follows: (1) age of 18 years or older; (2) no previous infection with SARS-CoV-2; (3) residing in mainland China; (4) ability to complete the survey in Chinese; and (5) willingness to participate in the survey. To improve the quality of collected data, responses were deleted if (1) there were logically contradictory answers and (2) the time to complete the questionnaire was less than 2 minutes.

This survey based on a convenience sampling method [19,20] (assuming a 60% response rate) had access to respondents with diverse demographic, socioeconomic, and geographic characteristics in China. The questionnaire was comprised of closed-ended questions. Respondents were required to respond to all closed-ended questions so that there were no missing values for those questions. To avoid unmotivated, dishonest, inattentive, or duplicate responses, we tried to improve the quality of the questionnaire responses by deleting such responses. Moreover, in the process of data cleaning, we set rigorous standards for valid responses from participants.

Ethical Considerations

The nationwide cross-sectional survey was conducted with the approval of the Ethics Committee of the School of Public Health (Shenzhen), Sun Yat-sen University (approval number: SYSU-SPH2022020). Respondents were recruited without compensation. Respondents had to provide informed consent before proceeding to the questionnaire response page in the survey.

This study was a secondary analysis of data from the survey; therefore, this study received an exemption from the Ethics Committee of the School of Public Health (Shenzhen), Sun Yat-sen University. The study data were deidentified.

Measures

The questionnaire was adapted based on past literature on similar topics [16,21,22] and was revised by a panel of epidemiologists. A pilot study was conducted to help improve the questionnaire. All closed-ended questions had a single-answer or multiple-answer format, including “yes/no” scale, nominal and ordinal scale, and Likert scale questions. The questionnaire covered the following 3 parts: (1) sociodemographic characteristics; (2) experiences of COVID-19 restrictions and knowledge of COVID-19; and (3) attitude toward COVID-19 and its screening.

Sociodemographic Characteristics

The sociodemographic variables considered in this study were gender, age, ethnicity, socioeconomic status, residence, education level, marital status, age of other family members, occupation type, monthly salary during the COVID-19 pandemic, change in monthly salary during the COVID-19 pandemic, presence of chronic diseases (cardiovascular diseases, respiratory diseases, diabetes, cancers, liver diseases, and renal diseases, among others), and frailty status. Participants from 31 provinces, autonomous regions, and municipalities in mainland China were reclassified into the following 3 groups of socioeconomic status [23]: high (eastern region), medium (central region), and low (western region). The 5-item FRAIL scale (fatigue, resistance, ambulation, illness, and loss of weight) was used to identify frail persons at risk of developing disability, as well as decline in health functioning and mortality [24]. FRAIL scale scores range from 0 to 5 (0, best; 5, worst) and represent robust (0), prefrail (1-2), and frail (3-5) health statuses.

Experiences of COVID-19 Restrictions and Knowledge of COVID-19

Experiences of COVID-19 restrictions and knowledge of COVID-19 included experience of any NPIs, number of roommates, self-reported number of close contacts (physical contact distance of <1 meter) daily, COVID-19 vaccination status (COVID-19 vaccines include inactivated vaccines administered on a 2-dose schedule, recombinant subunit vaccines administered on a 3-dose schedule, or recombinant adenovirus type 5–vectored vaccines administered as a single dose), number of PCR tests for COVID-19 in the last month, frequency of attention to information about COVID-19, and information sources and health literacy about COVID-19. Health literacy about COVID-19 specifically refers to an individual’s ability to access, comprehend, and apply information related to COVID-19. Having adequate health literacy about COVID-19 is essential for individuals to take appropriate measures to prevent the spread of the virus, protect themselves and their loved ones, and make informed decisions about COVID-19–related health care options. Examples of health literacy about COVID-19 include understanding how the virus spreads, knowing the symptoms and when to seek medical attention, following public health guidelines, such as wearing masks and practicing physical distancing, and understanding the safety and efficacy of COVID-19 vaccines. In addition, we used a 5-point Likert scale (strongly disagree, disagree, neither agree nor disagree, agree, and strongly agree) to assess items relating to health literacy about COVID-19.

Attitude Toward COVID-19 and Its Screening

Questions about attitude toward COVID-19 and its screening were asked, including perceived risk of infection of COVID-19, worries about COVID-19 infection, self-assessed mental health status, perceived burden or stress during the COVID-19 pandemic, and hesitancy about RAT. Mental health disorders related to COVID-19 refer to a range of psychological and emotional conditions that have arisen as a result of the COVID-19 pandemic. We asked respondents if they experienced mental health disorders related to the pandemic in the survey questionnaire. Respondents were asked whether they were unsure or unwilling to undergo SARS-CoV-2 RAT. The question we used in the questionnaire was as follows: “When SARS-CoV-2 RAT becomes available, will you take it?” The response options were “yes,” “not sure,” and “no.” Based on the answers, respondents were classified into the following 2 groups: willing and hesitant (including the answers of “not sure” and “no”).

Statistical Analysis

To tackle the question of the age of other family members with the multiple-answer format, the categorical variable was reclassified as follows: the age of other family members was reclassified by whether a participant had children (<6 years old) or elders (>60 years old). For other questions with the multiple-answer format, categorical variables were converted into binary dummy variables. Likert scale–type questions relating to health literacy about COVID-19 were treated as continuous variables. We calculated proportions or medians with interquartile ranges for all variables, stratified by hesitancy to undergo RAT. Chi-square tests (for proportions) and Wilcoxon rank sum tests (for medians) were used to assess statistically significant differences between the willing and hesitant groups.

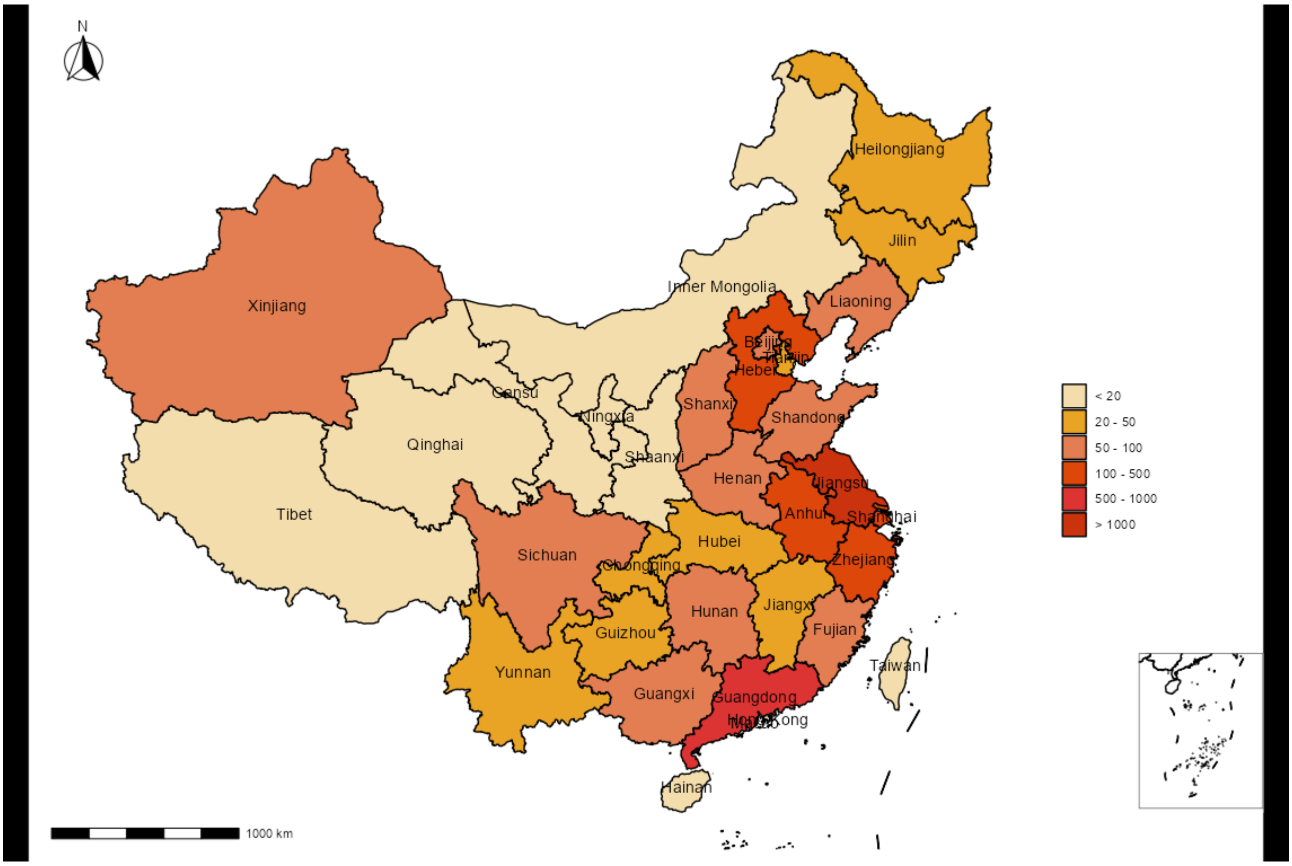
Logistic regression models were fitted to the data to assess correlates of hesitancy to undergo RAT. The outcome variable was whether a participant was willing to undergo RAT (coded as 0) or was hesitant (coded as 1). In addition, the questionnaire data had a group structure for all categorical variables, including 25 groups (ie, questions or covariates) that consisted of 44 variables (ie, the sum of [the number of answer choices for each binary dummy variable − 1], the number of other categorical variables, and the number of continuous variables). Due to the multicollinearity among covariates in regression analysis, we employed a variable selection step to determine the optimal covariate sets. In this study, to control multicollinearity effectively by assessing covariates with groups of variables as opposed to independent variables and to select the optimum group of variables by inducing sparsity in the number of covariates, we used the sparse group minimax concave penalty (MCP), which has been proven to outperform other penalties, such as the group LASSO (least absolute shrinkage and selection operator) [25]. Once the optimal penalty was estimated, the final logistic regression models were refitted without the penalty to debias the shrunken estimates in the coefficients due to the penalty [26]. All statistical analyses were performed using R software version 4.2.1 (R Core Team).

Results

Characteristics of the Study Participants

This survey had access to 8856 respondents with diverse demographic, socioeconomic, and geographic characteristics in China. In the process of data cleaning, we set rigorous standards for valid responses from participants. Ultimately, a total of 5388 participants (response rate of 60.84%; adults nationwide) was set as the fixed sample size. Figure 1 shows the geographical distribution (province level) of study participants in China. Among the participants, 2819 were women, and the proportions of women and men were 52.32% (2819/5388) and 47.68% (2569/5388), respectively. The median age of all participants was 32 years. In this survey, 88.33% (4759/5388) of participants were from urban areas, 80.31% (4327/5388) had an undergraduate education or above, 28.64% (1543/5388) were professional technicians, and 26.90% (1449/5388) had a monthly salary of at least 10,000 RMB (1 RMB=0.14 USD). With regard to health status, 86.06% (4637/5388) had absence of chronic diseases. Moreover 56.01% (3018/5388) had experienced any NPIs and 73.20% (3944/5388) were receiving or had completed the booster vaccination against COVID-19.

Figure 1. Geographical distribution of the study participants.



In this survey, among the 5388 participants, 687 (12.75%) expressed hesitancy to undergo RAT for COVID-19 and 4701 (87.25%) were willing to undergo RAT. The characteristics of study participants in the RAT willing and hesitant groups are shown in Tables 1-3. The 2 groups were roughly similar with respect to ethnicity, monthly salary, and COVID-19 vaccination status. Among 4701 participants in the willing group, 2529 (53.80%) were women, while among 687 participants in the hesitant group, 290 (42.21%) were women. The willing group was significantly older than the hesitant group (*P*<.001). Those in the willing group were more likely to be in the eastern region (3940/4701, 83.81% vs 479/687, 69.72%), be in urban areas (4186/4701, 89.04% vs 573/687, 83.41%), have a postgraduate education (901/4701, 19.17% vs 79/687, 11.50%), be married (2843/4701, 60.48% vs 387/687, 56.33%), and have elders in the family (2513/4701, 53.45% vs 248/687, 36.10%) than those in the hesitant group. In addition, the other variables (except ethnicity, monthly salary, and COVID-19 vaccination status) were correlated with willingness to undergo RAT.

Correlates of Hesitancy to Undergo RAT

In total, 21 groups that consisted of 40 variables selected by the MCP-penalized group regression were included in the final model. Only 13 groups were significantly associated with developing hesitancy to undergo RAT for COVID-19 (Table 4). The forest plot given in Figure 2 reveals the difference in the adjusted odds ratios (aORs) of the risk factors of hesitancy to undergo SARS-CoV-2 RAT between the willing group and hesitant group. Actually, Figure 2 shows the forest plot summarizing only the significant variables that were associated with hesitancy to undergo RAT. The complete table containing all variables left in the final model is presented in Multimedia Appendix 1.

Six sociodemographic variables were selected to be included in the model. Those who were women (aOR 0.720, 95% CI 0.599-0.864), were older (aOR 0.982, 95% CI 0.969-0.995), had a postgraduate education (aOR 0.612, 95% CI 0.435-0.858), and had children and elders in the family (aOR 0.685, 95% CI 0.510-0.911) showed willingness to undergo RAT. However, those who were from the central region (aOR 1.815, 95% CI 1.441-2.278) and had a decrease in the monthly salary by more than 10% (aOR 1.449, 95% CI 1.123-1.875) were significantly more likely to report hesitancy to undergo RAT for COVID-19 (*P*<.001 and *P*=.005, respectively). Five variables concerning experiences of COVID-19 restrictions and knowledge of COVID-19 were also selected to be included in the model. Those who had 21-30 close contacts daily (aOR 0.621, 95% CI 0.386-0.960), had >20 PCR tests for COVID-19 (aOR 0.279, 95% CI 0.205-0.377), and had more knowledge about COVID-19 (aOR 0.942, 95% CI 0.916-0.970) showed greater ease in accepting RAT. In addition, those who experienced any NPIs (aOR 1.613, 95% CI 1.322-1.973) and received COVID-19 information from traditional media (aOR 1.544, 95% CI 1.279-1.863) were significantly more likely to report hesitancy to undergo RAT for COVID-19 (both *P*<.001). Two psychological and attitudinal variables were also found to be significantly associated with developing hesitancy to undergo RAT for COVID-19. Those who had a better self-assessed mental health status (aOR 1.943, 95% CI 1.352-2.765) were significantly more likely to report hesitancy to undergo RAT for COVID-19 (*P*<.001), while those who had mental health disorders (aOR 0.795, 95% CI 0.646-0.975) showed higher wiliness to undergo RAT.

[a] aOR: adjusted odds ratio.

[b] N/A: not applicable.

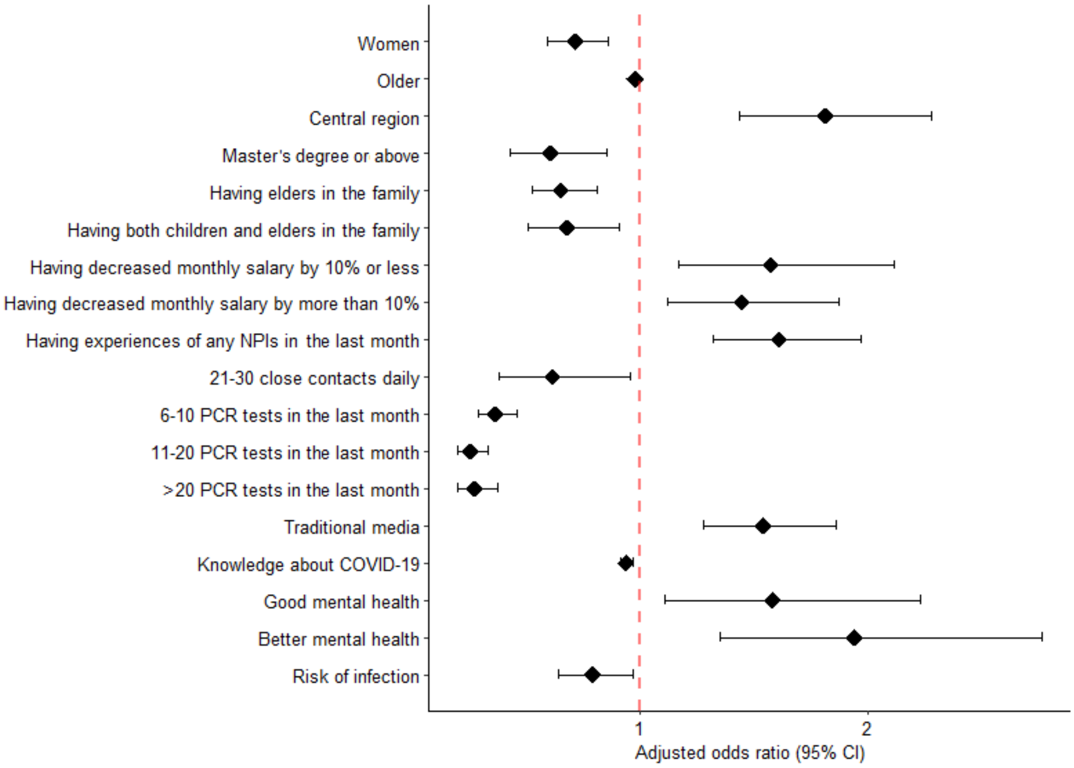
[c] The eastern region includes Beijing, Tianjin, Hebei, Liaoning, Shanghai, Jiangsu, Zhejiang, Fujian, Shandong, Guangdong, and Hainan. The central region includes Shanxi, Jilin, Heilongjiang, Anhui, Jiangxi, Henan, Hubei, and Hunan. The western region includes Sichuan, Chongqing, Guizhou, Yunnan, Tibet, Shaanxi, Gansu, Qinghai, Ningxia, Xinjiang, Inner Mongolia, and Guangxi.

[d] NPI: nonpharmaceutical intervention.

[e] Close contacts refer to contacts with a physical contact distance of <1 meter.

[f] PCR: polymerase chain reaction.

Figure 2. Forest plot summarizing only the significant variables that were associated with hesitancy to undergo SARS-CoV-2 rapid antigen testing. The central region includes Shanxi, Jilin, Heilongjiang, Anhui, Jiangxi, Henan, Hubei, and Hunan. Close contacts refer to contacts with a physical contact distance of <1 meter. NPI: nonpharmaceutical intervention; PCR: polymerase chain reaction.



Discussion

In this nationwide cross-sectional survey, we found that 12.75% (687/5388) of the participants were hesitant to undergo RAT for COVID-19, while 87.25% (4701/5388) were willing to undergo RAT. Several characteristics were found to be associated with hesitancy to undergo RAT, which could help identify subgroups to improve the awareness and acceptance of RAT.

Hesitancy about COVID-19 in China was low but may compromise the scale-up of RAT. A cross-sectional survey involving residents of Greece and Cyprus found that 79% (196/248) reported willingness to self-test in fighting the COVID-19 pandemic [27]. In another representative survey of the Greek population conducted in the first half of August 2021, two-thirds of responders characterized COVID-19 self-tests as unreliable and two-fifths believed they were dangerous [28]. An Indonesia study found that, if rapid COVID-19 antigen self-tests were available, 62.70% (395/630) would use them when necessary [29]. In addition to positive attitudes toward COVID-19 vaccination [30], this relatively high percentage of willingness to undergo RAT in China might reflect public trust in the government, and health authorities in China spared no effort to offer accessible health care services to increase safety and the perceptions of safety for the public. As the COVID-19 pandemic continues and in the postpandemic era, it would be important to monitor and promote public willingness toward RAT further in order to identify infected individuals in the early phase and keep COVID-19 incidence low, as well as improve the coverage of routine RAT for COVID-19.

Hesitancy to undergo RAT was found to be associated with being male, which is similar to the epidemiologic characteristic in the Greek population [28]. In addition, younger individuals reported low willingness to undergo RAT compared to their older counterparts. This association was also found in a representative survey of 17 countries on COVID-19 vaccine hesitancy [31]. There could be some possible explanations. Younger individuals may perceive themselves as being at lower risk of experiencing a severe illness associated with COVID-19, as the disease tends to affect older people more severely. This perception of lower risk could lead them to believe that RAT is unnecessary. In addition, younger individuals may have lower incomes or be more financially insecure, and the cost of RAT may be a barrier for them. They may also be more concerned about missing work or school if they test positive and need to isolate. Moreover, we found that socioeconomic status and education might play a role in determining hesitancy to undergo RAT. Areas further to the east in China have a better socioeconomic status and higher education level, and a better socioeconomic status and higher education level have been previously found to be associated with better health literacy and lower vaccine hesitancy [32,33]. This might have resulted in a situation where those who were from the central region and had a high school education or lower were significantly more likely to report hesitancy to undergo RAT, similar to vaccination for COVID-19. A change in the monthly salary during the COVID-19 lockdown was much more likely to be associated with hesitancy to undergo SARS-CoV-2 RAT compared with the current monthly salary. This could indicate that those who experience job loss, reduced income, and increased debt during the COVID-19 pandemic should receive much more attention to improve the awareness and acceptance of SARS-CoV-2 RAT. The pandemic has also highlighted existing social inequalities, with communities, who experienced heavier financial burden, being disproportionately affected by the virus. A study also found that individuals with lower salary were more likely to have higher similar mistrust about vaccines [33]. In addition, we found that not having children or elders in the family was correlated with hesitancy to undergo RAT. This may be due to the desire to protect children and elders in the family and prevent chains of intrahousehold transmission. Those having elders or having both children and elders in the family showed willingness to undergo RAT.

We identified 5 variables concerning experiences of COVID-19 restrictions and knowledge of COVID-19, which were significantly associated with hesitancy to undergo RAT. Those who experienced any NPIs and had 0-5 close contacts daily were more likely to report hesitancy. A prior study has found that more social contacts and large households increased the risk of SARS-CoV-2 infection [34,35]. The finding for the experience of any NPIs or the self-reported number of close contacts daily might be because the subgroup believed there was a low risk of SARS-CoV-2 infection and had stronger faith in the health condition, compared with those who did not experience NPIs for COVID-19 or had more close contacts in daily life. Moreover, those who had 0-5 PCR tests for COVID-19 in the last month were more likely to report hesitancy. PCR testing remains the gold standard in all countries, with the majority also employing it for diagnostic and surveillance purposes [36]. Fewer PCR tests might deepen hesitancy to undergo RAT. Furthermore, those who received COVID-19 information from traditional media were more likely to report hesitancy. Over the course of fighting the COVID-19 pandemic, health-related information and knowledge have played large roles in shaping vaccine hesitancy [37]. Increased likelihood of vaccine acceptance was seen among those who obtained COVID-19 information from digital media or nonhealth-related sources like influencers [38], and this likely was related to hesitancy to undergo RAT among participants in our survey. Traditional media like newspapers are not prone to misinformation, but do not have the same tremendous and popular health information available as other information sources like internet media. Moreover, inadequate knowledge has been found to be associated with vaccine hesitancy [39], which might be in line with our finding that those who had less knowledge about COVID-19 were significantly more likely to report hesitancy to undergo RAT.

We identified 2 psychological and attitudinal variables that were significant predictors of hesitancy to undergo RAT. Those who had good or better self-assessed mental health and did not perceive a high risk for SARS-CoV-2 infection were more likely to report hesitancy, which might be attributable to the belief that one ought to undergo RAT if they are at high risk for SARS-CoV-2 infection. This finding suggests that the government should offer appropriate recommendations on RAT, with the aim of identifying infected individuals in the early phase and keeping COVID-19 incidence low to tackle outbreaks in the future and especially to safeguard the shift from a pandemic phase to an endemic phase of the COVID-19 global response.

To reliably scale up RAT further for case management or self-isolation at the individual level and for large-scale screening and emergency responses at the population level, the government should offer more accurate recommendations on RAT to the target population. First, the public should be provided with the test as widely and freely as possible, which could be a strategy to improve the availability of RAT and the willingness to undergo RAT without additional financial cost for the public. Second, trust about RAT should be enhanced, including enough knowledge about COVID-19 and clear instructions about RAT via multiple media. Furthermore, the public should be provided with complete guidelines after undergoing RAT. For example, accessible PCR testing could be used to validate the results of RAT owing to the risk of false-positive results. If positive results are confirmed, guidelines about case management or self-isolation should be put in place.

SARS-CoV-2 has infected up to 900 million people as of January 11, 2023, in Mainland China after lifting of the COVID-19 policy [40]. The emergence of new variants (the Omicron sublineage XBB [41]) of the virus has also raised concerns about their potential to evade existing vaccines and treatments, highlighting the importance of ongoing surveillance and research. Given the reopening of society, vaccines; medication; and public health measures, such as masking, social distancing, and screening remain important tools in controlling the spread of the virus. Furthermore, by fully using the lessons learned from the mass screening (including timely scale-up of RAT) during the COVID-19 pandemic, this study could help to develop more resilient and prepared mass screening strategies, and could inform future responses to other novel infectious diseases.

In this study, we used group regression with an MCP penalty to discern variables that significantly shaped hesitancy to undergo RAT. It was found that several sociodemographic variables, variables concerning experiences of COVID-19 restrictions and knowledge of COVID-19, and psychological and attitudinal variables were associated with hesitancy to undergo RAT for COVID-19. Notably, variables, such as residence, marital status, and occupation type, were not selected for inclusion in the final model despite statistically significant differences between the study groups, which suggests that group regression with an MCP penalty was successful in not only selecting significant variables but also encouraging model sparsity. Some limitations of this study are worth acknowledging. In this survey, 88.33% of participants were from urban areas and 80.31% had an undergraduate education or above. Thus, it is very likely that individuals from rural areas and those with lower education are underrepresented. Individuals with SARS-CoV-2 infection were not included in the analysis. In addition, the sample size in this study was small compared to the large population size of China, which is another limitation of the study. Therefore, our findings should be interpreted and generalized with caution. Moreover, regarding hesitancy to undergo RAT, a single question was asked to assess hesitancy. Despite its simplicity and efficiency, more multidimensional items should be adopted to assess hesitancy in future studies.

In addition, the general bias for a cross-sectional design could not be dismissed, which limited our capacity to statistically discern causal relationships. Furthermore, given the reopening of society, the aim was no longer completely relevant, considering the lifting of global and Chinese preventive and control measures for COVID-19. However, the real-world evidence in this study could inform future responses to other novel infectious diseases.

In conclusion, our study found a low but potentially problematic level of hesitancy to undergo RAT. Although hesitancy to undergo SARS-CoV-2 RAT in China was low, it may influence the scale-up of RAT. Special efforts should be made to improve the awareness and acceptance of RAT among men, younger adults, individuals with a lower education or salary, families without children and elders, and individuals who access COVID-19 information via traditional media. Given the gradual reopening of society, this study could inform our responses to future novel infectious diseases and help to develop more resilient and prepared mass screening strategies (including timely scale-up of RAT).

Acknowledgments

This study was supported by the Special Support Plan for High-Level Talents of Guangdong Province (2019TQ05Y230) and the Programme of Science and Technology Development Plan of Wuxi Municipal Science and Technology Bureau (Y20222006). Abstract

Background: With COVID-19 being a newly evolving disease, its response measures largely depend on the practice of and compliance with personal protective measures (PPMs).

Objective: This systematic review aimed to examine the knowledge and practice of COVID-19 PPMs in African countries as documented in the published literature.

Methods: A systematic search was conducted on the Scopus, PubMed, and Web of Science databases using appropriate keywords and predefined eligibility criteria for the selection of relevant studies. Only population-based original research studies (including qualitative, quantitative, and mixed methods studies) conducted in Africa and published in the English language were included. The screening process and data extraction were performed according to a preregistered protocol in PROSPERO (CRD42022355101) and followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. The quality of the included studies was assessed using the Mixed Methods Appraisal Tool. Thematic analysis was used to systematically summarize the studies into 4 predefined domains: knowledge and perception of PPMs, mask use, social and physical distancing, and handwashing and hand hygiene, including their respective levels and associated factors.

Results: A total of 58 studies across 12 African countries were included, published between 2019 and 2022. African communities, including various population groups, had varying levels of knowledge and practice of COVID-19 PPMs, with the lack of personal protective equipment (mainly face masks) and side effects (among health care workers) being the major reasons for poor compliance. Lower rates of handwashing and hand hygiene were particularly noted in several African countries, especially among low-income urban and slum dwellers, with the main barrier being the lack of safe and clean water. Various cognitive (knowledge and perception), sociodemographic, and economic factors were associated with the practice of COVID-19 PPMs. Moreover, there were evident research inequalities at the regional level, with East Africa contributing 36% (21/58) of the studies, West Africa contributing 21% (12/58), North Africa contributing 17% (10/58), Southern Africa contributing 7% (4/58), and no single-country study from Central Africa. Nonetheless, the overall quality of the included studies was generally good as they satisfied most of the quality assessment criteria.

Conclusions: There is a need to enhance local capacity to produce and supply personal protective equipment. Consideration of various cognitive, demographic, and socioeconomic differences, with extra focus on the most vulnerable, is crucial for inclusive and more effective strategies against the pandemic. Moreover, more focus and involvement in community behavioral research are needed to fully understand and address the dynamics of the current pandemic in Africa.

personal protective measures; mask use; social distancing; hand hygiene; COVID-19; Africa; nonpharmaceutical interventions

Introduction

Background

After its emergence in December 2019, COVID-19 was declared a pandemic by the World Health Organization on March 11, 2020, and it has spread to almost all countries and regions, including Africa [1,2]. Spreading to the continent through travelers returning from hot spots in Asia, Europe, and the United States, COVID-19 was first recorded in Africa in Egypt on February 14, 2020, and within a few months, the virus had spread throughout the continent [1,3]. As of March 20, 2023, a total of 12,804,191 cumulative cases and 258,623 deaths have been reported in Africa compared with 682,546,389 cases and 6,819,835 deaths across the globe, showing a disproportionately low case fatality rate of COVID-19 in Africa [4].

As in the rest of the world, various response measures were implemented in different African countries to curb the spread of the virus, including statewide lockdowns, restrictions on movement, bans on social gatherings, and school closures [5,6]. Although the continent appears to have a lower absolute number of cases and deaths compared with other regions [7], which might also be related to the lower number of tests administered, the pandemic has had a deep impact on the socioeconomic systems of African countries [8,9]. The pandemic has also strained the weak and fragmented health systems, as shown by the lack of personal protective equipment (PPE), testing kits, and other treatment necessities, especially for patients with COVID-19 who are critically ill [6,8].

With COVID-19 being a newly evolving disease, its less-defined outcomes and unprecedented prevention, treatment, and control modes largely require indisputable collaboration among various stakeholders in the community [9]. Nonpharmaceutical interventions play an important role in the control and prevention of pandemics, including the COVID-19 pandemic, especially in its early phase and wave. Despite the availability of approved vaccines against COVID-19, response measures toward this pandemic still largely depend on the practice of and compliance with personal protective measures (PPMs), including face mask use, social and physical distancing, and hand hygiene [10]. Moreover, knowledge and perceptions of PPMs have been reported as among the key determinants of practice and compliance with PPMs against COVID-19 as they influence people’s behavior [10,11]. These were also considered in this study in the African context.

The pandemic has had a broad range of impacts and challenges across regions, and different communities have responded differently. However, given the diversity of social systems across regions and countries, preparedness and the search for a country- or region-specific practical solution to the pandemic require a better understanding of the challenges of practicing PPMs and hard-learned experiences through comprehensive research [9]. There has been a high research output documenting COVID-19 characteristics, clinical outcomes, response, and impact throughout the world but with much less research coming from African countries [12,13]. The unavailability of research information might be seen as a barrier to successful prevention and further as a sign of inequity between high- and low-income countries and regions [14]. This scant literature poses knowledge gaps on how African countries are responding to the pandemic in terms of PPMs. Nonetheless, a recent review by Nwagbara et al [15] reported that most communities in sub-Saharan Africa had a positive attitude toward and good practices regarding COVID-19. Notably, this review considered studies only from sub-Saharan Africa and those conducted in the first stages of the pandemic, so it lacked insights into the overall practice of PPMs in Africa.

Objectives

Thus, this systematic review aimed to examine COVID-19 PPM research from African countries as documented in the published literature. On the basis of specific keywords, the review looked at the levels and associated factors of (1) knowledge and perception of PPMs and (2) practice of COVID-19 PPMs in various populations (including face mask use, physical and social distancing, and handwashing and hand hygiene).

Methods

Study Design

This systematic review was conducted according to a preregistered protocol in PROSPERO (CRD42022355101) and the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (Multimedia Appendix 1) [16]. This systematic review considered literature concerning PPMs from African countries. Literature was sourced from the following databases: Scopus, PubMed, and Web of Science. These databases were considered as they sufficiently cover most of the key journals, including most African journals. In addition, 2 of these databases (Scopus and Web of Science) could refine the search based on countries and regions, unlike other databases, which enabled us to specifically assess publications from African countries only.

Search Strategy

We conducted a comprehensive search using a set of appropriate keywords and Medical Subject Heading terms to identify studies reporting on PPMs. For consistency and precision, similar keywords and Medical Subject Heading terms were used and searched for in the article titles across the databases. A comprehensive search of the published literature was performed in each of the 3 selected databases using combinations of key terms and Boolean operators (Textbox 1). These included “mask,” “nose covering,” “personal protective equipment,” “handwashing,” “hand washing,” “hand sanitizer,” “hand sanitiser,” “sanitation,” “hygiene,” “social distance,” “social distancing,” “physical distance,” “physical distancing,” “social acceptance," "COVID-19," "2019-nCoV," "coronavirus disease," "SARS-CoV-2," and "corona virus disease 2019."

Textbox 1. Key terms or Boolean operators used for the search.

- "Mask" OR "nose covering" OR "personal protective equipment" OR "handwashing" OR "hand washing" OR "hand sanitizer" OR "hand sanitiser" OR "sanitation" OR "hygiene" OR "social distance" OR "social distancing" OR "physical distance" OR "physical distancing" OR "social acceptance" AND "COVID-19" OR "2019-nCoV" OR "coronavirus disease" OR "SARS-CoV-2" OR "corona virus disease 2019"
- "Mask" OR "nose covering" OR "personal protective*" OR "hand wash*" OR "hand-wash*" OR "hand sanitize*" OR "hand sanitise*" OR "sanitation*" OR "hygiene*" OR "social distance*" OR "physical distance*" OR "social accept*" OR "social acceptance" AND "COVID-19" OR "COVID*"
- "Mask" OR "nose covering" OR "personal protective*" OR "hand wash*" OR "hand-wash*" OR "hand sanitize*" OR "hand sanitise*" OR "sanitation*" OR "hygiene*" OR "social distance*" OR "physical distance*" OR "social accept*" OR "social acceptance" AND "coronavirus*" OR "corona*"
- "Mask" OR "nose covering" OR "personal protective*" OR "hand wash*" OR "hand sanitize*" OR "hand sanitise*" OR "sanitation*" OR "hygiene*" OR "social distance*" OR "physical distance*" OR "social accept*" OR "social acceptance" AND "SARS-CoV-2*" OR "2019-nCoV*"

Inclusion and Exclusion Criteria

The inclusion and exclusion criteria are listed in Table 1. Only population-based original research studies (including qualitative, quantitative, and mixed methods studies) conducted in Africa, published in English, and reporting on PPMs against COVID-19 were considered in the full review. In addition, multicountry studies were considered if they included an African country as part of their study population. Only English-language articles published between November 1, 2019, and March 4, 2022, were considered.

Table 1. Summary of the inclusion and exclusion criteria.

Parameter	Inclusion criteria	Exclusion criteria
Article or study type	• Population-based original research studies • Qualitative, quantitative, and mixed methods studies • Multicountry studies	• Reviews, commentaries, and editorials • Dissertations, government reports, newspaper articles, textbooks, book chapters, and protocols • Gray literature and preprints • Laboratory studies, model and framework studies, and validation studies
Language	• English language	• All other non-English languages
Publication period	• November 1, 2019, to March 4, 2022	• All periods outside November 2019 to March 2022
Study setting	• African countries	• All non-African country settings

Data Extraction

After screening, data from the relevant studies were independently extracted by 2 reviewers (JK and PSC) onto a structured data extraction template, and a consensus was reached through discussion in case of disagreements on the extracted data. The following variables were extracted: first author, year of publication, study location, study design, key measurements, study population, sample size. and main findings.

Quality Assessment and Analysis

We assessed the information from the included articles using the Mixed Methods Appraisal Tool (version 2018) with detailed descriptions of the rating [17]. In total, 2 reviewers also independently assessed the quality of the included studies, and in case of discrepancies, a consensus was reached through discussion.

This study used thematic analysis, and the literature in this review was used to understand the practice of PPMs against COVID-19 in African countries. The studies were classified according to four main themes: (1) knowledge and perception of PPMs, (2) mask use, (3) social and physical distancing, and (4) handwashing and hand hygiene, including their respective levels or prevalence and associated factors. In addition, various population groups and challenges faced in practicing COVID-19 PPMs were examined under each of the main themes based on the available information in the analyzed studies. The 4 themes were drafted by a panel of public health experts after a series of discussions to reach a consensus.

The analysis process involved a six-step data synthesis process: (1) in total, 2 reviewers (JK and PSC) extracted relevant information on knowledge and practice of PPMs from each article independently; (2) after extraction, they discussed to reach a consensus on the key information identified in each article; (3) the extracted information was coded under the 4 predefined domains by the 2 reviewers independently; (4) after completing the coding independently, they discussed the results, where any discrepancies were resolved through discussion; (5) the revised coding results were read and checked by the 2 reviewers independently to ensure that all the extracted information was mapped to the 4 domains correctly; and (6) all the information in the codebook was adapted into a tabular format.

Results

Selection of Studies Conducted in Africa

The number of studies identified, reviewed, and selected, including the reasons for exclusion, is summarized in Figure 1. A total of 58 studies were selected through this process and further analyzed [18-75]. The information and main findings extracted from all included studies is detailed in Table 2.

Figure 1. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the selected studies. WoS: Web of Science.

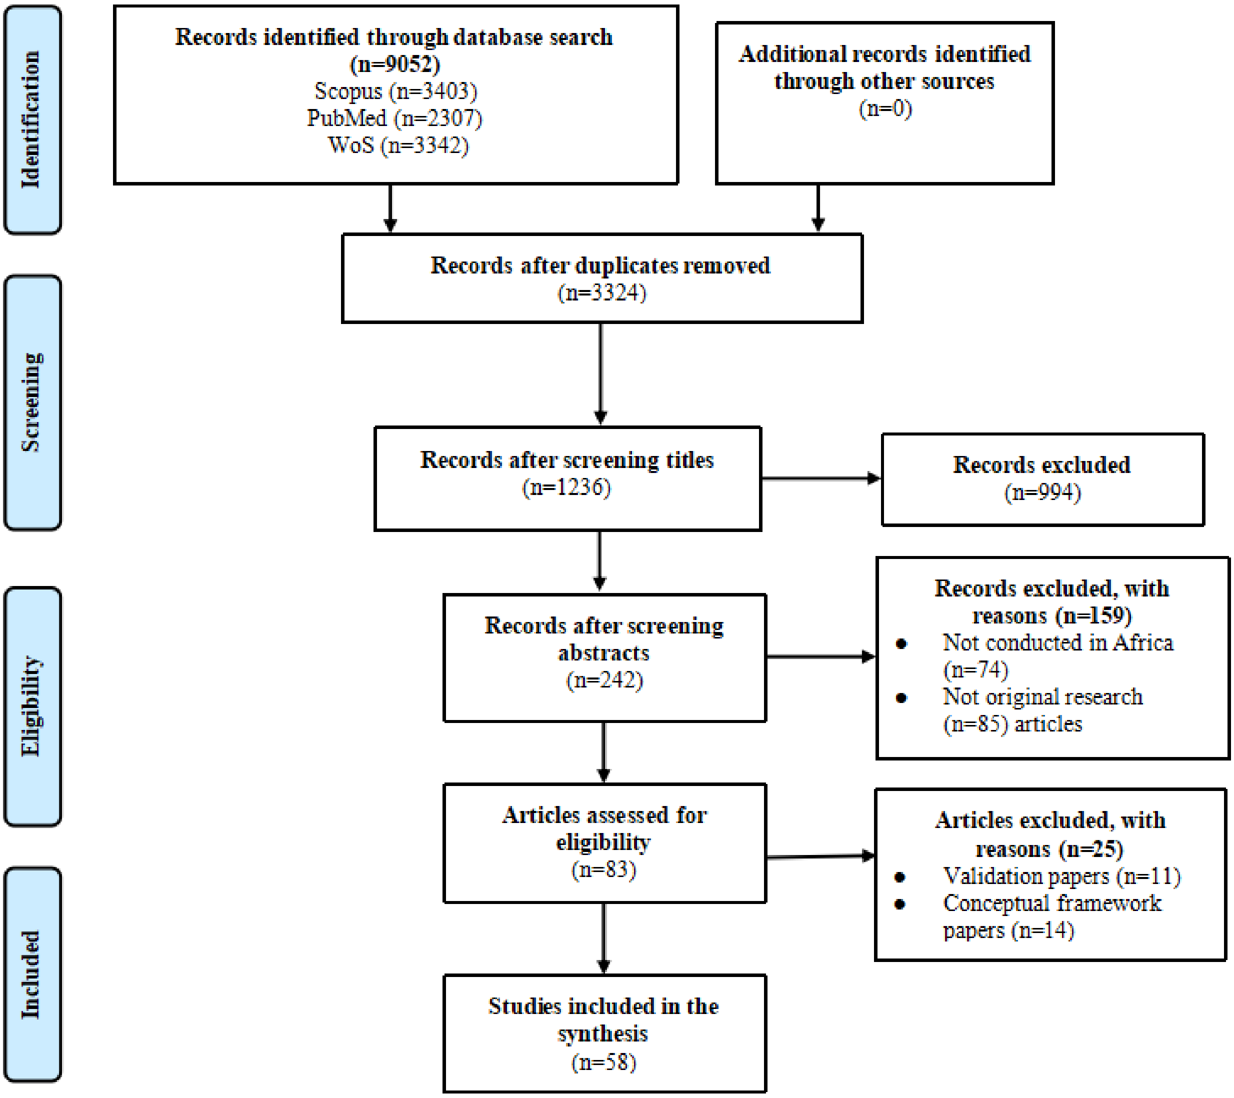

Table 2. Characteristics of the included studies.

Study	Study setting or country	Study type and key measures	Study population	Sample size, N	Adherence or noncompliance rates	Relevant findings
Sikakulya et al [18], 2021	Uganda	Cross-sectional; knowledge, attitudes, and practices regarding proper use of face masks	Community	1114	51.5% had poor mask use	• Most participants (60.1%) had satisfactory knowledge of the use of face masks, and this was greater among participants with tertiary educational levels. • Regarding attitude, 69.4% were confident enough to correctly put on a face mask, 83.4% believed that a face mask can protect against COVID-19, and 75.9% had never shared their face mask. Most (95.2%) agreed that wearing face masks in public places was important to protect themselves against COVID-19, and 60.3% reported washing their hands before wearing and after removing the face mask.
Hailu et al [20], 2021	Ethiopia	Cross-sectional and mixed methods; compliance with social distancing	Community	401	Overall, 55.4% had poor compliance with social distancing measures	• Most (63.84%) reported that they went to crowded places without putting on a face mask, but 60.6% and 76.3% had good knowledge of COVID-19 transmission and prevention, respectively. • Only age was associated with social distancing measures, with older persons more likely than younger persons to comply with social distancing guidelines.
Bakry and Waly [21], 2020	Egypt	Cross-sectional; perception and practice of social distancing	Community	1036	82% were not strictly practicing social distancing	• Most (70%) perceived that social distancing measures reduced the transmission of COVID-19. • There was a significant association between the practice of social distancing and some sociodemographic factors such as sex, age, education, working status, place of residence, and community of residence.
Tadesse et al [22], 2020	Ethiopia	Cross-sectional; predictors of preventive practices	Community employees	628	68.8% had poor COVID-19 prevention practice	• Most (>50%) had high perceived susceptibility, severity, benefit, barriers, cues to action, and self-efficacy regarding COVID-19 prevention practice. • Employees with a low level of perceived barriers were less likely to have a poor practice of COVID-19 prevention compared with employees with a high level of perceived barriers. • Moreover, employees with low cues to action and employees with a low level of self-efficacy practiced COVID-19 prevention measures to a lesser extent compared with those with high cues to action and high levels of self-efficacy.
Iyamu et al [23], 2022	MCP[a]—6 countries: Botswana, Kenya, Malawi, Nigeria, Zambia, and Zimbabwe	Cross-sectional; face mask use perception and social media	Community	1988	—[b]	• A total of 58.8% used social media as their main source of information, whereas 85% agreed that face masks were effective against COVID-19. • Respondents who used social media were more likely to agree that face masks were effective compared with those who did not.
Bukuluki and Kisaakye [24], 2021	Uganda	Cross-sectional; face mask wearing in public places	Community	1054	52% and 78% wore face masks sometimes inside in public spaces and always outside in public spaces, respectively	• Approximately 90% of respondents agreed that wearing a mask inside or outside in public spaces can prevent COVID-19 infection. • Age and frequency of face mask wearing inside or outside in public spaces were significantly related to belief in face mask efficacy.

Study	Study setting or country	Study type and key measures	Study population	Sample size, N	Adherence or noncompliance rates	Relevant findings
Nnama-Okechukwu et al [25], 2020	Nigeria	Qualitative study; knowledge of and compliance with preventive measures	Community	36	—	• Findings revealed that most of the respondents believed that the COVID-19 pandemic was more of a hoax than a reality. • Other findings showed that this poor knowledge negatively affected their compliance with preventive measures to curb the spread of coronavirus.
Kajiita and Kang'ethe [26], 2021	8 African countries	Cross-sectional and qualitative; social distancing perceptions	Community	20	—	• Results revealed varied conceptualizations and interpretations of the disease and social distancing. Notably, COVID-19 regulations such as social distancing and face mask wearing were perceived as an imported policy, a misconception responsible for nonadherence to COVID-19 protocols. • Furthermore, the study underscored that the disease and policies related to it disrupted ways of social life, infringed on people's social-cultural rights, and had adverse health consequences.
Fodjo et al [27], 2020	10 countries; DRC[c], Uganda, Mozambique, and Somalia	Multicountry web-based survey; compliance with mask use	General public	206,729	Face mask use—DRC: 43.2%; Uganda: 32.7%; Mozambique: 93.9%; Somalia: 51.2%	• Adherence rates were higher in countries where masking was mandatory or highly encouraged by the government during the early phases of the COVID-19 outbreak. • Reusable cloth masks (more cost-beneficial and environmentally friendly than surgical masks) were the most frequent, accounting for 51.1% of all mask types. • There were differential rates of mask uptake and use between sexes and age groups observed in different countries. Even in countries where no preexisting culture of mask use existed, high uptake of mass masking was feasible.
Sewpaul et al [28], 2021	South Africa	Cross-sectional; compliance with and determinants of social distancing	Community	17,563	20.3% reported having not left home	• A total of 50.6% were in close physical distance with 1-10 people, 21.1% were in close physical distance with 11-50 people, and 8% were in close physical distance with >50 people. • Larger household sizes and incorrect knowledge about the importance of social distancing were associated with being in contact with >50 people. Male sex, younger age, and being in the White and non-White population groups were significantly associated with being in contact with 1-10 people but not with larger numbers of people. • Employment, at least a secondary school education, the lack of self-efficacy in being able to protect oneself from infection, and moderate or high risk perception of becoming infected were all associated with increased odds of close contact with 1-10, 11-50, and >50 people relative to remaining at home.
Wondimu et al [29], 2020	Ethiopia	Cross-sectional; predictors of preventive practices	Community	803	Generally, 59.4% had good prevention practices for COVID-19	

Study	Study setting or country	Study type and key measures	Study population	Sample size, N	Adherence or noncompliance rates	Relevant findings
						- Approximately 64.7% had a history of going to crowded places, whereas only 30.3% of the participants had a history of wearing a mask when leaving home. - A total of 64.4% had a history of maintaining their distance at 2 meters, and 64.8% washed their hands with soap and water or used alcohol-based hand sanitizers. - Urban residence, family size, good knowledge, positive attitude, intention to seek care, and perceived mortality were positively associated with good prevention practices.
Fikrie et al [30], 2021	Ethiopia	Cross-sectional; social distancing and associated factors	Community	410	38.3% had good social distancing practices	- Younger age (26-35 years) and being employed were positively associated with good social distancing practice, whereas poor knowledge, negative attitude, and low perceived susceptibility had a negative association.
Mejjad et al [31], 2021	Morocco	Cross-sectional; mask use and disposal behavior	Community	185	70% used face masks at least once a day	- A total of 70% of the respondents threw their discarded masks and gloves in the house trash or trash bins after their first use, whereas nearly 30% of respondents admitted that they did not wear masks as they did not leave their homes during the lockdown.
Burger et al [32], 2022	South Africa	Longitudinal survey; predictors of mask wearing	Community	7074	74% wore face masks when in public	- Self-efficacy, the prevalence of others' mask wearing in the same district, and affluence were positively associated with reported mask wearing. - Those who reported staying at home were significantly less likely to report wearing a mask. - Despite having a higher mortality risk, older adults had significantly lower odds of mask wearing. - The prevalence of mask wearing increased significantly from May 2020 to August 2020 (from 50% to 74%) as COVID-19 cases increased and lockdown restrictions were eased, but staying at home, physical distancing, and social distancing decreased.
Amuakwa-Mensah et al [33], 2021	MCP—12 sub-Saharan African countries	Cross-sectional; handwashing and COVID-19 concerns	Community	4788	54.6% washed their hands for 20 seconds >5 times a day, and 4.2% did not wash their hands at all	- The level of concern about the spread of the virus increased the likelihood of washing hands with soap under running water for a minimum of 20 seconds at least 5 times a day. - Heterogeneous effects across gender and age groups, locality, and various water sources were noted.
Szczuka et al [19], 2021	MCP—Gambia	Observational study; handwashing adherence	Community	6064	—	- Higher handwashing adherence was associated with more frequent exposure to handwashing guidelines, being a health care professional, being older, being female, and being married. - Stricter containment and health policies were associated with lower handwashing adherence.
Iwuoha and Aniche [34], 2020	Nigeria	Cross-sectional and qualitative; impact of physical distancing policies	Slum residents	49	—	

Study	Study setting or country	Study type and key measures	Study population	Sample size, N	Adherence or noncompliance rates	Relevant findings
						• The study demonstrated that the peculiar and adverse conditions of low-income urban dwellers were not considered in the formulation of the COVID-19 lockdown and physical distancing policies in Nigeria. Thus, such policies worsened the living conditions of extremely low-income urban or suburban slum dwellers in Nigeria. • There is a need to engender an indigenous (Afro-centered) approach to the containment of the pandemic.
McCreesh et al [35], 2021	South Africa	Longitudinal survey; impact of social distancing regulations	Community	1704	—	• Extrahousehold social contact fell substantially following the imposition of COVID-19 distancing regulations in that there were substantial declines in close physical and conversational contacts and also in beyond-household sharing of indoor space. • However, there was ongoing contact within intergenerational households, highlighting a potential limitation of social distancing measures in protecting older adults.
De Backer et al [36], 2020	MCP—38 countries; Uganda, South Africa, and Egypt	Cross-sectional; impact of social distancing on healthy meals	Community	37,207	—	• Increases in planning, selecting, and preparing healthy foods were found for women and men and were positively related to perceived time availability and stay-at-home policies. • Psychological distress was a barrier for women and an enabler for men, whereas financial stress was a barrier and enabler depending on various sociodemographic variables.
Kim et al [37], 2022	Kenya	Cross-sectional; WASH[d] accessibility	Slum dwellers	647	—	• A total of 77.4% and 60.6% of people living in Kibera and Mathare, respectively, had limited WASH facility accessibility or opportunity. • Overall accessibility and opportunity were better in Mathare than in Kibera.
Ag Ahmed et al [38], 2021	Mali	Qualitative study; adoption of physical distancing measures	Internally displaced people	68	—	• The main challenges concerning the implementation and adoption of physical distancing measures included the proximity in which internally displaced people live, their beliefs and values, the lack of toilets and safe water on sites, internally displaced people's habits and economic situation, humanitarian actors' lack of financial resources and authority, and social pressure from religious leaders. • Implemented mitigation measures included the building of new shelters or their compartmentalization, the creation of income-generating activities and food banks, psychosocial support, promotion of awareness of internally displaced people, and night police patrols and surveillance to discourage internally displaced people from going out.
Mhlanga-Gunda et al [39], 2022	Zimbabwe	Qualitative study; social distancing and prevention measures	Prisoners and staff	80	—	

Study	Study setting or country	Study type and key measures	Study population	Sample size, N	Adherence or noncompliance rates	Relevant findings
						• Outdated infrastructure, severe congestion, interrupted water supply, and inadequate hygiene and sanitation were conducive to ill health and the spread of disease. • Health professionals had been well trained regarding COVID-19 control measures, and COVID-19 awareness among prisoners was generally adequate. • There was no routine COVID-19 testing in place beyond thermal scanning. • Access to health care was good, but standards were hindered by inadequate medicine and PPE[e] supply, and isolation measures were compromised by accommodation capacity issues. • The flow of prison entries constituted a transmission risk, and social distancing was impossible during meals and at night.
Assefa et al [40], 2021	Ethiopia	Cross-sectional; knowledge, attitude, practice, and challenges regarding hand hygiene	HCWs[f]	96	76% had good hand hygiene practices with alcohol-based hand sanitizers	• All the HCWs practiced different COVID-19 prevention methods, and most were knowledgeable (93.8%) and had a favorable attitude (74%). • However, 84.5% of the respondents faced challenges during alcohol-based hand sanitizer use owing to it being unavailable (68.8%) or expensive (52.1%); forgetting (11.5%); and experiencing health-associated risks such as skin irritation (28.1%), skin dryness (62.5%), and ocular irritation (11.5%).
Seid Yimer and Gebrehana Belay [41], 2021	Ethiopia	Hospital-based cross-sectional study; knowledge and practice of proper face mask use	HCWs	422	59.5% practiced proper mask use	• The overall good knowledge score of health care providers regarding proper face mask use was 65.8%. • Of them, 67.3% knew that face masks were worn with the white side facing in, 62.6% knew that face masks had 3 layers, and 78.4% knew that surgical face masks were worn for up to 8 hours.
Ahmed Sayed et al [42], 2021	Egypt	Cross-sectional; preparedness and attitude toward PPE	HCWs	254	—	• Only 28.74% of the house officers had good preparedness, whereas 85.83% had a good PPE attitude. • Preparedness and willingness were significantly associated with the overall worry related to the pandemic (fear of contracting COVID-19 and having family members at risk of severe COVID-19). • The house officers with good preparedness and willingness to deal with COVID-19 seemed to have a good PPE attitude.
Alao et al [43], 2020	Nigeria	Cross-sectional; knowledge, attitudes, beliefs, and use of PPE	HCWs	272	—	• Only 25.7% had adequate knowledge about PPE. Of the respondents who presumed that they had adequate knowledge about donning and doffing PPE, 94 (56%) were incorrect. • The predictors of good knowledge were younger age (<45 years) and practice location.
Daghmouri et al [44], 2020	Tunisia	Cross-sectional and institution-based; PPE use	HCWs	723	—	

Study	Study setting or country	Study type and key measures	Study population	Sample size, N	Adherence or noncompliance rates	Relevant findings
						• There was a likely overuse of PPE in addition to a high rate of side effects caused by PPE. • A total of 57.3% of participants reported a lack of PPE, which could be extremely stressful and detrimental to them. • A total of 72.5% of respondents reused disposable PPE, especially facial protective shields and FFP2^g. • Only 37.8% of frontline HCWs had received official training on the correct use of PPE, especially on how to fit FFP2 masks (only 32.6%). • A total of 89.1% of participants believed that they needed additional training.
Kassie et al [45], 2020	Ethiopia	Cross-sectional; preventive practices	HCWs	630	38.7% (95% CI 34.8%-42.5%) good preventive practice against COVID-19	• Being a male health care provider, having work experience of 6-10 years, and having a poor attitude toward COVID-19 were found to be significantly associated with poor COVID-19 preventive practices among HCWs.
Keleb et al [46], 2021	Ethiopia	Cross-sectional; PPE use and hand hygiene and associated factors	HCWs	489	32% and 22.3% were compliant with PPE use and hand hygiene practice, respectively	• Feedback for safety, training on COVID-19 prevention, and perception of infection risk were significant factors of good compliance with PPE use.
Birhanu et al [47], 2021	Ethiopia	Cross-sectional; PPE use	HCWs	418	37.6% had good practice of PPE use	• Being male, being a nurse or midwifery professional, regularly sanitizing hands and medical equipment, having national COVID-19 management guidelines, taking COVID-19 training, and the feeling of eventually contracting COVID-19 at the workplace had a positive association with PPE use. • However, not feeling safe at work when using standard precautions was negatively associated with PPE use.
El-Sokkary et al [48], 2021	Egypt	Cross-sectional; mask use and compliance	HCWs	404	53.2% were noncompliant with mask use	• Most reported a shortage in N95 respirators (91.3%) and practiced extended PPE use (88.1%). Better compliance with proper PPE use was reported among female individuals, physicians, and medical specialties with <10 years of work experience and working >8 hours per day. • Significant predictors of compliance were receiving previous training on the proper use of PPE, exposure to patients with COVID-19, and performing procedures that posed a high risk of exposure to COVID-19 to HCWs.
Afemikhe et al [49], 2020	Nigeria	Cross-sectional; transmission-based precaution practices	Nurses	367	85.6% maintained a good level of preventive practices, and 89.1% performed hand hygiene	• Academic qualification was a significant predictor of good practice in favor of respondents with a degree in Nursing. • Challenges identified were the lack of financial motivation, fear of infecting family members, and fear of contracting the virus (93.5%).
Elhadi et al [50], 2021	Libya	Cross-sectional; mask wearing	General population and HCWs	15,087	68.1% had mask wearing adherence	—

Study	Study setting or country	Study type and key measures	Study population	Sample size, N	Adherence or noncompliance rates	Relevant findings
Tabah et al [51], 2020	90 countries; Libya, Egypt, Morocco, and Tunisia	A cross-sectional, international survey; PPE use	HCWs	2711	For routine care, 58% used FFP2 or N95 masks, waterproof long-sleeved gowns (67%), and face shields or visors (62%)	• Powered air-purifying respirators were used routinely and for intubation only by 7% and 13% of respondents, respectively. • Surgical masks were used for routine care and for intubations by 15% and 2% of respondents, respectively. • At least one piece of standard PPE was unavailable for 1402 (52%) respondents, and 30% reported reusing single-use PPE. • PPE was worn for a median of 4 (IQR 2-5) hours. Adverse effects of PPE were associated with longer shift durations and included heat (51%), thirst (47%), pressure areas (44%), headaches (28%), inability to use the bathroom (27%), and extreme exhaustion (20%).
Mahmoud et al [52], 2021	Egypt and Saudi Arabia	Comparative and cross-sectional; effect of sanitizers and PPE use	HCWs	428	—	• The most affected areas from wearing PPE were the hands (49.8% and 54.5%), followed by the auricular area (44% and 40.9%), the nasal bridge (28.9% and 22.7%), the cheeks (16.9% and 13.6%), and the whole face (15.6% and 25%) among Saudi and Egyptian HCWs, respectively. • Approximately 70% of Egyptian HCW participants used 70% alcohol in the form of a gel as sanitizer, which was significantly higher than Saudi HCWs (59.1%). • The most adverse reaction to using sanitizers was skin dryness (55.1% and 63.6% among Saudi and Egyptian HCWs, respectively).
Shadi et al [53], 2022	MCP that included Egypt	Cross-sectional; PPE use and hand hygiene	HCWs	154	66.9% used N95, N98, or a surgical mask, and 86.4% had good hand hygiene	• A total of 77.3% had all the PPE and protective measures they needed. • A total of 66.2% had been recently educated on infection control. • A total of 20.8% always used a standard surgical mask and thought that it was sufficiently protective, 12.3% used either mask according to their availability, and none of the participants refrained from using masks.
Deressa et al [54], 2021	Ethiopia	Cross-sectional; availability and use of PPE and satisfaction with PPE	HCWs	1134	—	• Most (77%) of the HCWs reported that their hospital did not have adequate PPE. A critical shortage of N95 respirators was particularly reported; it only increased from 13% to 24% from before to during the COVID-19 pandemic. • The use of N95 increased from 9% to 21% from before to during the COVID-19 pandemic. Almost 72% of the respondents were dissatisfied with the availability and use of PPE in their hospital. • The independent predictors of the respondents' satisfaction levels with PPE were HCWs who reported that PPE was adequately available in the hospital and preparedness to provide care to COVID-19 cases.
Oladele et al [55], 2021	Nigeria	Cross-sectional and mixed methods; availability and use of PPE	HCWs	258	—	

Study	Study setting or country	Study type and key measures	Study population	Sample size, N	Adherence or noncompliance rates	Relevant findings
						• Only 22.1% of HCWs had regular access to PPE, and only 20.6% had access to N95 face masks compared with other PPEs. Male HCWs and those working at secondary or tertiary facilities had access to N95 face masks. • Facilitators of PPE use were the leadership quality of the hospital head and donation of PPE to the facilities, whereas barriers to PPE use included a limited supply of PPE as well as the facility's infrastructural and operational challenges.
Ashour et al [56], 2021	MCP—Egypt and Morocco	Cross-sectional; challenges and difficulties of using PPE	Ophthalmologists	172	—	• The analysis of the responses showed that most ophthalmologists used face masks without substantial problems during their examinations, whereas face shields followed by protective goggles were the most inconvenient PPE in the current ophthalmic practice. • Moreover, most (77.3%) noticed an increase in their examination time when using PPE. A considerable proportion (40.7%) stopped using one or more of the PPE because of inconvenience or discomfort.
Foula et al [57], 2021	Egypt	Cross-sectional; effect of wearing PPE on performance and decision-making	Physicians	272	—	• Results indicated that comfort, vision, and communication were significantly reduced because of PPE wearing in all physician groups (81.1%, 88.7%, and 75.5%, respectively). • In contrast, the handling of instruments was not significantly affected in the second group only. Moreover, decision-making and the rate of complications were not significantly affected.
Hajjij et al [58], 2020	Morocco	Cross-sectional; PPE and headaches	HCWs	155	—	• The overall prevalence of headaches related to PPE was 62%. It was experienced de novo by 32.9% of participants, whereas it was an aggravation of a preexisting headache in 29% of participants. • Working >8 hours per shift during the pandemic was correlated to de novo headache (*P*=.008). The profession of physician and working >12 hours per shift were correlated with aggravated headaches. HCWs experienced moderate discomfort, blurred vision, and reduced concentration. They judged their professional performance to be mildly reduced by the use of PPE.
Nwosu et al [59], 2021	Nigeria	Cross-sectional; impact of different face masks on comfort	HCWs	66	—	• HCWs wore masks for periods ranging from 68 to 480 minutes. The discomfort experienced with the use of the N95 mask was greater than with the surgical mask. • No significant change in arterial oxygen saturation was observed with the use of either mask type, and the tight strapping of the N95 mask was perceived as a contributor to the discomfort experienced with mask use.
Marraha et al [60], 2021	Morocco	Cross-sectional; skin reactions to PPE use	HCWs	273	—	

Study	Study setting or country	Study type and key measures	Study population	Sample size, N	Adherence or noncompliance rates	Relevant findings
						• A total of 80% of HCWs had adverse reactions, including skin problems, after wearing goggles (58%), wearing surgical masks and respirators (57%), handwashing and wearing gloves (45%), wearing a face shield (23%), and wearing protective clothing (11%). • Bleach immersion was highly significantly associated with hand reactions, whereas hand cream use more than twice daily was associated with fewer reactions. • The skin reactions were related to goggle use, wearing masks and N95 respirators was significantly associated with longer use duration, and adverse reactions to regular use of protective clothing were related to the frequency of its use per shift.
Jazieh et al [61], 2020	6 countries; Egypt, Algeria, and Morocco	Multicountry survey; behavioral response	Patients with cancer	1012	Adherence to handwashing (77%), keeping distance from others (67%), mask use (77%), and hand hygiene with hand sanitizer (69%) and soap (81%)	• Patients were worried about contracting the virus strongly (33%) or mildly (48%), and most (>80%) reported avoiding the following actions: hand shaking, hugging and kissing, social gatherings, meeting friends, and visiting markets. • Some reported adopting healthier diets (35%), using dietary supplements (18%), and reciting the Quran (61%) or supplications (75%). • Approximately 23% would choose not to show up for a scheduled medical appointment, and 43% had appointment cancellations at the request of the medical team (31%) or the patients themselves (12%). • Moreover, 84% preferred web-based medical appointments over regular visits.
Andarge et al [62], 2020	Ethiopia	Cross-sectional and facility-based; intention and practice of PPMs[h]	Adults with chronic conditions	806	52% and 76.3% intended to practice and had ever practiced PPMs	• Participants' subjective norms and perceived behavioral control were the factors associated with their intention. • Good knowledge and a positive attitude were found to be significant factors associated with the participants' actual practice of PPMs among other independent factors.
Mostafa and Hegazy [63], 2020	Egypt	Cross-sectional, observational study	Patients of dermatology	62	—	• There was an overall satisfaction and future use score of 91% among the interviewed patients who received teledermatology services; a usefulness score of 93.7%; interface and interaction quality scores of 85.9% and 87%, respectively; ease and use learnability score of 87.8%; and a reliability score of 86.7%.
Larebo and Abame [64], 2021	Ethiopia	Cross-sectional; face mask use and associated factors	University students	764	89.5% had good practice of face mask use	• Overall knowledge of the students was 29.2%, and their attitude was 88.1%. • Students from the College of Natural and Computational Sciences and students having good knowledge were found to be independently associated with face mask use.
Nalunkuma et al [65], 2022	Uganda	Cross-sectional; patterns of double mask use	Medical students	348	Only 20.5% reported double masking	

Study	Study setting or country	Study type and key measures	Study population	Sample size, N	Adherence or noncompliance rates	Relevant findings
						• A total of 68.7% believed that double masking was superior to single masking for COVID-19 prevention and control. • Those with a past COVID-19 positive test and those who believed that double masks had a superior protective advantage were more likely to double mask. • The lack of trust in the quality of masks (46.5%) was the most frequent motivation for double masking, whereas excessive sweating (68.4%), high cost of masks (66.4%), and difficulty in breathing (66.1%) were the major barriers.
Aronu et al [66], 2020	Nigeria	Cross-sectional; perception of masking in children	Mothers	387	—	• Only 44.7% of the mothers perceived masking in children as an appropriate measure for the prevention of COVID-19, and the frequent reasons for the inappropriateness of face masks in children given by most (55.3%) of the mothers included perceived difficulty in breathing (38.5%) and the child's readiness to take the masks off (29.3%). • A significantly higher proportion of children whose mothers were aged ≥35 years would wear face masks (64.2%) when compared with 31.7% of those whose mothers were aged <30 years. Similarly, 51% of the children who were aged >1 year would wear a face mask compared with 20.5% of those aged 8 days to 1 year. • The children whose mothers were aged <30 years were approximately 4 times less likely to wear a face mask when compared with those whose mothers were aged ≥35 years. The children whose fathers had attained tertiary education were approximately twice less likely to wear face masks when compared with those whose fathers had attained a secondary education or lower.
Haftom and Petrucka [67], 2021	Ethiopia	Cross-sectional; face mask use	Quarantined adults	331	46% did not wear a face mask when leaving home	• Face mask use was significantly associated with the knowledge score, employment status, gender, age, and educational status of the study participants.
Deressa et al [68], 2021	Ethiopia	Cross-sectional; social distancing and preventive measures	Government employees	1573	96% wore face masks, 94.5% practiced frequent handwashing, and 89.5% practiced physical distancing	• A total of 94.8% avoided close contact with people, including hand shaking; 95.6% consistently followed government recommendations; 88.1% avoided mass gatherings and crowded places; 71.8% restricted movement and traveling; and 35.6% stayed home. • A total of 80% perceived that consistently wearing a face mask was highly effective in preventing coronavirus infection, and the perception varied by region (Oromia residents being less likely to have good perceptions). • A total of 57% perceived that the policy measures in response to the pandemic were inadequate.
Dzisi and Dei [69], 2020	Ghana	Cross-sectional, roadside observer survey; adherence to social distancing and mask use	Commuters	850	98% of buses complied with the social distancing guidelines	• The policy on face masks was complied with only partially in most vehicles. • A total of 12.6% of the vehicles had <3 commuters without face masks, whereas 21.3% of buses had <3 people with face masks.
	Ghana			500	—	

Study	Study setting or country	Study type and key measures	Study population	Sample size, N	Adherence or noncompliance rates	Relevant findings
Agyemang et al [70], 2021		Cross-sectional; perception and mask use	Commercial drivers			- Most drivers had a high vulnerability perception to COVID-19. It further emerged that older drivers in particular consistently wore face masks and insisted on other persons in their commercial vehicles to follow suit. - Sociodemographic factors and the need to ensure one's safety and that of loved ones were critical determinants of face mask use among surveyed drivers.
Natnael et al [71], 2021	Ethiopia	Cross-sectional; knowledge, attitude, and frequent hand hygiene practices	Taxi drivers	417	66.4% had good frequent hand hygiene practices	- Good knowledge and positive attitude were reported in 69.8% and 67.6% of the drivers, respectively. - Educational level, place of residence, and attitude toward COVID-19 prevention were factors associated with good knowledge about COVID-19. Furthermore, age of >30 years, a secondary education or higher, income, and knowledge about COVID-19 in taxi drivers were factors associated with a positive attitude toward COVID-19 prevention. Moreover, attitude toward COVID-19 and educational level were the factors associated with good frequent hand hygiene practices.
Mboowa et al [72], 2021	Uganda	Cross-sectional; knowledge, attitudes, and practices regarding face mask use	High-risk groups	644	—	- Most had heard about COVID-19 (99.7%) and believed that face masks were protective against it (87.3%), whereas 67.9% reported having received information on face mask use. - Food market vendors and those with no formal education were 0.5 and 0.3 times less likely to have received information about face mask use than hospital workers and those who had completed secondary school, respectively. - Those who had received information on face mask use were 2.9 and 1.8 times more likely to own face masks and perceive them as protective, respectively. Food market vendors were 3.9 times more likely to reuse their face masks than hospital workers.
Fielmua et al [73], 2021	Ghana	Cross-sectional, observational study; hand hygiene and safety behaviors	Shoppers and shopkeepers	751	91.3% of the customers did not practice handwashing, and 84.2% did not wear face masks	- It was observed that adherence to COVID-19 safety protocols at shopping centers was very poor, and in 78% of the shops observed, no shop attendant wore a mask. - Despite the provision of handwashing facilities and widespread advocacy to minimize COVID-19 infections, the citizenry, especially the youth, demonstrated a poor attitude toward safety measures. Nonadherence to COVID-19 protocols was higher in shops where there was no pressure to conform to the protocols.
Ameme et al [74], 2021	Ghana	Observational study; hand hygiene and face mask wearing practices	Shop patrons	800	81.6% wore face masks, 12.3% performed hand hygiene, and 11.5% adhered to both measures	- A total of 72.3% of patrons wore face masks appropriately, whereas appropriate handwashing was recorded among only 10.1%. - Compared with inappropriate handwashing, appropriate handwashing was negatively associated with adherence to infection and control guidelines.
Yigzaw et al [75], 2021	Ethiopia	Observational cross-sectional study; handwashing practice	Bank visitors	415	—	

Study	Study setting or country	Study type and key measures	Study population	Sample size, N	Adherence or noncompliance rates	Relevant findings
						• Most (93.5%) heard and watched proper handwashing practice. The proportion of proper handwashing performance was 21.4% before the demonstration, but after the demonstration, it increased to 82.2%. • Older age, being married, and higher education were associated with proper handwashing practice. Overall, there was a significant change in handwashing practice after the demonstration.

[g] FFP2: filtering face piece 2.

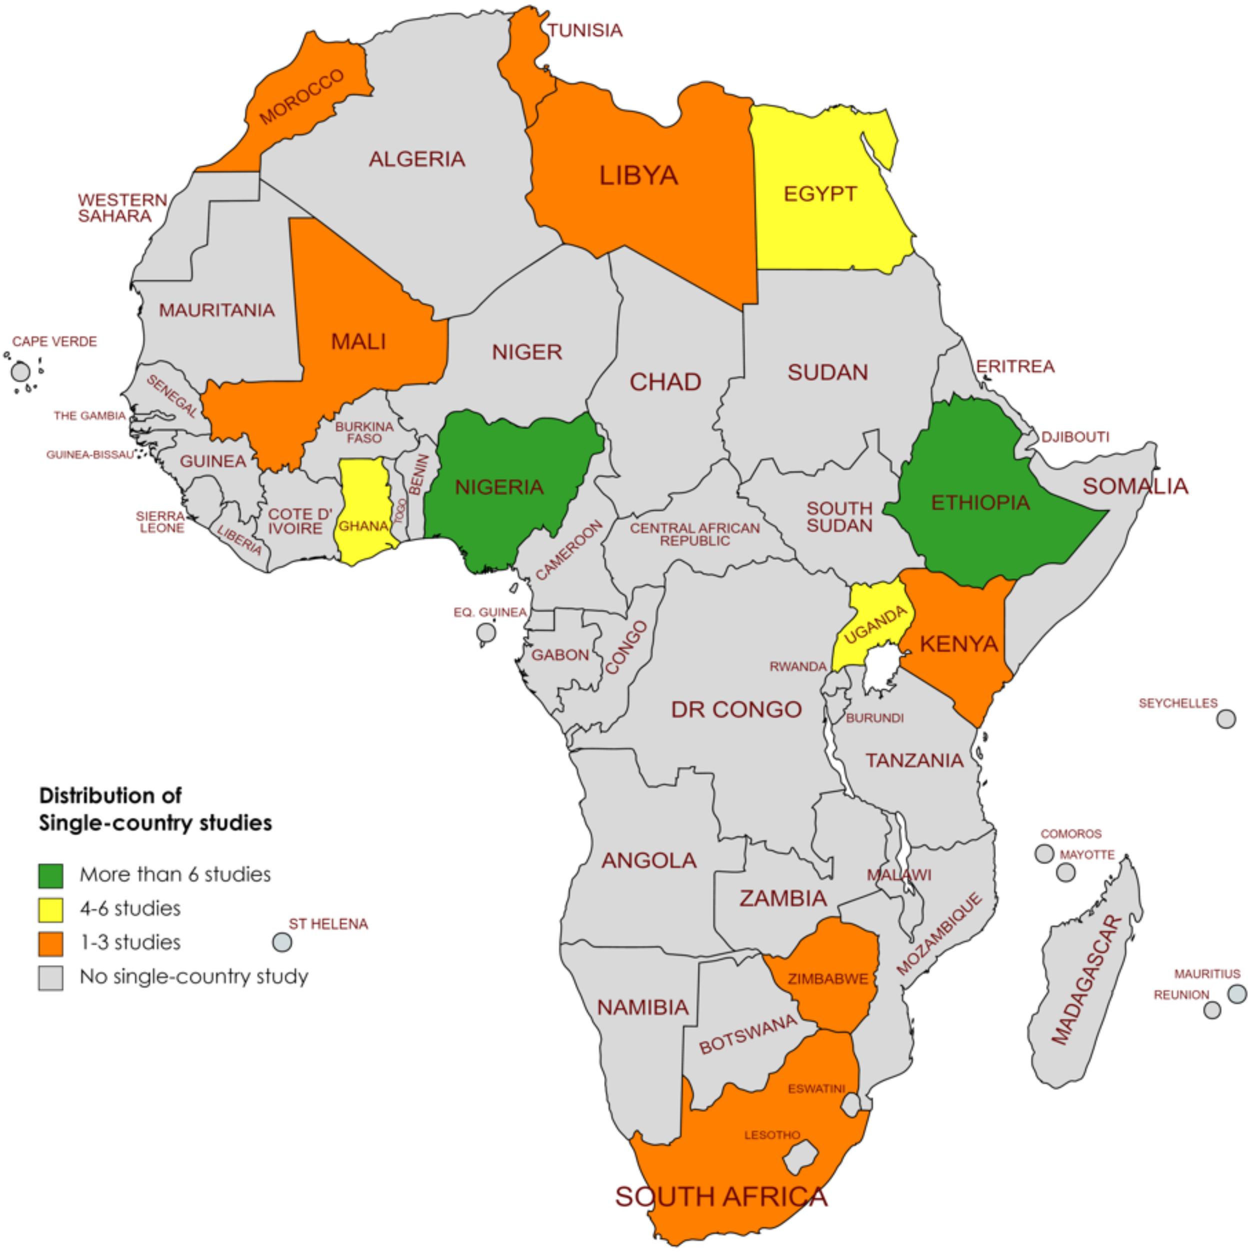
[h] PPM: personal protective measure.

Distribution and Characteristics of the Studies

Of the 58 analyzed studies that primarily reported on PPMs against COVID-19 in Africa, 47 (81%) were single-country studies and were conducted in only 12 of the 54 African countries, whereas the remaining 11 (19%) involved multiple countries (Figure 2). Of the single-country studies, 36% (21/58) were from East Africa, 21% (12/58) were from West Africa, 17% (10/58) were from North Africa, 7% (4/58) were from Southern Africa, and none were from Central Africa. Ethiopia (16/58, 28%), Nigeria (7/58, 12%), and Egypt (5/58, 9%) were the top contributors and altogether produced 48% (28/58) of the analyzed studies. Thus, no single-country studies regarding COVID-19 PPMs had been conducted in 42 African countries at the time of our literature search (Figure 2).

The 58 analyzed studies included 51 (88%) quantitative studies, 5 (9%) qualitative studies, and 2 (3%) mixed methods studies, and their sample sizes ranged from 20 to 206,729. The 4 themes were represented as follows: knowledge and perception of PPMs (21/58, 36%), mask use (37/58, 64%), physical and social distancing (17/58, 29%), and handwashing and hand hygiene (19/58, 33%), considering that most studies covered more than one theme. Moreover, 34% (20/58) of the analyzed studies were conducted among health care workers (HCWs), 33% (19/58) were conducted among the general public, 5% (3/58) were conducted among patients with comorbidities, 3% (2/58) were conducted among university students, and 22% (13/58) were conducted among other groups. The studies were published between 2019 and 2022, and their overall quality was generally good, meaning that the included studies satisfied most of the criteria. However, lower scores on item 4 (nonresponse bias) and item 5 (appropriateness of statistical methods used) were noted among several quantitative studies (9/51, 18% and 13/51, 26%, respectively), with a similar trend observed among qualitative studies, as detailed in Multimedia Appendix 2.

Figure 2. Country distribution of single-country studies. DR: Democratic Republic.



Knowledge and Perception of PPMs and Associated Factors

The results of the knowledge and perception of PPMs and other domains are summarized and presented in Table 3. Among the general public, higher rates of knowledge of COVID-19 preventive measures (>60%) were reported in Western Uganda [18] and Northwest Ethiopia [20]. Higher rates of good attitudes and perceptions were also reported in Western Uganda [18] and Egypt [21], but a lower rate of perceived benefits of preventive measures was reported in Addis Ababa, Ethiopia [22]. Similar findings of good perception were also reported in the Greater Kampala Metropolitan area of Uganda and in other 6 countries (Botswana, Kenya, Malawi, Nigeria, Zambia, and Zimbabwe), where a great majority of the residents believed that face masks were effective against COVID-19 spread and infection [23,24]. However, most individuals in Nigeria believed that COVID-19 was more of a hoax than a reality, and in several countries, preventive measures such as social distancing and face masking were perceived as imported policies that negatively affected their compliance with preventive measures to curb the spread of the disease [25,26].

Table 3. Levels and associated factors of personal protective measure (PPM) knowledge and perceptions and the practice of face mask use, social and physical distancing, and hand hygiene.

		Knowledge and perceptions of PPMs	Face mask use	Social and physical distancing	Handwashing and hand hygiene
General public					
	Levels	• Higher rates (>60%) of knowledge of PPMs [18,20] • Higher rates (>60%) of good attitude and perception [18,21,23,24] • Lower rates (<60%) of good attitude and perception [22,25,26]	• Higher rates (>60%) [24,27,31,32] • Lower rate (<60%) [18,20,22,27,29,39]	• Higher rate (>60%) information not available • Lower rates (<60%) [20-22,28-30,39]	• Higher rate (>60%) information not available • Lower rates (<60%) [33,37-39]
	Associated factors	• Educational level, age, frequency of PPE[a] practice, and social media exposure [18,23,24]	• Gender, age, educational level, marital status, working status, profession, place or community of residence, knowledge and attitude, strictness of containment and health policies, perceived risk and barriers, cues to action, and self-efficacy, among others [22,27,29,32]	• Gender, age, educational level, working status, place or community of residence, family size, knowledge and attitude, strictness of containment and health policies, perceived risk and barriers, cues to action, and self-efficacy, among others [20-22,28-30]	• Gender, age, educational level, marital status, profession, place or community of residence, knowledge and attitude, exposure to handwashing guidelines, strictness of containment and health policies, type and availability of water sources, and perceived risk and barriers, among others [19,22,29,33]
Health care workers					
	Levels	• Higher rates (>60%) of knowledge and attitude [40-42] • Lower knowledge rate (<50%) [43]	• Higher rates (>60%) [49-53] • Lower rates (<60%) [41,45-48]	—[b]	• Higher rates (>60%) [40,49,52,53] • Lower rates (<60%) [45-47]
	Associated factors	• Age, practice location, PPE attitude, and perceived threat [42,43]	• Gender, educational level, work experience, medical specialty (being a nurse or midwifery professional), hours of work, previous training on COVID-19 prevention and PPE use, perceived risk and attitude toward COVID-19, feedback on safety, having COVID-19 management guidelines, and ease and safety when using standard precautions, among others [44-49,55]	—	• Educational level, gender, work experience, medical specialty (being a nurse or midwifery professional), previous training on COVID-19 prevention and PPE use, perceived risk and attitude toward COVID-19, feedback on safety, having COVID-19 management guidelines, and ease and safety when using standard precautions, among others [45-47,49]
Other groups					
	Levels	• Higher rates of knowledge, good attitude, and perception among university students [64,65], patients with chronic diseases [61], government employees [68], taxi drivers [70,71], and market vendors [72] • Poor perception among mothers [66]	• Higher rates (>60%) among patients with chronic diseases [61,62], university students [64], government employees [68], patrons of convenience shops [74], and taxi drivers [70] • Lower rate (<60%) among medical students [65], children [66], quarantined individuals [67], commuters [69], and shopping centers [73]	• Higher rates (>60%) among patients with chronic diseases [61,62], government employees [68], and commuters [69] • Lower rate (<60%) information not available	• Higher rates (>60%) among patients with chronic diseases [61,62], government employees [68], taxi drivers [71], and bank visitors [75] • Lower rate (<60%) among shopping centers [73] and patrons of convenience shops [74]

	Knowledge and perceptions of PPMs	Face mask use	Social and physical distancing	Handwashing and hand hygiene
Associated factors	• Age, educational level, income, and residence (for taxi drivers and government employees) [68,70,71]	• Age, gender, knowledge, attitude, field of study (for university students), educational level, employment status, history of having COVID-19, and perceived benefit and susceptibility, among others [62,64-67]	• Knowledge and attitude [62]	• Age, marital status, knowledge, educational level, attitude, and adherence to infection and control guidelines, among others [62,71,74]

[a] PPE: personal protective equipment.

[b] Not available.

Among African HCWs, higher rates of knowledge and attitude regarding the use of PPE were reported in Ethiopia [40,41] and Egypt [42]. However, a lower knowledge rate of PPE use (<30%) was reported in Nigeria, and in the early stages of the pandemic, a large number of frontline HCWs in Tunisia had not received official training on the correct use of PPE as many believed that they needed additional training [44]. In Egypt, although a substantial proportion (>80%) of house officers (fresh medical graduates doing their 1-year training in different specialties) had good PPE attitudes, <30% had good preparedness and willingness to participate in COVID-19 management and care [42].

Among other groups, only 3% of patients with chronic conditions such as cancer in Egypt, Algeria, and Morocco knew someone who had a COVID-19 infection, but most were worried about contracting the virus [61]. In Ethiopia, although university students had higher rates (>85%) of good attitude toward face mask use, their overall knowledge about mask use was very low (<30%) [64], which contrasts with medical students in Uganda with a better knowledge rate and where close to 70% agreed on the superiority of double masking over single masking for COVID-19 prevention and control [65]. In Nigeria, >50% of mothers perceived masking in children as not an appropriate preventive measure against COVID-19 because of the perceived difficulty in breathing and discomfort among children [66]. Notably, government employees in Ethiopia were reported to have higher rates of good perception of COVID-19 PPMs, whereby approximately 80% perceived consistent mask wearing as highly effective against COVID-19 spread and infection [68]. High COVID-19 vulnerability perception was also reported among commercial drivers in Ghana, mostly among older drivers, who consistently wore face masks and insisted on other persons in their vehicles doing the same [70]. Similar findings were reported among Ethiopian drivers who had good knowledge and positive attitudes [71]. Furthermore, most of the high-risk individuals in Uganda, including market vendors, had received information on face mask use and believed that face masks were protective against COVID-19. Moreover, those who had received information on face mask use were more likely to own face masks and perceive them as protective despite market vendors being more likely to reuse face masks than hospital workers [72].

As possible predictors, educational level, age, income, residence, frequency of PPE practice, PPE attitude, social media exposure, and perceived threat were associated with knowledge and perception of PPMs among the general population, HCWs, and other groups (taxi drivers and government employees) [18,23,24,42,43,68,70,71]. Moreover, practice location was notably significantly associated among HCWs [43] (Table 3).

Mask Use and Associated Factors

Among the general public, largely lower adherence rates (range 20.3%-59.4%) of face mask use were reported in various African countries, including Uganda, the Democratic Republic of the Congo, Somalia [18,27], and Ethiopia [20,22,29]. Notably, adherence rates to mask use were reported to be higher (>60%) after the lifting of lockdown restrictions and in countries where mask use was mandatory, such as Mozambique [27], Uganda [24], Morocco [31], and South Africa [32]. In addition, reusable cloth masks, which are more cost-beneficial and environmentally friendly, were the most used mask type [27]. Interestingly, in South Africa, the prevalence of close others' mask wearing was reported to affect mask use, and older adults had poor mask use practices despite having a higher mortality risk [32]. In addition, the prevalence of mask wearing was noted to have increased substantially (50% to 74%) from May 2020 to August 2020 as COVID-19 cases increased and lockdown restrictions were eased, but staying at home, physical distancing, and social distancing decreased [32]. Regarding used mask disposal, poor disposal practices were reported in several African countries, including Morocco, where most threw their used masks and gloves in their house trash or trash bins, posing a transmission risk to sanitary workers or stray animals [31].

Among HCWs, varying rates of PPE use were reported in different regions and countries. Generally, lower rates (<60%) were reported in the Northwest [45], Northeast [46], Eastern [47], and Amhara regions [41] of Ethiopia, as well as in Egypt [48]. Nevertheless, higher rates (>60%) were reported in Nigeria [49], Libya [50], and 3 multicountry surveys [51-53]. The main challenges reported were inadequate PPE and side effects. The lack of PPE and, thus, the reuse of single-use PPE, especially facial protective shields and masks, were reported in several African countries, including Tunisia [44], Ethiopia [40,54], Egypt [48], and Nigeria [55], and in a multicountry survey including 4 North African countries [51].

Several side effects because of the use of PPE were also reported among African HCWs, including skin problems; heat; thirst; pressure areas; headaches; inability to use the bathroom; extreme exhaustion; discomfort; and reduced vision, concentration, and performance during or after wearing PPE [40,44,51,56-60].

Moreover, such side effects were associated with longer shift durations, the frequency of use, and medical specialty [51,58-60], and the most affected body areas from wearing PPE were the hands, the auricular area, the nasal bridge, the cheeks, and the whole face [52]. Notably, the most reported adverse reactions particularly because of using sanitizers were skin dryness, skin irritation, and ocular irritation [40,52]. Moreover, bleach immersion was reported to be highly associated with hand reactions, whereas hand cream use more than twice daily was associated with fewer reactions [60]. In contrast, a recent multicountry survey that included Egypt indicated that >70% of HCWs had all the PPE and protective measures they needed, >60% had been recently educated on COVID-19 infection control, and none of the interviewed HCWs refrained from using face masks [53].

Among other population groups, strict adherence to face mask use in public areas was reported among patients with cancer in a multicountry survey that included Egypt, Algeria, and Morocco [61]. In Ethiopia, >50% of adults with chronic conditions intended to practice and had ever practiced the recommended personal preventive measures against COVID-19 [62]. University students in Ethiopia were reported to have a higher adherence rate (>80%) of mask use [64]. Furthermore, approximately 20% of medical students in Uganda practiced double masking, where the lack of trust in the quality of masks was the most compelling factor for double masking [65]. Nonetheless, excessive sweating, the high cost of face masks, and difficulty in breathing were the major barriers to double masking among these medical students [65]. Moreover, poor adherence to mask use was highlighted among quarantined individuals in Ethiopia, where nearly half of them did not wear a face mask when leaving home [67]. However, high rates (>80%) of mask use were documented among government employees in Ethiopia [68]. Similar findings of high mask use (>70%) were also observed among taxi drivers [70] and patrons of convenience shops in Ghana [74] but with contrasting observations among commuters and in shopping centers, where less compliance with face mask use was reported [69,73].

Adherence to mask use was associated with gender, age, educational level, marital status, working status, profession, place or community of residence, knowledge and attitude, history of having COVID-19, perceived benefit, strictness of containment and health policies, subjective norms, perceived risk, barriers, cues to action, and self-efficacy among the general public, HCWs, and other groups (Table 3) [22,27,29,32,44-49,55,62,64,65,67,70]. Moreover, work experience, medical specialty (being a nurse or midwifery professional), hours of work, previous training on COVID-19 prevention and PPE use, having COVID-19 management guidelines, and ease and safety when using standard precautions were outstanding predictors among HCWs [44-49,55], and the field of study was a strong predictor of mask use among university students [64]. Surprisingly, mask use among children in Nigeria was highly dependent on the mother's opinions and characteristics, whereby it was associated with the mother's age, the age of the child, and the parental level of education [66].

Social and Physical Distancing and Associated Factors

Generally, lower adherence rates (range 18%-59%) of social distancing were reported in various African countries, including Egypt [21], South Africa [28], and Ethiopia [20,22,29,30]. Nonetheless, physical distancing policies disrupted social life and infringed on people's sociocultural rights, causing adverse socioeconomic and health consequences, especially for low-income urban or suburban slum dwellers [26,34]. Although the imposition of COVID-19 distancing regulations led to a substantial decrease in extrahousehold social contacts (close physical and conversational contacts) in several African countries, including South Africa, there was ongoing contact within intergenerational households, highlighting a potential limitation of social distancing measures in protecting older adults [35]. In contrast, such restrictive policies improved feeding habits through increased meal planning and selection and preparation of healthy foods among residents of various countries [36].

Regarding the implementation and adoption of physical distancing measures, despite the implementation of various mitigation measures, the internally displaced people in Mali still faced several challenges, including the proximity in which internally displaced people live, the lack of toilets and safe water, and the lack of financial resources [38]. Similar findings were reported among prisons in Zimbabwe, where there were several challenges in the adoption of COVID-19 PPMs, such as severe congestion, interrupted water supply, outdated infrastructure, and inadequate hygiene and sanitation [39]. Moreover, although prisoners had adequate COVID-19 awareness and prison health professionals received training on COVID-19 control measures, PPE supply was inadequate, with no routine COVID-19 testing in place beyond thermal scanning; isolation measures were compromised by accommodation capacity issues; and social distancing was impossible during meals and at night [39].

Among other population groups, strict adherence to social and physical distancing was documented among patients with cancer, and most preferred web-based medical appointments over regular visits. In addition, some adopted healthier diets, used dietary supplements, and recited the Quran or supplications [61]. Similar findings of good practice of social distancing were also reported among patients with chronic conditions in Ethiopia [62]. Moreover, in Egypt, patients preferred teledermatology services to the usual physical clinic visits as they perceived them as reliable and safe during the pandemic [63]. Government employees in Ethiopia also had higher rates (>80%) of good practice of physical distancing [68], and the same applied to commuters in Ghana, who had high compliance rates with social distancing guidelines [69].

Adherence to social and physical distancing was associated with gender, age, educational level, working status, place or community of residence, family size, knowledge and attitude, strictness of containment and health policies, perceived risk and barriers, cues to action, and self-efficacy among the general public and other groups (patients with chronic diseases; Table 3) [20-22,28-30,62].

Handwashing and Hand Hygiene and Associated Factors

Regarding community adherence to hand hygiene, lower rates (<60%) were reported in 12 sub-Saharan countries, where the likelihood of handwashing mainly varied with the level of concern about COVID-19 [33]. In resource-restricted settings, a recent study indicated that >60% of the slum dwellers in Nairobi, Kenya, had limited water, sanitation, and hygiene facility accessibility and opportunity, making adherence to COVID-19 PPMs impossible [37].

Concerning hand hygiene adherence among African HCWs, varying rates were reported in different regions and countries. Generally, lower rates (<60%) were reported in the Northwest [45], Northeast [46], and Eastern [47] regions of Ethiopia. Nevertheless, higher rates (>60%) were reported in Nigeria [49], Southwest Ethiopia [40], and 2 multicountry surveys [52,53].

Regarding other groups, strict adherence to proper hand hygiene was reported among patients with chronic conditions in various African countries, including Egypt, Algeria, Morocco [61], and Ethiopia [62]. A similar observation was made among government employees [68] and taxi drivers [71] in Ethiopia, both of whom had higher rates (>60%) of frequent handwashing and hand hygiene as a means of protection against COVID-19. However, poor adherence to COVID-19 safety protocols at shopping centers in Ghana was reported, whereby, although shops complied with providing handwashing facilities, most of the customers did not practice handwashing before entering the shops and did not wear face masks during shopping, and neither did the shop attendants [73]. Similarly, a very low rate (10%) of appropriate handwashing was reported among patrons of convenience shops in Accra, Ghana [74]. In contrast, an increase in proper handwashing performance was reported among bank visitors in Ethiopia after watching a handwashing demonstration [75].

Handwashing and hand hygiene during the COVID-19 pandemic was associated with gender, age, educational level, marital status, profession, place or community of residence, knowledge and attitude, exposure and adherence to handwashing guidelines, strictness of containment and health policies, type and availability of water sources, and perceived risk and barriers among the general public, HCWs, and other groups (Table 3) [19,22,29,33,45-47,49,62,71,74,75]. Moreover, work experience, medical specialty (being a nurse or midwifery professional), previous training on COVID-19 prevention and PPE use, feedback on safety, having COVID-19 management guidelines, and ease and safety when using standard precautions were notable predictors among HCWs [45-47,49].

Discussion

Principal Findings

To our knowledge, this is the first systematic review to evaluate PPMs against COVID-19 among various population groups in Africa. This systematic review has important implications as it reflects cognitive behavioral issues (knowledge and practice) regarding PPMs in some African countries during an infectious disease outbreak. Future outbreaks or waves of COVID-19 may force people to use PPMs again. The review used a multidimensional approach involving the systematic evaluation of evidence based on region, country, and population group. Moreover, comprehensive coverage of the literature was attained, and a reproducible search methodology was applied using a predefined framework, all of which are strengths of this review.

Among the general community, the review showed varying levels of knowledge, attitudes, and perceptions, which in turn influenced the practice levels of and compliance with COVID-19 PPMs, especially face mask use, hand hygiene, and physical and social distancing. This finding is in agreement with a previous study from sub-Saharan Africa [15], and similar findings have been reported in other regions where communities' cognition directly affected the practice and uptake of COVID-19 PPMs [76]. Nonetheless, the observed difference in the practice and adherence to PPMs across African countries may be due to the differences in COVID-19 control policies, income (gross domestic product), and the situation of the pandemic among the countries. Notably, the compliance rates of face mask use reported in most African communities were generally lower compared with those reported in studies from high-income countries [77,78]. This may partly be explained by the inability to afford to buy face masks and the differences in the strictness of such preventive measures [22,29,79]. Nevertheless, poor adherence to face mask use was also reported in some high-income countries such as Australia, Norway, and Sweden [80], the reasons for which may be other than just the inability to afford face masks. Moreover, lower rates of handwashing and hand hygiene were also reported in several African communities, especially among low-income urban and slum dwellers. This was partly due to a lack of safe and clean water in slum communities [37]. Moreover, buying soap or hand sanitizers was an additional financial constraint for low-income urban dwellers and, thus, may be seen as a luxury.

The results indicate a reduction in the rates of PPM practice (mainly mask use and social and physical distancing) noted in several African countries following the lifting of restrictive lockdown measures and the rollout of COVID-19 vaccination programs. This can be partly explained by pandemic fatigue as more people become demotivated and exhausted to follow the recommended infection prevention and control measures owing to the prolonged impact and existence of COVID-19 [81]. As COVID-19 PPMs complement the vaccination protective advantage, this implies a need for continued community sensitization and education programs to rectify the reluctance to practice PPMs amid the relaxation of preventive restrictions. Moreover, prompt management of infodemics in the current and future infectious outbreaks is needed to address the misinformation about PPMs [82].

Among African HCWs, generally good knowledge of PPE use was reported but with varying levels of practicing PPMs, and the low practice rates were attributed mainly to the lack of PPE and the side effects of prolonged PPE use. With HCWs being at the frontline of screening and managing suspects and patients with COVID-19, the lack of PPE increases the risk of infection when doing their work. Nonetheless, the lack of PPE has also been documented in other countries and regions outside Africa [83]. Furthermore, this review showed that most patients with comorbidities in Africa reported strict adherence to COVID-19 PPMs, which may be due to their perceived high vulnerability to COVID-19 infection and complications. Other studies outside Africa have reported similar findings among patients with comorbidities [84,85].

The study findings show that several cognitive (including knowledge, attitude, and perception), demographic, and socioeconomic factors were associated with the practice of and compliance with COVID-19 PPMs among African communities. COVID-19 being a newly evolving disease with varying cross-cutting impacts implies a need for consideration of such cognitive, demographic, and socioeconomic differences in the design of targeted response measures against the pandemic. Nonetheless, similar findings on the association of sociodemographics with the practice of COVID-19 PPMs have been reported in other regions outside Africa [80].

This review has some practical recommendations for improving COVID-19 control programs in Africa. Efforts are needed to improve the local capacity to produce and supply PPE, especially to HCWs, as the lack of PPE was the main barrier to PPE use. In the early phase of the pandemic, most countries were overwhelmed by the increased demand for PPE, which disrupted the global supply chain, and this had dire consequences for countries with inadequate local manufacturing and supply capacity [83]. In addition, providing free or subsidized face masks and soap, especially to low-income earners, would be a helpful strategy for improving PPM practice and adherence. Moreover, the consideration of vulnerable groups such as low-income urban dwellers and internally displaced people and targeted responses tailored to their socioeconomic dynamics are paramount for effective pandemic control programs. Knowledge and perception influenced the practice of PPMs, implying a need for continuous infodemic management, community education, and sensitization, and this should be tailored to address the existing misconceptions and barriers to PPM adherence. Notably, although several of the analyzed studies (11/58, 19%) evaluated the association between age and the practice of COVID-19 PPMs and showed varying rates and results, no single study focused on exploring COVID-19 PPMs among the older adult population of Africa. Given the known vulnerability of older people to severe COVID-19, efforts are needed to explore this special group to help fully understand their behavioral response to the pandemic, which is vital for guiding targeted responses.

The review also reveals substantial inequalities in terms of research output from different regions of Africa, with PPM studies mostly coming from East, West, and North Africa and only 3 countries (Ethiopia, Nigeria, and Egypt) producing >40% (28/58, 48%) of all the studies. This finding coincides with the study by Nwagbara et al [15], which showed the dominance of East and West Africa in COVID-19 research. The high PPM research output from North and West Africa could be because they were the first regions to record COVID-19 cases in the continent [86]. Although South Africa is known to lead African research with sound and more vibrant research institutions in the continent [14], its contribution to COVID-19 PPM research is far lower, as indicated by the study results. Regarding other African countries, the observed pattern may be explained by the differences in research capabilities and resources. Nonetheless, such research inequalities pose gaps in understanding how such countries and regions respond to the COVID-19 pandemic. This implies a need for more focus, funding, and involvement in behavioral health research, which is as important as clinical research and vital in guiding evidence-based and country-specific or tailored policies and responses in addressing the dynamics of the current COVID-19 pandemic.

Limitations

This systematic review has some limitations. Although we used a comprehensive keyword search strategy, some relevant studies might have been missed as only 3 databases and only English-language articles were considered. In addition, we did not consider gray literature and preprints in this review; thus, they should be considered in future or updated reviews on PPM practice for a more comprehensive search. Although a comprehensive search was performed, no relevant studies were found from 42 of the 54 African countries; thus, the findings might not provide a comprehensive picture of the knowledge and practice of PPMs across the entire continent. Moreover, the findings and conclusions of this review are based on studies that were mostly web-based surveys, which, although this was inevitable because of the restrictive preventive measures and lockdowns, are prone to selection bias based on internet accessibility. Owing to the self-report nature of these surveys, recall and social desirability bias cannot be overlooked. Moreover, assessments of statistical analyses of associations with the practice of COVID-19 preventive measures, as well as meta-analyses, were not performed as these were not the main focus of this review. Despite these limitations, this study provides valuable insights into the facilitators of and barriers to the practice of PPMs in Africa.

Conclusions

This review evaluated the knowledge and practice of COVID-19 PPMs in African countries. The findings, conclusions, and recommendations of this review specifically apply to the included countries and, thus, should be interpreted with caution. The results indicate that African communities, including various population groups, have varying levels of practice and compliance with COVID-19 PPMs, with the lack of PPE (mainly face masks) and side effects of PPE use being the major reasons for poor compliance, especially among HCWs. In addition, various cognitive, sociodemographic, and economic factors were associated with the practice of COVID-19 PPMs. Therefore, this review highlights a need for enhancing the local capacity to produce and supply PPE. The consideration of various cognitive, demographic, and socioeconomic differences, with extra focus on low-income urban dwellers and those who are less advantaged, is vital for inclusive and more effective strategies against the pandemic. Moreover, more focus, involvement, and funding of community behavioral (including protective measures) research is needed to fully understand and address the dynamics of the current pandemic in Africa.

Abstract

Background: The COVID-19 pandemic has the potential to accelerate another pandemic: physical inactivity. Daily steps, a proxy of physical activity, are closely related to health. Recent studies indicate that over 7000 steps per day is the critical physical activity standard for minimizing the risk of all-cause mortality. Moreover, the risk of cardiovascular events has been found to increase by 8% for every 2000 steps per day decrement.

Objective: To quantify the impact of the COVID-19 pandemic on daily steps in the general adult population.

Methods: This study follows the guidelines of the MOOSE (Meta-analysis Of Observational Studies in Epidemiology) checklist. PubMed, EMBASE, and Web of Science were searched from inception to February 11, 2023. Eligible studies were observational studies reporting monitor-assessed daily steps before and during the confinement period of the COVID-19 pandemic in the general adult population. Two reviewers performed study selection and data extraction independently. The modified Newcastle-Ottawa Scale was used to assess the study quality. A random effects meta-analysis was conducted. The primary outcome of interest was the number of daily steps before (ie, January 2019 to February 2020) and during (ie, after January 2020) the confinement period of COVID-19. Publication bias was assessed with a funnel plot and further evaluated with the Egger test. Sensitivity analyses were performed by excluding studies with low methodological quality or small sample sizes to test the robustness of the findings. Other outcomes included subgroup analyses by geographic location and gender.

Results: A total of 20 studies (19,253 participants) were included. The proportion of studies with subjects with optimal daily steps (ie, ≥7000 steps/day) declined from 70% before the pandemic to 25% during the confinement period. The change in daily steps between the 2 periods ranged from –5771 to –683 across studies, and the pooled mean difference was –2012 (95% CI –2805 to –1218). The asymmetry in the funnel plot and Egger test results did not indicate any significant publication bias. Results remained stable in sensitivity analyses, suggesting that the observed differences were robust. Subgroup analyses revealed that the decline in daily steps clearly varied by region worldwide but that there was no apparent difference between men and women.

Conclusions: Our findings indicate that daily steps declined substantially during the confinement period of the COVID-19 pandemic. The pandemic further exacerbated the ever-increasing prevalence of low levels of physical activity, emphasizing the necessity of adopting appropriate measures to reverse this trend. Further research is required to monitor the consequence of long-term physical inactivity.

KEYWORDS

COVID-19; daily steps; physical activity; meta-analysis

Introduction

Physical activity has been crucial for preventing and treating multiple chronic health conditions [1,2] and premature mortality [3,4], while the number of daily steps is a primary proxy measure for physical activity [5]. Daily step goals can be tailored to meet individual needs and when used with a monitor are effective in promoting physical activity [6]. Previous studies have found that higher daily steps are associated with multiple health benefits, such as lower risk of cardiovascular disease [7], diabetes [8,9], and all-cause mortality [10-13]. For example, the risk of all-cause mortality in adults shows a declining trend with an increase in daily steps and plateaus at approximately 7000 steps per day [12,13]. In contrast, a decrease in daily steps is responsible for a range of unhealthy outcomes, such as increased risk of cardiovascular disease [14], compromised muscle metabolism [15], and elevated systemic inflammation [15,16]. Specifically, the risk of cardiovascular events was reported to increase by 8% for every 2000 steps per day decrement [14]. A sharp reduction in daily steps might also reduce leg lean mass and induce impairments of myofibrillar protein synthesis in healthy elderly individuals, accompanied by increased circulating inflammatory markers [15,16].

Although global responses were far from homogeneous, most countries adopted restriction measures in varying forms to limit the transmission of COVID-19, such as physical distancing, working from home, and closing schools [17]. These measures have resulted in unprecedented changes in all aspects of daily life [18], and physical activity is certainly one of the aspects being most affected. Recently, several studies reported a significant decline in daily steps during the confinement period of the COVID-19 pandemic [19-23]. One study found that the daily steps of young adults in Singapore decreased by 42% on average during the lockdown period compared with the time before the pandemic [20]. Another study reported a sharp, 30% reduction in daily steps in Chinese citizens and a significant increase in the proportion of adults with frequent low daily steps (≤1500 steps/day for ≥14 days) during the confinement period [19]. By contrast, one study reported only a 5% reduction in daily steps 30 days after the start of lockdown in Australia [22]. These findings indicate the possibility of geographically specific variations in the relationship between COVID-19–related restrictions and daily steps, which limits the generalization of conclusions drawn from single country–based analyses. Therefore, a systematic review is needed to consolidate the current understanding of the impact of COVID-19 on daily steps in order to enlighten future interventions and research directions. In addition, a few studies have also evaluated whether the impact of COVID-19 on physical activity varied by gender. One study suggested that men had more reduction in time spent in moderate-vigorous physical activities and a larger increase in sedentary behaviors than women during the pandemic [24]. However, another study failed to confirm this finding [25].

To fill this knowledge gap, we conducted a meta-analysis of observational studies to quantify both global and regional impacts of confinement during the COVID-19 pandemic on daily steps in the general adult population, and we also examined whether the decline in daily steps differed between men and women.

Methods

Protocol and Registration

The MOOSE (Meta-analysis Of Observational Studies in Epidemiology) [26] and PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 [27] guidelines were followed for reporting this study (Multimedia Appendix 1). The protocol for this study was prospectively registered in the PROSPERO database (CRD42021291684).

Search Strategy

A preliminary search was conducted on PubMed, EMBASE, and Web of Science to retrieve studies that reported daily step data both before and during the confinement period of the COVID-19 pandemic in the general adult population published before November 22, 2021. Further, an updated search was performed on February 11, 2023, to add recently published articles. The detailed search strategy is listed in Multimedia Appendix 2 [28-31]. The International Standard Randomized Controlled Trial Number Register (ISRCTN) and the World Health Organization COVID-19 database were also searched for potential gray literature. The reference lists and citing articles of relevant literature on this topic were also checked to find possible studies that could be included in this research. The language of publication was not restricted.

Eligibility Criteria and Study Selection

We included observational studies that reported daily steps before and during the confinement period of the COVID-19 pandemic in the general adult population. The reference period was restricted to ≤2 years before the time points when the government implemented the confinement measures. Further eligibility criteria are listed in Textbox 1.

Textbox 1. Eligibility criteria for study screening.

Inclusion criteria

Study type: Observational studies

Participants: General adult population (average age over 20 years)

Outcomes: Daily steps, measured using monitoring devices including wearable physical activity trackers (eg, pedometers, accelerometers, smartwatches, and smart bands) and smartphones mobile apps (eg, iPhone Health, Google Fit, WeChat, and Exercise Health)

Other criteria: Daily step data collected both before and during the confinement period of COVID-19. The reference period was restricted to ≤2 years before the time points when the government implemented the confinement measures

Exclusion criteria

Study type: Any non–observational study (eg, reviews, randomized controlled trials, and case reports), conference abstracts

Participants: Children, adolescents, athletes, specific patient groups, participants with particular conditions (eg, pregnant women or elderly individuals at high risk of falls)

Outcomes: Data other than daily steps (eg, physical activity measured using questionnaires alone or data measured by wearable devices that are classified as light, moderate, or vigorous physical activity)

Other criteria: Studies offering financial incentives that may promote physical activity (eg, rewards for individuals who achieve predetermined goals through monitors), studies lacking available data for meta-analysis

Two independent reviewers (LS and WR) screened all titles and abstracts. The full text of potentially relevant literature was further evaluated. A third reviewer (ZW) arbitrated the decision if a consensus was not reached.

Data Extraction

Two authors (LS and WR) extracted the following data independently: study design, country and continent (Africa, Asia, Europe, North America, South America, and Oceania) where the study was conducted, the sample size used for daily step analysis, participant characteristics (ie, mean age and female ratio), monitoring devices used to measure daily steps, the algorithm used to analyze daily steps, data collection duration, and COVID-19 restriction measures by the government at the time of data collection. The outcomes of interest were the total number of daily steps before and during the confinement period of COVID-19 and the percentage change between the 2 periods. If not reported, the mean (SD) of the outcome was estimated based on the methods provided by the Cochrane Handbook [32]. If data needed to be extracted from graphs, the GetData digitizer was used [33]. This tool has been validated and has good accuracy and precision for data extraction; it has been used in meta-analysis by previous studies [34]. Disagreements, if any, were resolved by consulting with a third reviewer (ZW). When any desired information related to daily steps was missing or unclear, the corresponding author was contacted via email to request or confirm the relevant data, as appropriate. If the data could not be obtained, the study was excluded from the meta-analysis.

Risk of Bias and Quality of Individual Studies

The modified Newcastle-Ottawa Scale (NOS) for applicable observational studies was used to assess the methodological quality and risk of bias in each study [28-30]. Specifically, the modified NOS consists of 3 domains: *selection* (maximum 3 stars), *comparability* (maximum 2 stars), and *outcome* (maximum 2 stars). Therefore, 1 study can be awarded a maximum of 7 stars. Studies with 6 to 7 stars were rated as high quality, those with 5 stars were rated as moderate quality, and those with 4 or fewer stars were rated as low quality [29]. Two reviewers (LS and ZW) rated the methodological quality of each study independently, and discrepancies, if any, were discussed for consensus or resolved by consulting a third reviewer (YW).

Data Synthesis and Analysis

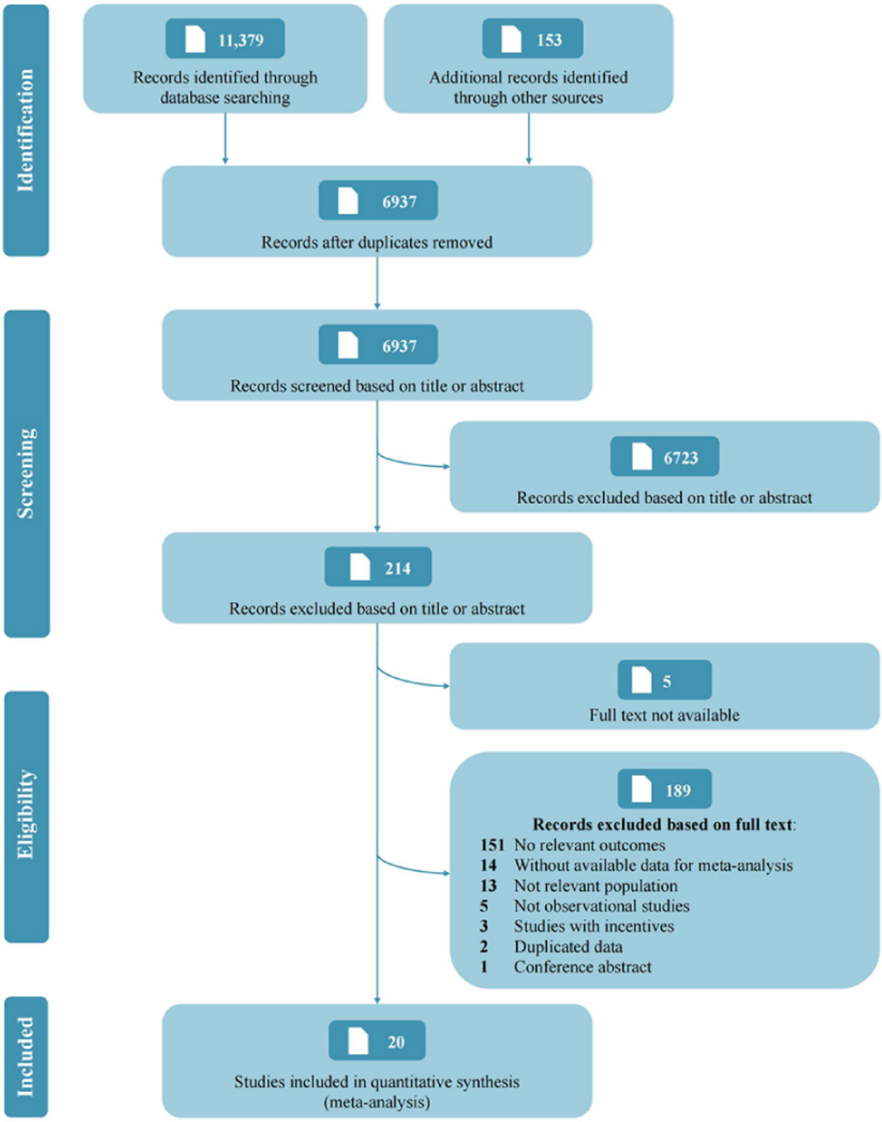
A random effects meta-analysis was conducted using Stata software (version 14.0; StataCorp). The change in daily steps was calculated using the mean difference (MD) with the 95% CI between the mean (SD) of daily steps before and during the confinement period of COVID-19. The Cochran Q statistic of the inconsistency index (I^2) was used to test statistical heterogeneity across studies [32,35]. An I^2 value of more than 75% indicated high heterogeneity [32]. Publication bias was assessed with a funnel plot and further evaluated with the Egger test [36]. To test the robustness of the findings on the primary outcome (ie, the number of daily steps), we performed 3 sensitivity analyses. First, we conducted an analysis that eliminated each study one at a time. Second, we performed an analysis that removed the studies rated as having low methodological quality. Third, we performed an analysis that excluded the studies with a small sample size (less than 140) based on the recommendations of Dunton and colleagues [37]. Finally, we also conducted subgroup analyses according to country, continent, and gender.

Results

Study Selection

A total of 6937 unduplicated records were preliminarily retrieved, and 214 potentially eligible studies were identified after the title and abstract screening. Then, 5 studies were excluded because the full text was unavailable, and full text assessments were made of the remaining 209 articles. Another 189 articles were eliminated. Of these, 151 studies did not report relevant outcomes (ie, daily steps), 14 did not provide necessary data for meta-analysis, 13 focused on irrelevant populations, 5 were not observational studies, 3 were conducted with financial incentives, 2 reported duplicated data, and 1 was a conference abstract. The remaining 20 studies were included in the meta-analysis [19,20,37-54]. Figure 1 shows the PRISMA flow diagram.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.



Study Characteristics

The included studies were conducted in Australia [38], Canada [39], China [19,40-43], France [38], Italy [44], Japan [45-48], Norway [49], Singapore [20], South Korea [50], Spain [51], the United Kingdom [38,52], and the United States [37,38,53,54], and all of them investigated the change in daily steps in the early stage of COVID-19 (from January to September 2020). The reference pre–COVID-19 period was from January 2019 to March 2020. The detailed duration of observation for each study is shown in Table 1. Nine studies measured daily steps with smartphones [19,37,40,41,43,45,46,50,54], 8 with wearable activity trackers [20,38,39,47,48,51-53], and 2 with both wearable activity trackers and smartphones [44,49]; 1 study did not specify the measurement device used in the survey [42]. One study provided 4 groups of data from 4 countries separately [38]. Therefore, the 20 studies included a total of 19,253 participants, and 23 sets of data were included in the meta-analysis. Additional study characteristics are summarized in Table 1.

Table 1. Characteristics of studies and participants included in the meta-analysis.

Study	Country/Continent	Participants, n	Age (years)	Female, %	Device	Algorithm	Definition of restriction measures	Observation period	Reference period

[a] Observations are reported instead of participants for these studies, because of uncertainty about the number of participants who were double counted (before and after the confinement period).

[b] Not available.

[c] Data for daily steps were obtained from the authors for these studies.

[d] Only 106 of 113 participants provided characteristics in this study.

[e] “Interstate border closures” means that Australia closed its borders to all noncitizens and nonresidents. This started on March 20, 2020, with no exceptions for Australian citizens, permanent residents, or their immediate families. Furthermore, a lockdown policy started in Australia on March 23, 2020.

Quality Assessment

Thirteen studies (65%) were rated as having moderate to high methodological quality (Multimedia Appendix 2, Table S1). Considering the widespread weaknesses of small sample size, imbalanced gender ratio, limited age range of the study sample, and poor nationwide representativeness, only 2 studies were rated as having national representativeness of the exposed cohort (ie, samples during the confinement period of COVID-19). Thus, 10% of the included studies received 3 stars in the *selection* dimension, 30% received 2 stars in the *comparability* dimension, and 60% received 2 stars in the *outcome* dimension.

Quantitative Synthesis

As shown in Figure 2, the proportion of studies with subjects with optimal daily steps (ie, ≥7000 steps per day) declined from 70% before the pandemic to 25% during the confinement period. The change in daily steps between the 2 periods ranged from –5771 to –683. The pooled MD from the random effects pooled analysis was –2012 (95% CI –2805 to –1218; Figure 3), with significant heterogeneity among studies ($P<.001$; I^2=97.6%).

The funnel plot shows a symmetrical horizontal distribution for each study relative to the vertical line, suggesting the absence of reporting bias (Multimedia Appendix 2, Figure S1). The Egger publication bias indicated a lack of publication bias (Multimedia Appendix 2, Figure S2). Sensitivity analysis, performed by omitting each study one by one, revealed that the change in daily steps was not significantly altered by any individual study (Multimedia Appendix 2, Figure S3). Moreover, the results remained robust in sensitivity analyses after removing low-quality studies (MD=–1714, 95% CI –2809 to –618) and after removing small-sample studies (MD=–2024, 95% CI –2836 to –1212). The percentage change in daily steps varied from –69.6% to –10.6% across different studies (Figure 4).

Figure 2. Average daily steps around the period before and during the confinement period across studies.

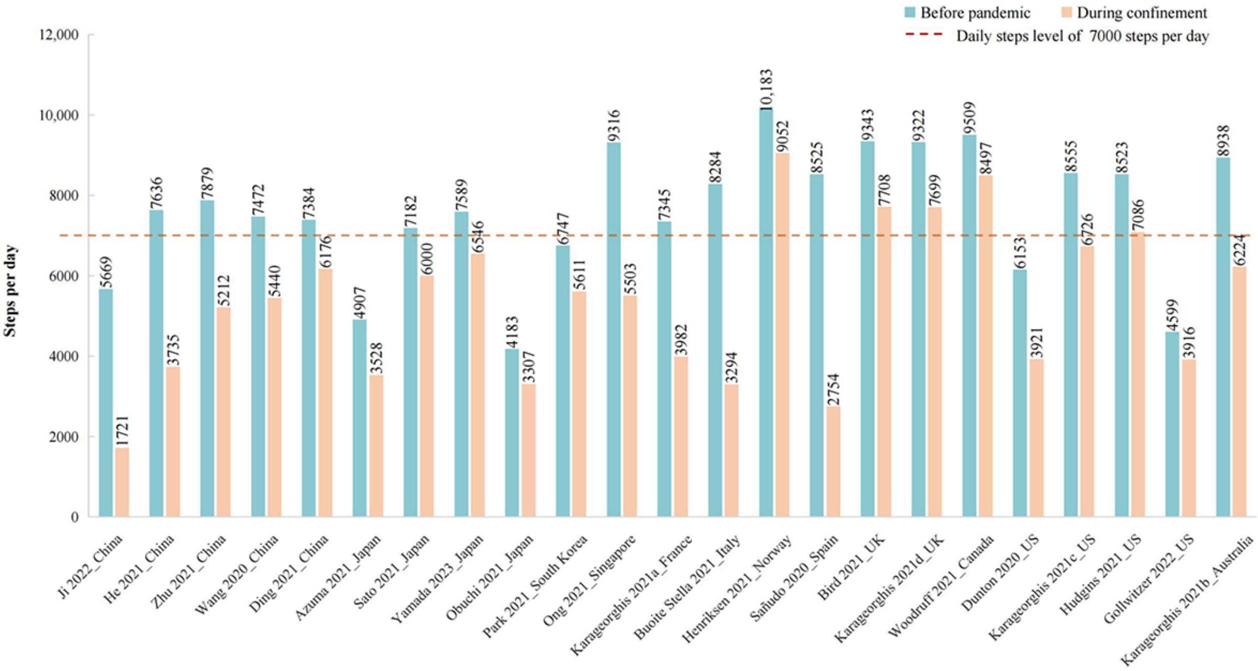

Figure 3. Forest plot of reduction in daily steps during the confinement period. DL: DerSimonian and Laird method.

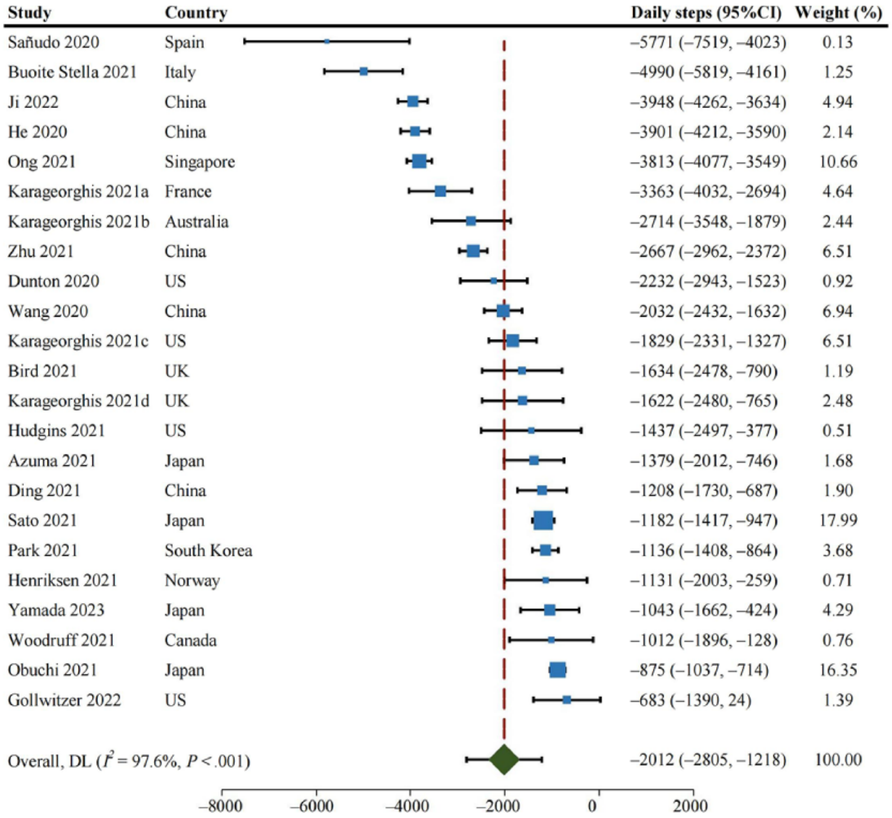

Figure 4. Percentage reduction in daily steps during the confinement period of the COVID-19 pandemic. DL: DerSimonian and Laird method.

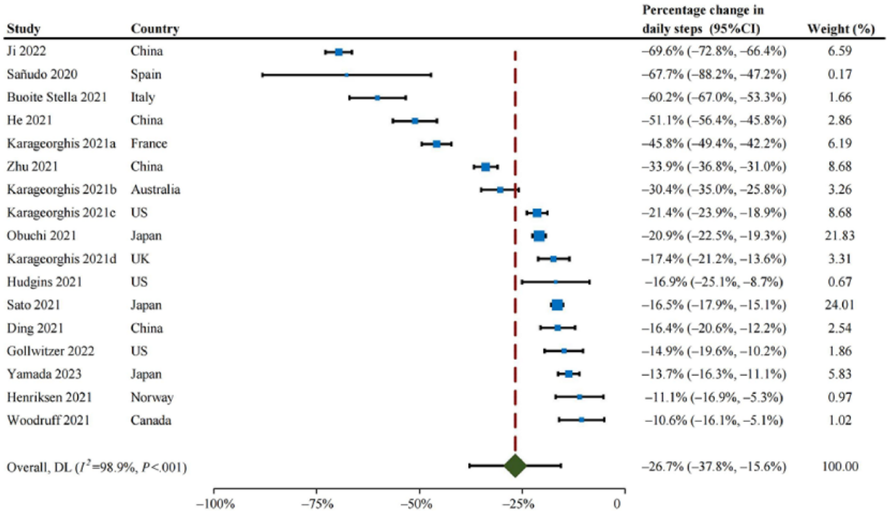
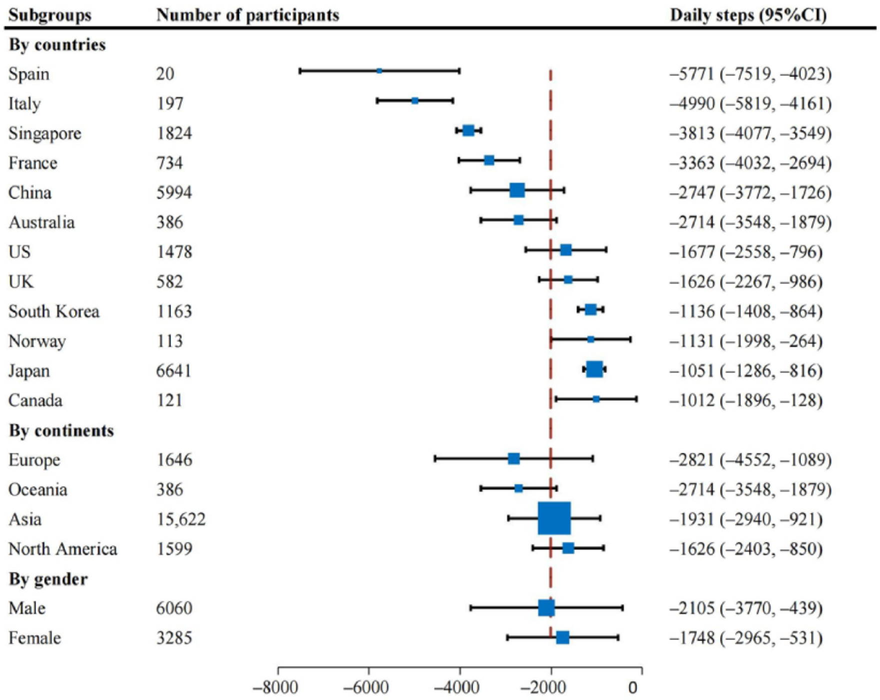


Country-specific analyses (Figure 5) showed that the most significant decline in daily steps occurred in subjects from Spain (MD=–5771, 95% CI –7519 to –4023), followed by Italy (MD=–4990, 95% CI –5819 to –4161) and Singapore (MD=–3813, 95% CI –4077 to –3549). The decline in daily steps was less in subjects from Canada (MD=–1012, 95% CI –1896 to –128), Japan (MD=–1051, 95% CI –1286 to –816), and Norway (MD=–1131, 95% CI –1998 to –264). In terms of continent, European subjects presented the most significant reduction in daily steps but with a wide CI (MD=–2821, 95% CI –4552 to –1089), followed by subjects from Oceania (MD=–2714, 95% CI –3548 to –1879) and Asia (MD=–1931, 95% CI –2940 to –921), while subjects from North America presented the smallest decline in daily steps (MD=–1626, 95% CI –2403 to –850). Of the studies that provided gender-specific data [20,41,43,45-47,52], no apparent difference was observed in the change in daily steps between men (MD=–2105, 95% CI –3770 to –439) and women (MD=–1748, 95% CI –2965 to –531).

Figure 5. Pooled subgroup results of reduction in daily steps during the confinement period of the COVID-19 pandemic.



Discussion

Principal Results

Our study quantified the change in daily steps during the confinement period of COVID-19. The proportion of studies with subjects with optimal daily steps (ie, ≥7000 steps/day) declined from 70% before the pandemic to 25% during the confinement period, and the average number of daily steps was reduced by 2000. Our results also suggest a possible inequality in physical activity across countries, whether before or during the pandemic. However, given that most included studies lacked sufficient nationwide representativeness, this difference should be interpreted cautiously. Furthermore, there was no apparent gender difference in the decline in daily steps before and during the confinement period of COVID-19.

Possible Explanations and Clinical Implications

The population-level trends in daily steps during the confinement period of COVID-19 may reflect public panic about the virus and adherence to confinement measures (ie, physical distancing and sheltering in place) [55,56]. Our findings are not surprising given that COVID-19 restriction measures deprived the general population of many opportunities for physical activity, such as commuting, shopping, sports, and vacations or trips. In addition, the observed differences in the change in daily steps across studies may reflect regional variations in enforcement and behavioral changes [57,58]. Socioeconomic inequalities might also influence such variations among regions and disparities in the ability to engage in or access recreational physical activity within areas [59].

Daily steps are strongly associated with health outcomes [7-16]. Recent studies indicate that over 7000 steps per day is the critical physical activity standard for minimizing the risk of all-cause mortality [12,13]. Moreover, the risk of cardiovascular events increases by 8% for every 2000 steps per day decrement [14]. We found that daily steps declined by 2000, and half of the included studies reported that average daily steps declined to below 7000 during the confinement period of the COVID-19 pandemic. Such findings imply that the pandemic further exacerbated the ever-increasing prevalence of low-level physical activity [60,61], emphasizing the necessity of adopting appropriate measures to reverse this trend. Furthermore, this meta-analysis focused on observational studies based on monitoring devices. Since monitoring devices may encourage users to engage in physical activities [6], the number of daily steps during the confinement period might have been even lower in the population than was currently observed in the samples. In addition, the impact of COVID-19 on daily steps may persist in the long term. Although some researchers report that daily steps gradually recovered to the prepandemic level after the lifting of restriction measures [49,62], more studies argue that worldwide daily steps remain depressed compared with the prepandemic level (ie, the immediate 2 years before the outbreak of COVID-19) [59,63-66]. Thus, the consequences of long-term physical inactivity, which may be further exacerbated, should be addressed.

Comparison With Previous Work

Our finding of a reduction in daily steps during the confinement period of the pandemic is consistent with findings from previous studies using different physical activity metrics [67,68]. An earlier meta-analysis found that sedentary time significantly increased, by 126.9 minutes per day in adults and by 46.9 minutes per day in the elderly, during the confinement period of the pandemic [67]. Another systematic review reported that most of the included studies revealed a decrease in physical activity in most participants [68]. All studies showed an increased sedentary time in healthy adults and those with medical conditions during the lockdown period [68]. According to this evidence, public health messages about staying active during the pandemic appear to have had little effect on the population's engagement in physical activity [69]. In addition, 2 studies explored gender differences in the change in physical activity during the COVID-19 pandemic but had inconsistent conclusions [24,25]. One study found that men had more clearly decreased moderate-vigorous physical activity and increased sedentary behaviors than women during the pandemic [24]. However, another study failed to show significant differences between men and women in self-reported decline in physical activity [25]. Our meta-analysis adopted a primary indicator of physical activity, ie, daily steps, and found that daily steps declined substantially during the COVID-19 confinement period. Such a decline varied by region but not by gender. These results are consistent with previous studies [24,25,67,68].

Based on data collected from 187 countries and districts by a smartphone app, Tison and colleagues [59] found that mean daily steps declined by 5.5% (287 steps) within 10 days of the pandemic declaration by the World Health Organization and by 27.3% (1432 steps) within 30 days. The authors also reported noticeable differences across regions; for example, Italy, France, Brazil, and Iran exhibited a more than 40% maximum decrease, while Sweden exhibited a maximum reduction of daily steps of less than 10% [59]. Furthermore, regional differences were significant. For example, several studies showed that the decline in daily steps during confinement varied considerably among Chinese adults from different provinces [40,41,43]. One nationwide study in Japan found that daily steps declined significantly after the declaration of a state of emergency in urban areas but not rural areas [62].

Limitations

Several limitations should be acknowledged. First, daily step data are lacking from Africa and South America, limiting the generalizability of our findings. Second, when comparing regional differences across countries, we could not rule out potential sampling bias, because most of the included studies lacked sufficient nationwide representativeness. Therefore, future studies are needed to verify our findings. Third, since long-term data from the period that confinement was lifted are not suitable for inclusion in a meta-analysis, we could not directly assess the long-term impact of COVID-19 on physical activity levels using meta-analysis techniques. As more published data become available [59,63-66], this will be an important direction for future studies. Fourth, we did not examine the impact of reduced daily steps on health outcomes, owing to a lack of relevant data. Future studies are expected to address this crucial issue. Finally, there was considerable study heterogeneity. Potential explanations include discrepancies in confinement measures across countries or districts and in the adherence to policy of residents, as well as unclear or different time frames over which the average daily steps were calculated, the possibility that monitoring devices were changed in the different reporting periods, and different durations of observation.

Conclusion

In summary, we found that daily steps declined substantially during the COVID-19 confinement period. Our findings indicate that COVID-19 further exacerbated the ever-increasing prevalence of low levels of physical activity, emphasizing the necessity of adopting appropriate measures to reverse this trend. Further research is required to monitor the consequence of long-term physical inactivity.

Abstract

Background: Both COVID-19 and pregnancy are associated with hypercoagulability. Due to the increased risk for thrombosis, the United States National Institute of Health’s recommendation for prophylactic anticoagulant use for pregnant patients has expanded from patients hospitalized for severe COVID-19 manifestation to all patients hospitalized for the manifestation of COVID-19 (no guideline: before December 26, 2020; first update: December 27, 2022; second update: February 24, 2022-present). However, no study has evaluated this recommendation.

Objective: The objective of this study was to characterize prophylactic anticoagulant use among hospitalized pregnant people with COVID-19 from March 20, 2020, to October 19, 2022.

Methods: This was a retrospective cohort study in large US health care systems across 7 states. The cohort of interest was pregnant patients who were hospitalized with COVID-19, without previous coagulopathy or contraindication to anticoagulants (n=2767). The treatment group consisted of patients prescribed prophylactic dose anticoagulation between 2 days before and 14 days after COVID-19 treatment onset (n=191). The control group was patients with no anticoagulant exposure between 14 days before and 60 days after COVID-19 treatment onset (n=2534). We ascertained the use of prophylactic anticoagulants with attention to the updates in guidelines and emerging SARS-CoV-2 variants. We propensity score matched the treatment and control group 1:1 on the most important features contributing to the prophylactic anticoagulant administration status classification. Outcome measures included coagulopathy, bleeding, COVID-19–related complications, and maternal-fetal health outcomes. Additionally, the inpatient anticoagulant administration rate was validated in a nationwide population from Truveta, a collective of 700 hospitals across the United States.

Results: The overall administration rate of prophylactic anticoagulants was 7% (191/2725). It was lowest after the second guideline update (no guideline: 27/262, 10%; first update: 145/1663, 8.72%; second update: 19/811, 2.3%; *P*<.001) and during the omicron-dominant period (Wild type: 45/549, 8.2%; Alpha: 18/129, 14%; Delta: 81/507, 16%; and Omicron: 47/1551, 3%; *P*<.001). Models developed on retrospective data showed that the variable most associated with the administration of inpatient prophylactic anticoagulant was comorbidities prior to SARS-CoV-2 infection. The patients who were administered prophylactic anticoagulant were also more likely to receive supplementary oxygen (57/191, 30% vs 9/188, 5%; *P*<.001). There was no statistical difference in a new diagnosis of coagulopathy, bleeding, or maternal-fetal health outcomes between those who received treatment and the matched control group.

Conclusions: Most hospitalized pregnant patients with COVID-19 did not receive prophylactic anticoagulants across health care systems as recommended by guidelines. Guideline-recommended treatment was administered more frequently to patients with greater COVID-19 illness severity. Given the low rate of administration and differences between treated and untreated cohorts, efficacy could not be assessed.

Introduction

Both COVID-19 and pregnancy are associated with thrombosis [1-13]. Severe COVID-19 is accompanied by Virchow's triad of endothelial injury, stasis, and hypercoagulable state: categories of factors contributing to thrombosis [1-10]. The related virus, SARS-CoV-2, directly invades endothelial cells, leading to endothelial injury, exocytosis, and endotheliitis [1-4,8,14,15]. Hospitalization causes stasis of blood flow due to decreased mobility regardless of the presence of the SARS-CoV-2 virus [16]. COVID-19–induced changes in prothrombotic factors are linked to an increased risk of hypercoagulability [5-7,17-26]. Studies have reported elevated factor VIII, elevated fibrinogen, circulating prothrombotic microparticles, neutrophil extracellular traps, and hyperviscosity among severely ill patients with COVID-19 [5-7,17-20]. Multiple meta-analyses studies report high rates of coagulopathy and thrombosis across multiple tissues and organ sites among patients infected with COVID-19 since early in the pandemic [21-26].

Hypercoagulability is a physiologically adaptive mechanism that prevents bleeding from miscarriage, childbirth, and postpartum hemorrhage. Women in pregnancy or the postpartum period are at a 4- to 5-fold higher risk of thromboembolism than nonpregnant women [11-13]. Normal pregnancy is accompanied by increased concentration of factors VII, VIII, X, and von Willebrand factor and by pronounced increases in fibrinogen [12,27,28]. Due to the combination of increased risk of hypercoagulability, the National Institutes of Health (NIH) COVID-19 Treatment Guideline Panel recommends using a prophylactic dose of anticoagulation for pregnant patients who are hospitalized for COVID-19 unless a contraindication exists, since February 24, 2022 [29].

We hypothesized that we would observe a high prophylactic anticoagulant administration rate after the second update in NIH COVID-19 treatment guidelines. As prophylactic anticoagulant was recommended to all hospitalized pregnant patients with COVID-19, we expected a minimal difference in clinical condition between the treatment and control group, leading to minimized confounding by indication. This would allow us to properly evaluate the impact of prophylactic anticoagulants on inpatient pregnant patients with COVID-19. No study yet has evidence for or against the guideline on recommending prophylactic anticoagulants on inpatient pregnant patients with COVID-19 [29].

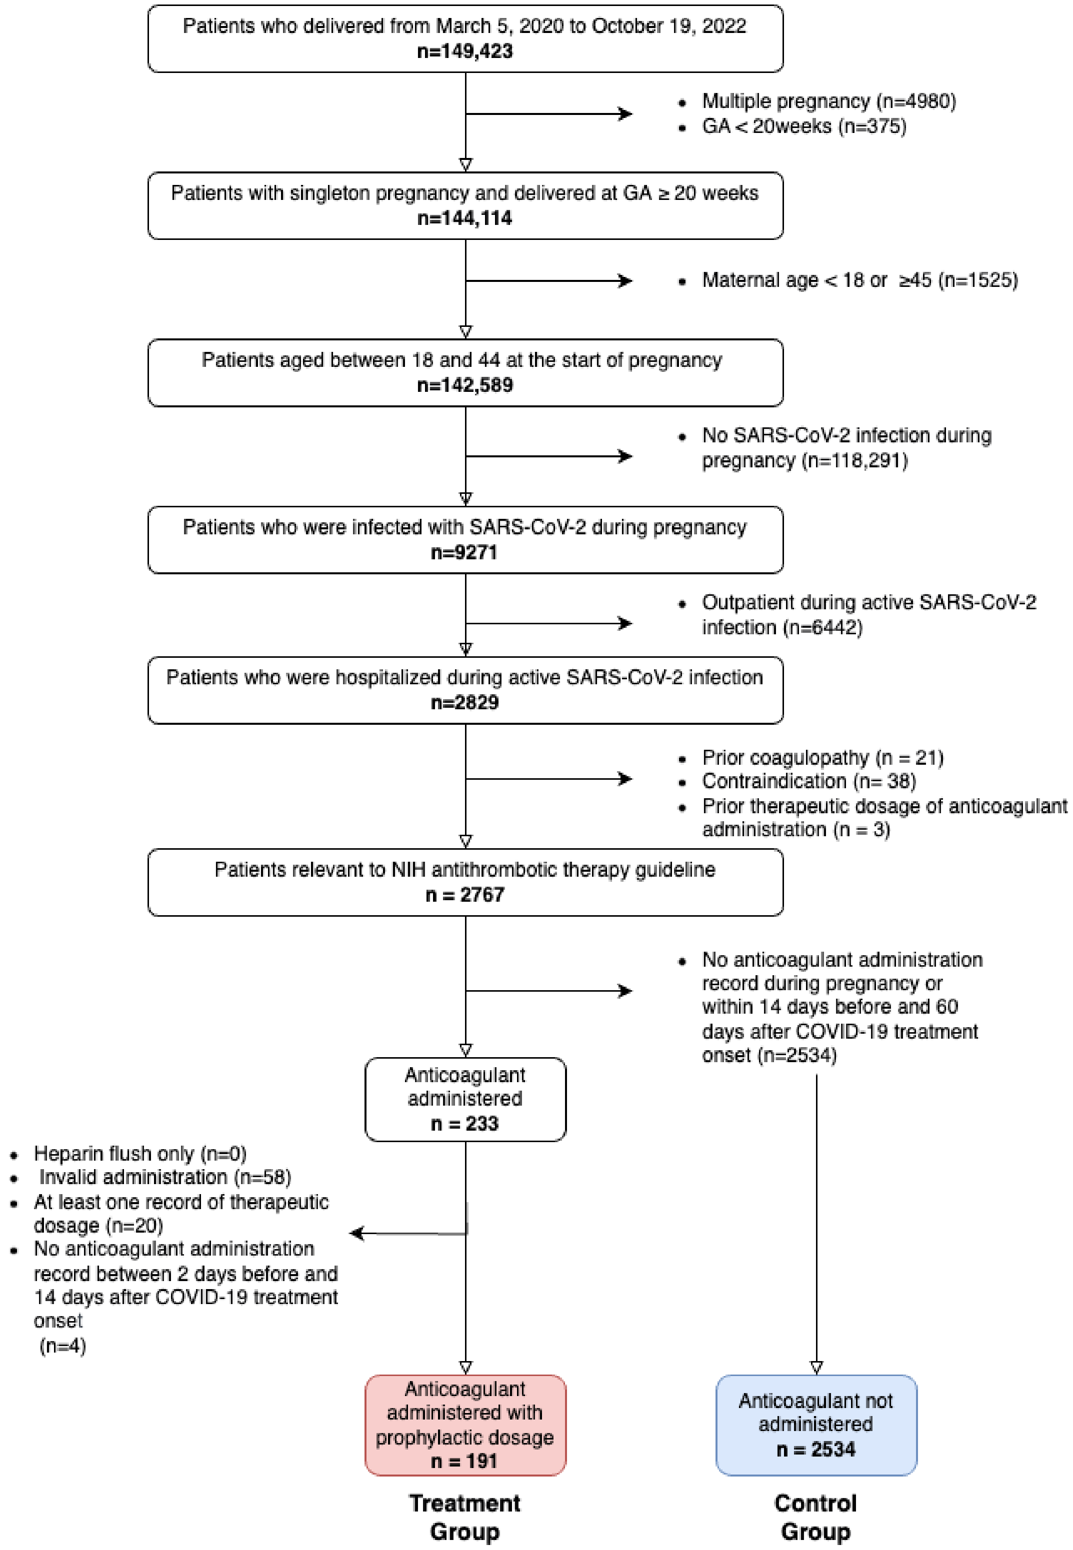
Here, we aim to characterize prophylactic anticoagulant use among hospitalized pregnant patients with COVID-19. We assessed the difference in the prophylactic anticoagulant use across the timeline of NIH guideline changes and SARS-CoV-2 variants. We evaluated the association between prophylactic anticoagulant use and risks of coagulopathy, COVID-19, and maternal-fetal health outcomes, after addressing the discrepancy in variables that could influence outcomes.

Methods

Study Setting and Population

Providence Health and Services and Affiliates (PHSA) is an integrated not-for-profit US community health care system that provides care in urban and rural settings across 7 states: Alaska, California, Montana, Oregon, New Mexico, Texas, and Washington. PHSA service includes 52 hospitals, 1085 clinics, and 120,000 caregivers. We used PHSA electronic health records of pregnant patients who delivered from January 26, 2020, through October 19, 2022 (n=149,423). Multimedia Appendix 1 ([30-36]) provides supplementary methods, tables, and figures. Figure S1 in Multimedia Appendix 1 and Figure 1 describe the cohort selection. Table S1 in Multimedia Appendix 1 defines variables and terminology. We excluded multiple pregnancies and deliveries with a gestational age of less than 20 weeks (n=126,261). We limited our analyses to pregnant patients aged between 18 and 45 years (n=144,114). Our inclusion criterion was COVID-19 diagnosis during the pregnancy period (n=9271). We excluded patients who were not hospitalized with COVID-19 (n=2829). The definition of this exclusion criterion was no overlap of hospitalization stay with an infection period between 7 days before and 14 days after the COVID-19 diagnosis date. This infection period was determined based on previous studies on incubation and symptomatic period [30]. We excluded patients with any coagulopathy event before COVID-19 diagnosis, contraindication to anticoagulant administration, or a record of therapeutic anticoagulant dosage [31] in the past 2 years (Tables S2 and S3 in Multimedia Appendix 1). We defined the remaining patients as our cohort of interest, relevant to the NIH antithrombotic therapy guideline (n=2767). This study was reported following STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines [37].

Figure 1. Cohort selection flowchart. We excluded patients with any history of coagulopathy before the time of SARS-CoV-2 infection. We excluded patients with any contradiction to anticoagulant if the diagnosis was between 2 years before the pregnancy and the time of SARS-CoV-2 infection. Contraindications included major bleeding, peptic ulcer, stage 2 hypertension, esophageal varices, intracranial mass, end-stage liver diseases, aneurysm, proliferative retinopathy, and bleeding disorders. We considered administration to be valid unless the administration status was “Canceled Entry,” “Held,” “Missed,” “Automatically Held,” “Held by Provider,” “MAR Hold,” “Stopped,” or “Paused.” GA: gestational age; NIH: National Institutes of Health.



Variables

Exposures

Figure S1 in Multimedia Appendix 1 and Figure 1 describe definitions of exposure groups. From the cohort of interest (n=2767), patients with no anticoagulant administration record during pregnancy or within 14 days before and 60 days after the SARS-CoV-2 infection date comprised the control group (no anticoagulant administration group, n=2534). We defined the treatment group (prophylactic anticoagulant administration group, n=191) as patients who received prophylactic anticoagulation between 2 days before and 14 days after the potential COVID-19 treatment onset (Figure S1 and Tables S1, S3, and S4 in Multimedia Appendix 1). Our definition of prophylactic included prophylactic and intermediate dosages (Table S4 in Multimedia Appendix 1) [31].

Outcomes

Variables and diagnoses are defined in Tables S1 and S2 in Multimedia Appendix 1. Our primary outcome of interest was coagulopathy. We additionally observed diagnoses relevant to the consequences of COVID-19-associated coagulopathy [8,38,39]. These included thrombosis, pulmonary embolism, thromboembolism, myocardial infarction, skin necrosis or purpura, and stroke (Table S1 in Multimedia Appendix 1). Secondary outcomes were COVID-19 severity and maternal-fetal health outcomes. COVID-19 complications included the need for supplemental oxygen, vasopressor usage, mortality, length of hospital stay, unique diagnosis count, and unique medication count. Maternal-fetal outcomes were stillbirth, preterm birth (PTB), low birth weight (LBW), and small for gestational age. We also assessed the risk of bleeding during pregnancy and postpartum hemorrhage to evaluate the safety of anticoagulant use.

Covariates

Maternal characteristics were evaluated, including parity, gravidity, history of preterm delivery, age, race, ethnicity, insurance, pregravid BMI, smoking, illegal drug use, Centers for Disease Control and Prevention Social Vulnerability Index (CDC-SVI), and rural-urban classification (Table S1 in Multimedia Appendix 1). The count of unique diagnoses before COVID-19 was used to reflect the patient's previous comorbidity. Missing values were imputed using the cohort median. COVID-19–related features assessed were vaccination, previous SARS-CoV-2 infection, presumed SARS-CoV-2 variant, timing of SARS-CoV-2 infection, and stage of NIH COVID-19 antithrombotic therapy guidelines (Supplementary Methods and Table S5 in Multimedia Appendix 1). We defined the stages of guidelines based on major updates in NIH antithrombotic therapy guidelines on pregnant women [29]. Up until December 20, 2020, there was no specific guideline for pregnant women. On December 21, 2020, there was an update to recommend the prophylactic use of anticoagulants among pregnant patients with severe COVID-19. On February 24, 2022, a second update expanded the recommendation to any hospitalized patient with COVID-19.

Analyses

Descriptive Statistics

P value was calculated using the chi-square test and the 2-sample *t* test. Multiple testing error was corrected using Bonferroni correction. We performed pairwise Pearson correlation between variables using python library scipy (version 1.6.2). We ranked the count of diagnoses each exposure group received between COVID-19 diagnosis and delivery.

Classification Model, Feature Importance, and Propensity Score Matching

We conducted a classification model and feature importance analysis to investigate the differences between the treatment and control groups, and to select variables to be addressed in propensity score matching. Using 28 covariates (Table S1 in Multimedia Appendix 1), we built classification models, including logistic regression, random forest, and gradient boosting machine (GBM) models (Supplementary Methods in Multimedia Appendix 1). We applied random undersampling to address a class imbalance between the control and treatment groups. Due to the small sample size, we leveraged leave-one-out cross-validation. We then used Gini feature importance and SHAP (Shapley additive explanation) [40] to identify which covariates were most important for classifying the administration of prophylactic anticoagulant during a COVID-19–related hospitalization in the best-performing model (Supplementary Methods in Multimedia Appendix 1). We evaluated whether the model trained with these top features achieved comparable performance to the original model with 28 features. We then performed propensity score matching to control for these top features between the treatment and control groups. Compared to other propensity score methods and covariate adjustment methods, propensity score matching provided exceptional covariant balance across most circumstances [41]. Given the extreme weights between treatment and control, the inverse probability treatment weighting method (IPTW) was considered unsuitable for this analysis. K-nearest neighbors (k=1) were used to match with replacement across covariates using propensity logit and caliper of 0.2 using Python library PsmPy (version 0.2.8) to identify patients most similar on the top features and generate a matched control group [42]. The number of neighbors (k) and caliper threshold value were selected based on recommendations from previous studies [43,44]. The effect size of these matched features was evaluated using Cohen *d* score before and after matching with a score of <0.2 indicating a small effect size [45]. We evaluated outcome differences between the treatment and matched control groups using Fisher exact test for categorical variables and the Mann-Whitney *U* test for continuous variables.

Sensitivity Analysis

We assessed the influence of illness severity at the time of SARS-CoV-2 infection using the count of medication 3 days before and 3 days after the potential COVID-19 treatment onset. These counts of medications are measures of relative clinical severity in a generally healthy patient population when patients are unlikely to need mechanical ventilation. Although they are imperfect proxies, they have been shown to provide valuable insight, especially in COVID-19–related research. The date range for collecting the medication count was selected based on the distribution of the time gap between the anticoagulant administration date and the COVID-19 treatment onset date (Figure S3 in Multimedia Appendix 1). We conducted propensity score matching on this medication count at the time of SARS-CoV-2 infection, in addition to the best-performing features. We also addressed the influence of maternal age and pregravid BMI, as these variables are known risk factors for coagulopathy.

Investigation of Inpatient Anticoagulant Administration Rate Across Multiple Health Care Systems Using Truveta

We calculated the rate of the inpatient anticoagulant administration rate in the Truveta patient population (Figure S2 in Multimedia Appendix 1). Truveta is a consortium of 28 health care systems, including PHSA, providing patient care in over 20,000 clinics and 700 hospitals across 43 states [46]. Similar data fields across systems are mapped following the common schema referred to as the Truveta Data Model [47]. Among pregnant patients aged between 18 and 45 years and delivered singleton from January 26, 2020, through October 19, 2022, we identified patients with a COVID-19 diagnosis during pregnancy. We excluded patients who did not have any inpatient encounters during the active COVID-19 infection. We further excluded patients who had any anticoagulant use before pregnancy and defined the remaining patients as our Truveta cohort of interest, relevant to NIH antithrombotic therapy guidelines. From this analytic cohort, we calculated patients who were administered inpatient anticoagulants.

Ethical Considerations

All procedures were reviewed and approved by the institutional review board at the PHSA through expedited review on November 4, 2020 (study number STUDY2020000196). Consent was waived because the disclosure of protected health information for the study involved no more than minimal risk to the privacy of individuals. Patient data in the Truveta Studio were deidentified.

Results

Our cohort of interest was composed of 2767 patients (Figure S1 in Multimedia Appendix 1 and Figure 1). A total of 191 and 2534 patients were in the treatment and control groups, respectively. The treatment group was older (mean age 30.9 years; *P*=.02), less likely to be vaccinated (33/191, 17%; *P*<.001), less likely to be infected during the third trimester (139/191, 72.8%; *P*<.001), and more likely to be infected with Delta variant (81/191, 42%; *P*<.001). The treatment group was exposed to enoxaparin and heparin only (Table 1). The date difference between the anticoagulant administration date and potential COVID-19 treatment onset (anticoagulant administration date – COVID-19 treatment onset) ranged from –2 to 14 days. A total of 74.9% (143/191) of the treatment group received anticoagulant prescriptions during the first 3 days of COVID-19 treatment (Figure S3 in Multimedia Appendix 1).

Figure 2 displays the overall timeline of the prophylactic anticoagulant administration status from March 20, 2020, to October 19, 2022. The overall prevalence rate of prophylactic anticoagulant administration was 7% (191/2725). The administration rate was the lowest when the Omicron variant was dominant (47/1551, 3%) and after the second guideline update (19/811, 2.3%). It was the highest when the Delta variant was dominant (81/507, 16%) and when there was no guideline (27/262, 10%). The top 10 diagnoses of the control group were subcategories of COVID-19 and pregnancy (Figure S4 in Multimedia Appendix 1). The treatment group additionally included COVID-19 complications, such as pneumonia, acute respiratory failure with hypoxia, and hypokalemia (Figure S4 in Multimedia Appendix 1).

Figure S2 in Multimedia Appendix 1 displays the cohort selection procedure in the Truveta patient population. We identified 14,075 patients as our Truveta cohort of interest. Among these patients, 973 (6.9%) patients were administered inpatient anticoagulants.

The GBM model had the best performance with an area under the receiver operating characteristics curve (AUC-ROC) of 0.84 (95% CI 0.81-0.87; Figure S5 and Table S6 in Multimedia Appendix 1). Pre–COVID-19 diagnoses count, variant-omicron, socioeconomic status, third-trimester infection, housing type and transportation vulnerability, minority status and language vulnerability, and household composition and disability vulnerability were the most important 7 features (Figures S5 in Multimedia Appendix 1). The GBM model trained with these 7 features reached an AUC-ROC of 0.85 (95% CI 0.83-0.89; Figure S5 in Multimedia Appendix 1 and Figure 3). In the SHAPley figure, red and blue dots indicate high and low feature values. Red dots of pre–COVID-19 diagnoses count were clustered in the positive end of the SHAP axis. Red dots of third-trimester infection and variant Omicron were clustered in the negative SHAP axis. The matched control group (n=188) was generated by propensity score matching on the 7 most important features. These features had small effect sizes after matching (Cohen *d* values <0.2 [45] Table S7 in Multimedia Appendix 1).

The GBM model trained with the 7 top features and initial medication count reached an AUC-ROC of 0.93 (95% 0.91-0.95; Figure S6 in Multimedia Appendix 1). The feature importance showed that initial medication count was the most important feature classifying prophylactic anticoagulant administration status (Figure S6 in Multimedia Appendix 1). The red and blue dots were spread out across extreme negative SHAP values and up to 0.2 SHAP value, but the end of the positive SHAP axis (SHAP value >0.2) was clustered with red dots (Figure S6 in Multimedia Appendix 1).

Compared with the control group, the treatment group had an increased risk of maternal death (relative risk [RR] not calculable due to the small number of cases; 3/191, 1.6% vs 0/2545, 0%; *P*<.001), O_2 assistance (RR 9.3, 95% CI 6.9-12.3; 57/191, 33% vs 91/2545, 3.6%; *P*<.001), LBW (RR 2.1, 95% CI 1.5-2.8; 36/190, 19% vs 233/2539, 9.2%; *P*<.001), PTB (RR 2.1, 95% CI 1.5-2.8; 47/191, 25% vs 295/2545, 12%; *P*<.001), and bleeding (RR 2.5, 95% CI 1-6.3; 5/191, 2.6% vs 27/2545, 1.1%; *P*=.08). After matching, risk of LBW (RR 1.2, 95% CI 0.8-1.8; *P*=.50), PTB (RR 1.2, 95% CI 0.8-1.8; *P*=.33), and bleeding (RR 1.0, 95% CI 0.3-3.3; *P*>.99) were reduced and no longer statistically significant. We also did not observe an increase or decrease in risk between the treatment coagulopathy and other maternal-fetal health outcomes (Tables S8 and S9 in Multimedia Appendix 1 and Figure 4). However, the treatment group had significantly worse outcomes regarding COVID-19 illness severity even after the matching. The treatment group had a higher likelihood of supplemental oxygen (RR 6.9, 95% CI 3.5-13.4; 57/191, 30% vs 9/188, 5%; *P*<.001), longer inpatient stay (median 6 vs 3; *P*<.001), higher medication (median 51 vs 39; *P*<.001), and diagnoses count (median 7 vs 0; *P*<.001). The statistical significance remained even in our sensitivity analysis (Tables S8 and S9 in Multimedia Appendix 1) where we additionally addressed the initial illness severity. Maternal age and pregravid BMI did not influence the association between the treatment and outcomes of interest.

Table 1. Descriptive statistics of treatment and control group. Variables are defined in Table S1 in Multimedia Appendix 1. This table was generated using tableone PyPI package. *P* value was calculated using the chi-square test and the 2-sample t test. Multiple testing error was corrected using Bonferroni correction.

	Missing, n	Overall (N=2736)	Control group (n=2545)	Treatment group (n=191)	*P* value (adjusted)

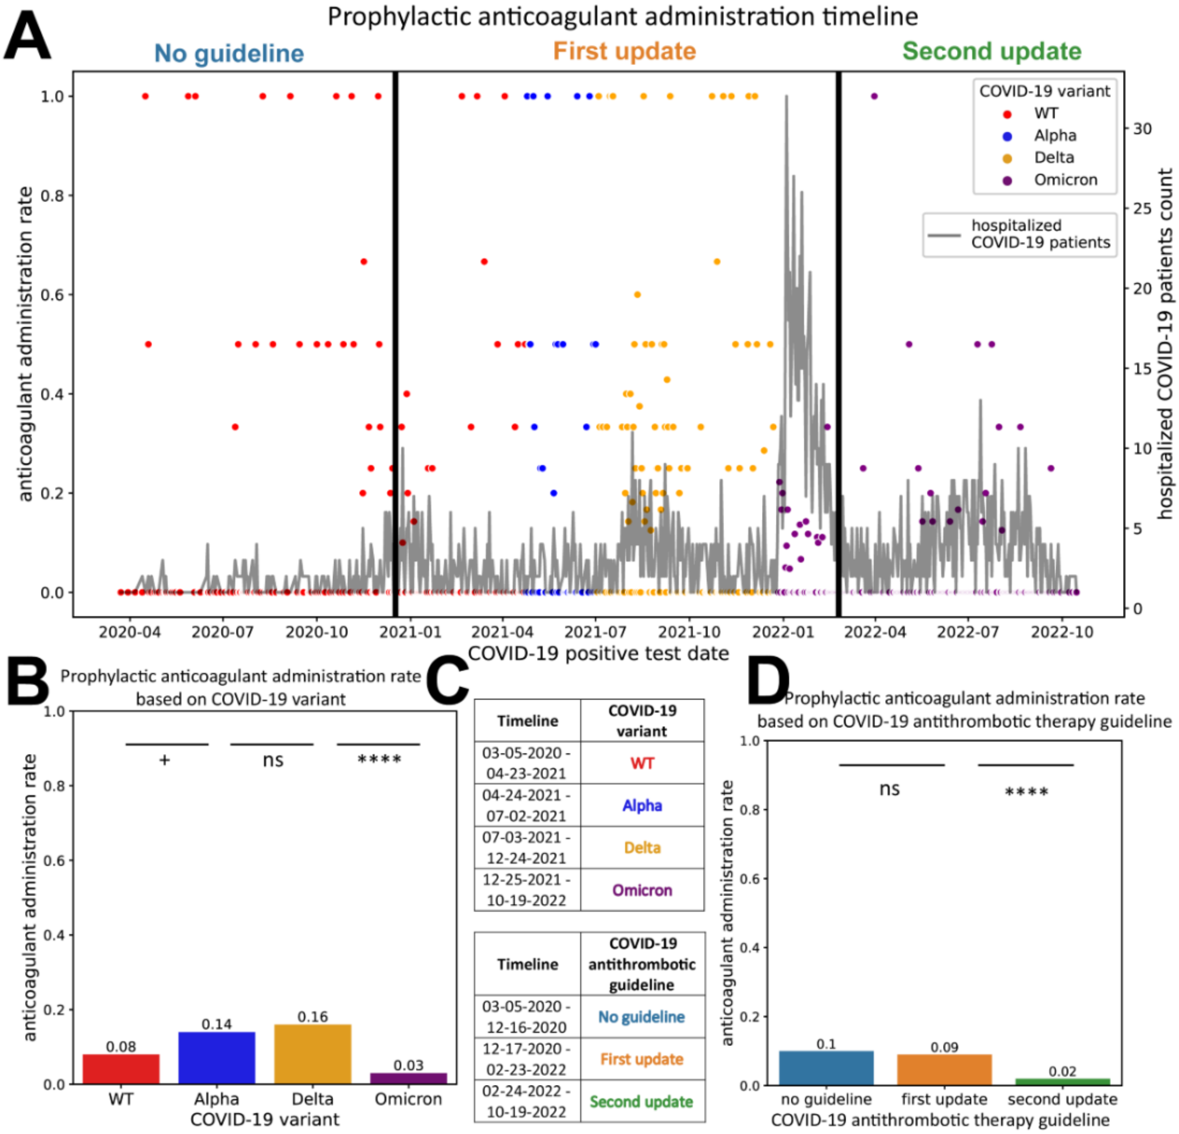
Figure 2. Timeline of prophylactic anticoagulant administration among hospitalized COVID-19 pregnant patients from March 20, 2020, to October 19, 2022. The anticoagulant administration rate is defined as the count of the patients who belong to the treatment group divided by the sum of patients who belong to the treatment group and control group. (A) Timeline of prophylactic anticoagulant administration rate among hospitalized COVID-19 pregnant patients from March 20, 2020, to October 19, 2022. Marked time points are described in part C of the figure. Timeline definitions: red, blue, yellow, and purple dots indicate the prophylactic anticoagulant administration rate among COVID-19 wild type, Alpha, Delta, and Omicron variants, respectively. Grayline chart indicates the count of hospitalized pregnant patients with COVID-19. The first (left) vertical line is on December 17, 2020, the first update date in COVID-19 antithrombotic therapy guidelines to recommend the administration of prophylactic anticoagulants on pregnant patients hospitalized with severe COVID-19 manifestation. The second (right) vertical line is on February 24, 2022, the second update date to expand the recommendation to all pregnant patients hospitalized with COVID-19 manifestation. The overall administration rate of prophylactic anticoagulants was 7% (191/2725) (B) Prophylactic anticoagulant administration rate based on SARS-CoV-2 variant. The SARS-CoV-2 variant was determined based on the period during which each variant was the dominant variant accounting for >50% of cases as part of the Centers for Disease Control and Prevention (CDC) genomic surveillance for SARS-CoV-2 in Region 10 (Alaska, Idaho, Oregon, and Washington; CDC 2022).(C) Prophylactic anticoagulant administration rate was lowest during the omicron-dominant period (Wild type: 45/549, 8.2%; Alpha: 18/129, 14%; Delta: 81/507, 16%; and Omicron: 47/1551, 3%) (C) Timeline definition. Text colors indicate the SARS-CoV-2 variant and COVID-19 antithrombotic therapy guideline time period in parts A, B, and D of the figure. (D) Prophylactic anticoagulant administration rate based on COVID-19 antithrombotic therapy guideline. The first update was to recommend the administration of prophylactic anticoagulants on pregnant patients hospitalized with severe COVID-19 manifestations. The second update expanded the recommendation to all pregnant patients hospitalized with COVID-19 manifestation. Prophylactic anticoagulant administration rate was lowest after the second guideline update (no guideline: 27/262, 10%; first update: 145/1663, 8.7%; second update: 19/811, 2.3%). WT: wild type. ^{ns}P>.05, *P≤.05, **P≤.01, ***P≤.001, ****P≤.0001.



Timeline	COVID-19 variant
03-05-2020 - 04-23-2021	WT
04-24-2021 - 07-02-2021	Alpha
07-03-2021 - 12-24-2021	Delta
12-25-2021 - 10-19-2022	Omicron

Timeline	COVID-19 antithrombotic guideline
03-05-2020 - 12-16-2020	No guideline
12-17-2020 - 02-23-2022	First update
02-24-2022 - 10-19-2022	Second update

Figure 3. Performance of best-performing classification model and feature importance. (A) Performance of original and limited gradient boosted machine learning model classifying prophylactic anticoagulant administration status among hospitalized pregnant patients with COVID-19. The limited model was trained with the 7 most important features from the original model. The feature importance result of the original model is in Figure S5 in Multimedia Appendix 1. The 95% CI of the original and limited models were (0.81-0.87) and (0.83-0.89), respectively. (B) Feature importance ranking of the limited model. Variables are defined in Table S1 in Multimedia Appendix 1. (C) Shapley permutation explainer of the feature contribution. SHAP value reflects the contribution of the 7 most important features from the gradient boosting models toward classifying prophylactic anticoagulant administration status. SHAP value is the average marginal contribution of a feature value across all permutations of features. Each row represents an individual feature, and the dot represents a sample. The dot color reflects the value of the feature of the sample relative to all samples. The evaluation was done on the sample set composed of a treatment group and a 1:1 randomly undersampled matched control group (n=382). AUC: area under the curve; GBM: gradient boosting machine.

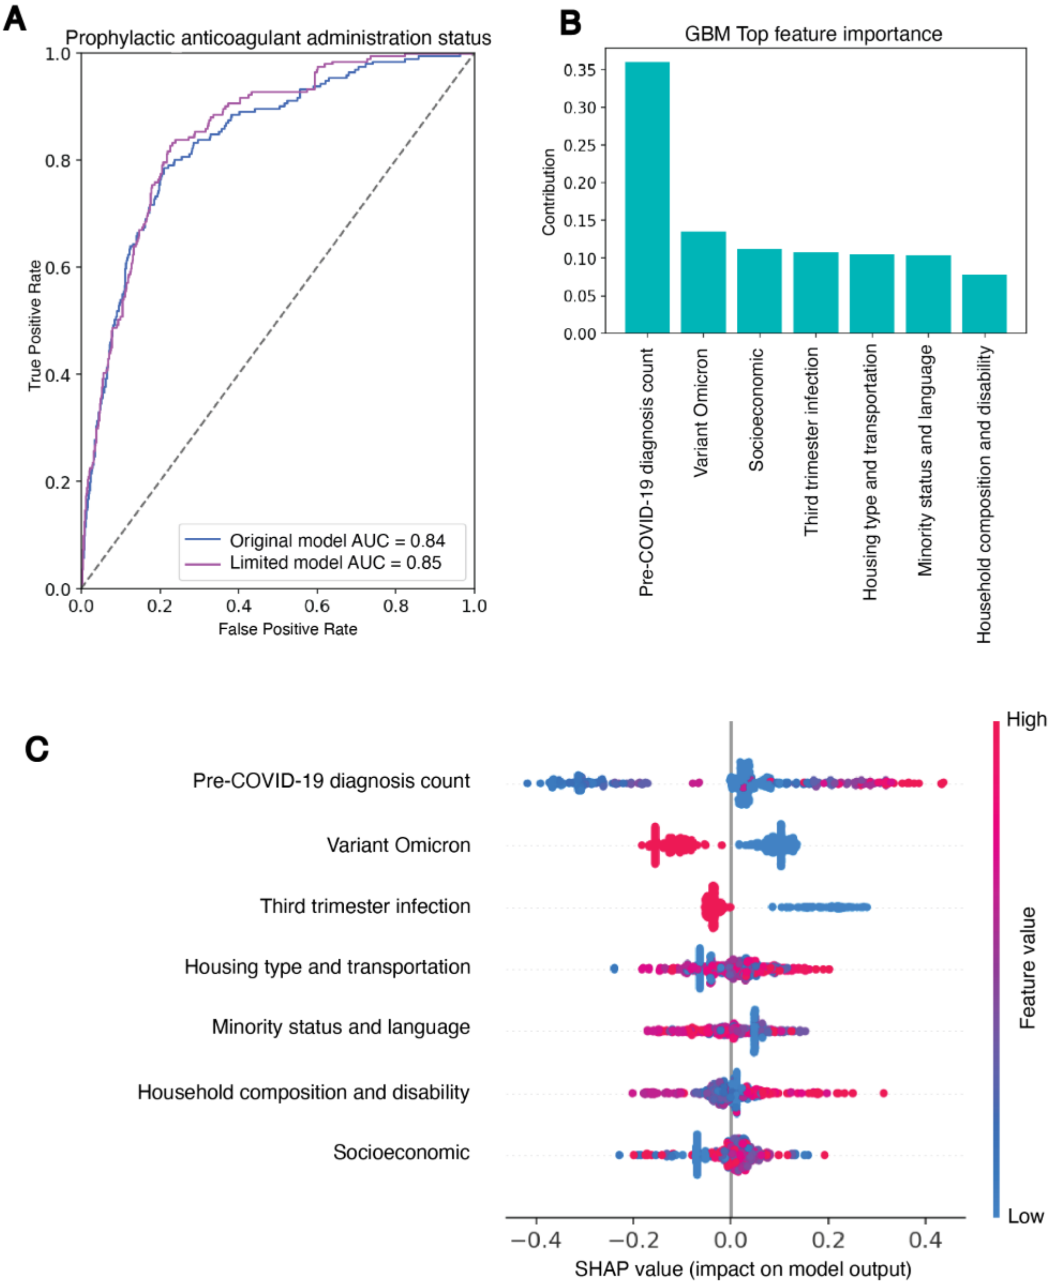


Figure 4. Clinical outcomes of the treatment and matched control. Results are presented in Tables S7 and S8 in Multimedia Appendix 1. Unless specified, the observation cutoff was the delivery date. The observation start point was the anticoagulant exposure date and potential COVID-19 treatment onset date, respectively. (A) Coagulopathy prevalence rate of the treatment and matched control. SNOMED codes we used for coagulopathy diagnosis are listed in Table S1 in Multimedia Appendix 1. (B) Bleeding and postpartum hemorrhage prevalence rate of the treatment and matched control. SNOMED codes we used for bleeding and postpartum hemorrhage diagnoses are listed in Table S1 in Multimedia Appendix 1. Postpartum hemorrhage was collected from the delivery date to +12 weeks postpartum. (C) O_2 assistance use, vasopressor use, maternal death prevalence rates for the treatment, and matched control groups. Violin plots of the length of inpatient stay (days), medication counts 48 hours after the potential COVID-19 treatment onset, and diagnoses count after the potential COVID-19 treatment onset. The cutoff point was the delivery date. (D) Stillbirth, low birth weight, preterm birth, small for gestational age prevalence rate of the treatment, matched control, and sensitivity analysis matched control group.

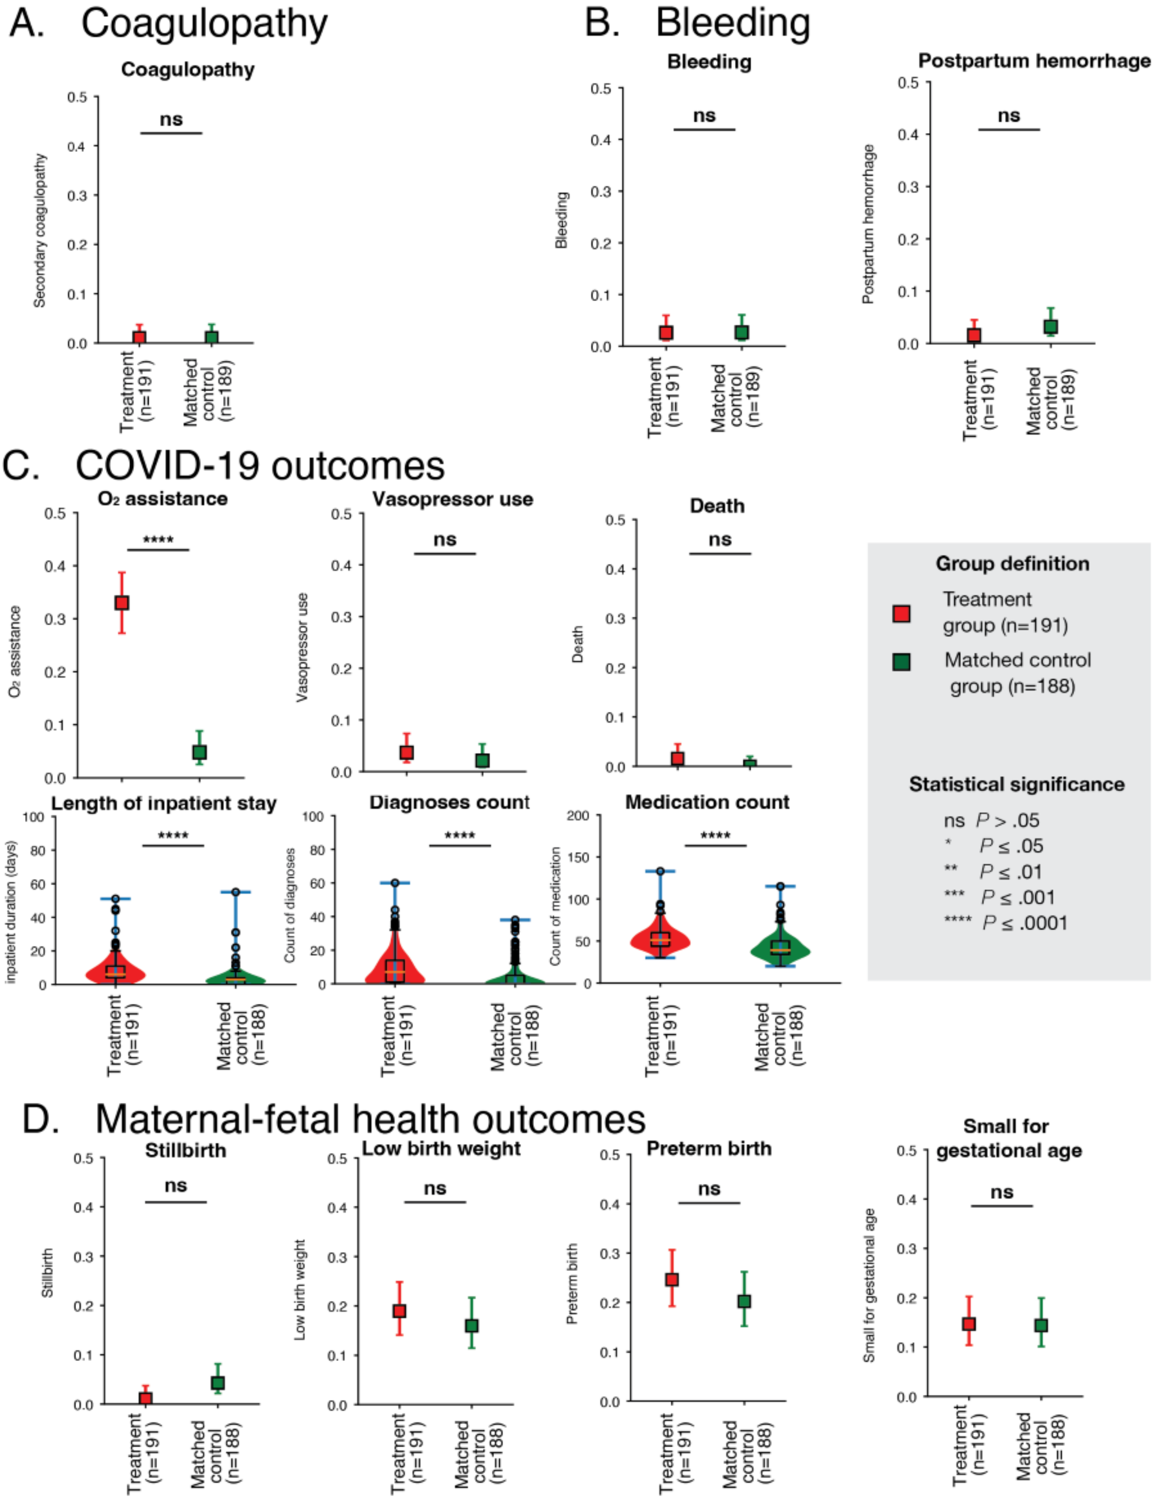

Discussion

Principal Results

To our knowledge, this was the first study evaluating the NIH antithrombotic therapy guideline on pregnant women. We initially hypothesized to observe a high prophylactic anticoagulant administration rate among hospitalized COVID-19 pregnant patients and minimal difference in patient characteristics between the treatment and control groups. However, we identified most patients relevant to NIH antithrombotic therapy guidelines, pregnant women hospitalized with COVID-19, did not receive prophylactic anticoagulant dosage. Instead, patients with higher comorbidity levels, infected in the first or second trimester, and infected with a non-Omicron variant were more likely to receive prophylactic anticoagulant. Despite having more severe COVID-19, the treatment group did not have an elevated risk of coagulopathy, bleeding, and maternal-fetal health outcomes.

Comparisons With Previous Works, Interpretation, and Implication

The most important and interesting finding was an unexpectedly low prophylactic anticoagulant administration rate among hospitalized COVID-19 pregnant patients across health care systems despite the guideline. A possible explanation for this observation is that clinicians administered prophylactic anticoagulants based on the patient's COVID-19 illness severity. The initial medication count, a proxy variable for COVID-19 illness severity at COVID-19 treatment onset, was the most important feature in the sensitivity analysis model classifying prophylactic anticoagulant administration status. It also enhanced the area under the curve score by 0.09 reaching 0.94. Besides, we noticed the treatment group was enriched with diagnoses indicative of severe COVID-19 symptoms, such as pneumonia, acute respiratory failure with hypoxia, and hypokalemia. In contrast, the control group was not. We presume clinicians did not follow the guideline because it was not strongly recommended and lacked studies to support it. The rating scheme of the NIH guideline is BIII. B and III, respectively, indicate a moderate recommendation and expert opinion evidence. This means no study yet has evidence for or against this recommendation [42]. Few studies describing COVID-19-positive pregnant patients have reported prophylactic use of anticoagulants during hospitalization. In these studies, the sample size was small, ranging from 9 to 20, and complications following the treatment were not evaluated [48-50].

We noted an elevated risk of respiratory assistance among the treatment group. This was inconsistent with previous studies. Although there was no study on pregnant patients, there have been multiple observational studies supporting prophylactic anticoagulant use on nonpregnant hospitalized patients with COVID-19. Studies showed that prophylactic anticoagulants improved freedom from intubation and lowered mortality, indicating better COVID-19 outcomes [51-53]. In these studies with a nonpregnant population, including men and an older population, the rate of prophylactic anticoagulant administration ranged from 45% (1959/4389) to 84% (3627/4297), whereas that of our study was 7% (191/2736). In addition, in our study, prophylactic anticoagulant administration was highly correlated with the comorbidity level before the SARS-CoV-2 infection and the initial illness severity. We do not think the increased risk in respiratory assistance in our study was influenced by the exposure to anticoagulants, but rather a byproduct of failure to overcome the confounding by indication.

Although we could only partially address the confounding by indication, we did not observe elevated risks of coagulopathy, bleeding, and maternal-fetal health outcomes among the treatment group. Given that severe COVID-19 is associated with coagulopathy and adverse pregnancy outcomes [1-10,54,55], this finding was somewhat promising as we expected worse outcomes in coagulopathy and maternal-fetal health outcomes. Based on our findings, we cannot support the benefit of the guideline, but can, at least, support its potential safety regarding maternal-fetal health outcomes. The treatment group had a similar likelihood to deliver low birthweight, preterm, and small for gestational age babies. This observation was less limited with a small sample size, compared to rare outcomes of interest, due to the high incidence rate of cases across groups. Considering this is the first study to evaluate the guideline, our study can contribute to our knowledge in treating hospitalized pregnant patients with COVID-19. Future research should be conducted in larger and various study settings and minimize the confounding by indication to understand better the risk, safety, and benefit of the treatment.

Strengths and Limitations

The small percentage of patients receiving guideline-recommended treatment was both an interesting observation and a major limitation. We expected to observe a high prophylactic anticoagulant administration rate after the second guideline update as all hospitalized COVID-19 pregnant patients were relevant, but only 7% (191/2736) were administered prophylactic anticoagulants. This led to confounding by indication. The treatment group had higher pre-COVID-19 comorbidity levels and included more critically ill patients. Although we attempted to minimize the bias using propensity score matching, we could not overcome it due to the unexpectedly small sample size and lack of appropriate variables reflecting COVID-19 illness severity at the time of infection. This study was conducted on retrospective structured data, which is insufficient to determine medical reasoning. In addition, individuals had a wide range of anticoagulant administration start times before and after the potential COVID-19 treatment onset. As covariates that occurred after the exposure are inappropriate for the propensity score method, we excluded them from the main matching model. Nevertheless, we performed sensitivity analysis on the impact of the initial medication count to partially address the COVID-19 illness severity at the time of treatment onset. Last, we did not verify whether the heightened risk of O_2 assistance among the treatment group resulted from confounding by indication or not. We assumed it was due to confounding by indication based on the previous studies [51-53] on hospitalized patients with COVID-19. More generally, electronic health record data are known to contain errors; inpatient medication administration records are carefully tracked and unlikely to be omitted, but it is not uncommon for comorbidities to be undiagnosed, unreported, or listed in more than one way. To address all of these limitations, a similar study should be conducted in a larger prospective cohort, with appropriate variables to assess COVID-19 illness severity at the time of admission.

This was the first study assessing the prophylactic use of anticoagulants on hospitalized patients after the guideline update on February 24, 2022. Although the guideline recommends on all hospitalized patients regardless of COVID-19 severity, no study to date has assessed the exposure of anticoagulants among COVID-19 hospitalized patients. Another strength of our study includes adjustments for social and economic risk factors. We adjusted for differences between CDC-SVI scores and rural and urban classifications in the treatment and control groups based on the census tract level. Social vulnerability and rural health disparities are significant risk factors for adverse pregnancy outcomes and severe COVID-19 symptoms [56-63]. As the census tract is more granular than the county level, it captures the environmental factors to which patients have been exposed more accurately. Indeed, all 4 CDC-SVI indexes were important predictors of anticoagulant administration status. This study was conducted on a COVID-19 maternity population that has been investigated by other researchers [64,65], allowing deeper insight into the study setting and population.

We validated the number of inpatient anticoagulant administration rates in Truveta's patient population, comprised of various health care systems. Overall inpatient anticoagulant administration rates in Truveta were similar to those observed in PHSA. This indicates that the unexpectedly low adaptation rate of NIH recommendations was not limited to the PHSA health care system. Here, we could not completely replicate our analysis as Truveta and Providence data models were different, and the leading researcher of this study had limited access to Truveta Studio. We did not exclude patients who were contraindicated to anticoagulants and did not differentiate between prophylactic and therapeutic dosage. Nevertheless, we expect our final estimation of the inpatient anticoagulant administration rate on the Truveta patient population would not drastically change based on the number we observed from the cohort selection procedure in the PHSA population.

Conclusions

We found that in a population of patients from multiple health care systems nationwide, only a small percentage of hospitalized pregnant patients received the prophylactic anticoagulation recommended by the NIH antithrombotic therapy guideline. Guideline recommended prophylactic anticoagulants were administered more frequently to patients with greater COVID-19 illness severity. We were not able to show the efficacy of prophylactic anticoagulation. However, anticoagulation was not associated with elevated risks of coagulopathy, bleeding, and maternal-fetal health outcomes despite the worse health conditions of the treatment group. This study cannot make a recommendation to administer prophylactic anticoagulant to hospitalized COVID-19 pregnant patients. However, as this was the first study characterizing prophylactic anticoagulant use after the NIH guideline update on February 24, 2022, these results can help inform patient-specific clinical decisions. An observational study with a larger sample size should be considered to further evaluate outcomes with prophylactic anticoagulation.

Acknowledgments

This work was funded by a grant from the National Institutes of Health (HD091527). We thank Providence Health and Services and Affiliates for sharing their data engineering expertise and computational resources. We would also like to acknowledge SNOMED International for developing and maintaining SNOMED-CT.

Data Availability

Results have been aggregated and reported within this paper to the extent possible while maintaining privacy from personal health information as required by law. Providence Health and Services and Affiliates data are archived within Providence Health and Services and Affiliates in a Health Insurance Portability and Accountability Act (HIPAA)–secure audited computer environment. Truveta data are available to Truveta subscribers. Requests to access these data sets can be directed to Truveta Inc., info@truveta.com. All clinical logic for data extraction has been shared within the paper and Multimedia Appendix 1. The code is publicly available on GitHub [66].

Authors' Contributions

YMH contributed to conceptualization, methodology, software, formal analysis, investigation, writing original draft preparation, and visualization. SP was involved in conceptualization, methodology, software, investigation, writing, reviewing, and editing. TS was responsible for supervision, writing, reviewing, and editing. LH contributed to conceptualization and supervision. JH was involved in conceptualization, supervision, writing, reviewing, and editing.

Conflicts of Interest

LH is a scientific advisor for Sera Prognostics, a company that develops diagnostic tests for pregnancy complications. The company is not associated with this study or any of the findings. JH reports grants from Pfizer and Novartis and research contracts from Janssen, Gilead Scientific, and Bristol Myers Squibb for work unrelated to this study. The remaining authors report no conflict of interest.

Abstract

Background: The Flexible Adaptive Algorithmic Surveillance Testing (FAAST) program represents an innovative approach for improving the detection of new cases of infectious disease; it is deployed here to screen and diagnose SARS-CoV-2. With the advent of treatment for COVID-19, finding individuals infected with SARS-CoV-2 is an urgent clinical and public health priority. While these kinds of Bayesian search algorithms are used widely in other settings (eg, to find downed aircraft, in submarine recovery, and to aid in oil exploration), this is the first time that Bayesian adaptive approaches have been used for active disease surveillance in the field.

Objective: This study's objective was to evaluate a Bayesian search algorithm to target hotspots of SARS-CoV-2 transmission in the community with the goal of detecting the most cases over time across multiple locations in Columbus, Ohio, from August to October 2021.

Methods: The algorithm used to direct pop-up SARS-CoV-2 testing for this project is based on Thompson sampling, in which the aim is to maximize the average number of new cases of SARS-CoV-2 diagnosed among a set of testing locations based on sampling from prior probability distributions for each testing site. An academic-governmental partnership between Yale University, The Ohio State University, Wake Forest University, the Ohio Department of Health, the Ohio National Guard, and the Columbus Metropolitan Libraries conducted a study of bandit algorithms to maximize the detection of new cases of SARS-CoV-2 in this Ohio city in 2021. The initiative established pop-up COVID-19 testing sites at 13 Columbus locations, including library branches, recreational and community centers, movie theaters, homeless shelters, family services centers, and community event sites. Our team conducted between 0 and 56 tests at the 16 testing events, with an overall average of 25.3 tests conducted per event and a moving average that increased over time. Small incentives—including gift cards and take-home rapid antigen tests—were offered to those who approached the pop-up sites to encourage their participation.

Results: Over time, as expected, the Bayesian search algorithm directed testing efforts to locations with higher yields of new diagnoses. Surprisingly, the use of the algorithm also maximized the identification of cases among minority residents of underserved communities, particularly African Americans, with the pool of participants overrepresenting these people relative to the demographic profile of the local zip code in which testing sites were located.

Conclusions: This study demonstrated that a pop-up testing strategy using a bandit algorithm can be feasibly deployed in an urban setting during a pandemic. It is the first real-world use of these kinds of algorithms for disease surveillance and represents a key step in evaluating the effectiveness of their use in maximizing the detection of undiagnosed cases of SARS-CoV-2 and other infections, such as HIV.

Introduction

Background

Columbus, Ohio—like much of the world during the first 3 years of the pandemic—experienced multiple waves of infections in which the number of SARS-CoV-2 infections overwhelmed and outstripped the capacity of efforts to detect new cases [1,2]. In fact, estimates suggest that even at the height of the Omicron surge, a significant number of infections went undetected by case-based surveillance systems and the rise of at-home testing [3]. As the epidemic continues, particularly as public testing sites are scaled back and closed, the ability to quickly identify individuals with SARS-CoV-2 and link them to treatment has become difficult, risking patient and population health [4,5]. Given the integral role of active surveillance efforts in identifying cases, linking patients to care, and managing COVID-19, local public health departments require ways to maximize the resources they have at their disposal to continue to find new cases of disease in their jurisdictions even as resources for these efforts continue to shrink [4,6,7].

How to optimize resource allocation over time is a well-studied problem in sequential decision-making and reinforcement learning. The introduction of a spatial component to these kinds of dilemmas has been applied in a variety of settings, from military search and rescue to oil exploration [8]. We have previously described the use of one set of tools, bandit algorithms, to address these kinds of problems for detection of HIV and SARS-CoV-2 in the community [8-10]. Up until now, these methods have only been evaluated in computer simulations. The study described here represents the first-ever real-world implementation that investigates these tools for active infectious disease surveillance.

An academic-governmental partnership—the Flexible Adaptive Algorithmic Surveillance Testing (FAAST) program—between Yale University, Ohio State University (OSU), Wake Forest University (WFU), the Ohio Department of Health (ODH), the Ohio National Guard (ONG), and the Columbus Metropolitan Libraries (CML) conducted a study of bandit algorithms to maximize the detection of new cases in SARS-CoV-2 in Columbus in 2021.

This initiative began as the Delta variant of SARS-CoV-2 established itself in Ohio in the summer of 2021, ending a period of decreasing case numbers in the state. From mid-August to mid-September, the daily case count rose from over 2000 to over 9000 [11]. Around the same time, the ODH started distributing home rapid antigen tests (RATs) for COVID-19 to allow people to monitor their own health status. These tests were provided to community-based organizations in Ohio, including over 246 library locations, which received more than 53,000 rapid tests in late summer 2021 [12]. While the high demand meant that these libraries quickly ran out of tests to distribute, the community's relationship and trust in libraries as a testing resource for COVID-19 enabled us to partner with the CML for this study [13]. The strong uptake of RATs is consistent with evidence that voluntary use of these tests is high in settings where they have been widely distributed [14], but it is important to note that decisions to opt in to population-level voluntary testing programs appear to be influenced by factors such as socioeconomic status rather than infection risk alone [15]. Thus, active surveillance has an important role in both prioritizing limited testing resources and in reaching individuals not seeking voluntary testing.

Working with our partners, we were able to offer an option to maximize the effectiveness of the scarce testing resources in Columbus by feeding our daily testing information into the bandit algorithm to target the next day's testing efforts. Our "learn by doing" method adaptively targeted locations in the CML system, with tests supplied by ODH and performed by ONG with student and faculty support from OSU, WFU, and Yale.

As the COVID-19 pandemic continues, we will further evaluate the tools in Columbus and the state of Ohio and elsewhere as opportunities arise. Given the flexibility of these methods, we can tailor them to identify new cases more efficiently in underserved communities, which may be at higher risk of transmission and serious clinical disease either due to undervaccination and the prevalence of underlying conditions or due to specific kinds of workplaces and high-risk settings (eg, skilled nursing facilities). Importantly, the potential utility of these tools is not limited to SARS-CoV-2. Evaluation of these tools for HIV, hepatitis C virus, and other sexually transmitted diseases is also being considered.

Goals of the Study

The purpose of this study was to evaluate the use of bandit algorithms to maximize the yield of testing for SARS-CoV-2 across multiple community sites in Columbus, Ohio, over a 3-month period from August to October 2021.

We sought to understand (1) if an algorithm-guided site selection would be operationally feasible for the branches of the CML system and ONG, since locations could shift from day to day, requiring staff to be ready and prepared for quick deployment and setup of testing efforts; (2) if shifting locales would present difficulties for uptake of testing services by the community, given the fact that the announcement of testing locations would only occur a few days in advance; and (3) how algorithm-guided site selection impacted the recruitment of minority residents of underserved communities in terms of number of tests conducted at each event among key demographic groups, particularly African-Americans, in Columbus.

In general, we were interested in a better understanding of the operational performance of the algorithm—as a formal analysis of the effectiveness of this algorithm-guided site selection approach to active disease surveillance would require a large cluster-randomized trial. Specifically, we chose 2 a priori indicators that the algorithm was homing in on hotspots for detecting new cases. Our goal was to sustain a testing positivity rate that was greater than (1) the estimated prevalence of the surrounding community and (2) the positivity rates of other types of testing events in the same zip codes. It is important to clarify that we were not attempting to estimate local prevalence of disease or positivity rates in this study nor making inferences about the effectiveness of the algorithm in practice but using these 2 metrics as a guide as to its basic performance as we assessed its initial feasibility in this research. The algorithm is a sequential decision-making tool; in this case, it was designed to guide resource allocation decisions for SARS-CoV-2 testing efforts.

Methods

Statistical Approach

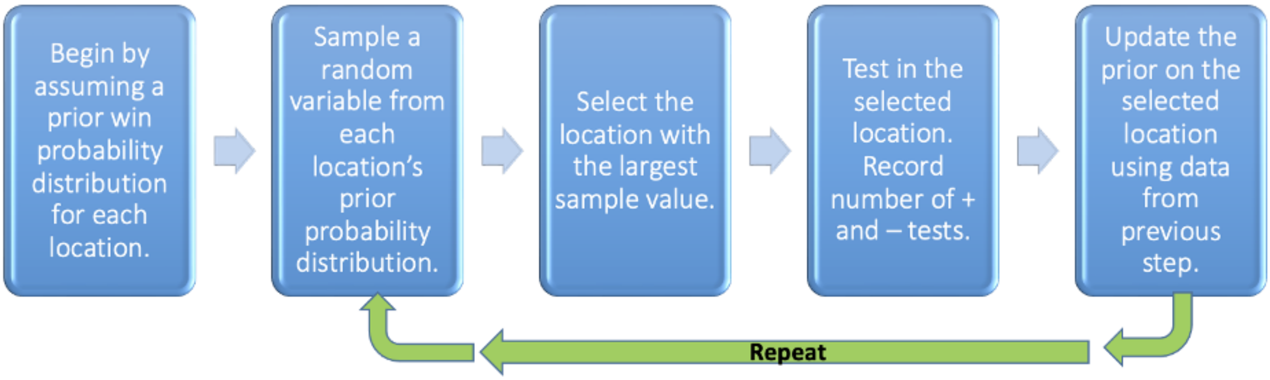
The algorithm used to direct pop-up SARS-CoV-2 testing for this project has been described in detail elsewhere [8-10]. The algorithm is based on Thompson sampling, which uses a Bayesian updating process involving iteratively sampling from prior probability distributions of all potential testing sites—the set of all locations at which testing is being considered—to home in on those with the highest probability over the long run in finding new cases of SARS-CoV-2 [16,17]. Multimedia Appendix 1 describes Thompson samplng in more detail. This approach is not being used to estimate the local prevalence or test positivity at each site in the community but to maximize success in finding new cases over time. This algorithm is not a sampling strategy in which we seek to learn about an underlying population parameter (eg, prevalence) but simply a process by which we can direct testing efforts most efficiently. In fact, the reason this algorithm is not designed to estimate local prevalence is because this metric, while related to testing yield, may be confounded by other factors at work in a given location. That is, while testing yield is indeed a function of prevalence in part, prevalence does not provide a one-to-one proxy for the number of tests obtainable at a given location. For instance, a given site may have a lower prevalence than another but be a place in which more new diagnoses are garnered for other reasons (eg, higher health-seeking behavior, fewer options for testing in other settings); thus, this algorithm is designed to maximize testing yields alone.

Testing sites are determined a priori and serve as a fixed list of potential locations for deploying testing. Initial prior probability distributions for each site can be assigned to be noninformative (ie, uniform), reflecting a lack of information about where yield might be highest, or informative based on local knowledge of the pandemic, previous testing efforts, or social and economic characteristics of a given neighborhood. While informative priors can aid convergence on hotspots if the information is accurate, they can delay convergence if the information is incorrect, so one should use caution when specifying the initial prior distributions.

For this study, we chose to specify informative prior distributions for each site based primarily on results from previous feasibility testing events that we conducted at each site prior to use of the algorithm, with slight modifications to account for the current pandemic conditions. To estimate the baseline values for the parameters for our prior distributions for each potential testing site, we consulted with experts on the local epidemiological conditions and considered the prior testing event results, the reported rate of SARS-CoV-2 infections, and the vaccination rate in the neighborhoods surrounding each site. Taken together, this process yielded assumed β distributions for the positivity rate at each site where the α parameter represented the assumed number of positive tests and the β parameter the assumed number of negative tests. The assumed positivity was $\alpha / \alpha + \beta$ and the total number of tests (ie, the sum of the α and β parameters). Details of the derived values for each site are shown in the Results section. While the true values of these parameters are unknown, we decided that given the short duration of our study period and the quality of the empirical and expert knowledge on these testing sites, estimating the values for these initial α and β parameters for each location was a reasonable choice.

Before assigning a location for a given day's testing efforts, the algorithm randomly samples from the probability distributions of all the potential testing sites. Then, the site which has the largest realized value from these random draws is selected for the day's testing deployment [18]. The data on the number of tests at that day's site and the number of new diagnoses among them is then used to update the prior probability distribution for the site. The resulting posterior distribution after that day's testing then becomes the updated prior distribution for the next day's testing deployment. Before the next outing, a random draw from all the sites' updated probability distributions happens again. This process is then repeated so the algorithm updates with each subsequent testing deployment. The entire procedure is described in Figure 1. The intuition here is that over time, using the knowledge accrued by each outing's successes or failures (positive and negative tests), the algorithm learns the expected yields at each site and refines the probability distributions used for the random draws. Though all sites will have a nonzero chance of being chosen, the Bayesian updating processes here will be drawn toward sites where successes are occurring in previous rounds of testing. What is important is that other sites can still be chosen by chance and offer the opportunity to keep gathering information on the entire landscape of testing sites, but through the algorithm, we will prioritize the ones with the current greatest yields. If a low-priority site gets picked by random draw and turns out to have a high yield of positive tests, that site's probability distribution now will shift its likelihood of being chosen in subsequent rounds.

Figure 1. Steps in the implementation of the Thompson sampling algorithm.



Based on this algorithm, a web app was created for this project [19]. The underlying code is also available [20]. The app requires data input from each location where a testing event took place. Based on the information received, the tool then suggests testing locations likely to yield the most undetected positive cases per test for the next event. Views of the app's regional and location pages are presented in Figures 2 and 3, respectively. Figure 2 shows a map of Columbus with pinned testing locations. After each testing event, data from the outing were entered into the algorithm in Figure 3 (eg, date and time, the total number of tests conducted, and number of positives). The app then integrates this data into the bandit algorithm, which delivers a new testing location for the next outing. Given conjugacy of the underlying Bayesian model, the computational cost of this process is minimal, as it only requires the ability to generate random draws from a beta distribution.

Program Design and Implementation Overview

The logic model for program design and implementation is shown in Textbox 1. The logic model depicts the program events and expected outcomes through the integration of resources, the execution of activities, and the participation of communities and community organizations, resulting in measurable near-term and long-term outcomes. The inputs include program partners and the resources they provided to the project. The activities represent the main programmatic tasks accomplished with the participation of those tested in underserved communities in Columbus and with the assistance of local community-based organizations. The achievements of the program are denoted in short-term, measurable outcomes and benefits to participants and the larger community, as well as long-term, large-scale outcomes and benefits for the city and beyond.

The project team established partnerships with ODH, ONG, the CML system, and the Columbus Department of Neighborhoods (CDN). ODH supported the project by providing BinaxNOW RATs (Abbott), while ONG became a clinical partner who deployed their clinical staff to the sites to conduct testing. The neighborhood liaisons from CDN consulted the team regarding the initial location selection and promoted testing events in their designated areas of oversight. Finally, CML provided 7 of their branch locations as sites for pop-up testing and promoted the testing events through the CML network.

The study lasted 3 months, from August to October 2021. The duration of each testing event was about 4 hours each day. We conducted a total of 16 testing events at 13 zip codes. Figure 4 shows dates of testing events, tests conducted, number of positive SARS-CoV-2 diagnoses, and the site positivity rate. Multimedia Appendix 2, Table S1 contains information about the sites and the zip codes where they were located.

Textbox 1. Logic model for the program and its implementation.

Inputs

- Resources
  - Research and statistical design
  - Funding
  - Staffing
  - Mobile van
  - Logistics
  - Testing sites
  - Rapid tests
  - Personal protective equipment
  - Clinical support
- Partners
  - Ohio State University
  - Yale University
  - Wake Forest University
  - Columbus Metropolitan Libraries
  - Ohio Department of Health
  - Ohio National Guard

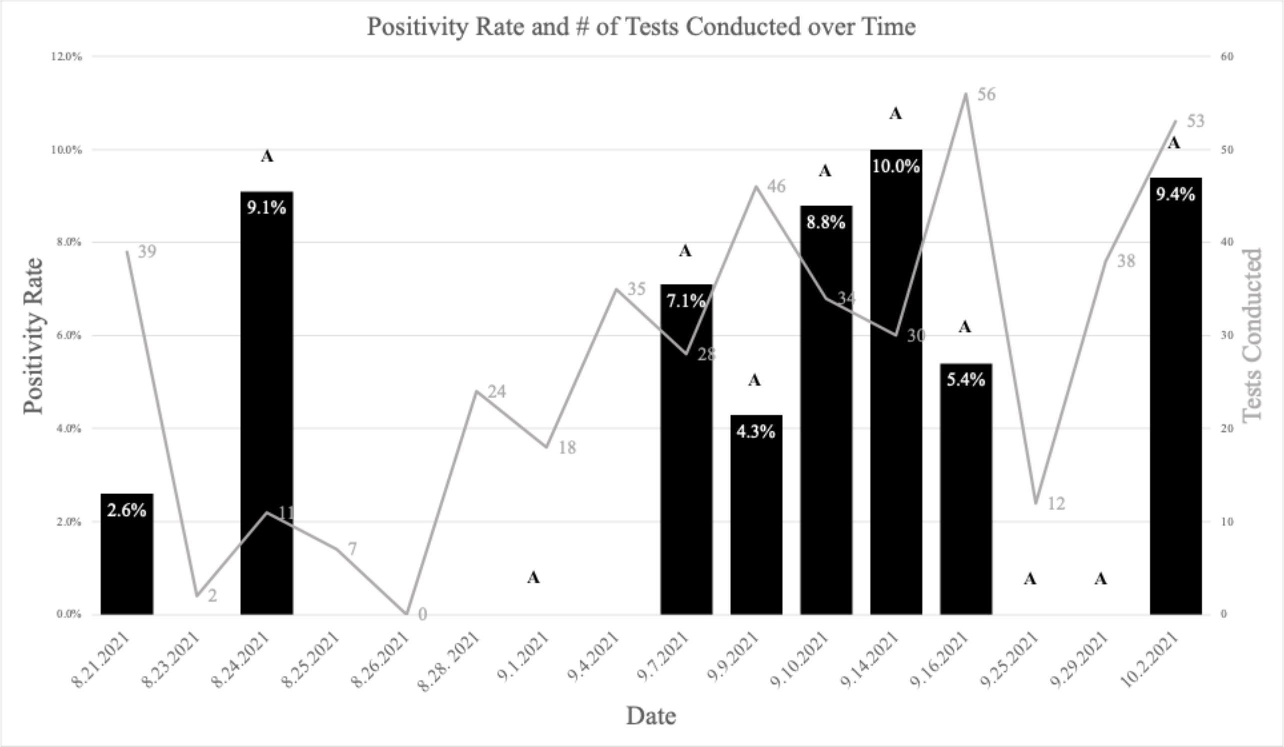
Processes

- Activities
  - Build the application
  - Conduct pop-up COVID-19 testing events
  - Distribute COVID-19 home test kits
  - Disseminate information about COVID-19
- Participants
- Target population: underserved communities in Columbus
- Community organizations (eg libraries, parks, and recreation centers)

Outcomes

- Near-term
  - Consistent detection of undiagnosed cases with the positivity rate being close to the state’s rate
  - Increased community access to COVID-19 rapid home tests
  - Increased community awareness about COVID-19 testing opportunities
- Long-term
  - Convenient and effective testing in low-opportunity areas in Columbus, Ohio
  - Prevention of transmission of COVID-19 in Columbus
  - Use of bandit approach in other infectious disease surveillance efforts

Figure 4. Positivity rate (black bars) and tests conducted (grey lines) for each testing session. The letter A is used to indicate testing at a library location. Starting on September 14, 2021, all testing locations were chosen by the algorithm.



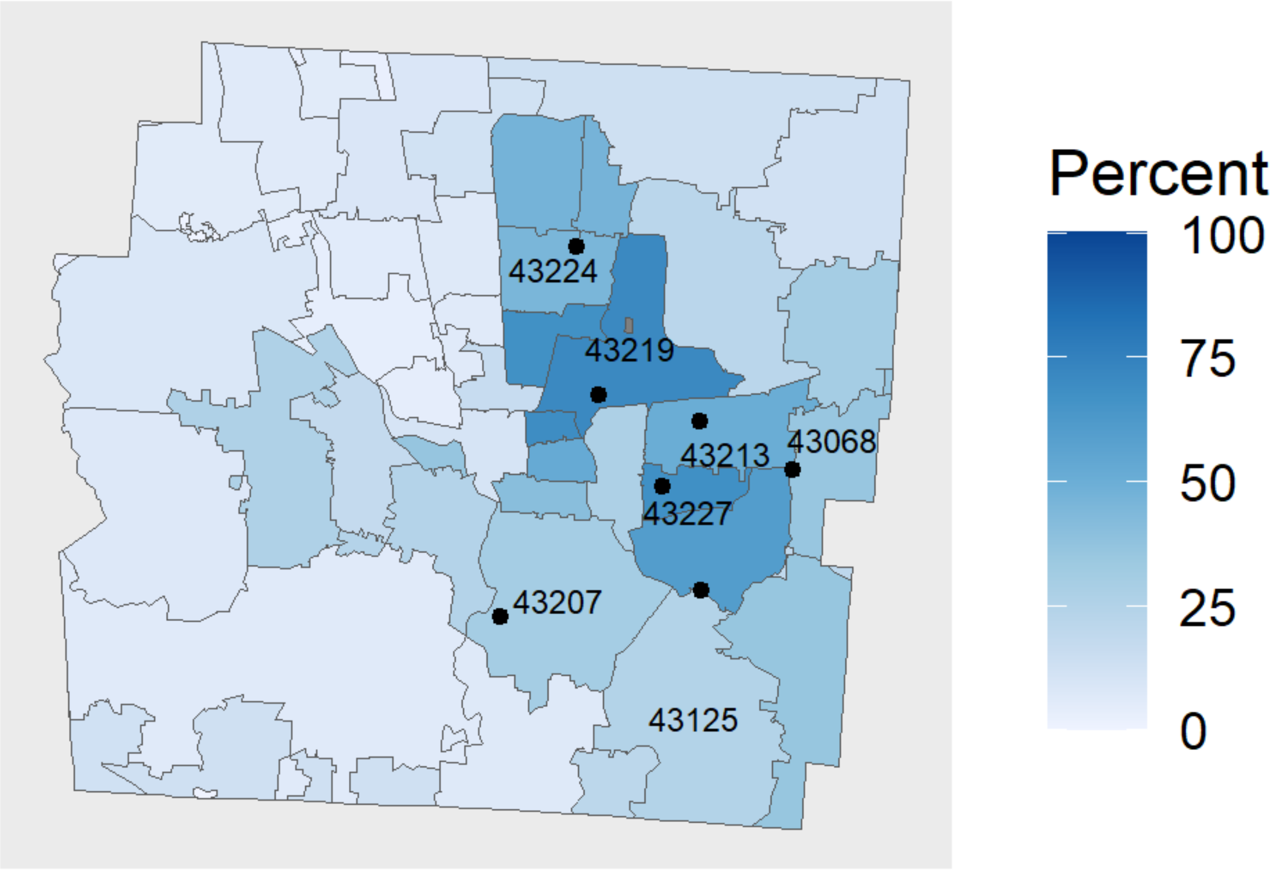
The initial choice of testing sites was derived from a set of highly trafficked candidate locations based on raw cellphone data from the UberMedia COVID-19 recovery data set spatially joined with Loveland Landgrid parcel data to produce indices of contacts and unique contacts per parcel ranked by volume [21,22]. From this list, 30 of the most highly trafficked locations from the data set were selected for further analysis. A team of volunteers from OSU then visited each location to assess the viability of each site in terms of the availability of the venue (whether it was private or public, its accessibility, its hours of operation, and the availability of onsite parking). The final step of the selection process was a discussion of each site with the neighborhood liaisons from the CDN, who shared their insights about the proposed locations and the potential for attracting participants to come forward for testing at each site.

Each testing event required the deployment of 2 volunteers from OSU and 2 ONG staff members. At the start of the study, events took place 2 to 3 times a week at community centers, movie theaters, parks, community events, shelters for the homeless, and libraries. These early weeks were dedicated to exploring the viability of the sites, constructing prior probability distributions for the algorithm for each site, and establishing an efficient operational workflow. In the last 2 weeks of the study, we deployed the bandit algorithm to choose sites for testing, restricting our sites to the branches of the CML, which turned out to be the most suitable sites for SARS-CoV-2 testing in the previous weeks. In these last weeks, the algorithm chose to send the team to sites 2, 4, 5, and 7, in that order, from September 16 to October 2, 2021 (site attributes can be found in Table 1). CML became an active partner in these efforts, promoting the testing events throughout their system with posters announcing the upcoming testing events distributed among the libraries in English, French, and Spanish. Figure 5 shows the location of the CML branches and underlying demographic information about these zip codes.

Table 1. Parameters for the assumed prior probability distributions for each testing site.

Site	Positivity	Tests, n	α	β
1	0.100	60	6	54
2	0.055	55	3.025	51.975
3	0.080	20	1.6	18.4
4	0.095	40	3.8	36.2
5	0.100	60	6	54
6	0.090	40	3.6	36.4
7	0.090	30	2.7	27.3

Figure 5. Location and zip codes of final testing sites with percentage of Black or African American residents.



Testing efforts were focused on reaching underserved communities through strategic selection of potential sites; however, testing was open to everyone. To invite undocumented immigrants to be tested as well, participants were not required to present identification documents. Results of the tests were entered in SimpleReport—a free tool built by the US Centers for Disease Control and Prevention that makes it easy for COVID-19 testing sites to record results for rapid point-of-care tests and quickly report required data to public health departments [23].

Ethical Considerations

The Office of Responsible Research Practices and the institutional review board at the Ohio State University deemed this project (2021E0496) exempt and not subject to regulations requiring institutional review board review and approval.

Results

We set a baseline goal of testing approximately 20 people at each event through consultation with other institutions that have deployed mobile pop-up testing sites (eg, New York City Health and Hospitals Corporation, University of Cincinnati Medical Center). Of 16 testing events conducted, 10 testing events met the baseline goal of testing over 20 participants. The total number of people tested over the course of the study was 405 (the mean number of tests conducted at each event was 25.3), producing 20 positive tests. This gave us an average positivity rate of 4.9% across all sites, with the highest being 9.5%. The positivity rates observed at our testing sites were comparable to or greater than the officially documented positivity rates in those same areas in central Ohio on the days of our testing events [24-26]. In particular, the proportion of symptomatic positive tests in our study exceeded those obtained from other providers in the state, which prioritized symptomatic individuals for diagnosis [27]. The rolling 2-week average positivity rate for all tests conducted in our study ranged from 2.9% (3/105) to 6.5% (9/138); for asymptomatic individuals, positivity ranged from 0% to 5% (3/57); and for symptomatic individuals, the range was from 0% to 21.4% (3/14). In each week of testing, and in each rolling 2-week period, the positivity of symptomatic testing was greater than the daily rate range of the surrounding county. In the final 2 weeks, when the bandit algorithm was used to select testing event sites, the average positivity rate for symptomatic testing was 17.4 (4/23)%, which nearly doubled the highest recorded daily positivity rate in Franklin county at that time (Table 1) [24-26]. Details are shown in Table 2.

Underrepresented communities were reached at testing events at rates higher than or near their proportion of the population in the zip codes we tested in. The percentage of Black or African American people tested was larger than the corresponding percentage of African Americans in 3 of 5 zip codes in which our testing sites were located [28]. Details are shown in Table 3.

Table 2. Study positivity rates compared to tests conducted by other providers in Franklin County, Ohio.

	Positivity for rolling 2-week periods in 2021							
	Aug 12-25	Aug 19-Sept 1	Aug 26-Sept 8	Sept 2-15	Sept 9-22	Sept 16-29	Sept 23-Oct[a]	Total
Flexible Adaptive Algorithmic Surveillance Testing clinic , n/N (%)								
All tests	3/65 (5)	5/96 (5.2)	4/99 (4)	8/146 (5.5)	9/138 (6.5)	3/105 (2.9)	6/106 (5.7)	22/408 (5.4)

Symptomatic individuals	0/8 (0)	1/14 (7.1)	3/14 (21.4)	5/30 (16.7)	6/33 (18.2)	3/27 (11.1)	4/23 (17.4)	13/78 (16.7)
Franklin County daily rate[b] (%), range	5.5-7.2	5.5-9	7-9.9	9.5-10.2	9.5-10.4	9.3-10.4	8.9-10	5.5-10.4

[a] Time period when bandit algorithm was used to select testing event sites.

[b] Absolute numbers were not available for county daily rate.

Table 3. Study representation of Black or African American people by zip code.

	Zip code, n/N (%)				
	43227	43125	43207	43068	43213
Black or African American participants in Flexible Adaptive Algorithmic Surveillance Testing clinics	18/24 (75)	17/31 (55)	8/31 (26)	13/29 (45)	13/28 (46)
Black or African American population of Franklin county (US Census; 2021 American Community Survey 5-year data)	16,740/24,779 (67.6)	3429/13,756 (24.9)	13,936/46,308 (30.3)	20,658/58,426 (35.4)	18,205/35,954 (50.6)

Throughout the study, 55% (156/284) of the population tested identified themselves as African American, and 36% (103/284) self-identified as White. Almost half of the population tested (105/227, 46%) stated their level of education was high school or below, and 47% (106/225) stated they worked full-time. Data about vaccination status against COVID-19 was collected as well: 56% (126/224) were vaccinated, compared to the vaccination rate in Franklin County of 54% [29].

Our survey results indicate that 27% (41/153) of those who attended our testing events found out about the testing event from others, 22% (34/153) by communicating with the library, and 29% (45/153) by walking or driving by.

Discussion

Principal Findings

This study demonstrated that a pop-up testing strategy using a bandit algorithm can be feasibly deployed in an urban setting during a pandemic. Although this was a limited roll-out of the strategy, positivity rates in this feasibility study were comparable or greater to those obtained by other testing initiatives primarily targeted at symptomatic individuals at the same time in these same areas of central Ohio on the days of our testing events, even though the bulk of those tested at our sites were asymptomatic, providing encouraging, though only preliminary, evidence that this bandit algorithm may be useful in improving case detection efforts [24-26]. It is the first real-world use of these kinds of algorithms for disease surveillance and represents the first step in evaluating the effectiveness of their use in maximizing the detection of undiagnosed cases of SARS-CoV-2 and other infections, such as HIV. In addition, the study showed that a simple, scaled-down testing approach with a total budget of under US $10,000 could carry out a program that could test up to 60 people in a single 4-hour event during its 3-month run. This shows that a flexible, adaptive approach to SARS-CoV-2 surveillance can be run efficiently with support for basic supplies (eg, tents, chairs, tables), and partnerships with organizations who could supply the tests (ODH) and carry them out (ONG) [30].

The program's ability to reach underserved communities is especially notable for several reasons. The quick-pivot nature of the program required that we give communities very little notice of upcoming events, potentially taxing their ability to hear about and be able to travel to locations to participate. Accessibility and transportation are barriers to health services in some of these communities [31,32]. In addition, there have been nationwide and state-wide trends of COVID-19 resources being allocated inequitably toward wealthier, predominantly White communities [33]. This is particularly troubling as both general determinants of health as well as the specific impact of COVID-19 make communities of color and other underserved communities more vulnerable to COVID-19 infection and the morbidity and mortality associated with the disease [34,35].

Libraries are important resources for communities in the context of population health [36,37]. A novel discovery during the study was the importance of the CML system in our active disease surveillance efforts. We learned that the CML is known and trusted by the communities of the city as a source of information and a site for social services. Subsequent studies in Columbus will now be done in partnership with the CML, as it excels at community outreach, has a network of facilities strategically placed in targeted neighborhoods, communicates well within its network, and is eager to work with public health partners. Our testing partner, ONG, was suitable for this study, but because of other commitments, we could not deploy the algorithm on less than 3 days' notice with them, and we are seeking out partners (a local federally-qualified health center) for the next phase of this work that have greater flexibility and can be available on short notice. While a major strength of our approach is its ability to deploy testing teams to locations based on emerging data in real time, it requires an operational nimbleness from partners, which may not be possible for some.

This study uses a novel approach to implementation science in that it addresses feasibility and acceptability of a new strategy for active surveillance of infectious diseases as a precursor to additional evaluation of the effectiveness of these algorithms in the field. Randomized controlled trials (RCTs) are expensive to mount and time consuming for both researchers and participants—this kind of preliminary research on implementation challenges is critical to understand the contextual factors that might present difficulties for the conduct of RCTs or real-world use of the intervention under study [38].

Limitations

This study has a number of limitations. First, it was conducted over a comparatively short period of time at a specific point of increasing concern in the pandemic. As such, the engagement of the community and the effectiveness of the algorithm must be set within that context. In addition, this study was only conducted in one midsized Midwestern city and may not be generalizable to other settings.

Conclusions

Through the implementation of a bandit algorithm in this study, we demonstrated the feasibility of such approaches to guide community testing for SARS-CoV-2. In addition, we established an efficient workflow and operational plan that can be extended to other organizations conducting mobile testing. In particular, we were pleased that the program appears to be well-suited to reach historically underserved communities in Columbus. As the COVID-19 pandemic persists in the United States, using our approach not only for active surveillance but as a core component of "test-to-treat" or "test-to-vaccinate" efforts targeted at the communities most at risk of the disease should be considered as well [39,40]. Finally, this algorithmic approach is pathogen-agnostic—it can be used for other infectious disease efforts. It was initially developed for maximizing the yield of undiagnosed HIV infections but could be used similarly for other infections to maximize case detection in the community (eg, for sexually transmitted diseases) or as an adjunct to other efforts, beginning with case identification (eg, test-to-treat for SARS-COV-2, HIV, hepatitis C virus, and sexually transmitted infections). The important next step is to evaluate the effectiveness of this algorithm in its ability to maximize the number of cases of disease detected in comparison to standard operating procedures for such deployment by public health practitioners. As an interim step, we have established a new partnership with a public health department in one of the largest US cities and will be evaluating the performance of Thompson sampling using historical data provided by it to compare how yields of testing using this algorithm would have differed from the actual number of positive tests collected for SARS-CoV-2 over the past 3 years with their fleet of mobile health vans. Depending on the outcome of this analysis, we will pursue funding for a prospective study of our approach in the context of a cluster randomized trial.

Acknowledgments

We thank Mark Hamlin and Philip Ennen (Ohio Department of Health) for providing rapid COVID-19 tests to support our operations; Captain Rodshana Ulery (Ohio National Guard) for providing clinical staff to administer COVID-19 testing; and Shaunessy Everett (Columbus Metropolitan Library) for support in organization of testing events at the library locations. We thank the College of Public Health at Ohio State University and the Yale School of Public Health for funding the pilot and Ohio State University students—volunteers Amanda Bleichrodt, Sophia Padgett, Aaron Cochran, John Hansen, Mitali Dalwalla, Lauren Putz, Manar Taleb, Maria Krantz, Ryan Borne, Lily Liu, Samantha Malone, and Jack Long—for their help with executing testing events.

Abstract

Background: The COVID-19 pandemic is characterized by rapid increases in infection burden owing to the emergence of new variants with higher transmissibility and immune escape. To date, monitoring the COVID-19 pandemic has mainly relied on passive surveillance, yielding biased epidemiological measures owing to the disproportionate number of undetected asymptomatic cases. Active surveillance could provide accurate estimates of the true prevalence to forecast the evolution of the pandemic, enabling evidence-based decision-making.

Objective: This study compared 4 different approaches of active SARS-CoV-2 surveillance focusing on feasibility and epidemiological outcomes.

Methods: A 2-factor factorial randomized controlled trial was conducted in 2020 in a German district with 700,000 inhabitants. The epidemiological outcome comprised SARS-CoV-2 prevalence and its precision. The 4 study arms combined 2 factors: individuals versus households and direct testing versus testing conditioned on symptom prescreening. Individuals aged ≥7 years were eligible. Altogether, 27,908 addresses from 51 municipalities were randomly allocated to the arms and 15 consecutive recruitment weekdays. Data collection and logistics were highly digitized, and a website in 5 languages enabled low-barrier registration and tracking of results. Gargle sample collection kits were sent by post. Participants collected a gargle sample at home and mailed it to the laboratory. Samples were analyzed with reverse transcription loop-mediated isothermal amplification (RT-LAMP); positive and weak results were confirmed with real-time reverse transcription–polymerase chain reaction (RT-PCR).

Results: Recruitment was conducted between November 18 and December 11, 2020. The response rates in the 4 arms varied between 34.31% (2340/6821) and 41.17% (2043/4962). The prescreening classified 16.61% (1207/7266) of the patients as COVID-19 symptomatic. Altogether, 4232 persons without prescreening and 7623 participating in the prescreening provided 5351 gargle samples, of which 5319 (99.4%) could be analyzed. This yielded 17 confirmed SARS-CoV-2 infections and a combined prevalence of 0.36% (95% CI 0.14%-0.59%) in the arms without prescreening and 0.05% (95% CI 0.00%-0.108%) in the arms with prescreening (initial contacts only). Specifically, we found a prevalence of 0.31% (95% CI 0.06%-0.58%) for individuals and 0.35% (95% CI 0.09%-0.61%) for households, and lower estimates with prescreening (0.07%, 95% CI 0.0%-0.15% for individuals and 0.02%, 95% CI 0.0%-0.06% for households). Asymptomatic infections occurred in 27% (3/11) of the positive cases with symptom data. The 2 arms without prescreening performed the best regarding effectiveness and accuracy.

Conclusions: This study showed that postal mailing of gargle sample kits and returning home-based self-collected liquid gargle samples followed by high-sensitivity RT-LAMP analysis is a feasible way to conduct active SARS-CoV-2 population surveillance without burdening routine diagnostic testing. Efforts to improve participation rates and integration into the public health system may increase the potential to monitor the course of the pandemic.

Introduction

Background

Epidemiological surveillance of populations using serological or nucleic acid–based diagnostics is a well-known public health preparedness tool and is, for example, implemented in the global influenza surveillance network. Here, a system of World Health Organization collaborating centers acts mainly reactively to seasonally adjust influenza vaccines depending on emerging variants in representative samples [1,2]. In contrast, the COVID-19 pandemic has been characterized by less seasonality and a comparatively faster periodicity of episodes in which the burden of infection in the population rapidly increased because of the emergence of new variants with higher transmissibility and immune escape. The ever-present threat of overburdening the health care systems resulted in the implementation of containment measures based on limited forecasting tools [3].

Both presymptomatic and asymptomatic SARS-CoV-2 carriers are able to transmit; thus, the proportion of asymptomatic cases plays a key role in the spread of the virus, challenging the containment of this highly contagious disease [4-7]. With respect to the SARS-CoV-2 alpha variant (B.1.1.7, prevalent at the time of the study), asymptomatic or minimally symptomatic SARS-CoV-2 carriers accounted for approximately 40% of all unvaccinated infected individuals [8]. A surveillance system that randomly samples a representative population to test for active infection is therefore needed for pandemic preparedness. If combined with longitudinal serological studies to monitor historical exposure and thus the extent of immunity, the prevalence estimates could be incorporated into a prognostic model to effectively monitor the pandemic and predict the further course of the outbreak. This would enable evidence-based decision-making, especially as strict lockdowns and curfews can only serve as temporary measures [9]. Furthermore, active disease surveillance could assess symptomatology in combination with downstream genome sequencing [10].

Most countries mainly used results from different testing purposes in the so-called passive surveillance as a surrogate for active systems to restrictedly monitor the course of the pandemic [11,12]. This involves recording persons presenting to the health system with COVID-19–like symptoms to initiate their treatment, as well as symptomatically and asymptomatically infected persons identified through targeted screening (eg, workplaces and retirement homes), supplemented by contacts of detected cases who tested positive with the aim of isolating these individuals and containing the spread of the infection [13]. Others extended existing primary care influenza surveillance systems to virological and serological SARS-CoV-2 surveillance [14]. However, these largely symptom-driven surveillance systems do not provide representative prevalence estimates and are therefore of limited use in terms of informing decision makers [11]. Similarly, surveillance studies that rely on syndromic surveillance rather than direct testing focus on symptomatic cases only and are further limited as they do not differentiate between respiratory pathogens [15,16]. In contrast, active surveillance would test a representative proportion of the population without necessarily assuming the presence of COVID-19 symptoms [17].

However, testing for SARS-CoV-2 for surveillance in communities requires extensive, complex testing capacities and different strategies compared with testing for individual health purposes and screening with respect to sampling, turnaround time, and reporting [18,19]. Real-time reverse transcription–polymerase chain reaction (RT-PCR), a laboratory technology used to detect viral RNA, is considered the gold standard for SARS-CoV-2 detection during acute infection and up to 2 to 3 weeks thereafter [20]. However, RT-PCR is costly and only applicable in population screening if pooling techniques are applied [21,22]. Alternatively, reverse transcription loop-mediated isothermal amplification (RT-LAMP)–based method allows for the detection of viral RNA with sensitivity similar to that of RT-PCR but with reduced cost and straightforward application, not requiring a thermal cycler, hence enabling scale-up testing [23-26].

In addition, there is sufficient evidence that saliva, gargle solution, and expectorated mucus are suitable sources of biological material for the sensitive detection of SARS-CoV-2 [27-32]. Saliva samples are very stable as their viral load hardly changes even over several days at room temperature (20-25 °C), which makes it easily transportable even by post [33]. Therefore, the combination of self-collected saliva samples shipped by post and analyzed by RT-LAMP appears to be a promising approach for active population surveillance.

However, there is limited evidence regarding the use of comprehensive and effective active surveillance strategies. Most of the active surveillance studies conducted in the general population have exhibited a repeated cross-sectional design. To date, the best-described active surveillance systems of similar type have been implemented in the United Kingdom using RT-PCR assays and self-administered swabs [19,34]. These 2 attempts have demonstrated the importance and viability of implementing active surveillance for SARS-CoV-2 in affluent areas by providing significant SARS-COV-2 prevalence estimates in the community during various time points. Some studies have observed fixed cohorts over time [35,36]. Although these studies have shown the feasibility of active surveillance, no study to date has compared different surveillance approaches to assess their comparative feasibility, effectiveness, and cost. Nonetheless, the combination of these factors is relevant to public health decision makers facing resource constraints, with testing capacity depending mainly on external factors (eg, production of reagents and test materials), independent of the testing strategy.

The question for decision makers in health policy is therefore which active surveillance strategy is most effective in monitoring the actual progress of an epidemic or pandemic with a limited number of available tests and without limiting the capacity of passive surveillance.

Objectives

The objective of this study was to compare 4 different approaches to population-level surveillance of active SARS-CoV-2 infection and to report the epidemiological outcomes and feasibility. The cost-effectiveness was reported separately [37].

Methods

This study followed the principles of CONSORT (Consolidated Standards of Reporting Trials; extension for multiarm parallel-group randomized trials) statement (Multimedia Appendix 1) [38]. Details regarding the methods and study design are provided in the study protocol by Deckert et al [39].

Ethics Approval

The trial was approved by the ethics committee at the University of Heidelberg on November 2, 2020 (amendment November 9, 2020; file number S790/2020).

Participation and Informed Consent

The study applied the Declaration of Helsinki ethical standards and adhered to the legal requirements for research on humans in Germany as stated in the guidelines for good clinical practice and the Medical Devices Act (Medizinproduktegesetz) issued by the Ministry of Health of Germany and implemented by the Federal Institute for Drugs and Medical Devices.

With the invitation letter, participants were informed about the study purpose and procedures in an age group–appropriate manner by means of a detailed brochure; all web-based information was also available in 5 languages. Children and adolescents were asked to assent their participation with a mandatorily complemented consent of their legal representatives. Consent or assent to participate could be given on the web or on paper, whereas additional consent or assent to get the gargle sample analyzed had to be provided on paper (Multimedia Appendix 2 [20-26,28-33,39-48]). Participants' addresses were provided by the registers of residents based on a German law (Bundesmeldegesetz, § 46 Gruppenauskunft) that allows research institutions to draw collective address data for research purposes; consent was sought from the population register offices.

Data protection measures were implemented according to the Basic Data Protection Regulation (article 6, paragraph 1, letter a Datenschutz-Grundverordnung) and the Federal Data Protection Act. The manner of data collection and scope and content of data collected were authorized by the data protection officer of Heidelberg University. The consent forms provided information about the data protection measures and pseudonymization of data to identify individuals who tested positive; data analyses were conducted with anonymized data only. Withdrawal from study participation and deletion of data were possible at any time during the study. Participants were informed that the data could be used beyond the study for other research purposes related to SARS-CoV-2 or other respiratory viruses; however, the gargle samples were destroyed after study completion.

Compensation for study participation was not provided.

Trial Registration

The trial was registered (November 30, 2020) on the German Clinical Trials Register (registration number DRKS00023271), and the study protocol has been published accordingly [49].

Study Design

The study was designed as a 2-factor factorial, multiarm parallel randomized controlled trial. The 4 study arms represented all combinations of two factors: i) testing unconditional (A) versus testing under the condition of upstream COVID-19 symptom prescreening (B), and ii) testing individuals (1) versus households (2). The designation of the 4 study arms A1, A2, B1, and B2 depict these combinations.

Individuals aged ≥7 years who consented (by legal guardian in the case of minors) were eligible and provided a self-collected gargle sample (all 4 study arms) after completion of a prescreening questionnaire (B1 and B2).

Study Setting

The trial was conducted during the second SARS-CoV-2 wave in fall 2020 in Germany in Heidelberg and the Rhine-Neckar district, which is the location of Heidelberg University and the catchment area of the closely cooperating district health authority. The public health authority of the Rhine-Neckar district, also responsible for Heidelberg city, is responsible for 56 municipalities with approximately 700,000 inhabitants. Containment measures were tightened by mid-December 2020, and vaccination was not yet available at that time.

Outcomes

We considered effectiveness, feasibility, and costs to comprehensively inform policy makers as trade-offs are to be expected when the evidence is reviewed by an evidence-to-decision framework, for example, Grading of Recommendations, Assessment, Development, and Evaluations [49]. Here, we report the feasibility and epidemiological outcomes and review the cost-effectiveness separately. The epidemiological outcomes included the following: (1) cumulative SARS-CoV-2 prevalence and (2) prevalence precision.

The secondary outcomes were the participation rate (number of gargle samples; A1 and A2), the prescreening results or gargle samples (B1 and B2) divided by the number of contacts, the population prevalence estimation, and the symptom frequencies.

Sample Size

As high-quality test capacity is a limiting resource in active surveillance, we designed the study so that each arm would end up with the same number of laboratory tests, competing for feasibility, effectiveness, and cost-effectiveness. However, a composite end point was not possible, and a priori assumptions regarding cost-effectiveness could only be made arbitrarily. Therefore, we powered the effectiveness part to finally receive the same number of gargle samples in each arm to estimate a specific prevalence with a certain precision, based on the estimator theoretically closest to the true prevalence in study arm A1 (randomly selected individuals). The costs required to achieve this equal number of gargle samples might differ by design in the study arms, as may the number of positive cases among the gargle samples. Strategy A2 was designed to account for the likelihood of higher infection rates within households of infected individuals. In contrast, the detection rates of strategies B1 and B2 were expected to differ because of the different effects of the upstream prescreening mechanisms.

At the time of planning the study, the 4-week cumulative SARS-CoV-2 prevalence was estimated to be 0.25% in the region, based on data from the first surge [50], mainly sourced from passive surveillance (ie, symptomatic persons). Assuming a similarly high proportion of asymptomatic SARS-CoV-2 carriers, the overall prevalence was estimated to be approximately 0.5%. Thus, in the most representative study arm A1, which used a purely random sample to directly reflect the pandemic events, a total of 2500 gargle samples could estimate such a prevalence with a relative precision of −0.35% to +0.35% (95% CI) and a power of 95% [51]. Hence, assuming a 50% response rate after one-time prompting, at least 5000 addresses were required for strategy A1. For strategy A2, assuming an average household size of 2 and a response rate of 50% after prompting, a gross sample of at least 2500 addresses was necessary [52]. For strategy B1, we assumed an 80% response to the sampling request after positive prescreening; hence, at least 3125 sample kits had to be mailed out to yield 2500 tested samples. On the basis of this and assuming a SARS-CoV-2 prevalence of 0.5% and a prescreening tool sensitivity of 90% and specificity of 70%, at least 10,313 participants had to complete the initial prescreening. Furthermore, expecting a 50% response to the prescreening request and 50% response to prompting required an initial gross sample of at least 13,750 addresses. Similarly, for strategy B2, a gross sample of at least 6875 addresses was required (average household size of 2). Consequently, a total gross sample of 28,125 addresses was required, and the participants were allocated in a ratio of 10:5:28:14 to the study arms (Figure S1 in Multimedia Appendix 2) [39].

Randomization

A stratified general population representative sample with 2 strata (Rhine-Neckar district plus Heidelberg city) and 2 different sampling approaches (Heidelberg—simple random sample and Rhine-Neckar—2 stage cluster sampling) were used to draw 3 weekly batches to avoid negative impacts on the response rate owing to uncertain external circumstances (such as holidays or a higher rate of infections). Because of the considerably larger population of Heidelberg city, the stratification was used to avert a decrease in statistical power for estimation in rural areas. The batches were then divided among 15 consecutive recruitment weekdays and randomly assigned to the 4 study arms. The gross sample included 21,739 individuals in the Rhine-Neckar district and 6386 individuals in the Heidelberg stratum. Potential participants were randomly drawn from municipalities’ (51/53, 96%) population registers as samples proportional to the population size of the municipalities (Multimedia Appendix 2) [39].

The 2-stage sampling was designed by the Leibnitz Institute for Social Sciences in Mannheim, Germany. The Heidelberg Institute of Global Health requested the addresses from the municipalities.

Recruitment and Study Materials

Study recruitment started on November 18, 2020, and ended on December 11, 2020, and one-time reminders were sent until December 16, 2020. The general implementation (including testing activities and hotlines) lasted until December 23, 2020.

The study website displayed information in 5 languages (German, Turkish, English, Russian, and Italian) and contained a gargling demonstration video. The study information (brochure and website) and the consent forms were separately presented in adequate language for children (aged 7-11 years), adolescents (aged 12-17 years), parents, and adults. In addition, a hotline was implemented and made accessible during the study period (weekdays 7-11 AM and 2-6 PM).

A prescreening questionnaire was provided to all initially contacted individuals. Its completion was voluntary in A1 and A2 and mandatory in B1 and B2 study arms.

Logistics

The study arms A1 and A2 immediately received gargle sample collection kits, whereas the study arms B1 and B2 had to complete the prescreening questionnaire first. The differences in logistics in are discussed in detail as follows:

1. Study arm A1: Randomly selected individuals (hereinafter referred to as initially contacted individuals) received an invitation letter by post containing the study information, a sample collection kit, and a stamped biohazard return envelope (Multimedia Appendix 3).
2. Study arm A2: The procedures were the same as in A1 with the difference that the initially contacted individuals received 4 kits to sample household members. Additional kits could be ordered by email or via the hotline if needed.
3. Study arm B1: Initially contacted individuals first received an invitation letter with the study information, a stamped return envelope, and the prescreening questionnaire, asking about 16 typical COVID-19 symptoms to be completed web-based or in print. Next, the questionnaire was evaluated using a random forest algorithm that had been trained on data sets of patients with COVID-19 to classify participants into COVID-19–free and potentially sick individuals. If the questionnaire was flagged by the algorithm, the individual received a second envelope containing the sample collection kit and a stamped biohazard return envelope.
4. Study arm B2: The procedures were the same as in B1 with the difference that the initially contacted individuals who were classified as having COVID-19 by the prescreening algorithm subsequently received 4 sample collection kits for household members.

In each study arm, participants who received the sample collection kits were asked to collect a gargle sample themselves after gargling 5 mL of saline at home and return it to the laboratory (Multimedia Appendices 2 and 3). The participants were expected to take the sample latest 1 day after they received the sample collection kit.

Laboratory and Blinding

To enable scale-up of testing while maintaining sensitivity, an RT-LAMP was used for analyzing the liquid gargle samples. Weakly (<3 replicates positive) and clearly positive gargle samples (all replicates positive) were subsequently analyzed using RT-PCR as a confirmation test [24-26].

Laboratory staff who conducted the RT-LAMP and the RT-PCR confirmation tests were blinded with regard to the study arms. The vials carried a unique barcode only, and the laboratory data were kept on a separate server; linkage of laboratory data with participants’ data was performed after the laboratory analysis was completed.

Data Processing

Data cleaning was performed using SAS software (version 9.4 TS1M4; SAS Institute Inc). Statistical analyses were performed using R (version 4.1.1; R Foundation for Statistical Computing) and Stata (version 15.1; StataCorp).

Statistical Methods

Prescreening Questionnaire

We developed a symptom screening algorithm using machine learning. The underlying data sets were from various settings with and without SARS-CoV-2 infected patients, including samples from a general population screen and persons tested for SARS-CoV-2 infection because of symptoms or high-risk exposure (Multimedia Appendix 2). The threshold of the algorithm was optimized toward sensitivity (80% sensitivity and 75% specificity).

Descriptive Statistics

Differences in demographics, frequency of COVID-19 symptoms, and epidemiological variables between the trial arms were assessed using the chi-square test and ANOVA (no adjustment for multiple testing). The significance level α was set at 5%.

Prevalence Estimation

The total number of SARS-CoV-2 cases was calculated using the Horvitz-Thomson estimator to account for unequal selection probabilities in the 2-stage sampling [40]. The individual probability to get selected for participation was based on the number of primary sampling units per municipality, the population in this municipality obtained from the Leibniz-Institute for the Social Sciences, and was normalized for each study arm separately to match the number of performed tests. The Brewer approximation was used to calculate the estimate’s variance [41]. We refrained from calculating cluster-adjusted prevalence in A2 and B2 as the number of positive cases was too small to take the within household transmission rates into account. To compare the results of our study with the reported number of cases, we estimated the reported prevalence based on official data from the Robert Koch Institute (RKI; Multimedia Appendix 2).

Sensitivity Analysis

The trial was implemented in parallel to the existing passive surveillance system; hence, persons could have been captured by both systems. Some hotline callers refused to participate because they had already tested positive in the passive surveillance. Therefore, we conducted a sensitivity analysis and recalculated the prevalence estimates to account for missed positive cases owing to overlap with passive surveillance (Multimedia Appendix 2).

Results

Recruitment

Altogether, 30,629 addresses were provided by 51 municipalities’ registration offices. After excluding duplicates, 27,908 (99.23%) addresses out of the planned sample size of 28,125 were randomly allocated to the arms (Figure 1; Table

S1 in Multimedia Appendix 2). Considering the longer individual study course in B1 and B2 because of the prescreening questionnaire, shipment of study materials and recruitment of participants started on November 18, 2020, for B1 and B2 and on November 23, 2020, for A1 and A2 and stopped on December 8, 2020, for B1 and B2 and on December 11, 2020, for A1 and A2 (Figure 2). Similar gargle sampling days should be achieved for all study arms. In total, 11,855 participants were recruited.

Figure 1. Study flowchart. A1: individuals without mandatory prescreening; A2: households without mandatory prescreening; B1: individuals with mandatory prescreening; B2: households with mandatory prescreening; LAMP: loop-mediated isothermal amplification.

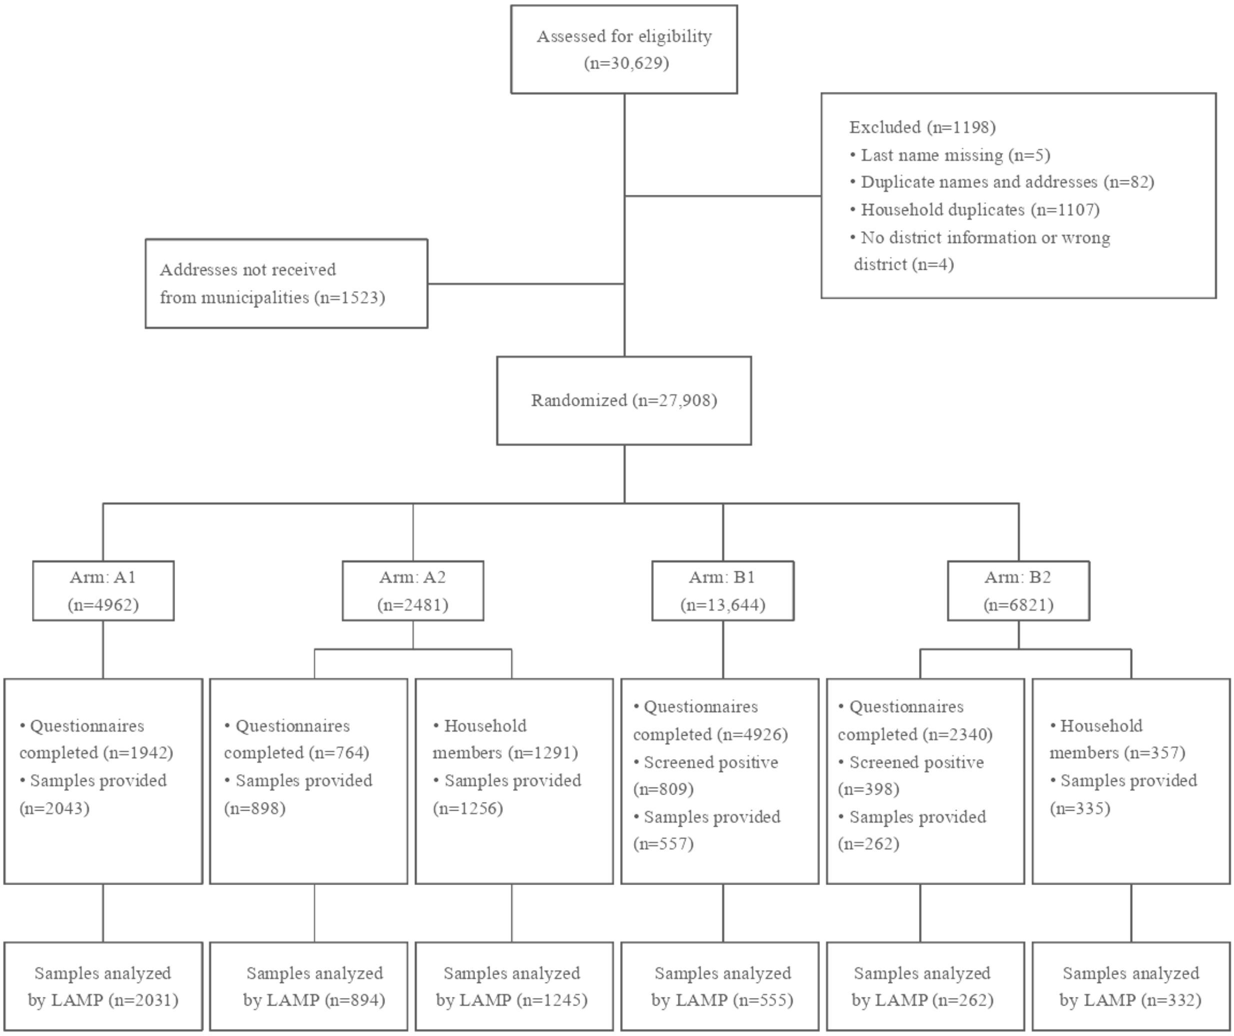

Figure 2. Study timeline. A1: individuals without mandatory prescreening; A2: households without mandatory prescreening; B1: individuals with mandatory prescreening; B2: households with mandatory prescreening.

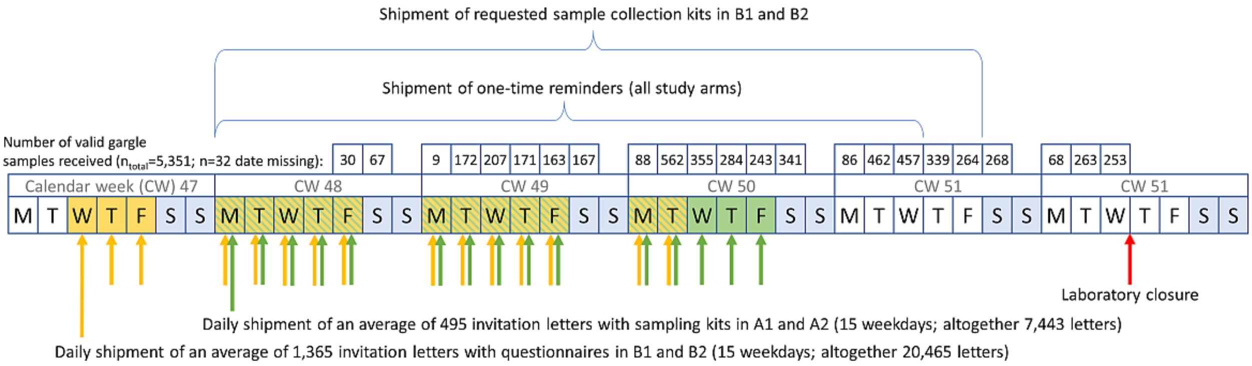

Demographics

The participants were slightly older than the general population (mean age 44.5 years in 2019; [53]), mainly because of the exclusion of children aged <7 years (Table S2 in Multimedia Appendix 2; Table 1). The study arms differed with regard to the education level of participants who provided a valid questionnaire (Table 2).

Table 1. Demographics of initially contacted individuals who decided to participate (initially contacted individuals who either provided a sample [A1 and A2] or a questionnaire [B1 and B2]).

[a] A1: individual participants without mandatory prescreening who voluntarily completed the prescreening questionnaire.

[b] A2: household members without mandatory prescreening who voluntarily completed the prescreening questionnaire.

[c] n=764 initially contacted individuals (n=730+34 initially contacted individuals who did not provide a valid sample or consent but answered or consented the questionnaire) plus 60 household members who additionally filled out a questionnaire.

[d] B1: individual participants with mandatory prescreening.

[e] B2: initially contacted individuals in households with mandatory prescreening.

[f] n=2340 initially contacted individuals plus 6 household members who additionally filled out a questionnaire.

[g] Age and sex were available for initially contacted individuals from the registration offices and for household members from the consent form.

[h] Pearson chi-square test.

[i] Number of participants with missing information.

[j] Linear model ANOVA.

[k] Welch 2-sample *t* test (2-tailed) between study arms A2 and B2.

Response Rates

Overall, 36.57% (10,207/27,908) of the individuals who were contacted responded by either directly providing a gargle sample (A1 and A2) or by completing the prescreening questionnaire (B1 and B2; Table 3). The response rates (A1: 41.2%, A2: 36.2%, B1: 36.1%, and B2: 34.3%) differed significantly among the study arms (*P*<.001; chi-square test), with the study arms involving household members responding the least. The lowest variation in response rates across the study region could be observed in A1 and B1 (Figure 3). Nonresponders were younger (44.2 years vs 46.6 years; *P*<.001) and comprised a larger proportion of males (50.5% vs 47.3%; *P*<.001). However, there were no additional study arm–related selection effects (responders' age: ANOVA *P*=.52; sex: chi-square *P*=.64; Table 1).

[a] A1: individuals without mandatory prescreening.

[b] A2: households without mandatory prescreening.

[c] B1: individuals with mandatory prescreening.

[d] B2: households with mandatory prescreening.

[e] Defined as the number of people initially contacted who provided a gargle liquid sample (arms A1 and A2) or who answered the prescreening questionnaire (arms B1 and B2), referred to as "responders," out of the total number of people contacted in each arm.

[f] N/A: not applicable.

[g] 7 questionnaires in A1 and A2 could not be considered in the random forest algorithm because of missing values in the paper version.

[h] LAMP: loop-mediated isothermal amplification.

[i] The denominator consists of the number of samples provided by initially contacted individuals in study arm A2 and their household members. The numerator consists of the samples tested by LAMP for initially contacted individuals (n=898) plus the samples tested by LAMP for household members (n=1241).

[j] The denominator consists of the number of samples provided by initially contacted individuals in study arm B2 and their household members. The numerator consists of samples tested by LAMP for initially contacted individuals (n=262) plus the samples tested by LAMP for household members (n=332).

[k] Samples with an initial weakly positive SARS-CoV-2 result by the LAMP assay.

[l] Samples that initially had a (weakly) positive SARS-CoV-2 result by the LAMP assay and that tested LAMP positive for SARS-CoV-2 upon retesting.

[m] PCR: polymerase chain reaction.

[n] Samples that initially had a weakly positive SARS-CoV-2 result by the LAMP assay, followed by a PCR positive test without an intermediate LAMP positive test.

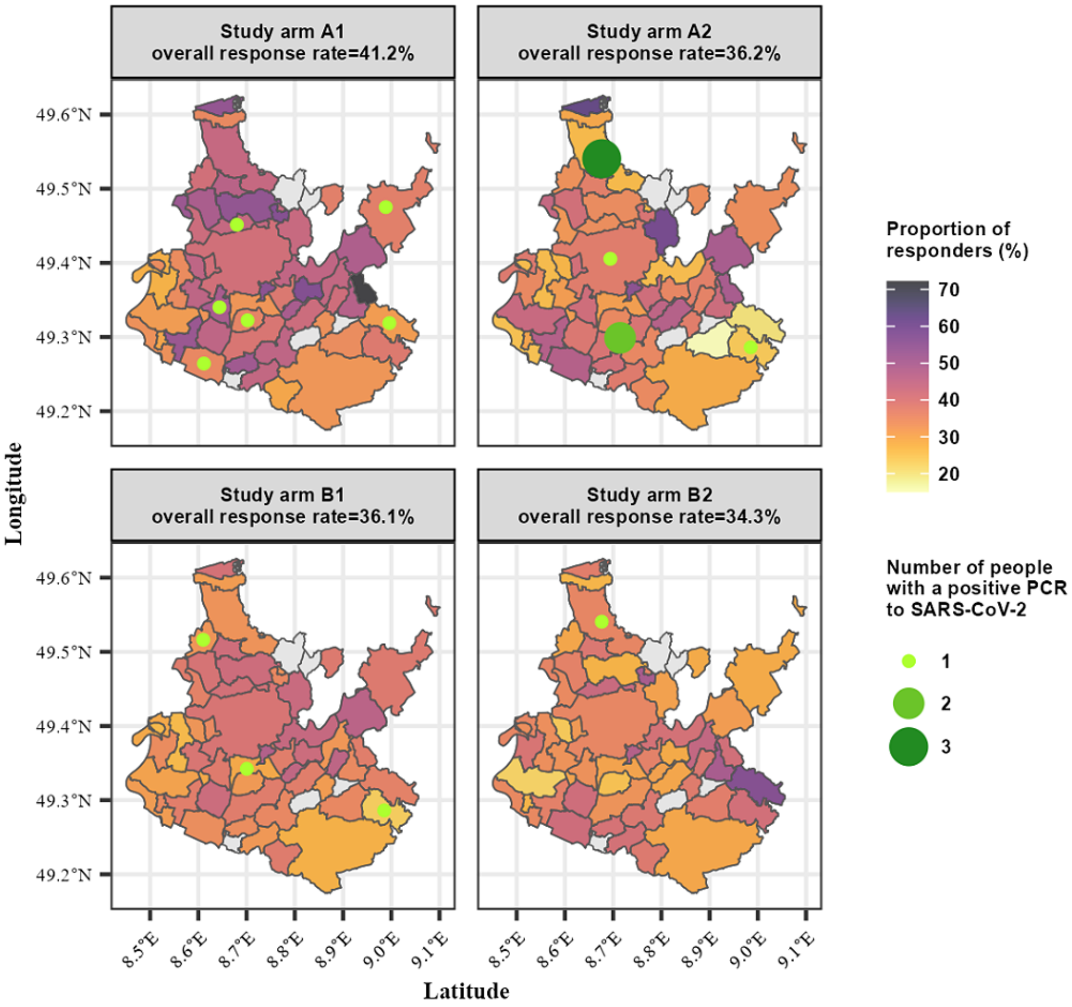
[o] Out of 1 PCR positive sample, 1 is from a household member.

[p] Samples that tested LAMP positive for SARS-CoV-2 and were then confirmed positive by PCR.

[q] Of the 5 PCR positives for SARS-CoV-2, a total of 3 were from household members.

[r] Cases without any of the following symptoms among all positive cases: fever, cough, cough with sputum, sore throat, difficulty breathing, exhaustion, headache, runny nose, muscle ache, chest pain, diarrhea, nausea, no taste or smell, chills, short breath, and confused; denominator: total number of PCR samples with questionnaire data available.

Figure 3. Response rates in the 51 municipalities; newly detected SARS-CoV-2 infections by study arm (the gray areas indicate municipalities randomly excluded in the cluster sampling approach). A1: individuals without mandatory prescreening; A2: households without mandatory prescreening; B1: individuals with mandatory prescreening; B2: households with mandatory prescreening; PCR: polymerase chain reaction.



Outcomes

Although the prescreening was not compulsory in A1 and A2, approximately 92.71% (1894/2043) of the participants in A1 and 81.3% (730/898) of the initially contacted individuals in A2 completed the optional questionnaire. The random forest algorithm classified approximately 16.61% (1207/7266) of the initially contacted individuals in B1 and B2 to have suspicious COVID-19 symptoms (Table 3). Of those who were classified as having COVID-19 in the prescreening, only 68.9% (557/809) provided a valid gargle sample upon subsequent request in B1 and 65.8% (262/398) provided a valid gargle sample upon subsequent request in B2. However, of the household members, 97.29% (1256/1291) provided valid gargle samples in A2 and 93.8% (335/357) provided valid gargle samples in B2.

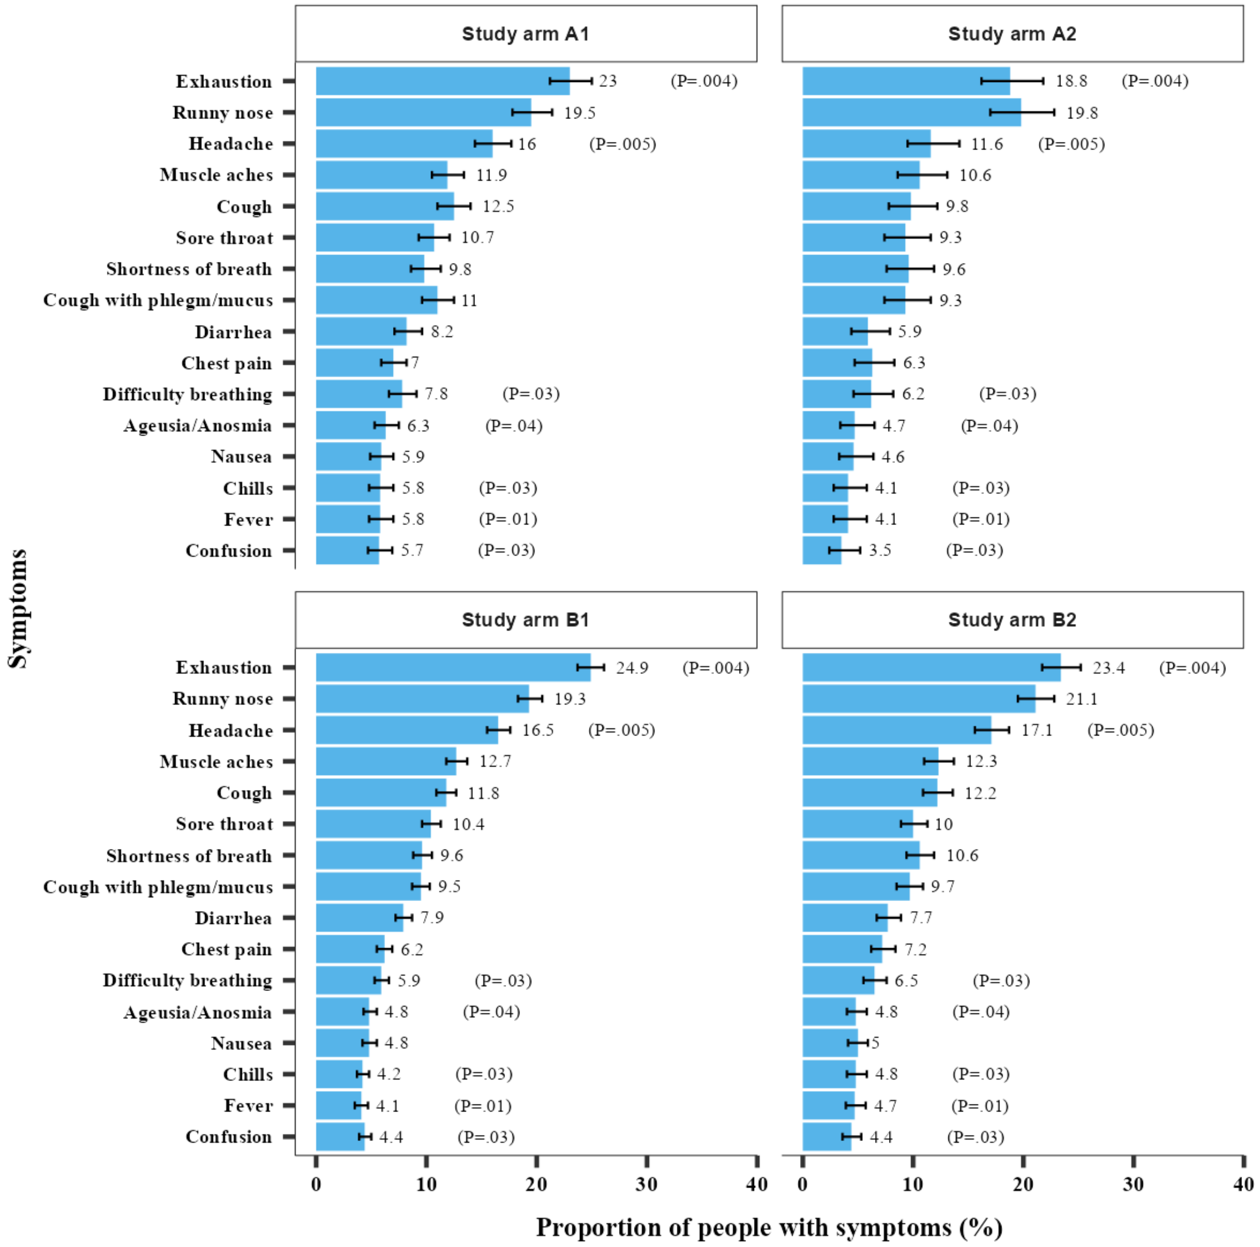
In all study arms, 99.40% (5319/5351) of the gargle samples were analyzed; only 0.60% (32/5351) of the samples could not be processed because of the viscosity being too high. All positive LAMP results were confirmed by RT-PCR. Of the weakly positive LAMP results, approximately 5% yielded a positive result in the PCR analysis. Overall, 17 SARS-CoV-2 infections were detected in this study (Figure 3; Table 3).

Of the 17 positive cases, 8 (47%) were symptomatic and 3 (18%; n=2, 67% adults in A1 and n=1, 33% child in A2) were completely asymptomatic SARS-CoV-2 carriers. Of the 8 symptomatic cases, 6 (75%) had <3 acute COVID-19 symptoms (n=4, 67% A1 and A2 and n=2, 33% B2), 1 (13%) had 8 symptoms (A1), and 1 (13%) had all 16 symptoms (B2). COVID-19 symptom data were missing for 5 participants in A2 (voluntary questionnaire) and 1 participant in B2 (household member); hence, some asymptomatic cases may not have been counted.

Overall, 8 hotline callers reported having recently tested positive and declined to provide a gargle sample. Of the 8 hotline callers, 5 (63%) received the sample collection kit or called the hotline within 14 days of testing positive elsewhere. These cases might have been detected in our study as well. In addition, as recorded at the local health authority, 51 of the nonresponders had been tested positive elsewhere within 14 days before our invitation (not considered in the sensitivity analysis).

The arms differed substantially regarding some COVID-19 symptoms (Figure 4; Table S3 and Figures S2 and S3 in Multimedia Appendix 2). Approximately 20.60% (2054/9972) either worked with children or in the medical field (Table S4 in Multimedia Appendix 2).

Figure 4. Frequency of COVID-19–related symptoms among those who filled out the prescreening questionnaire (initially contacted individuals only; *P* values based on Pearson chi-square test). A1: individuals without mandatory prescreening; A2: households without mandatory prescreening; B1: individuals with mandatory prescreening; B2: households with mandatory prescreening.



Prevalence Estimates

The weighted prevalence estimates (initial cases only) differed considerably between combined arms A with 0.36% (95% CI 0.14%-0.59%) and B with 0.05% (95% CI 0.00%-0.10%). However, we did not detect a significant difference between the single arms (household members in A2 and B2 included). In A1, the prevalence was 0.32% (95% CI 0.06%-0.58%), and in A2, the prevalence was 0.35% (95% CI 0.09%-0.61%), with lower estimates in B1 and B2 (0.07%, 95% CI 0.00%-0.15% and 0.02%, 95% CI 0.00%-0.06%; Figure 5; Table S5 in Multimedia Appendix 2). We also compared our daily case estimates with the RKI data (Figure S4 in Multimedia Appendix 2). Assuming that the participants remained positive on average 14 days, the estimated prevalence range based on RKI data (0.23%-0.48%) stayed within the 95% CI 0.14-0.59 of our estimate for the combined arms A. Assuming an average duration of 10 days, the RKI-based prevalence range (0.16%-0.36%) was completely within the lower half of our 95% CI (Figure 6). Figure S5 in Multimedia Appendix 2 depicts the minimum number of positive cases that should have been detected in the trial, with the lower bound determined by the prevalence estimate based on RKI data (Figure 6). If we additionally considered the hotline callers that tested positive elsewhere, the prevalence increased further to 0.37% (95% CI 0.10%-0.65%) in A1, 0.35% (95% CI 0.09%-0.61%) in A2, 0.14% (95% CI 0.03%-0.26%) in B1, and 0.07% (95% CI 0.00%-0.15%) in B2 (Figure S6 and Table S5 in Multimedia Appendix 2).

Figure 5. Weighted prevalence estimates in study arms A1 (individuals without mandatory prescreening) and A2 (households without mandatory prescreening) combined, B1 (individuals with mandatory prescreening) and B2 (households with mandatory prescreening) combined, and each arm separately. Light blue indicates the fraction of positive cases among all the performed tests. For combined arms, only the initially contacted participants are included to avoid household bias in arms A2 and B2.

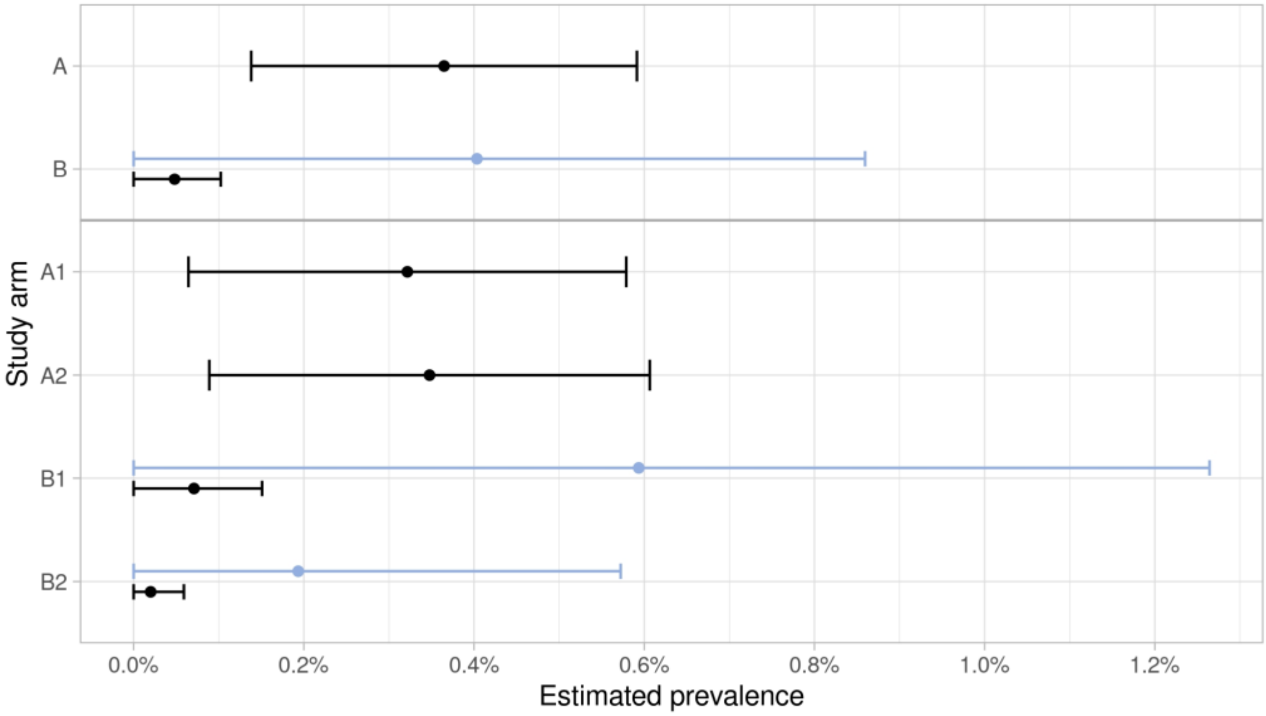


Figure 6. Variation in the prevalence estimate derived from Robert Koch Institute incidence data, depending on the assumed duration of polymerase chain reaction positivity (each prevalence curve is labeled by the corresponding duration in days; horizontal dashed line is the estimated prevalence based on the combined results from arms A1 and A2, with 95% CI indicated by the shaded area).

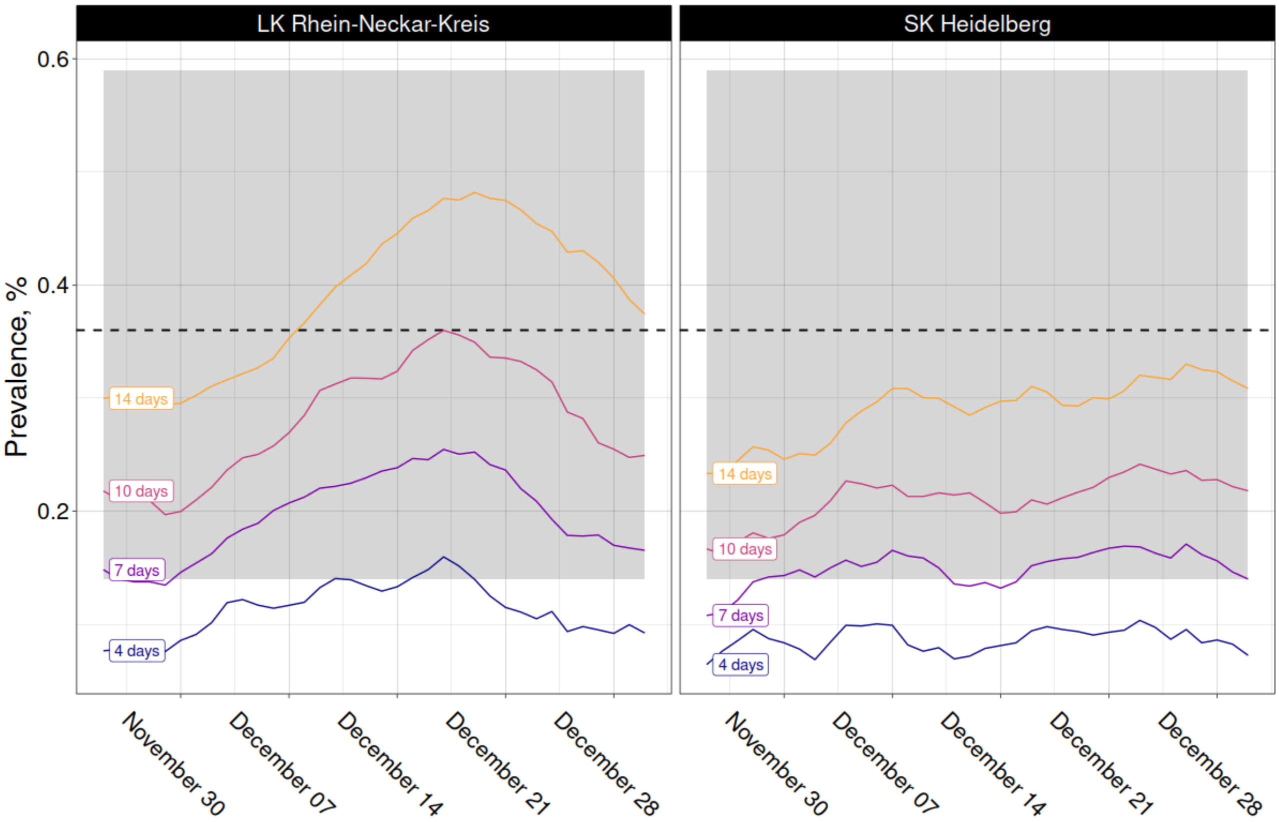

Discussion

Principal Findings

To the best of our knowledge, this is the only study to date that has simultaneously tested different approaches to active SARS-CoV-2 surveillance for the general public based on daily renewed random and population representative samples in a seamless chronology. In this paper, we focused on the feasibility and epidemiological outcomes of the trial.

Our study demonstrated that in general, the combination of postal mailing of sample collection kits and return of gargle liquid samples followed by high-sensitivity RT-LAMP analysis is a feasible way to conduct active SARS-CoV-2 surveillance in the general population without placing an additional burden on the capacity of PCR analysis and routine diagnostic testing [26]. Furthermore, our study suggests that the primarily symptom-based prescreening did not add benefit to case finding but rather complicated processes. Even if optimized, such a tool is unlikely to capture presymptomatic or asymptomatic cases and might have to be adapted with each new SARS-CoV-2 variant. The surveillance strategies could detect additional cases, some of them being asymptomatic, which were not captured by passive surveillance.

We were able to design and implement this complex trial in just 8 weeks by using innovative digital tools, agile development, and flat communication structures, which resulted in highly digitized processes and ensured that the study logistics were highly functional from the program outset. We are, therefore, convinced that a similar active pandemic surveillance system deployed outside a scientific study could be set up even faster, provided appropriate laboratory infrastructure and open-source software are held at the ready and standards are introduced [54].

Active SARS-CoV-2 surveillance should capture a sufficient proportion of symptomatic and asymptomatic cases to allow continuous estimation of the true prevalence trend with sufficient precision. However, despite the random drawing of potential participants, the nonresponders in our study were not missing at random, as selection owing to voluntary self-enrollment occurred, which was reflected in the younger and more male responders on average. Taking this into account, study arm A1 (random selection of individuals) was most likely to yield the best estimate of the true prevalence, although it was slightly biased because of voluntary self-enrollment. Investing in measures (eg, incentives and analytical corrections) to minimize the proportion of nonresponders may further reduce bias and increase accuracy.

The prevalence estimates derived from the RKI data based on passive surveillance constituted the lower bound of the prevalence estimates. As expected, the prevalence detected in our study tended to be higher, and the estimates of A1 and A2 were the most accurate. However, we cannot make a definitive statement regarding the most effective strategy because the number of positive cases was too low because of the actual sample size and the stage of the pandemic. It is important to note that this study was a research project not embedded in the public health system with data fusion and reconciliation. The inclusion of theoretically detectable cases who refused to participate but reported a recent infection to the study hotline upwardly adjusted the prevalence estimates. If other nonresponders who tested positive shortly before the invitation had been considered, the prevalence estimate would have been well above the official figures.

Study Participation

The overall participation rate of 36.57% (10,207/27,908) was lower than the envisaged 50%. First, the complexity of the information material necessary for a 4-arm trial might have been difficult to understand, thereby hindering a timely and appropriate participation [55]. Second, the different demands on the participants in a difficult overall situation (ie, lockdown) and an increasing pandemic fatigue before Christmas 2020 might have influenced the response [55]. One complicating aspect, the requested sampling before breakfast, seems to be less relevant based on new data (Multimedia Appendix 2).

Complementary qualitative data from approximately 80 responders and nonresponders shed light on these barriers. For example, some of the nonresponders thought they were selected because they participated in other studies or because acquaintances had to quarantine themselves. The study invitation also triggered fear of being infected in a few selected persons. The amount of information and perceived test complexity overwhelmed many [55].

Our study participation rates were similar to or exceeded those of other studies. In the United Kingdom, repeated community-based RT-PCR testing based on self-administered throat and nasal swabs estimated prevalence on a monthly basis. The number of invitation letters sent between May 2020 and December 2021 increased from 395,000 to 804,000, but the response rate (number of tests/letters) decreased from 30.5% to 12.1% and the PCR test return rate (number of tests performed/kits requested) varied between 67.2% and 78.9% [56]. During the same period as our study, 28.4% of the invitees requested sample collection kits, and the actual response rate was 22.4% [57]. We provided sample collection kits immediately along with the invitation letter in A1 and A2. In addition, we requested a gargle sample instead of a swab sample, which resulted in response rates of 41.2% and 36.2%, respectively. This may indicate that a low-barrier approach and an alternative to throat and nasal swabs could unlock further potential for participation.

Some methodological changes could have increased participation. Government support, media campaigns, and adding incentives could foster participation [58,59]. This might be particularly important if rapid antigen tests are widely available; therefore, adequate but not overly complicated information should educate participants about test quality and the purpose of active surveillance. Furthermore, the methodology was tailored to the ethical requirements for scientific trials, the mere extent of information materials might have deterred, and the label of a scientific study might have unsettled potential participants [55]. In contrast, routine implementation accompanied by a legal framework would only have to follow the general data protection laws, simplifying paperwork, and could be integrated into pandemic containment strategies, eliminating the chance for double sampling by linking data with passive surveillance systems.

Acceptability of Self-Sampling

In our study, mail-in gargle self-sampling proved to be feasible. The method was perceived as pleasant, allowed for high test accuracy in asymptomatic patients, and reduced the risk of spreading infections. Liquid gargle sampling was valued as more convenient than nasopharyngeal swabs, and although self-sampling was cumbersome for some older participants, many respondents found accurate self-sampling with gargling easier. The acceptability was mainly driven by communication (content of information, letters, support system, and rapidity of test results) and trust in the sampling or laboratory-based testing method [55]. Gargling a saline solution is a low-barrier sampling method applicable in almost all age groups [60] and suitable not only for LAMP but also for PCR analysis. Independently, the RT-LAMP analysis allows high-throughput testing with low costs and can be combined with nasopharyngeal, nasal, or throat swab samples without compromising sensitivity. Sample pooling can further multiply the testing capacity [21,22].

Cost-Effectiveness

From an epidemiological perspective, we identified A2 as the most cost-effective strategy, closely followed by A1, based on evidence from a parallel economic evaluation [37]. We postulate that surveillance strategies similar to A1 and A2 likely yield the best estimates and are most efficient. They are also logistically simpler than the strategies with a prescreening tool.

Limitations

This study had several limitations. First, the actual execution of the trial was limited to 3 weeks; time constraints limited adequate testing of the prescreening tool and impeded pilot studies. Second, random samples from most municipalities yielded a representative pool of potential participants; however, Heidelberg and its surrounding area have a higher socioeconomic level than an average German municipality. Voluntary participation likely correlates with gradients in wealth; thus, the participation rate could have been different elsewhere in Germany. As high socioeconomic strata are simultaneously less susceptible to SARS-CoV-2 infection and more likely to participate in studies, this possibly led to slightly underestimated prevalence estimates [61]. Third, participants in each study arm were expected to return samples no later than 1 day after receiving the sample collection kits. However, for some participants, the instructions in the invitation letter were not clear enough as this could not be tested in a pilot study owing to time constraints. Therefore, some participants collected samples on a day that was more convenient for them [55]. However, these untimely samples were most likely random, which may explain the lower sample return at the beginning and some late samples. Clear communication could yield timely sample return and thus more stable return numbers throughout the surveillance period. Finally, the calculation of the sample size and thus the accuracy of the prevalence were limited by the available financial resources and various uncertainties in the assumptions.

We expected to receive a similar number of gargle samples in each arm to enable systematic bias estimation. Because B1 uses a symptom-based prescreening that cannot capture asymptomatic cases, the prevalence should be systematically underestimated. However, B2 could also capture asymptomatic household members, and depending on the intrahousehold transmission rate, B2 could systematically overestimate the prevalence in certain scenarios. However, the average time between positive prescreening and LAMP result in B1 and B2 was 8.4 days; many of these participants had to be reminded to send the sample back. Hence, although an average duration of PCR positivity for 10 to 14 days seems reasonable, some people may have been positive when first receiving the study materials but cleared the infection before sampling [62]. In addition, the number of samples in B1 and B2 was considerably lower than that in A1 and A2 (1152 vs 4179 samples), which resulted in inaccurate prevalence estimates. Furthermore, the lower number of positive cases in B1 and B2 may have been because of the poor performance of the prescreening tool. The data sets used to train the random forest algorithm may not have been optimal to develop a sensitive discriminator. Including all household members in the prescreening could increase the chance of detecting symptomatic persons and might increase acceptance in parallel. However, this was omitted because of increased complexity and time constraints.

Active Versus Passive Surveillance

In Germany, the RKI's COVID-19 figures stem from passive surveillance, aiming to capture all positive test results (tested symptomatic persons and positively tested contact persons) to monitor the pandemic's progress. However, data are transmitted through multiple tiers from physicians and laboratories to the RKI via local and state health departments, causing time delays that affect the official reporting of case numbers. The RKI therefore applies the nowcasting method for estimation by means of assumptions and imputation of missing values [3]. Asymptomatic cases are also underrepresented, making it challenging to assess the situation accurately. In contrast, an active surveillance system would not claim completeness of cases but test population representative random samples that represent the actual occurrence of infections. Furthermore, it would not rely on bottom-up reporting but sample infections directly with less delays and yielding more accurate prevalence estimates. Decentralized active surveillance systems could also detect regional differences timely. Furthermore, a Bayesian sliding-window estimator could enable the prediction of the number of hospitalizations above a certain prevalence threshold.

Conclusions

The pandemic developed in a highly dynamic manner in most countries, with scarcely comparable trends. The succession of gradually increasing bouts of infection has been interrupted by periods of low infection activity. There is no reason to believe that future pandemics with similar hazard potential will evolve in a less chaotic manner; therefore, SARS-CoV-2 can be seen as a blueprint for future outbreaks. Therefore, rapidly deployable outbreak surveillance systems should be developed and put on standby.

Continuous active SARS-CoV-2 surveillance based on general population representative random samples of individuals or households and postal mailing of gargle sample collection kits for low-barrier home-based self-sampling, combined with a rapid, highly sensitive, and specific nucleic acid amplification test, is a feasible way to detect presymptomatic and asymptomatic cases without overburdening PCR capacities. However, additional measures are required to improve participation. Information material and consent processes should be tailored to real-life routine rather than scientific trials. In addition, the information material should be more concise and tested in pilot studies.

Acknowledgments

The authors would like to thank the local health authority Rhine-Neckar for their valuable support and the successful collaboration, with special thanks to Dr Britta Knorr, Dr Rainer Schwertz, Dr Andreas Welker, and Doreen Kuss. The authors would also like to thank Daniel Ürge and Victoria Witte for their contribution to the reverse transcription loop-mediated isothermal amplification analysis. Claudiu Grozea from the European Molecular Biology Laboratory produced the gargling and sampling demonstration video for the study website. In addition, the authors would like to thank the cohort of students who supported this study with the assembly and shipment of sample collection kits as well as sample processing, their service in the hotline, and support in data processing and analyses. Nicholas Kyei and Miriam Compton kindly proofread the manuscript. Finally, the authors would like to thank all the individuals and households of the Rhine-Neckar region in the state Baden-Württemberg in Germany who responded to their request and provided the survey data and gargle samples. The Cov Surv study was embedded in the nationwide research network "Applied Surveillance and Testing" (Bundesweites Forschungsnetz "Angewandte Surveillance und Testung," B-FAST) and the University Medicine's Network (Netzwerk Universitätsmedizin, NUM) for COVID-19 research in Germany. The trial was financed by the Federal Ministry of Education and Research (Bundesministerium für Bildung und Forschung, BMBF). The laboratory robot was funded within the framework of the Excellence Strategy of the Federal and State Governments of Germany and by the Ministry of Science, Research and the Arts Baden-Württemberg. For the publication fee we acknowledge financial support by Deutsche Forschungsgemeinschaft (DFG) within the funding program "Open Access Publikationskosten" as well as by Heidelberg University. The funders had no role in the study design, data collection, data analysis, interpretation of data, or writing of the manuscript.

Data Availability

Anonymized data and a data dictionary will be made available in a public repository. Consent forms, invitation letters, and information material for the study are made available upon official request to the Network University Medicine for COVID-19 research in Germany. The study protocol has been published.

Authors' Contributions

CD, AD, and TB envisioned the study, developed the concept, and applied for the grant. SA and MK developed the sampling procedures and established the laboratory processes (collection and analyses of the samples) and the data processing. MDA and HTN were responsible for the cost-effectiveness measurement, with support from SB. AS and SM contributed the qualitative study component. MS accounted for the calculations with regard to the random sampling of addresses from the registration offices. LK together with LMH, CD, TR, and TJA designed, developed, and validated the prescreening tool. LB, RB, and M Marx set up the sample shipment logistics. M Meurer, KH, RB, DL, SA, and SO developed data processing pipelines and set up the server. KH developed the questionnaire scanner software. M Meurer, DL, and RB validated the sampling strategy and the sample analysis procedures. PS was responsible for confirmation of positive samples by real-time reverse transcription–polymerase chain reaction. SB registered the trial and was responsible for publishing the study protocol. AD, IM, and SO accessed and verified the data presented in this manuscript and performed the epidemiological analyses. CD performed data linkage with the health authority and supported the sensitivity analyses. AD, MDA, MK, CD, HTN, and SO drafted the manuscript. All authors contributed to the interpretation of the results and manuscript writing and read and approved the final manuscript.

Abstract

Background: Wastewater surveillance provided early indication of COVID-19 in US municipalities. Residents of long-term care facilities (LTCFs) experienced disproportionate morbidity and mortality early in the COVID-19 pandemic. We implemented LTCF building-level wastewater surveillance for SARS-CoV-2 at 6 facilities in Kentucky to provide early warning of SARS-CoV-2 in populations considered vulnerable.

Objective: This study aims to evaluate the performance of wastewater surveillance for SARS-CoV-2 at LTCFs in Kentucky.

Methods: We conducted a mixed methods evaluation of wastewater surveillance following Centers for Disease Control and Prevention (CDC) guidelines for evaluating public health surveillance systems. Evaluation steps in the CDC guidelines were engaging stakeholders, describing the surveillance system, focusing the evaluation design, gathering credible evidence, and generating conclusions and recommendations. We purposively recruited stakeholders for semistructured interviews and undertook thematic content analysis of interview data. We integrated wastewater, clinical testing, and process data to characterize or calculate 7 surveillance system performance attributes (simplicity, flexibility, data quality, sensitivity and positive predictive value [PPV], timeliness, representativeness, and stability).

Results: We conducted 8 stakeholder interviews. The surveillance system collected wastewater samples (N=811) 2 to 4 times weekly at 6 LTCFs in Kentucky from March 2021 to February 2022. Synthesis of credible evidence indicated variable surveillance performance. Regarding simplicity, surveillance implementation required moderate human resource and technical capacity. Regarding flexibility, the system efficiently adjusted surveillance frequency and demonstrated the ability to detect additional pathogens of interest. Regarding data quality, software identified errors in wastewater sample metadata entry (110/3120, 3.53% of fields), technicians identified polymerase chain reaction data issues (140/7734, 1.81% of reactions), and staff entered all data corrections into a log. Regarding sensitivity and PPV, using routine LTCF SARS-CoV-2 clinical testing results as the *gold standard*, a wastewater SARS-CoV-2 signal of >0 RNA copies/mL was 30.6% (95% CI 24.4%-36.8%) sensitive and 79.7% (95% CI 76.4%-82.9%) specific for a positive clinical test at the LTCF. The PPV of the wastewater signal was 34.8% (95% CI 27.9%-41.7%) at >0 RNA copies/mL and increased to 75% (95% CI 60%-90%) at >250 copies/mL. Regarding timeliness, stakeholders received surveillance data 24 to 72 hours after sample collection, with delayed reporting because of the lack of weekend laboratory staff. Regarding representativeness, stakeholders identified challenges delineating the population contributing to LTCF wastewater because of visitors, unknown staff toileting habits, and the use of adult briefs by some residents preventing their waste from entering the sewer system. Regarding stability, the reoccurring cost to conduct 1 day of wastewater surveillance at 1 facility was approximately US $144.50, which included transportation, labor, and materials expenses.

Conclusions: The LTCF wastewater surveillance system demonstrated mixed performance per CDC criteria. Stakeholders found surveillance feasible and expressed optimism regarding its potential while also recognizing challenges in interpreting and acting on surveillance data.

wastewater surveillance; wastewater-based epidemiology; evaluation; long-term care facility; COVID-19; SARS-CoV-2

Introduction

Background

Two years into the COVID-19 pandemic, myriad public health challenges remain. Preventing disease in populations considered vulnerable is among the most persistent and pressing issues. Older adults, particularly those living in long-term care facilities (LTCFs), experienced disproportionate morbidity and mortality during the COVID-19 pandemic [1]. An estimated 23% of the COVID-19 deaths in the United States occurred among LTCF residents or staff as of early 2022 [2]. A combination of age-related relative immunosuppression, high prevalence of comorbid conditions, and increased exposure in congregate living settings contributes to a greater burden of infection and mortality among LTCF residents [1].

Early efforts in the pandemic to prevent and mitigate COVID-19 at LTCFs focused on limiting exposure (physical distancing and personal protective equipment) and symptom screening to identify potential cases [3]. There was limited availability of clinical testing; for example, in June 2020, all LTCF staff and residents in Kentucky underwent a single comprehensive round of SARS-CoV-2 testing, and, at the time, it was unclear whether more frequent clinical testing was feasible. We identified wastewater surveillance for SARS-CoV-2 as a promising approach to direct the limited clinical testing resources and potentially mitigate the spread of infection at LTCFs.

Wastewater surveillance analyzes samples of wastewater for the presence of disease markers, such as SARS-CoV-2 RNA [4]. Many individuals who have been infected with SARS-CoV-2 shed the virus in their stool [5], and there is evidence that wastewater viral trends precede clinical case detection by several days [6]. Monitoring wastewater for SARS-CoV-2 RNA can identify previously unknown cases in a population [7] and guide clinical testing and infection prevention activities to mitigate new infections [7,8].

Wastewater surveillance has potential advantages over clinical testing. Foremost, it measures disease presence in a population via a single sample, making it more efficient than individual surveillance [9]. It also has the potential to detect SARS-CoV-2 from asymptomatic individuals who might not otherwise seek clinical testing [6]. It is noninvasive, which means that it may be more acceptable to individuals than repeated clinical testing [10]. Wastewater surveillance may provide more timely information on disease presence and trends than clinical testing owing to the earlier detection of SARS-CoV-2 shed by asymptomatic or presymptomatic individuals in the population [6]. However, there is little evidence to guide the implementation of wastewater surveillance at LTCFs.

Objectives

We share our experience of implementing wastewater surveillance for SARS-CoV-2 at 6 LTCFs in Kentucky during the second year of the COVID-19 pandemic. We evaluated the LTCF wastewater surveillance according to the framework put forth by the Centers for Disease Control and Prevention (CDC) Guidelines Working Group [11] for evaluating public health surveillance systems.

Methods

Evaluation Approach and Manuscript Organization

The surveillance evaluation followed CDC guidelines for evaluating public health surveillance systems [11]. We followed the guidelines' evaluation steps, including (1) engaging stakeholders, (2) describing the surveillance system, (3) focusing the evaluation design, (4) gathering credible evidence, and (5) generating conclusions and recommendations. We describe step 1 (engaging stakeholders) and how we gathered and analyzed credible evidence (steps 4 and 5) in this *Methods* section. In the *Results* section, we describe the surveillance system (step 2) and share credible evidence (step 4). In accordance with CDC surveillance evaluation guidelines, we gathered evidence on 7 general performance attributes of surveillance systems (simplicity, flexibility, data quality, sensitivity and positive predictive value [PPV], timeliness, representativeness, and stability). We incorporated additional concerns that arose during stakeholder interviews into the evaluation. We provide conclusions and recommendations (step 5) in the *Discussion* section.

Stakeholder Interviews and Qualitative Analysis

The CDC guidelines identified stakeholder groups potentially relevant to surveillance system evaluation to include public health practitioners, health care providers, data providers and users, representatives of affected communities, governments, and professional and private organizations. The study team identified the following stakeholder groups to focus the evaluation design (step 3) and provide credible evidence (step

4) relevant for the evaluation: LTCF management (encompassing the categories of data provider and user, health care provider, representative of affected community, and private organization), public health practitioners, and wastewater testing field and laboratory staff (another category of data provider). We purposively recruited individuals from these groups based on their involvement with LTCF wastewater surveillance and jurisdictional relationship (eg, local public health department) for semistructured interviews tailored to stakeholder roles. Interview questions asked about LTCF wastewater surveillance usefulness, resources, challenges, communication, concerns, and actions. The semistructured interview guides are presented in Multimedia Appendix 1. Author JL, a medical student not involved in implementing the wastewater surveillance system, conducted the interviews remotely using videoconferencing. Stakeholder interviewees provided written informed consent before the interview; they did not receive compensation for their participation. Each stakeholder was interviewed once, and the interviews lasted 18 to 35 minutes. We recorded and transcribed the interviews for qualitative analysis. We analyzed interview content using the rigorous and accelerated data reduction approach for qualitative analysis [12]. The rigorous and accelerated data reduction method involved identifying key points and moving pertinent quotes or thoughts into a central spreadsheet. After each interview transcript underwent this process, we identified common themes and moved these data into a secondary spreadsheet. The data went through several rounds of this reduction process to isolate the most pertinent ideas and generate representative quotations. We used information from the stakeholder interviews to focus the evaluation design (step 3).

Other Credible Data Sources

Credible evidence (step 4 of the evaluation process) came from several sources. The project's LTCF partner shared deidentified staff and resident clinical testing results from the 6 facilities during the wastewater surveillance period. LTCF clinical testing occurred per state, CDC, and Centers for Medicare and Medicaid Services guidance and varied from twice weekly to monthly screening of unvaccinated staff per local disease transmission levels. Wastewater testing data came from the study team. The stakeholder interviews provided qualitative data. Additional data came from the project team's administrative records.

Wastewater Surveillance Performance

We calculated the sensitivity and specificity of wastewater surveillance by comparing wastewater positivity with clinical test positivity for SARS-CoV-2 at wastewater thresholds ranging from 0 to 250 copies/mL of SARS-CoV-2 RNA. The study team obtained wastewater measurements using a method developed by our team and described in the *Surveillance System Description* subsection of the *Results* section. We compared the wastewater data with clinical test results during the week that followed a wastewater measurement in a 2×2 contingency table (true positives, true negatives, false positives, and false negatives) at multiple wastewater SARS-CoV-2 threshold values. We then estimated the sensitivity and specificity of wastewater surveillance at each threshold and plotted a receiver operating characteristic curve. To evaluate whether wastewater testing identified SARS-CoV-2 at LTCFs earlier than routine clinical screening, we conducted a lead-lag time correlational analysis. We estimated the correlation between the average wastewater RNA concentration and the number of known SARS-CoV-2 infections at a specific LTCF by shifting the wastewater result 1 to 7 days before and after the clinical test collection date. We calculated the Kendall rank correlation coefficient because this estimator is conservative compared with the Pearson and Spearman correlation coefficients. We used Microsoft Excel for descriptive analyses of administrative data and SAS 9.4 (SAS Institute Inc) to estimate the wastewater surveillance performance metrics of sensitivity and PPV, and the correlation of the wastewater RNA signal with clinical test data.

Ethics Approval

The University of Kentucky Institutional Review Board reviewed and approved the study protocol (62384).

Results

Surveillance System Description

Overview

The study team collaborated with Trilogy Health Services, an LTCF organization that manages >100 facilities across the Midwest in the United States. The study team identified 6 LTCFs in Lexington and Louisville, Kentucky, for wastewater surveillance. Proximity to the University of Kentucky campus and the ability to access facility-specific wastewater effluent guided facility site selection. The 6 participating LTCFs each had 67 to 160 residents and 76 to 117 staff. Wastewater sampling began on March 19, 2021, and ended in Louisville on December 16, 2021, and in Lexington on February 23, 2022.

Wastewater Collection

The study team visited each LTCF to identify wastewater effluent access points with facility management. For each facility, there was manhole access to a sewer pipe that contained the entirety of the facility's wastewater effluent and did not contain effluent from neighboring buildings. Field technicians obtained LTCF wastewater effluent samples using autosamplers suspended under the manhole covers that collected 100 mL of wastewater every 20 minutes during a 24-hour period (ie, a composite sample). Rechargeable batteries provided power for the autosamplers. Ice packed around the autosampler jug refrigerated the composite sample to minimize RNA degradation. The technicians collected three to four 24-hour composite samples each week from the Lexington LTCFs and 2 to 3 samples each week from the Louisville LTCFs. Field technicians recorded wastewater composite sample collection date, location, volume, and temperature using tablet computers and a custom REDCap (Research Electronic Data Capture; Vanderbilt University) database. The field technicians transported 250 mL from each 24-hour composite sample to the University of Kentucky in Lexington for analysis. The team collected 811 composite wastewater samples across the 6 facilities during the study period.

Laboratory Analysis

Laboratory analysis of the wastewater included (1) heat-mediated viral lysis, (2) nucleic acid extraction using paramagnetic particles with exclusion-based sample extraction [13], and (3) SARS-CoV-2 RNA quantification using CDC-recommended N1 primers and real-time qualitative polymerase chain reaction (RT-qPCR) analysis. Laboratory staff processed 8 aliquots from each sample and reported the average SARS-CoV-2 RNA concentration across the 8 aliquots. Strike et al [14] provide a detailed description of the laboratory method. Laboratory quality control measures included negative RT-qPCR controls, positive RT-qPCR controls, spiked SARS-CoV-2 samples to assess RNA extraction efficiency, and a visual inspection of RT-qPCR readouts for concurrence with automated cycle threshold reads. In addition, the laboratory measured crAssphage DNA concentrations in 2 aliquots from each wastewater composite sample as an indicator of the sample's fecal load using the same general laboratory method as for SARS-CoV-2 quantification. crAssphage is a human gut bacteriophage that is ubiquitous in human stool at high concentrations.

Data Architecture and Communication

The study team developed a custom computer program to join the wastewater sample data stored in the REDCap database with the RT-qPCR wastewater RNA data, which resulted in a text file. The program incorporated multiple data validity checks and generated an error log that triggered study team members to investigate and rectify data quality issues. The team created a web-based password-protected data visualization dashboard that provided up-to-date results of wastewater surveillance to Trilogy management. The study team also shared wastewater surveillance results with Trilogy facility leadership via email and telephone. Trilogy decided how to respond to the wastewater surveillance data, including any enhanced clinical testing of staff or residents.

Wastewater Surveillance Performance

In accordance with CDC surveillance evaluation guidelines, we present credible evidence from stakeholder interviews (N=8), administrative records, wastewater analysis, and clinical testing results to address 7 general performance attributes of public health surveillance systems.

Simplicity: How Cumbersome Was the Process of Collecting Samples, Processing Them, and Sharing Surveillance Data With Stakeholders?

Testing wastewater samples 3 to 4 times per week at 6 facilities across 2 municipalities required 1 full-time laboratory technician, 1 full-time field technician, and 1 part-time field technician. Several part-time student laboratory assistants worked ≤10 hours a week to conduct wastewater laboratory analyses under the supervision of the full-time laboratory technician. The field technicians had no relevant experience at surveillance onset and acquired wastewater collection skills through apprenticeship during several field site visits.

The method of communicating wastewater results evolved over the study. Data sharing transitioned from emails and telephone calls to a web-based data dashboard, complemented by emails and telephone calls for results with perceived urgency. The dashboard displayed levels of SARS-CoV-2 RNA in wastewater by LTCF location and included clinical testing data from Trilogy's public-facing COVID-19 dashboard.

Flexibility: Did Wastewater Surveillance Adapt to the Changing Realities of the Pandemic, and If So, How Much Effort Was Needed, and How Successful Was the Transition?

Wastewater surveillance demonstrated flexibility in sampling frequency and duration, population under surveillance, and pathogens targeted. Initially, the field team collected wastewater samples 3 times weekly (Lexington) and twice weekly (Louisville). The team increased the sampling frequency to 4 times weekly (Lexington) and 3 times weekly (Louisville) to optimize the timely identification of new infections in the LTCF population. In addition, the study team reported that they efficiently resumed wastewater surveillance in January 2022 (after planned completion in December 2021) in Lexington because of concern for infections related to the SARS-CoV-2 Omicron variant in the LTCF population.

Although the focus of the wastewater surveillance system was SARS-CoV-2, the study team piloted testing LTCF wastewater for *Clostridioides difficile*, a pernicious colonic bacterium that can cause severe gastrointestinal illness. The testing of LTCF wastewater identified pathogenic (toxin producing) *C difficile* DNA, suggesting the flexibility of LTCF wastewater surveillance for pathogens beyond SARS-CoV-2.

Data Quality: How Complete Were the Wastewater Surveillance Data? How Was Data Quality Assured?

The wastewater surveillance system obtained 24-hour composite wastewater samples from the LTCFs 2 to 4 days per week. In Lexington, wastewater effluent was tested 47.3% (160/338) of the days in the study period. In Louisville facilities, wastewater testing covered 35.8% (98/274) to 37.2% (102/274) of the days in the study period. The subsection describing system stability provides additional information regarding wastewater sample collection issues that may have affected data quality. Of the 811 wastewater samples collected, 31 (3.8%) were not processed owing to reagent shortages (n=21, 68%), processing delays after winter storms (n=9, 29%), and contamination during laboratory extraction (n=1, 3%). Of the 780 samples analyzed for SARS-CoV-2, 40 (5.1%) had no detectable concentration of crAssphage or were not analyzed for crAssphage. The absence of detectable crAssphage in a wastewater sample suggests low or negligible presence of fecal material, which makes the detection of SARS-CoV-2 RNA less likely.

Custom software identified data inconsistencies in the REDCap database and the polymerase chain reaction (PCR) output files. In addition, laboratory personnel visually reviewed PCR curves and data generated by the PCR instrument to identify erroneous machine-estimated results. To maintain data integrity, technicians entered corrections into an Excel workbook. The software applied these corrections to the REDCap data before joining the data with the PCR results. The frequencies of identified data issues are presented in Table 1.

Table 1. Frequency of identified quality issues in long-term care facility wastewater surveillance data.

Data source and data quality issue	Values, n (%)
REDCap[a] (n=780)	
Inaccurate sample ID	89 (11.4)
Inaccurate location ID	16 (2.1)
Inaccurate collection method	0 (0)
Inaccurate sample date	5 (0.6)
RT-qPCR[b] (n=7734)	
False-positive PCR[c] value	91 (1.2)
False-negative PCR value	2 (0)
Inaccurate PCR value	19 (0.2)

[a] REDCap: Research Electronic Data Capture.

[b] RT-qPCR: real-time qualitative polymerase chain reaction.

[c] PCR: polymerase chain reaction.

Sensitivity and PPV: What Proportion of the Time When There Was a Known SARS-CoV-2 Case Was There a Positive Wastewater SARS-CoV-2 Signal? What Was the Probability That a Positive Wastewater Signal Indicated an Active SARS-CoV-2 Infection?

We used Trilogy's clinical testing data to estimate the performance of wastewater surveillance for detecting SARS-CoV-2 infections. Trilogy primarily used antigen-based SARS-CoV-2 tests. Trilogy tested LTCF staff per CDC and state guidance, which recommended PCR testing of staff who were symptomatic and every-other-week to twice-a-week testing of unvaccinated staff based on COVID-19 activity in the facility's county. Residents received SARS-CoV-2 testing when symptomatic and twice weekly after the identification of a case in the facility until no new cases were identified for 2 weeks. Trilogy did not require visitors to test.

Wastewater surveillance sensitivity for detecting the presence of identified clinical cases was 30.6% (95% CI 24.4%-36.8%) using a signal threshold of >0 RNA copies/mL and decreased to 11.5% (95% CI 7.2%-15.8%) with a signal threshold of >250 RNA copies/mL (Figure 1). Wastewater surveillance specificity ranged from 79.7% (95% CI 76.4%-82.9%; >0 RNA copies/mL) to 98% (95% CI 97.7%-99.6%; >250 RNA copies/mL). When limiting clinical test data to residents, wastewater surveillance sensitivity at a signal threshold of >0 RNA copies/mL improved to 48% (95% CI 36.5%-59.4%), with a specificity of 80% (95% CI 77%-82.9%; Figure 1). The PPV of wastewater surveillance ranged from 34.8% (95% CI 27.9%-41.7%) to 75% (95% CI 60%-90%) for wastewater signal thresholds of >0 copies/mL and >250 copies/mL, respectively, when including all clinical data and ranged from 19.7% (95% CI 13.8%-25.5%) to 39.3% (95% CI 21.2%-57.4%) when considering only clinical tests from residents (Figure 2).

Figure 1. Receiver operating characteristic curves depicting the sensitivity and specificity of wastewater surveillance at varying SARS-CoV-2 wastewater signal thresholds to discriminate the presence of staff and residents with a positive SARS-CoV-2 clinical test at 6 long-term care facilities. Note: panel A includes resident and staff clinical test results; panel B includes only resident clinical test results. cp: copies.

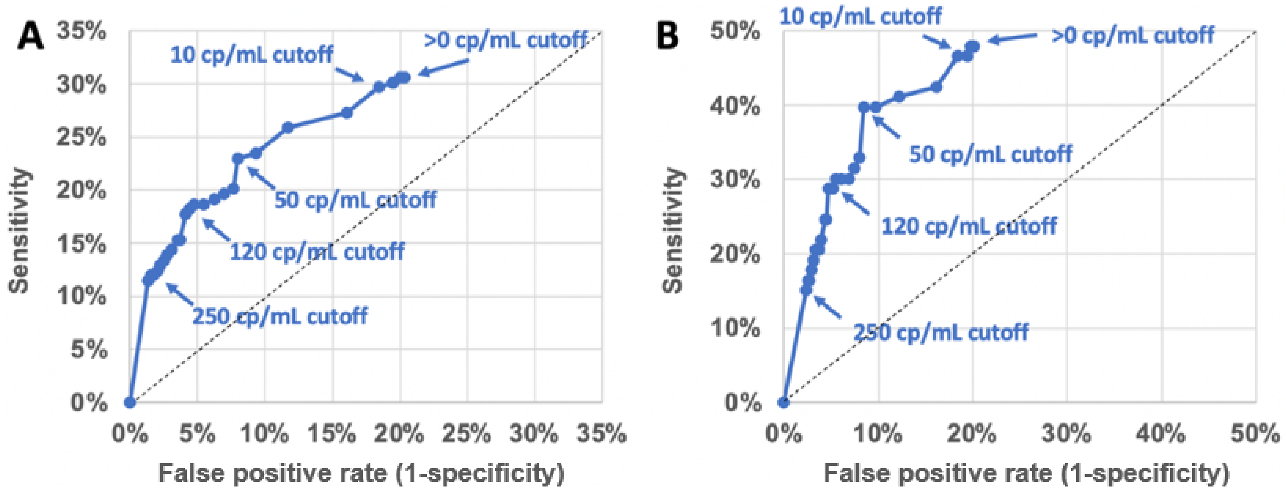

Figure 2. Positive predictive value (PPV) of a SARS-CoV-2 wastewater signal at various threshold values for the presence of a long-term care facility staff member or resident with a positive SARS-CoV-2 clinical test. cp: copies.

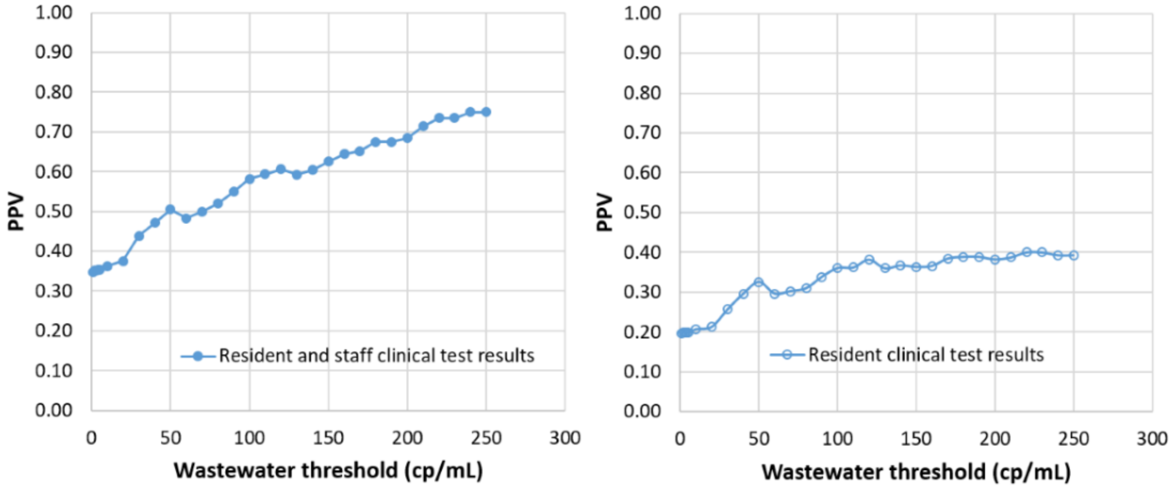


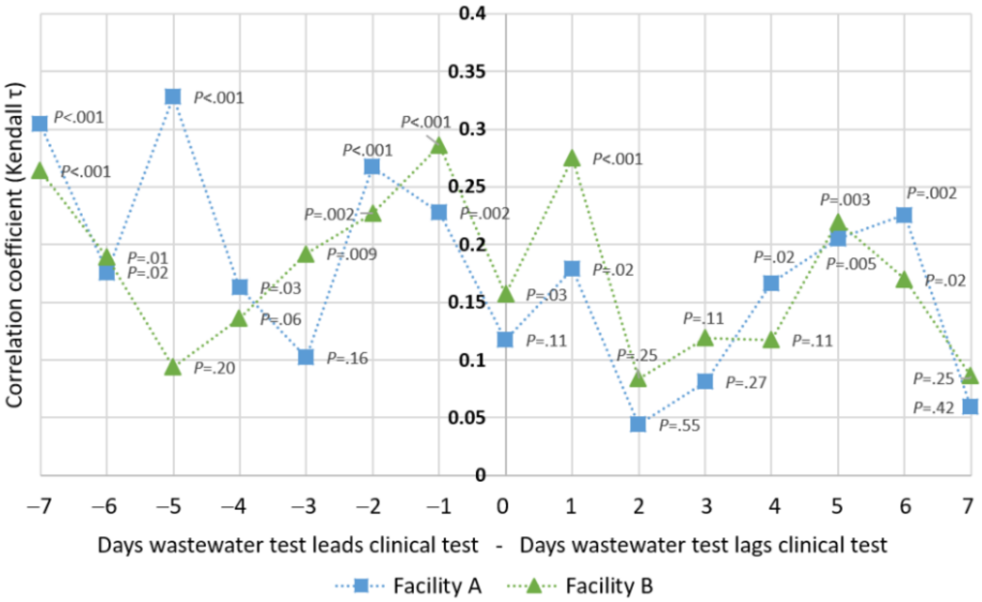
Limitations of the clinical testing data likely affected the estimates of wastewater surveillance performance. Rapid antigen test sensitivity is poor in asymptomatic individuals [15], and there was incomplete and variable testing of residents and staff. There was likely underascertainment of SARS-CoV-2 infections in the LTCF population, which would falsely deflate the estimates of wastewater surveillance specificity and PPV and inflate the estimates of sensitivity.

Timeliness: How Much Time Elapsed Between Collecting a Wastewater Sample, Analytic Results, and Infection Prevention Action by the Facility? Did Facility-Level Wastewater Surveillance Detect the Presence of SARS-CoV-2 Sooner Than Routine Clinical Testing or Testing Triggered by Symptom Screening?

Wastewater surveillance data were typically available for stakeholders 24 to 72 hours after sample collection. Variation in data timeliness was due primarily to personnel availability for sample processing and data entry. In general, turnaround time was faster for samples collected on Tuesdays, Wednesdays, and Thursdays than for samples collected on Fridays because laboratory staff did not work on weekends. Median turnaround times for results for samples collected on Tuesdays, Wednesdays, and Thursdays were 26, 37, and 28 hours, respectively. For results for samples collected on Fridays, the median turnaround time was 74 hours.

A lagged correlation analysis between the wastewater signal and clinical case detection showed variable correlation across the 6 facilities. At the 2 Lexington facilities with the greatest number of clinical cases, the wastewater signal correlated temporally with clinical testing results (Figure 3). Although wastewater positivity generally led clinical positivity (rather than lagged), there was not a specific lead time that outperformed all others because significant correlations were seen for lead times ranging from 1 (P<.001) to 7 (P<.001) days.

Figure 3. Lagged correlational analysis of wastewater SARS-CoV-2 positivity with SARS-CoV-2 clinical test positivity at 2 long-term care facilities. The x-axis indicates the number of days the wastewater data are offset relative to the clinical data, with negative values indicating the number of days that wastewater data lead, and positive values indicating the number of days that wastewater data lag, the clinical test data.



Representativeness: How Thoroughly Did Wastewater Testing Monitor the Population in the LTCFs?

Wastewater surveillance was representative of the population contributing to the wastewater at LTCFs because it examined building-wide sewer effluent over 24 hours. However, there were important caveats. The LTCF population that potentially contributed to wastewater at the facility was dynamic: there were resident admissions and discharges, staff worked at ≥1 locations, and the LTCFs reinstated resident visitation during the surveillance period. In addition, members of the LTCF population may not have contributed to the sewer effluent because they used toilets outside of the facility (staff) or because of incontinence and the use of adult briefs (residents). As previously mentioned, the inclusion of staff clinical results alongside resident results substantially affected the sensitivity (lower) and PPV (higher) of wastewater surveillance.

During a cluster of 10 identified resident cases at 1 LTCF, the surveillance team noted an intermittently positive wastewater signal. An investigation of this unexpected variability revealed that 6 (60%) of the 10 residents were fully or partially incontinent and using adult briefs. Their feces did not enter the wastewater stream and therefore did not contribute to a measurable SARS-CoV-2 wastewater signal.

Stability: What Issues Arose With Surveillance Equipment, Processes, Data Collection, or Reporting, and How Did This Affect Surveillance? How Much Did the System Cost to Operate?

Global supply chain issues owing to the COVID-19 pandemic required flexibility. At the study onset, autosamplers were unavailable, which delayed surveillance implementation by a month. Intermittent vendor shortages of laboratory supplies forced reuse protocols when possible and resulted in a reduction of replicates analyzed in 9.5% (74/780) of the samples. Several environmental and infrastructure factors challenged wastewater collection. Autosampler logs identified periods of low flow in the wastewater effluent stream, which resulted in smaller sample volumes and less representative composite samples at 1 facility in particular. We did not observe clogging of the strainers at the end of the autosampler tubing; however, intermittent clogging may have occurred and contributed to the low flow measured by the autosamplers. The results from the days and locations with smaller composite volumes may not represent conditions from the 24-hour collection period. In addition, sewer architecture resulted in a likely false-positive wastewater signal at 1 LTCF (Textbox 1).

Wastewater composite samples exceeded the goal temperature threshold of 4 °C (for optimal RNA stability) during summer months. Decreasing the composite sample volume (to 6000 mL) and increasing the volume of ice used in the autosamplers increased the frequency with which the composite wastewater samples stayed below the target temperature.

The reoccurring cost to conduct 1 day of wastewater surveillance at an LTCF was approximately US $144.50, or approximately US $18.06 per replicate. This estimate included transportation, labor, and materials based on wastewater testing at 6 sites (Table 2). Additional 1-time equipment expenses, such as laboratory equipment (notably a PCR machine) and autosamplers, contribute to start-up costs for wastewater surveillance. Amortized over the lifetime of the equipment, these expenses will increase per-sample costs by approximately US $5 to US $10. There are potential economies of scale related to labor because there are time efficiencies when obtaining and processing samples from multiple facilities.

Textbox 1. Adapting wastewater sampling to mitigate sewer architecture challenges.

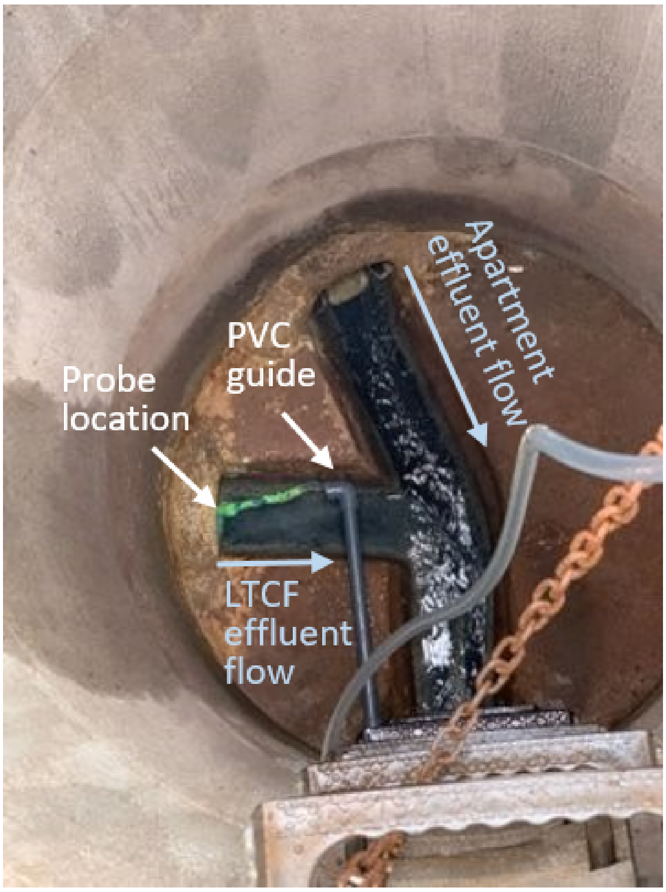
During routine wastewater surveillance, the team detected a strongly positive wastewater signal at a facility with no known COVID-19 infections. This happened on a Friday, and the surveillance team notified long-term care facility (LTCF) leadership shortly before the close of business. Over the subsequent 2 days, the LTCF leadership tested all residents and staff at the facility but did not identify an individual with SARS-CoV-2 infection. LTCF site management shared that there were COVID-19 cases at a neighboring apartment building. An examination of sewer architecture revealed that wastewater effluent from the LTCF and the apartment building converged at our sampling point (Figure 4). Although the field technician placed the autosampler probe into the LTCF wastewater effluent channel, the technician noted intermittent probe migration into the convergent channel. We presume that the strongly positive wastewater signal came from the apartment building. We addressed this sampling issue by designing an autosampler probe guide made using a polyvinyl chloride pipe and rigid wire. This custom device ensured that the probe remained in the channel containing only LTCF wastewater.

Table 2. Cost estimates for wastewater surveillance at long-term care facilities by expense category.

	Cost/replicate (US $)	Cost/sample (US $)	Cost per capita[a]/sample (US $)
Reagents	6.47	51.78	0.28
Labor	7.30	58.38	0.31
Transportation	4.29	34.33	0.18
Total	18.06	144.50	0.77

[a] On the basis of the total population (N=1124) of residents and staff at the 6 long-term care facilities at the conclusion of wastewater surveillance.

Figure 4. Autosampler probe guide designed to address the sampling issue at a long-term care facility (LTCF). PVC: polyvinyl chloride.



Additional Wastewater Surveillance Considerations

Stakeholders mentioned that the relative newness of wastewater surveillance added complexity to surveillance implementation. The collaboration between university researchers and the LTCF organization raised data sharing and privacy issues related to resident and staff COVID-19 testing results. A formal data use agreement clarified expectations.

All interviewed stakeholders raised the issue of how best to interpret, and respond to, the wastewater data. LTCF and local health department leadership expressed a desire for a clear course of action. They asked questions about the strength of a wastewater signal that should trigger clinical testing and about how wastewater RNA concentrations correlated to the numbers of infections at the facility. Study scientists stressed that, at best, wastewater data indicated trends and not absolute numbers of infections. Local health department officials could not foresee incorporating wastewater surveillance into daily practice without a high level of evidence and guidance supporting its adoption.

Several stakeholders mentioned the importance of goal setting between LTCF leadership and the study team. Scientists expressed a desire to define ideal parameters such as target sensitivity and PPV, turnaround time, and methods of communication. LTCF leadership prioritized a streamlined approach to wastewater surveillance, such as an *industry build out* with established resources to easily set up and maintain systems *off the shelf*, such as commercially available fire protection systems.

Discussion

Principal Findings

Our evaluation of wastewater surveillance for SARS-CoV-2 at LTCFs found the approach feasible and timely, with results available to stakeholders within approximately 24 to 72 hours. Wastewater surveillance demonstrated decent specificity but poor sensitivity for identifying known SARS-CoV-2 clinical cases, although sensitivity improved when using only clinical test results from LTCF residents (excluding staff). LTCF wastewater surveillance was stable; solutions to environmental challenges were manageable, and there were minimal disruptions in sampling.

Stakeholders consistently raised questions about wastewater surveillance performance and results interpretation. The limitations of clinical testing data, such as less frequent testing of residents and the use of rapid antigen tests, affected the team’s ability to accurately estimate the performance of wastewater surveillance (ie, there was not a gold standard on which to base sensitivity and specificity calculations). Uncertainties also existed regarding the population under wastewater surveillance. Family visits resumed during the surveillance period, staff bowel habits were unknown, and residents with fecal incontinence used adult briefs, meaning that their feces did not enter the wastewater stream. Staff with COVID-19 isolated at home for a variable period before returning to work and potentially contributing to the wastewater stream. These limitations eroded confidence in wastewater surveillance performance.

Stakeholders wanted to quantify the number of COVID-19 cases represented by a specific wastewater signal intensity. The relationship between wastewater signal intensity and number of cases was not clear, owing in part to uncertainties regarding the population under surveillance described in the preceding paragraph. In addition, viral shedding of SARS-CoV-2 is variable in frequency, intensity, and duration [16]. These parameters likely vary among SARS-CoV-2 variants and across host characteristics (age, disease intensity, and comorbid conditions) [17]. Additional facility and environmental considerations may have affected measured wastewater SARS-CoV-2 concentrations, such as variations in wastewater flow, presence of inhibitor substances (cleaning agents and disinfectants), ambient temperature, and the heterogeneous nature of wastewater [18,19]. However, water quality differences among facilities may not correlate with changes in SARS-CoV-2 concentrations [20]. Because of these factors, precisely delimiting the relationship between wastewater SARS-CoV-2 concentration and COVID-19 cases was difficult and may not be realistic at the facility level. Furthermore, once there is an established case in a building, identifying new infections using wastewater measurements remains a hurdle because convalescing individuals continue to shed virus [21]. SARS-CoV-2 RNA present in wastewater from convalescing individuals may decrease the estimated specificity and PPV of the wastewater signal for detecting new SARS-CoV-2 infections.

Variability in turnaround time from sample collection to result dissemination was primarily because of staffing and the day of sample collection. Samples collected on Tuesday through Thursday underwent analysis the same day, with results typically reported the next morning, whereas samples collected on Friday had delayed reporting of results owing to limited weekend staffing. Turnaround times observed in this evaluation were comparable with those reported by a wastewater laboratory in Berkeley, California [22]. Wastewater testing results turnaround time, regardless of the day of the week, was quicker than typical turnaround times for PCR clinical testing (48-72 h) but slower than rapid antigen tests (15 min to 1 h) [7]. Adding staff in the evening or during the weekend could mitigate the observed variability in results turnaround times and support wastewater surveillance as an effective early warning system.

Wastewater surveillance at LTCFs may provide an early warning of infection at a facility before detection by routine screening practices as suggested by the time-shifted correlation analysis. A positive wastewater signal could trigger enhanced clinical testing and infection prevention actions. To maximize the potential lead time provided by the wastewater signal, an LTCF would need clear operating procedures in place. These include capacity to test, perform contact tracing, and isolate individuals who have been potentially infected, as demonstrated on university campuses that used wastewater surveillance to trigger disease mitigation responses [23-25]. Uncertainties in how to interpret the wastewater data and how best to communicate this information within our academic-private partnership limited actions taken in response to wastewater data and require additional investigation in how best to use wastewater surveillance as an infection-detection modality.

Facility wastewater surveillance was flexible, as demonstrated by the rapid resumption of surveillance at the onset of the SARS-CoV-2 Omicron variant wave in January 2022; however, there are structural limitations to this surveillance. Sewer architecture is an important consideration when evaluating facility suitability for wastewater surveillance [26]. Situations where facility-level wastewater surveillance is less suitable include facilities where sewer access is limited to manholes in busy streets, there is low effluent flow, and convergent wastewater streams prohibit the selective sampling of wastewater from the facility of interest. Labor availability or lack of access to a laboratory skilled in RT-qPCR might prolong results turnaround time to a point where wastewater surveillance may not provide an early warning of disease [25].

Most stakeholders expressed enthusiasm for wastewater surveillance, recognizing its cost-effective noninvasive nature and potential for monitoring SARS-CoV-2 variants of concern and other pathogens, including methicillin-resistant *Staphylococcus aureus* and *C difficile*, as well as viruses that cause respiratory infections such as influenza. The specific use cases for wastewater surveillance will vary based on stakeholder priorities, institutional wastewater infrastructure, and available resources. Wastewater surveillance may also serve purposes beyond disease surveillance, such as maintaining relationships with external stakeholders [27]. In our case, the leadership at the LTCF organization were interested in wastewater surveillance as an emerging technology that could protect the well-being of their residents and demonstrate their commitment as an industry leader in safety.

Stakeholders in the LTCF industry cited the lack of easily deployable wastewater surveillance systems as a major hurdle to wider adoption. They described a desire for *off-the-shelf, ready-to-go* wastewater surveillance systems, akin to fire protection systems. The COVID-19 pandemic is driving rapid innovation of wastewater surveillance technology, and as the industry develops and technology improves, LTCF managers may be open to broader adoption of this tool. Alternatively, LTCFs could partner with local utilities or health departments to build sustainable wastewater surveillance systems.

Although reports describing the use of wastewater surveillance at LTCFs are sparse, there are other facility-based settings where wastewater surveillance flourished during the COVID-19 pandemic. Universities, in particular, were early adopters and implemented building-level wastewater testing, while developing wastewater sampling strategies, laboratory assays, and public health response measures [25]. Schools were another congregate setting where wastewater surveillance demonstrated utility in identifying and potentially mitigating SARS-CoV-2 infection [28,29]. Correctional settings have also used and evaluated wastewater surveillance [30], and former inmates have voiced a preference for wastewater surveillance over individual testing for SARS-CoV-2 [31]. Many of the lessons learned from this evaluation of wastewater surveillance at LTCFs may apply to wastewater surveillance in other facility-level settings.

This surveillance evaluation had limitations in addition to the challenges we have already described. Sparse data from relatively few positive clinical tests during the surveillance period reduced the power of the statistical analyses and may have affected surveillance performance estimates. The stakeholders interviewed for the evaluation shared perspectives that may not represent the opinions and experiences of individuals involved in wastewater surveillance in other settings, meaning that the findings from this evaluation may not generalize to other LTCF-based wastewater surveillance settings. However, by adhering to the CDC guidelines for evaluating public health surveillance systems, we used reproducible methods and provide credible data and insight into the performance of wastewater surveillance for SARS-CoV-2 at 6 LTCFs in Kentucky.

Conclusions and Recommendations

Facility-level wastewater surveillance can monitor populations considered vulnerable for the presence of infectious diseases. Stakeholders found the surveillance feasible and expressed optimism regarding its potential while also recognizing challenges in interpreting, and acting on, the data. Further studies of the performance of facility-level wastewater surveillance will improve the interpretation of wastewater data and increase the utility of this emerging surveillance modality.

Specific recommendations based on this evaluation are to (1) investigate the relationship between wastewater SARS-CoV-2 RNA levels and the number of individuals infected and convalescing at a facility (fecal shedding studies may help elucidate this relationship); (2) synthesize facility-based wastewater surveillance data across projects to develop and test guidance on data interpretation; and (3) foster relationships among academic partners, LTCF organizations, and public health officials to clarify and strengthen communication practices to understand the priorities and limitations of wastewater surveillance.

Acknowledgments

The authors would like to thank Steven Roggenkamp for creating the data architecture for this study. The authors acknowledge and thank the facilities staff at the Trilogy Health Services facilities where the wastewater surveillance occurred. This work was funded by the National Institutes of Health (P30 ES026529) and the Centers for Disease Control and Prevention (BAA 75D301-20-R-68024). The contents are solely the responsibility of the authors and do not represent the official views of the National Institutes of Health or Centers for Disease Control and Prevention.

Data Availability

The wastewater and interview data evaluated for this study are available from the corresponding author on reasonable request. Clinical test data are available on the Trilogy COVID-19 dashboard [32].

Authors' Contributions

JWK and SMB conceived of, and secured funding for, this study. JL, ML, BM, CO, WS, and AN generated data for this study. PL provided access to data. JL, RA, JWK, SMB, and ML analyzed the data. JL and JWK drafted the manuscript. PL, SMB, TS, and ML reviewed and edited the manuscript. JWK is the guarantor of this manuscript.

Conflicts of Interest

SMB reports ownership interest in Salus Discovery, LLC, which licenses the technology used for the wastewater analysis described in the text. All other authors declare no other conflicts of interest.

Abstract

Background: The COVID-19 pandemic had wide-ranging systemic impacts, with implications for social and behavioral factors in human health. The pandemic may introduce history bias in population-level research studies of other health topics during the COVID-19 period.

Objective: We sought to identify and validate an accessible, flexible measure to serve as a covariate in research spanning the COVID-19 pandemic period.

Methods: Transportation Security Administration checkpoint travel numbers were used to calculate a weekly sum of daily passengers and validated against two measures with strong face validity: (1) a self-reported item on social distancing practices drawn from a continuous tracking survey among a national sample of youths and young adults (15-24 years) in the United States (N=45,080, approximately 280 unique respondents each week); and (2) Google's Community Mobility Reports, which calculate daily values at the national level to represent rates of change in visits and length of stays to public spaces. For the self-reported survey data, an aggregated week-level variable was calculated as the proportion of respondents who did not practice social distancing that week (January 1, 2019, to May 31, 2022). For the community mobility data, a weekly estimate of change was calculated using daily values compared to a 5-week prepandemic baseline period (January 3, 2020, to February 6, 2020). Spearman rank correlation coefficients were calculated for each comparison.

Results: Checkpoint travel data ranged from 668,719 travelers in the week of April 8, 2020, to nearly 15.5 million travelers in the week of May 18, 2022. The weekly proportion of survey respondents who did not practice social distancing ranged from 18.1% (n=42; week of April 15, 2020) to 70.9% (n=213; week of May 25, 2022). The measures were strongly correlated from January 2019 to May 2022 (ρ=0.90, *P*<.001) and March 2020 to May 2022 (ρ=0.87, *P*<.001). Strong correlations were observed when analyses were restricted to age groups (15-17 years: ρ=0.90; *P*<.001; 18-20 years: ρ=0.87; *P*<.001; 21-24 years: ρ=0.88; *P*<.001), racial or ethnic minorities (ρ=0.86, *P*<.001), and respondents with lower socioeconomic status (ρ=0.88, *P*<.001). There were also strong correlations between the weekly change from the baseline period for checkpoint travel data and community mobility data for transit stations (ρ=0.92, *P*<.001) and retail and recreation (ρ=0.89, *P*<.001), and moderate significant correlations for grocery and pharmacy (ρ=0.68, *P*<.001) and parks (ρ=0.62, *P*<.001). A strong negative correlation was observed for places of residence (ρ=−0.78, *P*<.001), and a weak but significant positive correlation was found for workplaces (ρ=0.24, *P*<.001).

Conclusions: The Transportation Security Administration's travel checkpoint data provide a publicly available flexible time-varying metric to control for history bias introduced by the pandemic in research studies spanning the COVID-19 period in the United States.

Introduction

On March 11, 2020, the outbreak of the disease resulting from SARS-CoV-2 (COVID-19) was declared a pandemic by the World Health Organization [1]. As cases surged in the United States, public health and government officials engaged in unprecedented efforts to limit the spread of the virus. Without effective pharmacological interventions and vaccines, social distancing emerged as the primary mitigation strategy [2,3]. Furthermore, many governments enacted stay-at-home mandates and the closing of nonessential businesses, with the reasoning that with fewer people traveling outside their homes, there would be less close physical contact between infected and uninfected individuals [4]. According to a growing body of research evaluating the effectiveness of these interventions, these actions were instrumental in reducing infection rates [5].

The COVID-19 pandemic, and subsequent control measures, had wide-ranging systemic impacts with implications for social and behavioral factors in human health. The time-dependent nature of the pandemic introduces history bias into longitudinal and time series analyses, with the pandemic's many impacts acting as confounders in population-level research studies. A commentary by Tuttle et al [6] noted that potential bias introduced by the COVID-19 pandemic has important considerations for analysis and interpretation in clinical research, and suggested that potential confounding may be addressed by examining pre-and postpandemic data with a control for COVID-19 behaviors. Such a control variable should have validity within a variety of target populations addressed by public health (eg, by age, socioeconomic status, race, or ethnicity).

Mobility data have the ability to provide nearly real-time information about changes in patterns of human movement as measured by activity on mobile phones, GPS tracking, and social media platforms. For the past several years, researchers have used mobility data to inform epidemiological modeling, situational awareness, and resource allocation during public health crises [7-14]. Thus, most of the available literature leverages mobility data to track the movements of individuals during the COVID-19 pandemic, to identify areas of high transmission, or evaluate the efficacy of interventions, such as social distancing [7-12]. In contrast, few studies have applied these data to other areas of public health research concurrent with the COVID-19 pandemic. It was 1 study from the United Kingdom that used mobility data to assess the impact of COVID-19 pandemic restrictions on physical activity levels [14]. Another in the United States established an association between county-level social distancing patterns during the COVID-19 pandemic and other county-level indicators of health behavior (eg, smoking, obesity, flu vaccination, and mammography screening) using data from GPS-enabled mobile devices [13].

The purpose of this study is to identify a suitable control variable for longitudinal or time series social and behavioral studies that span the COVID-19 pandemic period. We sought to determine whether air travel metrics can be used as a time-varying endogenous indicator of COVID-19 impacts on societal activities. The airline industry was detrimentally impacted by the COVID-19 pandemic. Passenger air travel was the largest contributor to industry losses during the pandemic, when the number of air travel passengers dropped by approximately 60% in 2020 [15,16]. Thus, we believe this may be a suitable control variable to integrate retrospectively into data sets that span the COVID-19 period. We will validate this measure against 2 time-varying population-level measures with strong face validity: the first is calculated by aggregating individual-level self-reported social distancing practices at a weekly level, drawn from a continuous tracking survey of youths and young adults in the United States; and the second is from Google's COVID-19 Community Mobility Reports, which calculate daily values at the national level to represent rates of change in visits and length of stays to public spaces [9].

Methods

Data and Measures

Checkpoint Travel Data

Publicly available data from the Transportation Security Administration (TSA) was used to construct an exogenous indicator of COVID-19's population-level impacts. TSA maintains a daily count of travelers screened at TSA airport checkpoints. As of this writing, data have been made available by TSA on the internet from 2019 to the present [17]. A weekly checkpoint travel variable was constructed by summing the TSA's daily checkpoint travel numbers within each week (Wednesday-Tuesday), which was used for the analysis correlating this measure to self-reported social distancing (Multimedia Appendix 1). For analyses comparing checkpoint travel data to community mobility data, the weekly checkpoint travel data were calculated as a weekly change score compared to the median checkpoint travel value for the corresponding day of the week, during the 5-week prepandemic period spanning January 3, 2020, to February 6, 2020.

Self-Reported Social Distancing Data

The self-reported measure of social distancing used data from a cross-sectional, continuous tracking survey of youths and young adults (aged 15-24 years) drawn from the Dynata national web-based panel. The survey is administered continuously (ie, sampling occurs every day) and receives responses from approximately 280 unique participants per week. Participants who completed a survey between January 1, 2019, to May 31, 2022 (N=45,080) were included in the analysis. Sampling quotas were used and survey weights were applied using age, race or ethnicity, and sex based on demographic benchmarks from the US Census to approximate a national sample.

A self-reported, single-response item on the frequency of social distancing during the past week was added to the survey instrument on March 25, 2020, and remained throughout the study period. Respondents were presented with the following question: “Social distancing means people stay home as much as possible to prevent catching and spreading the virus, and if they go outside, they stay at least 6 feet away at all times from any person who they don’t live with. Other terms for social distancing that some people use are self-quarantine and self-isolation. In the past week, have you done social distancing…?” Responses were coded as 0=at all times, 1=usually, 2=sometimes, 3=very little, and 4=not at all. Responses to the self-reported measure on social distancing were dichotomized (0=at all times or usually, 1=sometimes or very little or not at all). An aggregated week-level variable was calculated as the proportion of respondents that week who reported social distancing sometimes or very little or not at all (ie, coded as “1” for the dichotomized variable; Multimedia Appendix 2). In weeks prior to March 9, 2020, respondents were coded as “1” to reflect a lack of social distancing during the pre–COVID-19 period. The survey did not ask about social distancing during the first 2 weeks of the pandemic (weeks of March 9 and March 16), so the Next Observation Carried Backward method was used to impute values for the weeks of March 9 and March 16 using the proportions from the week of March 23. The aggregated values in weeks prior to March 9 were 100%, representing no social distancing across all respondents (n=280) within each of those weeks.

We constructed 2 additional aggregate measures of self-reported social distancing using only data from population subgroups (ie, racial or ethnic minorities and lower socioeconomic status) to determine if the correlation to the endogenous measure is similar for target populations commonly found in public health research. For racial or ethnic minorities, we limited the aggregation of the self-reported measure to those from respondents who self-identified as being non-White (ie, Black or African American, Asian, Native Hawaiian or other Pacific Islander, American Indian or Alaska Native, or multiracial) or Hispanic (n=14,657). For socioeconomic status, we used a subjective measure of household income that has been validated among young adults. Young adult respondents are asked: “Considering your own income and the income from any people who help you, how would you describe your own overall financial situation? Would you say you… (live comfortably; meet needs with a little left over; just meet basic expenses with nothing left over; don’t meet basic expenses).” This measure was adapted to respondents aged 15 to 17 years, who are asked: “Considering all income earners in your family, how would you describe your family’s overall financial situation, would you say you…” with the same response options as the original measure. The aggregated measure for low socioeconomic status was limited to respondents who reported having their basic needs met with nothing left over or not having their basic needs met (n=30,054).

COVID-19 Community Mobility Data

Google’s COVID-19 Community Mobility Data compare how visits and length of stay in various sites within communities changed compared to a 5-week prepandemic baseline period (January 3, 2020, to February 6, 2020) [18]. Data are drawn from mobile devices where users are signed into their Google accounts. Data collection is limited to Google users who have elected to activate their Location History; the default setting is off. To be comparable to the TSA’s checkpoint travel data, the analysis for this paper used country-level data for the United States.

A daily change score is calculated using values from each day compared to the median value for the corresponding day of the week during the 5-week baseline period. For the purposes of this study, we calculated weekly change scores for the TSA data from the same baseline period.

Google classifies community locales using the following categories: retail and recreation (eg, restaurants and cafes, shopping centers, theme parks, museums, libraries, and movie theaters), grocery and pharmacies (eg, grocery markets, food warehouses, farmer’s markets, specialty food shops, drug stores, and pharmacies), parks (eg, local parks, national parks, public beaches, marinas, dog parks, plazas, and public gardens), transit stations (eg, subway, bus, and train stations), workplaces, and places of residence.

Ethics Approval

The study was conducted in accordance with the Declaration of Helsinki. Checkpoint travel data and community mobility report data were obtained from anonymous, aggregated publicly available sources (TSA and Google, respectively). The protocol for the survey providing self-reported social distancing data was approved by the Advarra Institutional Review Board (Protocol ID: Pro0010120). Informed consent was obtained from all survey respondents aged 18 years or older, or from a parent or legal guardian for all respondents under 18 years of age. Respondent incentives were in accordance with their membership in a web-based panel maintained by Dynata.

Statistical Analysis

The Shapiro-Wilk test for normality determined that measures were not normally distributed for weekly air travel (W=0.919, $P<.001$), aggregated weekly social distancing (W=0.942, $P<.001$), and community mobility data (grocery: W=0.892, $P<.001$; recreation: W=0.877, $P<.001$; transit: W=0.986, $P<.001$) during the pandemic period, likely due to the high level of social distancing and reduction in travel observed during a short duration at the beginning of the pandemic period.

Spearman rank correlation coefficient was calculated for the weekly sum of travel checkpoint data, as were (1) the weekly proportion of survey respondents who did not practice social distancing and (2) the weekly percent change in visits to public spaces compared to the prepandemic baseline.

A secondary analysis was conducted using first-order differencing to remove the effects of the overall trend spanning the study period and determine the checkpoint travel data’s usage in controlling for weekly change.

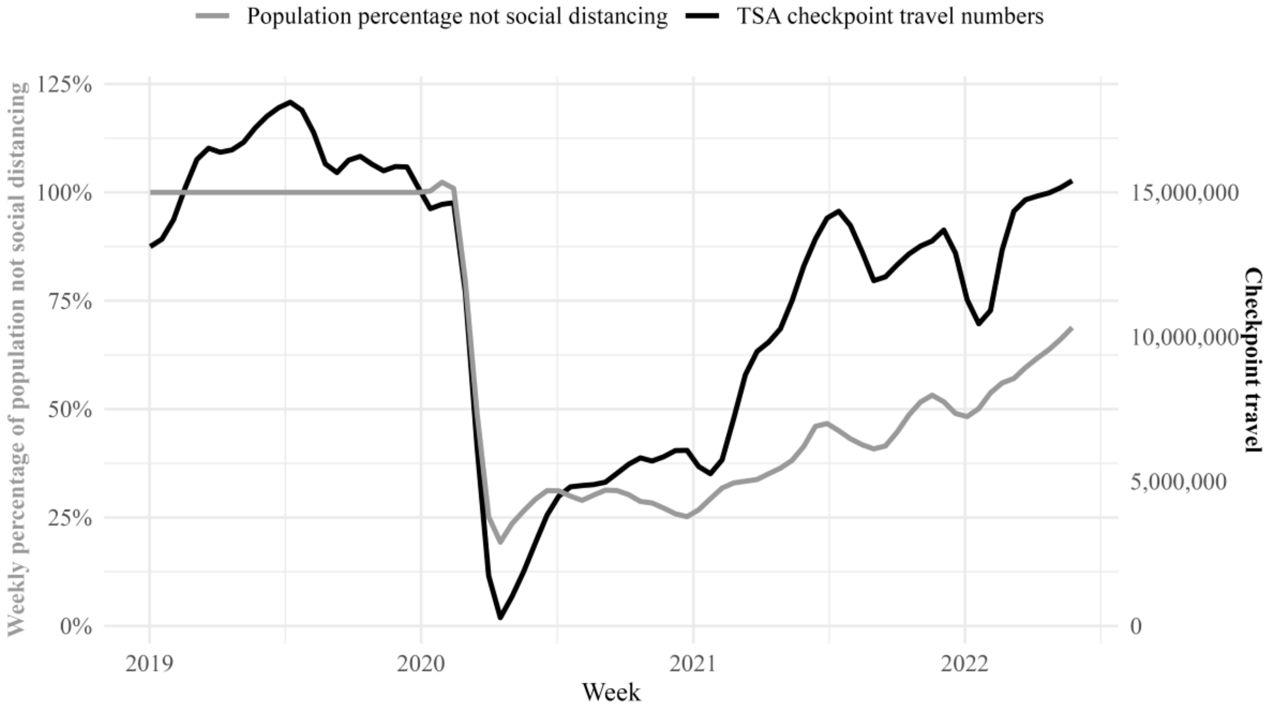
All analyses were conducted using RStudio (version 2021.09.0), developed by Posit, formerly known as RStudio Inc.

Results

Correlations Between Checkpoint Travel Data and Self-Reported Social Distancing

The relationship between the checkpoint travel data and self-reported social distancing measure (Figure 1) was visually inspected. The plot suggested a positive linear relationship between checkpoint travel numbers with no significant outliers when examining the prepandemic period and pandemic periods separately. Additional graphs were created to inspect whether a positive relationship could also be observed between checkpoint travel data and population subgroups (Multimedia Appendix 3) and whether checkpoint travel varied in relation to surges in COVID-19 variants (Multimedia Appendix 4).

Figure 1. Weekly checkpoint travel volume and proportion of youths and young adults reporting not social distancing before and during the COVID-19 pandemic. TSA: Transportation Security Administration.



Checkpoint travel data showed the minimum weekly sum of travelers (n=668,719) occurring the week of April 8, 2020, peaking at nearly 15.5 million the week of May 18, 2022 (Multimedia Appendix 1). The weekly proportion of survey respondents who did not practice social distancing followed a similar trend, ranging from 18.1% (n=42; week of April 15, 2020) to 70.9% (n=213; week of May 25, 2022; Multimedia Appendix 2). The measures were strongly and significantly correlated from January 2019 to May 2022 and March 2020 to May 2022 (Table 1). Strong correlations were observed when analyses were restricted to age groups (ie, 15-17, 18-20, and 21-24 years), racial or ethnic minorities, and respondents with lower socioeconomic status, all of which were significant (Table 1). First-order differencing correlations between weekly checkpoint travel data and self-reported social distancing were not significant for either the overall sample, neither for racial or ethnic minorities nor for respondents with lower socioeconomic status. A weak positive and significant correlation was observed for first-order differences of weekly checkpoint travel data and self-reported social distancing among youths aged 15-17 years (Table 1), but no other correlations using first-order differencing were significant for other age groups.

Table 1. Correlation of Transportation Security Administration's weekly checkpoint travel volume with other weekly indicators of behavioral impacts of the COVID-19 pandemic, January 2019 to May 2022.

	ρ	*P* value
Self-reported social distancing[a]		
Total population (aged 15-24 years)	0.90	<.001
Racial or ethnic minorities	0.86	<.001
Low SES[b]	0.88	<.001
Age 15-17 years	0.90	<.001
Age 18-20 years	0.87	<.001
Age 21-24 years	0.88	<.001
Change in community mobility[c]		
Transit stations	0.92	<.001
Retail and recreation	0.89	<.001
Grocery and pharmacy	0.68	<.001
Parks	0.62	<.001
Workplaces	0.24	<.001
Places of residence	−0.78	<.001

[a] Aggregated weekly percent reporting socially distancing sometimes or very little or not at all in the past week.

[b] SES: socioeconomic status.

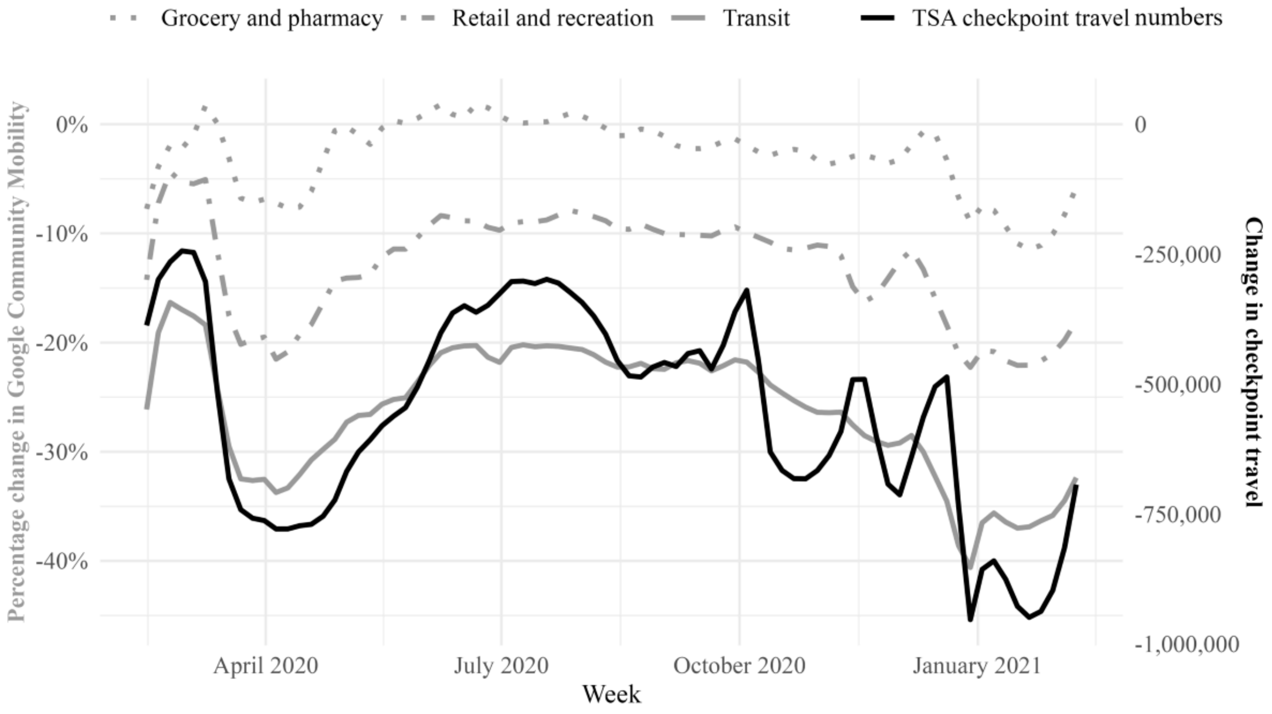
[c] Aggregated weekly change score compared to baseline weeks (January 3, 2020, to February 6, 2020).

A consistent visual pattern was observed when we inspected checkpoint travel data during the 10-week period before and after the emergence of new variants or surge in cases over the course of the study period (Multimedia Appendix 3). New variants included Alpha B.1.1.7 (emerged December 29, 2020), Delta B.1.617.2 (emerged June 1, 2021, and surged July 27, 2021), and Omicron B.1.1.529 (emerged December 1, 2021), with surges of both Omicron and Delta variants identified on January 1, 2022 [19]. Increased checkpoint travel numbers reflected a rise in air travel during the winter holiday and summer months. A rise in checkpoint travel numbers directly preceded surges in new variants of COVID-19: Alpha B.1.1.7 (December 2020), Delta B.1.617.2 (July 2021), and Omicron B.1.1.529 and Delta B.1.617.2 (December 2021). A drop in checkpoint travel numbers immediately followed each surge before rising again in subsequent months.

Correlations Between Checkpoint Travel Data and Community Mobility Data

The relationship between the checkpoint travel measure and community mobility measure was visually inspected (Figure 2).

Figure 2. Change in weekly checkpoint travel volume and community mobility estimates compared to baseline weeks preceding the COVID-19 pandemic (January 3, 2020, to February 6, 2020). TSA: Transportation Security Administration.



There was a strong positive, significant correlation between the weekly change from the baseline period for checkpoint travel data and community mobility data for transit stations and retail and recreation, and moderate significant correlations for grocery and pharmacy as well as parks (Table 1). A strong negative correlation was observed for places of residence, and a weak but significant positive correlation was found for workplaces (Table 1).

First-order differencing of changes in weekly checkpoint travel and community mobility from baseline had moderate positive and significant correlations for transit stations, retail and recreation, grocery and pharmacy, and parks. A weak but significant negative correlation was observed for places of residence and workplaces (Table 1).

Discussion

Principal Findings

The TSA's daily travel checkpoint data provide a publicly available, flexible metric that may be easily incorporated into national data sets to serve as a proxy for the intensity of COVID-19 activity in the population at a given time interval. As of this writing, these data are available on the internet and span back to 2019. It is unknown whether these data will continue to be tracked and published on the internet indefinitely.

Future data collection efforts may consider including a self-reported measure on social distancing in population-based surveys for as long as new strains of COVID-19 are expected to impact social dynamics to a varying extent over time. Public health officials have noted that society continues to be vulnerable to other emergent and resurgent diseases with pandemic potential [20]. This measure may be applicable to other pandemic diseases requiring self-isolation and quarantine at a broad scale.

Changes in checkpoint travel data used in our study correlated in the expected direction with changes in community mobility, with strong correlations observed for transit stations, and retail and recreation sites. A moderate correlation was observed with places to access essential goods and services (ie, grocery stores and pharmacies) as well as parks, which were popular outdoor recreational options during the pandemic. A weak correlation was observed for workplaces, likely reflecting the adoption of remote work policies by many employers. As expected, a strong negative correlation was observed between checkpoint travel data and being at home. Google ceased publication of its COVID-19 Community Mobility Reports (used in this study) as of October 15, 2022, yet daily checkpoint travel data remain available. Mobility data are subject to proprietary data processing methods and policies, including changes in parameters used by Google in the change score calculation over time (for example, to account for shifts in regional population size or retailer density). For this reason, Google cautions against comparing time periods that span longer than 6 months. By contrast, checkpoint travel data do not rely on third parties to generate estimates and can be applied to data sets spanning multiple years. Checkpoint travel data are available in the years preceding the COVID-19 pandemic, whereas the mobility data used in our study could only be viewed as a percent change from the prepandemic baseline determined by the company.

First-order differencing analysis at a weekly level found few significant correlations between checkpoint travel data and self-reported social distancing, and weak to moderate correlations with community mobility data. These results suggest that the measure is less useful as a control for time intervals with high granularity, such as time series studies examining week-to-week changes within the COVID-19 period. Similarly, Google cautions against using its Community Mobility Reports to compare day-to-day activity and calculates its change score from a median value from a pre-COVID baseline period spanning several weeks. The use of checkpoint travel data as a proxy for COVID-19 activity is, therefore, best applied to analyses that need to control for time-dependent trends attributable to the COVID-19 pandemic, such as analyses that encompass the prepandemic and pandemic periods, or the first several months of the pandemic when lockdowns occurred compared to periods later in the pandemic after societal activities began to resume.

Limitations

This study was subject to limitations. First, the daily air travel metrics of interest to this study were validated against a national sample of youths and young adults, rather than a nationally representative data set of the general population. While we are encouraged that the strength of the correlation was similar within defined subgroups in our sample, these subgroups remain restricted to people younger than 25 years. It is unclear how similar the social distancing practices of young people in our sample would be to those of the general adult population.

Second, the metric against which checkpoint travel data were validated (Google Community Mobility Data) is only available for Google account users with Location History settings activated and thus is also subject to an unknown degree and direction of bias.

Finally, while initially checkpoint travel numbers declined sharply following the emergence of COVID-19 and society's attempts to limit its transmission, later in the pandemic a predictive pattern was evident between a rise in checkpoint travel numbers and subsequent COVID-19 variant surges. A rise in seasonal travel (ie, holidays and summer vacations) appeared to prompt surges in the incidence of emerging COVID-19 variants. The steep drop in checkpoint travel numbers immediately after each COVID-19 surge may have been driven in part by individuals' desire to avoid further transmission, but it is also likely that these are normal seasonal fluctuations after a popular travel period. These data illustrate the extent to which air travel not only reflects but almost certainly contributes to COVID-19 transmission. Therefore, although they may serve as an appropriate proxy for COVID-19 dynamics in the population, checkpoint travel numbers are not a completely independent indicator of this phenomenon.

Conclusions

We recommend using the TSA's checkpoint travel data in longitudinal or time series studies that span the COVID-19 pandemic period. This variable can control for the potential confounding effect of COVID-19 activity in population-based studies of a range of public health topics and within demographic subgroups.

Data Availability

The Transportation Security Administration's checkpoint travel data and Google's COVID-19 Community Mobility Reports are publicly available [1,2]. Investigators seeking access to the self-reported social distancing survey data used in this study should make a written request to Truth Initiative authors and submit a detailed research plan including the purpose of the proposed research, required variables, duration of the analysis phase, institutional review board approval with Federalwide Assurance information, and investigator training in human subjects. A data sharing agreement is required for use of all data. Truth Initiative does not share data with tobacco industry representatives or affiliated researchers. Approved investigators must access data sets via an analytic Portal owned and administered by Truth Initiative.

Conflicts of Interest

None declared.

Abstract

Background: The COVID-19 pandemic severely affected everyday life and working conditions for most Europeans, particularly health care professionals (HCPs). Over the past 3 years, various policies have been implemented in various European countries. Studies have reported on the worsening of mental health, work-related stress, and helpful coping strategies. However, having a closer look is still necessary to gain more information on the psychosocial stressors and unmet needs of HCPs as well as nonmedical staff.

Objective: This study aimed to obtain quantitative information on job-related stressors of physicians and nurses and the coping strategies of HCPs and nonmedical staff at 2 periods of the COVID-19 pandemic. By further analyzing qualitative comments, we wanted to gain more information on the psychosocial stressors and unmet needs of HCPs as well as nonmedical staff on different levels of experience.

Methods: A cross-sectional survey was conducted at 2 time points during the COVID-19 pandemic in several European countries. The first study period (T1) lasted between April 1 and June 20, 2020, and the second study period (T2) lasted between November 25, 2021, and February 28, 2022. On a quantitative level, we used a questionnaire on stressors for physicians and nurses and a questionnaire on coping strategies for HCPs and nonmedical staff. Quantitative data were descriptively analyzed for mean values and differences in stressors and coping strategies. Qualitative data of free-text boxes of HCPs and nonmedical staff were analyzed via thematic analysis to explore the experiences of the individuals.

Results: T1 comprised 609 participants, and T2 comprised 1398 participants. Overall, 296 participants made 438 qualitative comments. The uncertainty about when the pandemic would be controlled (T1: mean 2.28, SD 0.85; T2: mean 2.08, SD 0.90) and the fear of infecting the family (T1: mean 2.26, SD 0.98; T2: mean 2.02, SD 1.02) were the most severe stressors identified by physicians and nurses in both periods. Overall, the use of protective measures (T1: mean 2.66, SD 0.60; T2: mean 2.66, SD 0.60) and acquiring information about COVID-19 (T1: mean 2.29, SD 0.82; T2: mean 1.99, SD 0.89) were identified as the most common coping strategies for the entire study population. Using thematic analysis, we identified 8 themes of personal experiences on the micro, meso, and macro levels. Measures, working conditions, feelings and emotions, and social climate were frequently mentioned topics of the participants. In T1, feelings of isolation and uncertainty were prominent. In T2, feelings of exhaustion were expressed and vaccination was frequently discussed. Moreover, unmet psychosocial needs were identified.

Conclusions: There is a need for improvement in pandemic preparedness. Targeted vocational education measures and setting up of web-based mental health support could be useful to bridge gaps in psychosocial support needs in future crises.

Introduction

Background

The COVID-19 pandemic had a drastic impact on daily life and working conditions in Europe. By mid-March 2020, preventive measures such as physical distancing were implemented across European countries such as France, Italy, Spain, the United Kingdom, and Belgium. In many countries, a shortage of health care resources required reasonable distribution and sustainable use of personal protective equipment (PPE), human resources, and intensive care unit (ICU) beds. Triaging patients with COVID-19 became necessary. The collapse of the health care system proved serious in some countries such as Italy. Spain was more affected than neighboring countries, such as Portugal, which had fewer reported cases in March 2020. Before COVID-19, there were 9.7 ICU beds per 100,000 people in Spain versus 33.9 ICU beds per 100,000 people in Germany [1]. At the beginning of the pandemic, Austria, Germany, and Switzerland were successful in managing the crisis and reported lower mortality rates than Belgium, the United Kingdom, France, Spain, and Italy. Early efforts were made to contain the number of cases, such as the implementation of information websites. In Germany, for example, health care system preparedness was improved by rapidly creating new ICU resources rather than repurposing them, as was the case in Switzerland and Austria. Furthermore, there was a large increase in video consultations in terms of telehealth. However, in some cases, policies in different federal states within the country were not consistent [2].

As virus transmission subsided, eventually, these policies were eased [3]. From June to September 2020, borders were reopened [4] and detailed testing protocols were established for health care professionals (HCPs) [5]. Italy was one of the first countries to mandate vaccinations for HCPs in May 2021. By September 2021, mandatory vaccination protocols for HCPs were adopted by Greece and France [6], followed by Germany [7]. Austria became the first country to implement mandatory vaccinations for all people. Italy and Greece followed the mandatory vaccination for people above a certain age [8]. In some European countries such as Germany, France, and Italy, only completely vaccinated individuals or those who had already been infected with COVID-19 had access to particular public spaces [7]. Emergency measures such as curfews, school closures, and a shift to working from home or job losses are a few examples of the challenges that people had to face. With the introduction of vaccines, the topic of vaccine hesitancy became a focus of attention [9]. As many new policies were introduced during the COVID-19 pandemic, it was not surprising that the general population in Europe was distressed and, in many cases, had mental health problems [10]. On the one hand, a COVID-19 infection directly impacted mental health [11], whereas on the other hand, there was the deterioration of mental health among the general population [12] as an indirect effect of the pandemic, for example, in terms of psychosocial problems. A psychosocial problem can originate in a variety of domains (eg, environmental problems, occupational problems, inadequate social support, educational problems, inadequate access to health and other services, and interpersonal losses), which can have a negative influence on the individual and might cause mental illnesses [13].

The COVID-19 pandemic posed major challenges for health care systems and HCPs worldwide.

For European HCPs, there was an increase in workload [14]. In the nursing profession, staff shortages and increased workloads were already commonplace before the pandemic [15] and, during COVID-19, the burnout of nurses was identified [16]. The negative impact of mental health on HCPs due to COVID-19 has already been proven [17,18], whereby nurses and frontline HCPs were particularly strained psychologically. Nevertheless, in a study by Hummel et al [19], we found significantly lower mean scores for depression and anxiety among HCPs than among nonmedical staff.

As nurses and frontline HCPs (eg, physicians) seem to be the most affected groups during the pandemic, it is worth focusing on these professions regarding work-related stressful events (hereafter referred to as stressors and psychosocial burden). Stress occurs when the demands overwhelm the person [20]. Several stressors of HCPs were identified during the severe acute respiratory syndrome (SARS) outbreak in 2003 [21] and during the COVID-19 pandemic [22]. In 1 study, nurses rated the fear of infection as the most important stressor, followed by death [23]. Coping can be understood as an adaptation that helps the individual deal with challenges that exceed their capacities [20]. Coping strategies are, in our context, to be understood as profession-independent ways of dealing with the strain of the COVID-19 pandemic in general. Taking personal protective measures was a frequently used coping strategy by nurses and physicians along with talking to family and friends or doing relaxation activities in a study on the COVID-19 pandemic by Rose et al [22].

By adding qualitative data, one might gain more insights into the participants' way of thinking than by using only the results of quantitative data. Responses to such questions can differ in length and detail, and the participants have the opportunity to explain themselves in detail. Open-ended survey questions help to supplement the quantitative results by providing additional information [24], which can be helpful in exploring psychosocial factors and unmet needs. According to social work research, individuals can be studied at a macro, meso, and micro level. The micro level describes the level of the individual, the meso level describes the interaction between groups, and the macro level addresses social structures and institutions [25]. Considering the deterioration of HCPs and the nonmedical staff's mental health during the COVID-19 pandemic, assessments are needed with different levels of individual experiences (macro, meso, and micro) to identify existing gaps in psychosocial care.

Objectives

This study aimed to gain quantitative information on work-related stressors of physicians and nurses and the coping strategies of HCPs and nonmedical staff during 2 periods of the COVID-19 pandemic. By further analyzing the qualitative comments, we obtained more information on the psychosocial stressors and unmet needs of HCPs as well as nonmedical staff at different levels of experience.

Methods

Study Design

A cross-sectional web-based survey was conducted at 2 different stages during the COVID-19 pandemic. The first period lasted from April 1 to June 20, 2020, during the first lockdown in Europe [26]. The second phase lasted between November 25, 2021, and February 28, 2022, when the second and third lockdowns ended in Europe [27,28].

Ethics Approval

The study was approved by the ethics committee of the Heidelberg University Medical Faculty (S-361/2020).

Data Collection, Informed Consent, and Participation

Data collection was conducted in compliance with the European General Data Protection Regulation. The survey questionnaire was distributed in 10 European countries, and all health care workers and associated staff at hospitals as well as nonmedical staff were eligible to participate. Consent to participate was included in the web-based questionnaire and obtained without a signature. No allowance was provided for participation in the survey. All the questionnaires were completed anonymously. Data security was granted using the Secure Sockets Layer–encrypted platform, SoSci Survey [29].

Questionnaire

A questionnaire comprising 3 sections on demographics, stress factors, and coping strategies was administered. As no COVID-19–specific questionnaires were available at the beginning of the pandemic, we derived our instrument from a study by Lee et al [21] on SARS. The original 23-item questionnaire focused on work-related stressors for nurses during SARS. Therefore, we modified the questionnaire to include physicians and nurses working in hospitals [19]. For the stress factors section, participants indicated on a Likert scale from 0 (not at all) to 4 (very much) how often they thought about or were concerned about 23 specific stressors in their everyday lives or at clinical work. Only physicians and nurses were eligible to complete this section.

The section on coping strategies was also derived from the study by Lee et al [21]. Participants responded to 12 items on a scale from 0 (almost never) to 3 (almost always) to assess how frequently these 12 coping strategies were applied in their everyday lives. This section was available to all participants, as it did not focus on medical issues. Considering the utility of gaining qualitative data, at the end of the questionnaire, we included an open-ended question with free-text boxes for the participants to leave one or more comments at the end of the survey. To ensure neutral responses within the context of the study objectives, the question was framed as, "If there is anything else you would like to tell us, you can do so here."

Recruitment

The questionnaire was translated by native speakers or professional translators into several European languages, including English, Italian, German, French, Spanish, and Portuguese, to obtain a larger sample population. Accordingly, the questionnaire was also distributed in the respective countries. It was made available on the web via the platform SoSci Survey [29]. The link to the survey was distributed via email to our personal and professional networks using the snowball sampling method. Invitation emails were sent to colleagues at the Heidelberg University Hospital and further distributed to related institutions and to European contacts with their partner organizations, hospitals, and professional associations. Participants were also recruited via personal networks or public social networking groups, such as Twitter, LinkedIn, and Facebook.

Participants

The HCPs included physicians and nurses, as well as a group of *other job in health care* comprising health care psychologists, physiotherapists, other nursing professions, laboratorians, technicians, and occupational therapists. The nonmedical staff was a heterogeneous group, which, for example, consisted of administrators, managers, engineers, teachers, retired persons, or secretaries. However, not all nonmedical participants revealed their actual profession.

Data Analysis

Overview

Quantitative and qualitative data were analyzed independently. In the first study period, the sample comprised 609 participants, of whom 78 submitted 111 qualitative comments. In the second phase, 1398 participants completed the survey, with 218 participants submitting 327 qualitative comments. Overall, 438 qualitative comments were made by 296 participants, of whom 31.4% (n=93) were nurses, 17.2% (n=51) were physicians, and 19.9% (n=59) were nonmedical staff. As the stressors' questionnaire was specific for people working at hospitals, we only analyzed the answers from physicians and nurses for this questionnaire. The coping questionnaire was analyzed for the entire study population. For not fulfilling the inclusion criteria, 69 cases were excluded from the data analysis of the first phase, whereas 41 cases were excluded from the second period. The population demographics and quantitative results for the first study period were published earlier [19].

Quantitative Data

Missing data occurred only for the stressors section during the first study period. Questionnaires with >10% missing data per participant were excluded using a pragmatic and rigor approach following previous recommendations [30]. In total, we analyzed 346 questionnaires for stressors in the first period and 696 in the second period. For coping strategies, 609 questionnaires were analyzed in the first period and 1398 in the second period.

Means and SDs were calculated for all items on stressors for physicians and nurses and coping strategies for all participants. We used Cronbach α to determine the internal consistency of the stressors and coping scales for both study periods. Cronbach α >.80 was considered a threshold for acceptance [31,32]. For the stressors questionnaire, the internal consistency of the first study period was assessed from a Cronbach α of .92 and that of the second study period was assessed from a Cronbach α of .93. For the coping questionnaire, the internal consistency of the first study period was assessed from a Cronbach α of .74 and of the second study period was assessed from a Cronbach α of .72. *t* tests (2-tailed) were conducted for independent groups to compare the mean values of stressors and coping items of the 2 study periods. In all analyses, *P* values <.05 were considered statistically significant. Quantitative data were analyzed using SPSS (version 26; IBM Corp) [33].

Qualitative Data

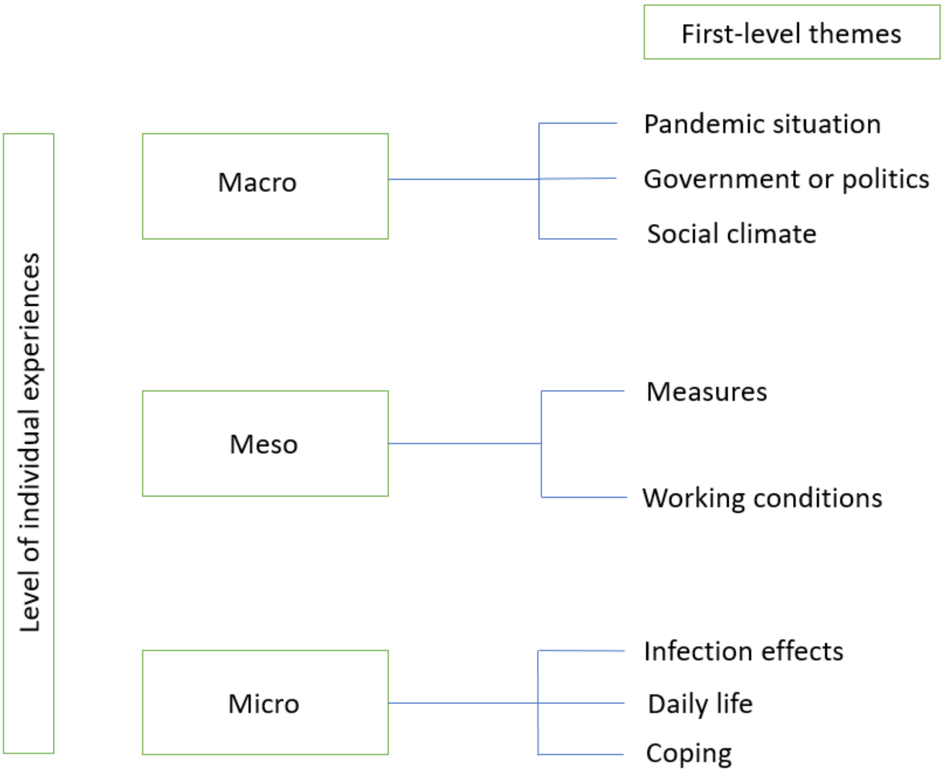
All comments in the free-text comment boxes by HCPs and nonmedical staff were considered for analysis. We provided the demographics of our qualitative data with means and SDs for age, frequencies, and percentages. The length of the comments made by the participants ranged from 3 words (eg, "not enough staff") to >100 words. The comments were translated and analyzed for each study period separately using inductive thematic analysis [34] to identify themes that tell a story about what concerns people beyond quantitative data. We used the 6-step approach developed by Braun and Clarke [35].

Codes and resulting themes were elaborated by 2 authors (SH and IM). After each step, the authors discussed the results to create a common theme map. Second-level and third-level themes were developed when the first-level theme revealed multiple aspects. The key themes identified were located at different levels in relation to the individual based on the levels of experience. Therefore, the themes were divided into *macro*, *meso*, and *micro* levels based on recommendations for social work research [25].

As the *pandemic situation*, *government or politics*, and *social climate* themes described the overarching sociopolitical impacts of COVID-19, these themes were categorized to the macro level. The topics *measures* and *working conditions* could be located at a more individual impact level and were assigned the meso level. The micro level included topics dealing with the individual and included the themes *daily life*, *coping*, and *infection effects* (Figure 1).

The 8 key themes and the most important second- and third-level themes are presented in this paper, with relevant quotes to illustrate the themes. The complete list of themes is available in Multimedia Appendix 1 [36].

Figure 1. First-level themes at their assigned levels of individual experience.



Results

Quantitative Data

Stressors for Physicians and Nurses

For both study periods, *Uncertainty about when the epidemic will be under control* was rated as the most stressful factor, followed by *Worry about inflicting COVID-19 on family*. In the first period, *Worry about nosocomial spread* and *Frequent modification of infection control procedures* were the third and fourth biggest stressors, respectively. In the second period, *Worry about lack of manpower* was the third and *Frequent modification of infection control procedures* was the fourth biggest stressor. The highest significant mean difference ($t_{752.58}$=10.09, *P*<.001) between first and second study period was found for *Worry about nosocomial spread* (first study period: mean 2.04, SD 0.91; second study period: mean 1.41, SD 1.01; mean difference 0.63, 95% CI 0.50-0.75).

Another item with the most significant mean difference ($t_{656.97}$=7.39, *P*<.001) was *Worry about lack of proper knowledge and equipment* (first study period: mean 1.66, SD 1.04; second study period: mean 1.17, SD 1.17; mean difference 0.50, 95% CI 0.36-0.63). The mean values and 2-tailed *t* test results for all the items are presented in Table 1.

Table 1. Stressors for nurses and physicians during COVID-19 for both study periods (first n=346 and second n=696).

Items[a]	First study period		Second study period		*t* test (*df*)	*P* value
	Values, n (%)	Values, mean (SD)	Values, n (%)	Values, mean (SD)		
Uncertainty about when the epidemic will be under control	345 (99.7)[b]	2.28 (0.85)[b]	696 (100)[b]	2.08 (0.90)[b]	3.48 (1039)	.001[c]
Worry about inflicting COVID-19 on family	346 (100)[b]	2.26 (0.98)[b]	696 (100)[b]	2.02 (1.02)[b]	3.60 (1040)	<.001[c]
Worry about nosocomial spread	345 (99.7)[b]	2.04 (0.91)[b]	696 (100)	1.41 (1.01)	10.09 (752.58)	<.001[c]
Frequent modification of infection control procedures	345 (99.7)[b]	2.03 (0.88)[b]	696 (100)[b]	1.73 (0.96)[b]	5.03 (741.61)	<.001[c]
Protective gears cause physical discomfort	345 (99.7)	1.75 (1.02)	696 (100)	1.50 (1.06)	3.57 (1039)	<.001[c]
Deterioration of patients' condition	345 (99.7)	1.70 (1.00)	696 (100)	1.52 (1.04)	2.70 (1039)	.01[c]
Worry about lack of proper knowledge and equipment	346 (100)	1.66 (1.04)	696 (100)	1.17 (0.99)	7.39 (656.97)	<.001[c]
Worry about being negligent and endangering patients	346 (100)	1.66 (1.07)	696 (100)	1.25 (1.04)	6.03 (1040)	<.001[c]
Worry about getting infected	346 (100)	1.62 (1.03)	696 (100)	1.41 (1.00)	3.10 (1040)	.002[c]
Patients' emotional reaction	346 (100)	1.57 (0.96)	696 (100)	1.53 (0.99)	0.61 (1040)	.54
Worry about lack of manpower	346 (100)	1.57 (1.05)	696 (100)[b]	1.97 (1.04)[b]	−5.86 (1040)	<.001[c]
Documentation and reporting procedures unclear	345 (99.7)	1.54 (1.01)	696 (100)	1.26 (1.00)	4.17 (1039)	<.001[c]
Patient families' emotional reaction	345 (99.7)	1.52 (1.01)	696 (100)	1.44 (1.01)	1.26 (1039)	.21
Coworkers being emotionally unstable	346 (100)	1.53 (0.97)	696 (100)	1.59 (1.00)	−0.92 (1040)	.36
Being without properly fitted environment	346 (100)	1.51 (1.08)	696 (100)	1.27 (1.06)	3.47 (1040)	.001[c]
Conflict between duty and safety	346 (100)	1.48 (1.07)	696 (100)	1.30 (1.00)	2.66 (649.35)	.01[c]
Worry about being negligent and endangering coworkers	346 (100)	1.48 (1.04)	696 (100)	0.98 (0.97)	7.44 (652.43)	<.001[c]
Be infected by the colleagues	346 (100)	1.30 (1.01)	696 (100)	1.10 (0.97)	3.08 (662.88)	.002[c]
Protective gears being a drag in providing quality care	346 (100)	1.28 (1.05)	696 (100)	1.15 (1.04)	1.93 (1040)	.05
Coworkers displaying COVID-19–like symptoms	346 (100)	1.25 (0.97)	696 (100)	1.09 (0.96)	2.54 (1040)	.01[c]
Equivocal definition of the responsibility between physicians and nurses	346 (100)	1.19 (1.04)	696 (100)	1.08 (1.02)	1.57 (1040)	.12
Yourself displaying COVID-19-like symptoms	346 (100)	1.12 (1.04)	696 (100)	1.05 (0.98)	1.00 (1040)	.32
Blaming from commanding officers	345 (99.7)	0.70 (0.95)	696 (100)	0.85 (1.04)	−2.38 (1039)	.02[c]

[a] Mean and SD for the question: "When you think about COVID-19 in your life and work, how often did you think or worry about the following things?" (0=not at all and 3=very much).

[b] Frequently used stressor.

[c] *P* value <.05 was considered statistically significant.

Coping Strategies of the Whole Population

Taking protective measures (washing hands, wearing mask, taking own temperature, etc) was the most often used coping strategy, followed by *Actively acquiring more knowledge about COVID-19 (symptoms, transmission pathway, etc)* in both study periods. In the first period, the third most reported coping strategy was *Video-chatting with family and friends by phone to share concerns and support*, whereas in the second period, it was *Engaging in recreational activities (web-based shopping, social media, internet surfing...)*.

The highest significant mean difference ($t_{1218.57}$=11.14, *P*<.001) between the first and second periods was found for *Video-chatting with family and friends by phone to share concerns and support* (first study period: mean 1.85, SD 0.88; second study period: mean 1.36, SD 0.93; mean difference 0.49, 95% CI 0.40-0.57). Another item with a significant mean difference (t_{2005}=7.09, *P*<.001) was *Actively acquiring more knowledge about COVID-19 (symptoms, transmission pathway, etc*; first study period: mean 2.29, SD 0.82; second study period: mean 1.99, SD 0.89; mean difference 0.30, 95% CI 0.22-0.38). The mean values and 2-tailed *t* test results for all the items are presented in Table 2.

Table 2. Coping strategies during COVID-19 for the whole study population of both study periods (first n=609 and second n=1398).

Items[a]	First study period		Second study period		*t* test (*df*)	*P* value
	Values, n (%)	Values, mean (SD)	Values, n (%)	Values, mean (SD)		
Taking protective measures (washing hands, wearing mask, taking own temperature, etc)	609 (100)[b]	2.66 (0.60)[b]	1398 (100)[b]	2.66 (0.60)[b]	0.06 (2005)	.95
Actively acquiring more knowledge about COVID-19 (symptoms, transmission pathway, etc)	609 (100)[b]	2.29 (0.82)[b]	1398 (100)[b]	1.99 (0.89)[b]	7.09 (2005)	<.001[c]
Video-chatting with family and friends by phone to share concerns and support	609 (100)[b]	1.85 (0.88)[b]	1398 (100)	1.36 (0.93)	11.14 (1218.57)	<.001[c]
Engaging in recreational activities (web-based shopping, social media, internet surfing...)	609 (100)	1.67 (0.94)	1398 (100)[b]	1.57 (0.90)[b]	2.18 (2005)	.03[c]
Engaging in health-promoting behaviors (more rest, exercise, balanced diet, etc)	609 (100)	1.63 (0.97)	1398 (100)	1.41 (0.99)	4.57 (2005)	<.001[c]
Switching thoughts and facing the situations with positive attitude	609 (100)	1.58 (0.88)	1398 (100)	1.45 (0.92)	2.93 (2005)	.003[c]
Limiting oneself from watching too much news about COVID-19	609 (100)	1.42 (0.98)	1398 (100)	1.55 (0.99)	−2.71 (2005)	.01[c]
Distracting oneself from thinking about COVID-19 issues by suppression or keeping busy	609 (100)	1.35 (0.94)	1398 (100)	1.28 (0.94)	1.62 (2005)	.11
Acquiring mental health knowledge and information	609 (100)	1.10 (0.97)	1398 (100)	1.13 (0.97)	−0.63 (2005)	.53
Practicing relaxation methods (meditation, yoga, Tai Chi, etc)	609 (100)	0.57 (0.91)	1398 (100)	0.76 (0.97)	−4.04 (1226.25)	<.001[c]
Venting emotions by crying, screaming, smashing things, and so on	609 (100)	0.54 (0.85)	1398 (100)	0.44 (0.76)	2.48 (1065.30)	.01[c]
Using alcohol or drugs	609 (100)	0.35 (0.65)	1398 (100)	0.39 (0.66)	−1.45 (1203.59)	.15

[a] Mean and SD for the question “When you think about COVID-19 in your life and work. How often did you use or try to use the following methods to handle the situation?” (from 1=almost never to 4=almost ever) for all participants in the order of their frequency of use.

[b] Frequently used coping strategy.

[c] *P* value <.05 was considered statistically significant.

Qualitative Results

Study Participants

Table 3 provides the sociodemographic characteristics of the study population for the qualitative analysis of each study period. For the overall population, the age range was 22 to 76 years.

Table 3. Demographic characteristics of the study participants in the first period, second period, and total.

Characteristics	First study period (n=78)	Second study period (n=218)	Total (n=296)
Age (years), mean (SD)	46.12 (12.74)	44.53 (11.09)	45.33 (11.92)

Nonmedical	26 (33.3)	33 (15.1)	59 (19.9)

Themes

From the thematic analysis, 8 key themes emerged, namely *pandemic situation*, *government or politics*, *social climate*, *measures*, *working conditions*, *infection effects*, *daily life*, and *coping*. Among these key themes, 27 second-level themes were identified. For some second-level themes, third-level themes were also identified. A total of 3 themes were assigned to the macro level of experience, 2 referred to the meso level, and 3 referred to the micro level of experience. Most topics were related to the societal impact of the COVID-19 pandemic; one topic addressed the impact of the COVID-19 infection itself on the individual.

Macro Level

Pandemic Situation

Some participants talked about aspects that came along with the pandemic situation in general. One aspect was uncertainty in terms of not knowing how the pandemic would develop. Another point is the feeling of isolation. Comments referring to isolation revolved mostly around social isolation due to social distancing. Many participants voiced criticism of the vaccine itself, for example, on its effectiveness. Other criticisms targeted mandatory vaccinations.

> *I have a feeling of emptiness, seeing my life just floating by and a lot of uncertainty in the future...a*

> *lot of loneliness and a strong feeling of not being able to move on because there is no security in the future.* [Female, aged 57 years, nonmedical staff; clerk, first study period]

Government or Politics

Many participants criticized the management of the pandemic by their governments or politicians. Frequently mentioned issues were the lack of trust in politicians and dissatisfaction with political decisions. On the other hand, there were participants who were satisfied with the governmental crisis management:

> *...Anger at executives for failing to act proactively, particularly over mask distribution and lack of testing. Anger at leaders for conflicting announcements, late, vague pronouncements or actions aimed at getting us back to work at full steam to get the economy back on its feet before the pandemic is quite over.* [Female, aged 69 years, nonmedical staff; legal secretary, first study period]

Social Climate

The participants frequently discussed the social climate. The social climate was indirectly reflected in the comments of many participants, who either directly described it or expressed its effects through comments such as fear, anger, frustration, or annoyance. Many participants talked about a deterioration in emotional well-being unrelated to their working conditions. The unmet needs were mostly discussed during the second study period. Societal split as a social response was directly mentioned by some participants, primarily in relation to the decision to vaccinate. The topic of radicalization was also related to attitudes toward vaccination. Many participants described the phenomenon of questionable information—we call this an "infodemic," according to the World Health Organization (WHO) [36]—within society, for example, through the media.

> *People make me sick!* [Female, aged 33 years, nonmedical staff; administrator, first study period]
>
> *I'm so annoyed and can't hear the word corona anymore.* [Female, aged 57 years, nurse, second study period]

Meso Level

Measures

Measures in general other than vaccination were frequently discussed by the participants. Topics included the implementation of and reaction to the measures. Participants voiced their complaints about side effects, for example, of wearing masks. There were also comments on the impact of the measures on daily life or work regarding their implementation and inconsistencies.

> *Wearing the mask for more than 8 hours a day doesn't exactly help, but we have to live with that for now.* [Female, aged 47 years, other job in health care; clinical pharmaceutical laboratory analyst, second study period]

Working Conditions

Working conditions were a frequently mentioned topic. There were comments on feelings or emotions such as the feeling of pressure, for example, due to high workload and lack of appreciation. Structural changes at work due to the pandemic were mentioned by all profession groups. The HCPs reported on how patient care had changed. Some reported thoughts of quitting their jobs or having already done so. The need for protection and supply was mentioned, for example, in terms of psychological support.

As the *other job in health care* group was very heterogeneous, there were also comments on nursing experiences given by this group. Participants from all professions reported how well or poorly they felt they had been cared for by their employers.

> *The pressure on the nursing staff has increased greatly as a result of the pandemic and there is little support from politicians and employers.* [Male, aged 40 years, nurse, second study period]
>
> *I miss citizen support and acceptance. It cannot be that nursing staff is denied access to grocery stores.* [Female, aged 56 years, nurse, first study period]
>
> *Recognizing of caregivers only at the peak of the pandemic, and then when the pandemic ends, it is over.* [Female, aged 52 years, nurse, second study period]

Micro Level

Infection Effects

The experiences of participants who had a COVID-19 infection or experiences about the infection of acquaintances or relatives also emerged, including the long-term effects of a past infection.

> *To date I have been diagnosed with long COVID. It's been a year now since I was infected. I still have after-effects [loss of taste and smell, shortness of breath, cough, fatigue, joint pain].* [Female, aged 46 years, nurse, second study period]

Daily Life

Many participants wrote about the upcoming challenges in their daily lives due to the COVID-19 pandemic, mentioning caring for children at home, dealing with vaccine opponents in everyday life and reduced social life in general. However, positive aspects, such as an increase in family activities, were also reported.

> *I'm in a privileged situation, have a good family life, a big house with lots of outdoor space...* [Female, aged 52 years, dentist, first study period]

Coping

Some participants reported on how they tried to deal with the pandemic. Specifically, exercising and positive thinking seemed to have helped the participants.

> *In terms of positive feelings, I have been able to adapt by maintaining a healthy lifestyle and exercising at home, taking time to read and after a few weeks appreciating a slower pace of life [before I was very*

> *frantic and out of the house all day], I have not felt any fear of contracting the disease, nor have I become obsessed with the subject [I have followed recommended prevention guidelines].* [Female, aged 34 years, nonmedical staff; occupational therapist, first study period]

First Versus Second Period

Supporting quotes for the 2 periods are available in Multimedia Appendix 2. For the first study period, participants talked about isolation due to social distancing and voiced a lack of support and protection, for example, regarding PPE. The sense of uncertainty and insecurity was evident in many comments, but there were also comments on the advantages of curfews. During the second study period, vaccination and its effect on society were frequently mentioned topics. The implementation and impact of the COVID-19 pandemic measures were also discussed. Working conditions, measures, social climate, and feelings and emotions were mentioned during both the first and second study periods. All second-level and third-level themes that emerged in the data of the first study period could also be found in the second study period, but some of the second-level themes came up only in the second phase, for example, vaccination and splitting and radicalization of the society. In addition, unmet psychological needs mostly emerged during the second study period.

> *I don’t feel adequately protected by the protective clothing that we currently have and I am afraid of the day when we will no longer have any protective clothing.* [Female, nurse, aged 27 years, first study period]
>
> *OP's started again...letting everything go back to normal during this time means more work for the same thing.* [Female, aged 30 years, nurse, second period]

Discussion

Principal Findings

In this study, we investigated work-related stressors for physicians and nurses and the coping strategies of both HCPs and nonmedical staff at 2 different periods during the COVID-19 pandemic. In addition, qualitative data were analyzed to gain more information on psychosocial stress factors and unmet needs at different levels of experience of the population during the COVID-19 pandemic crisis.

On the quantitative scale, the uncertainty about when the pandemic will end and the fear of infecting the family were the worst stressors for physicians and nurses at both periods. The most frequent coping strategies for the entire study population were the use of protective measures and active acquisition of knowledge about COVID-19. Significant mean differences were found for stressors such as *Worry about nosocomial spread* ($t_{752.58}$=10.09, P<.001) and coping strategies such as *Video-chatting with family and friends by phone to share concerns and support* ($t_{1218.57}$=11.14, P<.001).

On the qualitative level, at the beginning of the pandemic, the feeling of insecurity and uncertainty was present, and participants talked about protective equipment and how to handle the social distancing situation. During the second study period, unmet psychosocial needs, exhaustion, and vaccination were frequently mentioned. In the second phase, the topics were more widely spread, as many participants used the free-text fields to “process” their experiences in the previous years.

Overall, these results provide a deeper insight into the perceived problems, burdens, and challenges that our participants faced during the pandemic. By sorting the themes to different levels of experience, the identification of targets for possible necessary psychosocial support was easier. It turned out that the need for psychosocial interventions existed and was even possible to implement at the macro level (eg, more governmental support), at the meso level (eg, working conditions and support of employers), and at the micro level (eg, psychological support).

Changing of Themes Over the Study Periods

Analyzing the themes over 2 study periods, a shift in topics within the population was observed. Social climate, measures, emotions, and working conditions were frequently discussed during both study periods, but there were different focuses in some places. When the pandemic situation was new to the people and protective gear was in short supply [14], the themes of social distancing reflected feelings of isolation and a general feeling of insecurity and uncertainty. In the second stage, the sentiments of exhaustion and annoyance were more prominent. Vaccination, in general, was a frequently discussed topic in the second period, which in some cases can be connected to comments on the increasing splitting and radicalization of society. An earlier longitudinal study on the challenges of the pandemic found a kind of indignation among their participants in the later stages of the study, whereas at the beginning, participants tended to express a sense of tiredness and monotony [37].

Comments from the second study period mentioned the consequences of the pandemic, such as side effects of the measures or their implementation. Apart from vaccinations, unmet needs, such as additional psychosocial support, mostly emerged in the second study period. A possible explanation might be that in the first study period, the whole situation was new and unknown, so people were busier trying to handle the situation rather than thinking about what could be helpful to them.

This shift in topics illustrates the usefulness of studies at different periods when attempting to understand the psychosocial situation of society during the course of a pandemic. People were overwhelmed by the situation and were more concerned with basic care issues at the beginning, whereas psychosocial burdens and needs seemed to emerge later in time.

Work Stressors of HCPs and Working Conditions of All Participants

Uncertainty about control over the pandemic and possible infection of family members was the most relevant stressor on a quantitative level for physicians and nurses during both study periods. For the first period, the third and fourth most relevant stressors were concerns about nosocomial spread and constant change in infection control procedures. The measures and their implementation were also discussed in the qualitative comments, especially in the second study period. Considering how often measures, guidelines, and policies have changed [38-40] during the COVID-19 pandemic following the rising or falling infection rates, this concern is easy to understand. Several federal states within a country with differing policies have made this even more complicated [2]. The stressors *Worry about lack of proper knowledge and equipment* and *Worry about nosocomial spread* seemed to be less important for the participants in the second study period, as in the first study period, PPE was in short supply [14].

Working conditions were frequently mentioned in the comments, emphasizing the importance of this theme to participants. As the *other job in health care* group was very heterogeneous, this group also commented on their nursing experiences. One theme was the lack of appreciation, which was frequently mentioned by nursing people. Appreciation at work was proven to be especially important when there were interruptions at work [41], which might be the case in terms of the COVID-19 pandemic. An increased workload, as well as a lack of support from employers, was reported. Feelings of exhaustion, pressure, and thoughts about quitting the job were mostly reported by HCPs. An increase in workload due to the COVID-19 pandemic for HCPs has already been discussed [14], as well as the decline in mental health [17]. Some participants reported how caring for patients has changed or how work processes, in general, have changed due to the pandemic. In addition, telehealth and telework were discussed as working from home increased, especially during the first period of the pandemic [9]. Working from home can indicate a decrease in mental well-being status [42], and it also seemed to be a challenge for some participants in our study. Another European study reported that there were more people who wanted to work from home from the end of 2020 to the beginning of 2021 [9]. However, at this point, the opinions of our participants differed, as many of them also expressed criticism of telemedicine or teleworking regarding the irreplaceability of personal contacts. Staff shortages and high workloads have been a longstanding problem in nursing [15], and there was even more workload during the pandemic [14], as it was also reflected in our study. The fear of staff shortages was also represented on a quantitative level as the third most frequent stressor in the second study period. This feeling might be aggravated by the high COVID-19 infection rates of HCPs in general [3], which worsened again during the omicron wave at the beginning of 2022 [43]. As nurses have been identified as a vulnerable group regarding mental health during the pandemic [17], our results indicated that this professional group needs to be heard for its unmet psychological support.

Vaccination in general and mandatory vaccinations for HCPs was a huge topic in the second study period. This was associated with feelings of being forced and having limited freedom. Regarding working conditions, the emerging themes in our study represent the areas where better preparedness is necessary, for example, proper support by employers, reliable information, employee protection, for example, in the sense of PPE but also regarding workload and work processes, appreciation, more options to combine family and career, and proper psychological support. A European study on working conditions reported a decrease in mental well-being, a decrease in work-life balance for young parents, an increase in people in a financially fragile situation, tiredness with regard to home schooling, and job losses due to the pandemic [9].

Coping Strategies

When considering the results of the questionnaire on coping strategies, low Cronbach α, which is below the threshold of acceptance, must be considered. The most frequently rated stressors were reflected in the most frequently rated coping strategies. The best coping strategies for the entire study population were to protect themselves and gather more information about the virus. By comparing quantitative data with qualitative comments on coping, the importance of digital offers became clear. The third most often used coping strategy in the first study period was *Video-chatting with family and friends by phone to share concerns and support*, and in the second study period, it was *Engaging in recreational activities (web-based shopping, social media, internet surfing...)*. The use of video-chatting may have decreased during the pandemic, as we found a significant decrease in the mean values of the first and second study periods. One reason for this could be the possibility of returning to personal contact during the pandemic. However, it should be noted that few participants also emphasized the non-substitutability of personal contacts by digital contact. On a qualitative level, some participants shared how they dealt with the pandemic situation, for example, by going out, trying to relax, doing hobbies on the web, doing sports, positive thinking, or being with the family. Gaining information was one of the most often used coping strategy on a quantitative level and not being sufficiently informed was also often voiced by participants on a qualitative level, which might be another important approach. Clear information is important for mental health, especially for HCPs [44]. In this context, vocational and educational training for pandemic preparedness of HCPs might be a helpful approach that has already been initiated by various organizations such as the WHO [45].

Psychosocial Approaches for Future Pandemic Preparedness

Our results emphasize the necessity of an improvement regarding *pandemic preparedness*, which is defined by the WHO as having plans and resources in place to actively respond to a pandemic. It includes, for example, prevention, detection, and containment measures but also plans to respond to any shortages that may arise. Preparing for possible future crises beforehand using the lessons learned from the current pandemic is necessary to face future challenges [46]. In this study, some participants wished for more psychological support. One participant reported that no mental or relaxing therapies were offered at work, whereas another voiced that they were not supported on a psychological level. The stated needs are in line with findings from another study on the psychosocial impact of the COVID-19 pandemic, where the authors argued that support services for future pandemics should be implemented [47].

Previous studies have reported similar needs for HCPs, calling for mental health support services for HCPs in particular [17]. A participant in our study mentioned video- or web-based interventions to help HCPs dealing with stress. The emerging use of e-mental health might be one way to address these psychosocial needs in future crises, as the effectiveness of e-mental health interventions has already been proven [48], and the pandemic has accelerated further advancements [49]. However, it should be noted that few participants also emphasized the non-substitutability of personal contacts by digital contact. Regarding the need for sufficient information, vocational and educational training may be an important approach for future pandemic preparedness. *Infodemic* can have adverse side effects [36] and clear and rapid information for the general population [46] and for HCPs [44], in particular, is important. For future psychometric approaches, attention to the different macro, meso, and micro levels is relevant when collecting psychosocial quantitative data, which might be realized by the combination of qualitative and quantitative approaches.

Limitations

Several limitations of this study should be considered when interpreting these findings. First, as the questions in our study questionnaire focused on the negative aspects or problems of the pandemic and the open-ended question was very unspecific, the open comments at the end of the study may also be biased toward negative statements or inappropriate statements. Second, the link to the web-based survey was distributed via social media and via the personal and professional networks of the authors. As the contact networks in the individual European countries were not equally strong and web-based distribution was difficult to control, the number of participants for each country was different. Despite the large sample size, these results cannot be generalized for Europe as our participants came from only 10 countries out of the 27 European Union countries. Furthermore, only a small subset of the entire population provided qualitative feedback. Third, the different groups within the HCP group of nurses, physicians, and other professionals in health care organizations were somewhat heterogeneous, as well as the group of nonmedical staff, of whom not all revealed their actual profession. We have attempted to explain these groups in as much detail as possible.

Moreover, the study phases did not always occur at the exact time of the lockdowns or peaks in infection rates in individual European countries, which may have influenced the results. At best, there was a partial overlap between respondents in the first and second study periods. The validation of questionnaires on stressors and coping should be part of future studies.

Conclusions

This mixed methods study provides valuable insights into the individual and psychosocial problems faced by European HCPs as well as nonmedical staff over the course of 3 years of the COVID-19 pandemic. Open-ended questions supplemented our quantitative surveys to identify the core problems on different levels of experience of the individuals. Using thematic analysis of qualitative data, we identified 8 major themes of experiences in the pandemic situation: *government or politics*, *social climate*, *measures*, *working conditions*, *infection effects*, *daily life*, and *coping mechanisms*. These different levels of experiences could be assigned to the macro, meso, and micro levels of social structures.

Uncertainty about the end of the pandemic and the fear of infecting family members were identified as the most important stress factors for physicians and nurses. The most commonly used coping strategies of the entire study population were the use of protective measures and acquiring up-to-date information on the COVID-19 pandemic. In the first study period, social distancing, uncertainty, and the need for protection were the topics mentioned. During the second study period, topics such as vaccination, exhaustion, and unmet psychosocial needs emerged. Working conditions were frequently discussed by all participants during both periods. An improvement in pandemic preparedness, with emphasis on vulnerable groups such as HCP in general and nurses in particular, is needed. Several psychosocial approaches should be considered for future research, for example, the development of easily accessible digital psychosocial services and educational and vocational training.

Acknowledgments

The authors thank all the participants of the 2 study periods for their willingness to share their personal views and experiences with them. For the publication fee, the authors acknowledge financial support from Deutsche Forschungsgemeinschaft within the funding program “Open Access Publikationskosten” as well as by Heidelberg University. In addition, the authors are thankful to Mrs Eva Quintero for her support in translation and data organization and Mr Maximilian Selic for his support in data analysis.

Data Availability

The data sets generated during and analyzed during this study are available from the corresponding author upon reasonable request.

Conflicts of Interest

None declared.

Abstract

Background: COVID-19 vaccination is crucial in combating the COVID-19 pandemic. Messenger RNA COVID-19 vaccines were initially authorized as a 2-dose primary series and have been widely used in the United States; completing the 2-dose primary series offers protection against infection, severe illness, and death. Understanding the risk factors for not completing the 2-dose primary series is critical to evaluate COVID-19 vaccination programs and promote completion of the 2-dose primary series.

Objective: This study examined potential risk factors for not completing a 2-dose primary series of mRNA COVID-19 vaccination.

Methods: We conducted a retrospective cohort study among members aged ≥18 years from a large integrated health care system, Kaiser Permanente Southern California, from December 14, 2020, to June 30, 2022. Noncompletion of the 2-dose primary series was defined as not completing the second dose within 6 months after receipt of the first dose. Crude noncompletion rates were estimated overall and by demographic characteristics, health care use patterns, comorbidity, and community-level socioeconomic factors. A Poisson regression model was fit to examine associations of individual-level and community-level risk factors with noncompletion of the 2-dose primary series.

Results: Among 2.5 million recipients of ≥1 dose of mRNA COVID-19 vaccines, 3.3% (n=81,202) did not complete the second dose within 6 months. Members aged 25-44 years, 65-74 years, and ≥75 years were less likely to not complete the 2-dose primary series than those aged 18-24 years, while members aged 45-64 years were more likely to not complete the 2-dose primary series (adjusted risk ratio [aRR] 1.13, 95% CI 1.10-1.15). Male sex was associated with a higher risk of noncompletion (aRR 1.17, 95% CI 1.15-1.19). Hispanic and non-Hispanic Black race/ethnicity were associated with a lower risk of noncompletion (range aRR 0.78-0.91). Having Medicaid and prior influenza vaccination were associated with a higher risk of noncompletion. Having SARS-CoV-2 infection, experiencing an adverse event, or having an inpatient and emergency department visit during the minimum recommended dose intervals were associated with a higher risk of not completing the 2-dose primary series (aRR 1.98, 95% CI 1.85-2.12; 1.99, 95% CI 1.43-2.76; and 1.85, 95% CI 1.77-1.93, respectively). Those who received the first dose after June 30, 2021, were more likely to not complete the 2-dose primary series within 6 months of receipt of the first dose.

Conclusions: Despite limitations such as being a single-site study and the inability to consider social factors such as employment and vaccine attitudes, our study identified several risk factors for not completing a 2-dose primary series of mRNA vaccination, including being male; having Medicaid coverage; and experiencing SARS-CoV-2 infection, adverse events, or inpatient and emergency department visits during the minimum recommended dose intervals. These findings can inform future efforts in developing effective strategies to enhance vaccination coverage and improve the completion rate of necessary doses.

Introduction

The COVID-19 pandemic started in December 2019 and has tragically resulted in millions of deaths worldwide. In combating the pandemic, various mitigation measures have been implemented, including social distancing, wearing masks, promoting hygiene practices, testing, and using therapeutic interventions. Among these measures, vaccination has played a crucial role in our collective efforts to combat and control the impact of the COVID-19 pandemic. Among 4 COVID-19 vaccines (BNT162b2, mRNA-1273, Ad26.COV2.S, and NVX-CoV2373) authorized in the United States since December 2020, the 2 (messenger RNA) mRNA COVID-19 vaccines (BNT162b2, manufactured by Pfizer-BioNTech, and mRNA-1273, manufactured by Moderna) have been the most widely used [1]. These COVID-19 vaccines are effective at preventing infection, hospitalization, and death due to SARS-CoV-2 infection [2-5]. Despite these benefits, a major obstacle to COVID-19 vaccination has been vaccine hesitancy. This hesitancy has been linked to concerns regarding vaccine safety, a lack of knowledge about novel COVID-19 vaccines, demographic factors, limited health care access, attitudes toward COVID-19 vaccines, and use and trust in social media [6-11].

Two mRNA vaccines, BNT162b2 and mRNA-1273, were initially authorized as a 2-dose primary series. Optimal protection depends on completing the initial 2-dose primary series of mRNA vaccines according to recommended dose intervals, as well as receiving booster shots to counteract waning immunity and new variants [5,12-19]. As of December 8, 2022, 89.5% (n=231,012,435) of the US population aged 18 years and older received at least 1 COVID-19 vaccine dose, and 76.8% (n=198,386,322) had completed the primary series [1]. Although the vast majority of those who received an mRNA vaccine dose completed the 2-dose primary series, some did not complete the primary series and thus remained underprotected against severe COVID-19 illness and death.

Understanding the risk factors for not completing a 2-dose primary series is critical to evaluate COVID-19 vaccination programs and to promote completion of the 2-dose primary series. Although some studies examined the completion of multidose series of hepatitis A and B vaccines [20,21] and recombinant herpes zoster vaccine [22,23], studies of risk factors associated with not completing a 2-dose primary series of mRNA COVID-19 vaccines are limited. Nguyen et al [24] found associations of sociodemographic characteristics with each of 3 COVID-19 vaccination categories: receipt of at least 1 dose, receipt of the full primary series, and receipt of a booster dose after the primary series. Although sampling methods and data weighting were designed to produce nationally representative results, the sample size was moderate with 74,995 responses from the Household Pulse Survey from December 29, 2021, to January 10, 2022 [25]. Vaccination status for respondents was self-reported and was subject to social desirability bias.

The goal of this study was to examine potential risk factors for not completing a 2-dose primary series of mRNA COVID-19 vaccination in a large health care system in the United States. We considered a range of risk factors including individual-level demographics, clinical comorbidities, prior health care usage, and community-level socioeconomic characteristics, as well as health care usage, adverse events, and SARS-CoV-2 infection during the minimum recommended interval between doses.

Methods

Sample and Data

We conducted a retrospective cohort study using electronic health records of members aged ≥18 years from a large integrated health care system, Kaiser Permanente Southern California (KPSC). KPSC serves 4.7 million members of diverse sociodemographic, racial, and ethnic backgrounds at 15 medical centers [26]. To evaluate potential risk factors for not completing a 2-dose primary series of mRNA COVID-19 vaccination, we required members to receive their first dose of either mRNA COVID-19 vaccine from December 14, 2020, to December 31, 2021. We also required members to have continuous membership (allowing up to a 31-day gap) from at least 1 year before to 6 months after the first dose. The study outcome was assessed by June 30, 2022.

Ethics Approval

Ethics approval for this study was obtained from the KPSC Institutional Review Board On July 5, 2022 (approval 13270). In accordance with 45CFR 46.116, the need for informed consent was waived by the institutional review board because the research activities (secondary analyses of electronic health records data) presented no more than minimal risk to subjects. To protect the privacy and confidentiality of human subjects, all staff working on the research study were trained in procedures to protect the privacy of medical record information. All research data are stored behind a firewall in a password-protected network within the Department of Research & Evaluation at KPSC. Study participants were not compensated given the observational nature of the study.

Measures of Variables

We assessed the completion rates of 2 mRNA vaccines, BNT162b2 and mRNA-1273. The outcome, noncompletion of the 2-dose primary series, was defined as not completing 2 doses of mRNA vaccination (2 doses of BNT162b2, 2 doses of mRNA-1273 or 1 dose of each) within 6 months after receipt of the first dose. The minimum recommended intervals between dose 1 and dose 2 are 17 days and 24 days (allowing for a 4-day grace period) for BNT162b2 and mRNA-1273, respectively [27,28].

We considered individual-level risk factors including age at receipt of the first dose, sex, race and ethnicity, Medicaid status, health care usage (number of outpatient visits, virtual visits, inpatient visits, and emergency department [ED] visits) within 1 year prior to the first dose date, inpatient or ED visit within 7 days prior to the first dose date (yes or no), Charlson Comorbidity Index within 1 year prior to the first dose date, and receipt of influenza vaccine in the 2 years prior to the first dose date. We also considered community-level risk factors such as neighborhood median household income and neighborhood education level defined as 50% or more than or less than 50% of the neighborhood attaining more than high school education.

Additional individual-level risk factors that were measured during the minimum recommended interval between doses included SARS-CoV-2 infection, encounters with prespecified serious adverse events (AEs), any inpatient or ED visit, and any outpatient visit. SARS-CoV-2 infection was determined by a positive laboratory test for SARS-CoV-2 or a COVID-19 diagnosis. In identifying encounters with serious AEs, 21 types of prespecified AEs were evaluated based on their inclusion as outcomes of interest in COVID-19 vaccine safety studies [29].

In April 2021, COVID-19 vaccinations were expanded from a phased allocation to all eligible adults. To consider the impact of this expansion, we created an indicator for the time of receipt of the first dose of mRNA vaccine before and after June 30, 2021.

Model and Data Analysis Procedure

Characteristics of completers and noncompleters of the 2-dose primary series were described and compared with chi-square test and 2-tailed *t* test for categorical and continuous risk factors, respectively. To examine the association between potential risk factors and not completing the 2-dose primary series, we fit a multiple Poisson regression model with noncompletion of the 2-dose primary series within 6 months after the first dose as the dependent variable and potential risk factors as the independent variables. The specification of the Poisson regression model is as follows:

where μ_i is the expected value of y_i given a set of risk factors; y_i is the outcome for the ith subject, $y_i=1$ for not completing and $y_i=0$ for completing the 2-dose primary series; α is the intercept; X_i is a row vector of individual- and community-level risk factors, and β is a column vector of corresponding coefficients to be estimated. Because we required members to have continuous membership for at least 6 months after the first dose and the outcome was assessed within 6 months after the first dose, the follow-up period was identical across all individuals; therefore, there was no need to adjust for person time as an offset in the Poisson model. Exponentials of coefficients from the Poisson model can be interpreted as risk ratios.

We reported unadjusted risk ratios (RRs), adjusted risk ratios (aRRs), and 95% CIs. All analyses were conducted using SAS Enterprise Guide (version 8.2; SAS Institute).

Results

Among more than 4 million members of KPSC who received their first dose of mRNA COVID-19 vaccine during December 14, 2020, to December 31, 2021, 3.3 million (83.4%) were aged ≥18 years (Figure 1). Among members aged ≥18 years who received ≥1 dose of mRNA COVID-19 vaccine, 2.5 million met the membership requirement, and 3.3% (n=81,202) of them did not complete the 2-dose primary series within 6 months after receipt of the first dose (Table 1). Members who were <65 years old, male, or Hispanic were more likely not to complete the primary series. Noncompletion rates were slightly higher among members in communities with a median household income <US $60,000 and lower education level than those in communities with a higher median household income and higher education level. Noncompleters of a 2-dose primary series of mRNA COVID-19 vaccination were less likely to have had influenza vaccine in the 2 years prior to receipt of dose 1 than completers (n=48,886, 60.2% vs n=1,721,833, 72.5%). Noncompleters were more likely to receive the first dose after June 30, 2021, than completers (n=45,216, 55.7% vs n=255,354, 10.8%).

Among the 2.5 million members in the study cohort, 6641 (0.3%) members had SARS-CoV-2 infection during the minimum recommended dose interval (Table 1), of whom 858 (12.9%) did not complete the primary series in the 6 months after receipt of the first dose, higher than the overall noncompletion rate of 3.3% (n=81,202). Among 446 (0.02%) members who experienced an AE during the minimum recommended dose interval, 36 (8.1%) did not complete the primary series in the 6 months after receipt of the first dose. Among 37,415 (1.5%) members who had an ED or inpatient visit during the minimum recommended dose interval, 2363 (6.3%) did not complete the primary series in the 6 months after receipt of the first dose.

Unadjusted RRs for noncompletion of the 2-dose primary series are displayed in Figure S1 in Multimedia Appendix 1. The multiple Poisson regression showed that after adjusting for other potential risk factors, members aged 25-44 years, 65-74 years, and ≥75 years were more likely to complete the 2-dose primary series than those aged 18-24 years (aRR for noncompletion 0.94, 95% CI 0.92-0.96; aRR 0.90, 95% CI 0.87-0.93; and 0.92, 95% CI 0.88-0.96, respectively), while members aged 45-64 years were more likely to not complete the 2-dose primary series (aRR 1.13, 95% CI 1.10-1.15) (Figure S2 in Multimedia Appendix 1). Male sex was associated with a higher risk of noncompletion (aRR 1.17, 95% CI 1.15-1.19).

Hispanic and non-Hispanic Black race and ethnicities were associated with lower risk of noncompletion (aRR 0.91, 95% CI 0.90-0.93; aRR 0.78, 95% CI 0.76-0.80, respectively), while Asian and Pacific Islander race was associated with a slightly higher risk of noncompletion (aRR 1.07, 95% CI 1.04-1.09). Having Medicaid in 1 year prior to receipt of dose 1, having influenza vaccine in the 2 years prior to receipt of dose 1, and certain health care use patterns (1-4 and 5-9 outpatient visits, ≥2 inpatient visits, and ≥1 ED visits in the year prior to receipt of dose 1) were associated with a higher risk of noncompletion.

Members with SARS-CoV-2 infection during the minimum recommended dose interval were more likely to be noncompleters (aRR 1.98, 95% CI 1.85-2.12) (Figure S2 in Multimedia Appendix 1). Experiencing an AE during the minimum recommended dose interval was also associated with not completing the primary series (aRR 1.99, 95% CI 1.43-2.76). In addition, members with an inpatient or ED visit during the minimum recommended dose interval were more likely to be noncompleters (aRR 1.85, 95% CI 1.77-1.93), but having an outpatient visit during the minimum recommended dose interval significantly decreased the risk of not completing the primary series (aRR 0.53, 95% CI 0.52-0.53). Receipt of the first dose after June 30, 2021, was associated with a higher risk of not completing the primary series (aRR 9.78, 95% CI 9.63-9.93).

Discussion

Principal Findings

Acting in synergy with community pharmacy services and local government mass vaccination efforts, the KPSC health care system was very successful in promoting COVID-19 vaccination and completion of the 2-dose primary series. During the pandemic, KPSC implemented a community-oriented and geographically targeted vaccine strategy aimed at identifying specific zip codes that required additional resources. This proactive approach proved helpful in enhancing COVID-19 vaccination coverage and effectively addressing the disparities in vaccine uptake within underserved communities [30]. Several other aspects should also be considered in designing effective public policy to address future pandemic crises such as Peltzman effects in vaccinations, the emergence of new variants of concern, investment in health care, and the impact of environmental pollution and climate factors [31].

This study showed some impact of sociodemographic characteristics on the completion of a 2-dose primary series of mRNA COVID-19 vaccination in KPSC. For example, after adjusting for other risk factors, the characteristics of being aged ≥65 years, female, and Black or Hispanic, as well as living in a neighborhood with a lower education level, were associated with a lower risk of not completing the 2-dose primary series within 6 months of receipt of the first dose. Members who had ≥2 ED visits in the year prior to receipt of dose 1 were less likely to complete the primary series (aRR for noncompletion 1.23, 95% CI 1.16-1.30). Having SARS-CoV-2 infection, experiencing an AE, or having an inpatient or ED visit during the minimum recommended dose intervals were associated with a higher risk of not completing the 2-dose primary series (aRR 1.98, 95% CI 1.85-2.12; 1.99, 95% CI 1.43-2.76; and 1.85, 95% CI 1.77-1.93, respectively). Those who received the first dose before June 30, 2021, were more likely to complete the 2-dose primary series within 6 months of receipt of the first dose.

In this study, male sex was associated with a higher risk of not completing the 2-dose primary series, while a study by Nguyen et al [24] did not find an association between sex and noncompletion. Although the association of age with noncompletion of the 2-dose primary series in unadjusted analyses (Figure S1 in Multimedia Appendix 1) was largely consistent with those of Nguyen et al [24], the strength of association attenuated after adjusting for other risk factors, from unadjusted RRs of 0.37-0.80 to aRRs of 0.90-1.13. Our finding of lower risk of not completing the 2-dose primary series among

Black and Hispanic race and ethnicity was consistent with the study by Nguyen et al [24]; for Asian race and ethnicity, our study found a weak association with not completing the 2-dose primary series (aRR 1.07, 95% CI 1.04-1.09), while Nguyen et al [24] found that Asian race/ethnicity was strongly associated with completion of the 2-dose primary series. Those with lower household income had unadjusted RR ≥1 of not completing the 2-dose primary series (Figure S1 in Multimedia Appendix 1), which is similar to Nguyen et al [24]; however, after adjusting for other risk factors, the association became null. The 2 studies differed in several aspects including the study population (insured vs a general population), study design (retrospective cohort study using electronic health records vs survey study), and risk factors considered. These differences may have contributed to the different findings. In comparison to mRNA COVID-19 vaccination, completion rates for hepatitis A and B vaccinations were observed to be lower, ranging from 40% to 65% across a broad age range [20]. Notably, individuals with Medicaid coverage were found to be associated with a lower completion rate for both the 2-dose primary series of mRNA COVID-19 vaccination in our study and the multidose vaccinations of hepatitis A (2 doses) and B (3 doses) in the study by Nelson et al [20].

With more than 12 months of first-dose data from a large health care organization, this study examined a broad range of potential risk factors including individual- and community-level sociodemographic characteristics, Medicaid status, comorbidities, health care usage, and medical encounters during minimum recommended dose intervals. In a study examining potential factors associated with completing 2 doses of recombinant zoster vaccine among individuals aged ≥50 years, local and systemic reactions after receipt of the first dose were examined in addition to sociodemographic characteristics and health care usage; however, medical encounters with serious AEs were not examined [23]. A unique strength of our study is that we examined the association between medical encounters with serious AEs during minimum recommended dose intervals and noncompletion of the mRNA COVID-19 vaccine 2-dose primary series. Only 87.1% (n=5783) of those who had SARS-CoV-2 infection during the minimum recommended dose intervals completed the primary series, which is significantly lower than the overall completion rate of 96.7% (n=2,375,538). The noncompleters might have felt that it was not necessary to get the second dose because of natural immunity gained from infection. Only 8.1% (n=36) of those who experienced an AE during the minimum recommended dose intervals did not complete the primary series.

There are some limitations in this study. First, the study population is an insured population from a large health care system. The completion rate of the 2-dose primary series among KPSC members aged 18 years and older is 96.7% (n=2,375,538). In contrast, the national completion rate for the primary series, which includes individuals from various health care providers and uninsured individuals, is notably lower at 76.8% (n=198,386,322). The findings in this study may not be generalizable to other health care systems and uninsured populations. Second, data on other risk factors such as members' employment were not available. Mandatory completion of a 2-dose primary series for employment would decrease the likelihood of noncompletion. Third, we did not consider the requirement of 3 doses for the primary series among immunocompromised individuals [27]. Finally, while we included SARS-CoV-2 infection during the minimum recommended dose intervals as a risk factor for completing the second dose, the impact of SARS-CoV-2 infection prior to receipt of the first dose was not considered.

Conclusions

To adequately prepare for the pandemic, it is crucial to attain a sufficient level of vaccination coverage, contributing to herd immunity. This will effectively halt the spread of potential virus, thereby protecting people against severe illness and death [32]. Despite limitations such as a study of a single site of an insured population and inability to consider social factors such as employment and attitude to vaccination, our study identified several risk factors for not completing a 2-dose primary series of mRNA vaccination. These factors include being male; having Medicaid coverage; and experiencing SARS-CoV-2 infection, AEs, or inpatient and ED visits during the minimum recommended dose intervals. These findings can inform future efforts in developing effective strategies to enhance vaccination coverage and improve the completion rate of necessary doses.

Acknowledgments

Funding for this study was provided by the National Institute of Allergy and Infectious Diseases of the National Institutes of Health under Award Number R01 AI168209. The findings and conclusions in this report are those of the authors and do not necessarily represent the official views of the National Institutes of Health.

Data Availability

Individual-level data reported in this study involving human research participants are not publicly shared due to potentially identifying or sensitive patient information. Upon request to the corresponding author, and subject to review and approval of an analysis proposal, KPSC may provide the deidentified aggregate-level data that support the findings of this study within 6 months. Anonymized data (deidentified data including participant data as applicable) that support the findings of this study may be made available from the investigative team in the following conditions: (1) agreement to collaborate with the study team on all publications, (2) provision of external funding for administrative and investigator time necessary for this collaboration, (3) demonstration that the external investigative team is qualified and has documented evidence of training for human subjects protections, and (4) agreement to abide by the terms outlined in data use agreements between institutions.

Conflicts of Interest

LSS reports research support from Moderna, GlaxoSmithKline, and Dynavax for unrelated studies. LQ received research support from Moderna for a COVID-19 vaccine effectiveness study and GlaxoSmithKline and Dynavax for unrelated studies. VH reports research funding from Pfizer sent directly to their institution and unrelated to this study. KJB reports research funding from Dynavax, GlaxoSmithKline, Moderna, and Pfizer unrelated to this study. All other authors declare no conflicts.

Abstract

Background: COVID-19 mitigation behaviors, such as wearing masks, maintaining social distancing, and practicing hand hygiene, have been and will remain vital to slowing the pandemic.

Objective: This study aims to describe the period prevalence of consistent mask-wearing, social distancing, and hand hygiene practices during the peak of COVID-19 incidence (August-December 2020) and just before COVID-19 vaccine availability, overall and in demographic subgroups.

Methods: We used baseline survey data from a nationwide household probability sample to generate weighted estimates of mitigation behaviors: wearing masks, maintaining social distancing, and practicing hand hygiene. Weighted logistic regression explored differences in mitigation behaviors by demographics. Latent class analysis (LCA) identified patterns in mitigation behaviors.

Results: Among 4654 participants, most (n=2727, 58.6%) were female, were non-Hispanic White (n=3063, 65.8%), were aged 55 years or older (n=2099, 45.1%), lived in the South (n=2275, 48.9%), lived in metropolitan areas (n=4186, 89.9%), had at least a bachelor's degree (n=2547, 54.7%), had an income of US $50,000-$99,000 (n=1445, 31%), and were privately insured (n=2734, 58.7%). The period prevalence of consistent mask wearing was 71.1% (sample-weighted 95% CI 68.8-73.3); consistent social distancing, 42.9% (95% CI 40.5-45.3); frequent handwashing, 55.0% (95% CI 52.3-57.7); and frequent hand sanitizing, 21.5% (95% CI 19.4-23.8). Mitigation behaviors were more prevalent among women, older persons, Black or Hispanic persons, those who were not college graduates, and service-oriented workers. LCA identified an optimal-mitigation class that consistently practiced all behaviors (n=2656, 67% of US adults), a low-mitigation class that inconsistently practiced all behaviors (n=771, 20.6%), and a class that had optimal masking and social distancing but a high frequency of hand hygiene (n=463, 12.4%).

Conclusions: Despite a high prevalence of COVID-19 mitigation behaviors, there were likely millions who did not consistently practice these behaviors during the time of the highest COVID-19 incidence. In future infectious disease outbreak responses, public health authorities should also consider addressing disparities in mitigation practices through more targeted prevention messaging.

Introduction

The COVID-19 pandemic was first documented in China in December 2019, with cases identified in the United States shortly afterward [1,2]. As of December 2020, there were more than 20 million COVID-19 cases and more than 360,000 COVID-19–related deaths in the United States [3]. Because the vaccine did not become available to select groups until late December 2020, the primary means of preventing COVID-19 infection during the first year of the pandemic included the consistent use of mitigation behaviors of mask wearing, social distancing, and hand hygiene [4].

Multiple published studies have explored the prevalence of mitigation behaviors among US adults during the first year of the pandemic, but many of these are convenience samples or from limited geographic areas. Those that explored mask usage in public settings have reported a highly variable prevalence (40%-90%) of usage by the type of public setting for mask wearing and the timing of local mask mandates [5-10]. Social distancing, which can encompass limiting exposure to persons outside of one’s household and keeping at least 6 feet apart from others when outside the home, has been reported by a few previous studies, and estimates have also been prone to variation (70%-87%) due to rapidly changing local mandates for limiting travel and closure of public venues [11,12]. Recommended hand hygiene practices, such as frequent handwashing or the use of alcohol-based hand sanitizers, have been infrequently reported by studies of the general population but have more consistently shown high variation (74%-93%) [13-15].

The COVID Impact Survey is one of the most comprehensive and well-published studies of mitigation behaviors using cross-sectional samples and emailed surveys at multiple time points [12]. The study found that mask usage grew significantly from 78% in April 2020 to 89% in June 2020. The authors also found reductions in attending public venues, and >80% of participants reported keeping at least 6 feet apart from others, although there was a decreasing trend in these behaviors between April and July 2020, likely associated with the easing of local travel restrictions and business closures. Finally, the authors found that the proportion of US adults who frequently washed or sanitized hands was the highest (90%) in April 2020 but declined through July 2020 [12].

Just as there has been substantial heterogeneity in COVID-19 cases, morbidity, and mortality among US adults from various demographic backgrounds [16-19], there have also been some reported differences in the uptake of mitigation practices during the COVID-19 pandemic. Mask wearing may be more prevalent among women, non-White persons, and those who do not live in rural areas [5,9]. Handwashing may also be more prevalent among women, older adults, and those who identify as Black or Hispanic/Latinx [15]. Evidence from ecological analyses of mobility data found that social distancing was higher in counties with lower levels of poverty, a larger proportion of Black residents, and a higher population density [20].

Despite these high-quality studies of COVID-19 mitigation practices, there remain substantial gaps in our knowledge. Currently published estimates of the prevalence of mitigation practices were from before the peak of COVID-19 incidence, and few were from probability-based samples of the general US population. Having minimally biased information at multiple time points during the pandemic is critical to understanding the ongoing needs for public health communications regarding these mitigation practices. Having additional reliable estimates from later time points during the pandemic are also useful parameters for COVID-19 modeling activities.

We collected and analyzed baseline assessment data of a prospective cohort of a representative household-based sample of US adults. The main objective of this study was to describe the period prevalence of consistent mask-wearing, social distancing, and hand hygiene practices during the peak of COVID-19 incidence (August-December 2020) and just before COVID-19 vaccine availability, overall and in demographic subgroups. We also explored whether people engage in mitigation practices as a set of activities or as individual unconnected behaviors.

Methods

Participants and Procedures

COVIDVu is a prospective observational cohort study with a nationwide household probability sample of US adults using sampling methods that have been previously described [21]. A total of 39,500 US households were sampled using addresses derived from the US Postal Service Computerized Delivery Sequence File, including oversampling of households with census tracts comprising >50% Black residents and households with surnames likely to represent Hispanic ethnicity. The sampled households also include oversamples in California (16.5%) and Georgia (30.4%) to allow state-level estimation. All sampled households were shipped a study kit each. One adult resident enumerated the number of household members and each person’s age. One enumerated household member aged ≥18 years was randomly selected and offered participation in the study. Consenting participants were asked to complete an online survey, self-collect an anterior nares swab and a dried blood spot card, and return the specimens to a central laboratory via a prepaid mailer. Participants who returned the specimens were compensated at least US $40. Using procedures previously described for this study, sample and design weights were applied to estimate unbiased measures for noninstitutionalized, housed US adults in 2020 [21].

Ethical Considerations

Informed consent was obtained from each participant in the study. The study was conducted in compliance with federal regulations governing protection of human subjects and was reviewed and approved by Emory University's Institutional Review Board (protocol 00000695).

Measures

The following primary dependent measures were used in this study: mask wearing, social distancing, handwashing, and hand sanitizer use. Mask wearing was defined by the question "When you go out, do you wear a face mask?" with response options of always, often, sometimes, rarely, and never. Social distancing was defined by the question "How often are you trying to keep at least 6 feet between you and other people you don't live with to avoid spreading illness?" with response options of always, often, sometimes, rarely, and never. Those who reported always wearing masks or maintaining social distancing were defined as consistently practicing these behaviors. Handwashing was defined by the question "In the past 24 hours, about how many times did you wash your hands with soap and water?" Hand sanitizer use was defined by the question "In the past 24 hours, about how many times did you use an alcohol-based hand sanitizer spray, gel, or wipes?" Based on a prior study examining handwashing effectiveness at preventing seasonal coronavirus [22], we categorized handwashing and hand sanitizer use as 0-5 times per day (the prior study referent group), 6-10 times per day (the prior study effective intervention group), and ≥11 times per day (the prior study intervention group that was not effective). For dichotomous analyses, those in the categories of 6-10 and ≥11 times per day were defined as frequently practicing hand hygiene.

Independent analysis measures included standard demographic characteristics of gender, race/ethnicity, age group, US Census region, ZIP code–based urbanicity, highest education, annual household income, and current health insurance. For those working, the job type was collected using 2018 US Bureau of Labor Statistics major job categories [23]. Some types of jobs, such as food service, education, health care, retail, and transportation services, may have had additional recommendations about mask wearing and hand hygiene [24]. These job types were differentiated from others in the analyses. For those who leave home for work, we assessed whether their jobs were completely indoors or outdoors/mix/other.

Analyses

We developed sample weights to represent noninstitutionalized, housed adults (aged ≥18 years, US population). In brief, hierarchical hot deck imputation was performed to ensure no participants were missing data for key variables needed for weighting, such as gender, education, race, ethnicity, and marital status; each had <3% missingness [25]. Design weights, adjusted with classification and regression tree (CART) analysis for a differential nonresponse, were developed to facilitate population inference. A raking procedure aligned weighted distributions to the observed distributions from the Census along the lines including age, race-ethnicity, education, and income [26]. To address outlier weights, those at the 99th percentile of each distribution side were trimmed.

Using the sampling weights, we estimated the weighted prevalence and 95% modified Wilson score confidence limits for (1) consistent mask wearing, (2) social distancing, (3) handwashing, and (4) hand sanitizer use. Prevalence estimates were descriptively summarized by sociodemographic factors (race, sex, age, region, urbanicity, highest level of education, annual income, health insurance, job type), personal behaviors (leaving home for work), knowledge of mitigation behaviors, and month of sampling. To identify significant differences in the prevalence of mitigation behaviors by sociodemographic factors, prevalence ratios (PRs) and corresponding 95% CIs were estimated using weighted logistic regression procedures. All prevalence analyses were performed using SAS v9.4 (SAS Institute) and SUDAAN (RTI International).

People may follow all public health recommendations for mitigation practices similarly, or there may be individual variations in mitigation practices. This information may be useful for understanding how different groups respond to multicomponent prevention messages. We therefore conducted latent class analysis (LCA) with polytomous outcomes variables to classify participants based on their responses to the 4 primary dependent measures (mask wearing, social distancing, handwashing, and hand sanitizer use). Each measure was included as a single item. Considering we did not know the number of classes represented by these data, we fit several models with a different number (1-6) of classes. All models were fit using the *polCA* package in R v4.1.0 (R Foundation for Statistical Computing), which uses maximum likelihood parameter estimation with robust SEs. Each model was estimated with 30 different sets of starting values and allowed a maximum of 3000 iterations for convergence. To select the final model, we compared fit statistics (ie, Bayesian information criteria [BIC], Akaike information criteria [AIC], adjusted BIC) and accuracy statistics (eg, entropy) [27]. Each participant was classified into a latent class (ie, mitigation) group by the largest posterior probability for belonging to each class indicated by the final model. We estimated the weighted prevalence of each latent class group in the entire sample and by sociodemographic characteristics. Finally, as a minimal internal validity check, we examined whether class membership was associated with answering the following statements with "true": "Consistently wearing a face mask will provide me with 95% or better protection from getting infected with the new coronavirus" and "It is not necessary for children and young adults to take measures to prevent infection by the COVID-19 virus." PRs and corresponding 95% CIs were estimated using weighted logistic regression procedures in SUDAAN to identify any differences by sociodemographic characteristics.

Results

Participants

A total of 4654 participants completed baseline enrollment procedures and were included in this study (Table 1). These participants represented 242,875,582 US adults in 2020. Most were female, were non-Hispanic White, aged 55 years or older, lived in the South, lived in metropolitan areas, had at least a bachelor's degree, had an income of US $50,000-$99,000, and were privately insured. The highest monthly enrollment occurred in November 2020. Among the available response options in this study for job types, most respondents worked in health care and social services; however, most had other job types not available for selection in the study. Most of those whose jobs required leaving home worked completely indoors.

Table 1. Prevalence of consistent mask wearing among a household probability sample of 4654 US adults (August-December 2020).

Characteristics	Unweighted	Weighted

Mask Wearing

The estimated national period prevalence of consistently wearing a mask from August through December 2020 was 71.1% (95% CI 68.8-73.3; Table 1). Consistent mask wearing was significantly more prevalent among those who were female; were Hispanic or non-Hispanic Black; lived in a metropolitan area; had a graduate degree, were insured through Medicare, Medicaid, or other public health insurance; worked in educational services; or worked completely indoors (among those who were working from somewhere other than at home). Consistent mask wearing was significantly less prevalent among those who were less than 65 years old, lived in the Midwest (compared to the West), and worked in transportation or warehouse services.

Social Distancing

The estimated national prevalence of consistently practicing social distancing was 42.9% (95% CI 40.5-45.3; Table 2). Consistent social distancing was significantly more prevalent among those who were female, were Hispanic or non-Hispanic Black, lived in the South (compared to the West), had a graduate degree or some college education, or had an annual income of less than US $25,000. Consistent social distancing was significantly less prevalent among those aged 18-34 years (compared to ≥65 years) or lived in the Midwest (compared to the West).

Table 2. Prevalence of consistent social distancing among a household probability sample of 4654 US adults (August-December 2020).

Handwashing

Among the 4090 participants who were administered the hand hygiene questions, the average number of times the participants washed hands in the past 24 hours was 8.8 (SE 0.3). The estimated national prevalence of individuals frequently washing hands was 55.0% (95% CI 52.3-57.7; Table 3). Frequent handwashing was significantly more prevalent among those who were female, were Hispanic or non-Hispanic Black, were aged 35-54 years (compared to ≥65 years), were enrolled in November 2020 (compared to August 2020), or worked in health care and social assistance services.

Hand Sanitizer Use

Among the 4090 participants who were administered the hand hygiene questions, the average number of times the participants used a hand sanitizer in the past 24 hours was 4.99 (SE 0.2). The estimated national prevalence of frequently using a hand sanitizer was 21.5% (95% CI 19.4-23.8; Table 4). Frequent use of a hand sanitizer was significantly more prevalent among those who were female, Hispanic or non-Hispanic Black, less than 65 years of age, lived in the South (compared to the West), had an annual income of less than US $25,000, were enrolled in September or November 2020 (compared to August 2020), or worked in accommodation, food services, health care, social assistance, retail trade, or transportation/warehouse services. Frequent use of a hand sanitizer was significantly less prevalent among those who had an annual income of US $100,000-$199,000 or were insured through Medicare, Medicaid, or other public health insurance (compared to those uninsured).

Table 4. Prevalence of frequent hand sanitizer use among a household probability sample of 4090 US adults (August-December 2020).

Mitigation Classifications

The final classification model identified 3 latent classes: (1) optimal mitigation, (2) optimal mitigation with additional hand hygiene, and (3) lowest mitigation. Optimal mitigation was consistent mask wearing, consistent social distancing, and handwashing or hand sanitizer use 6-10 times per day. Optimal mitigation with additional hand hygiene was consistent mask wearing, consistent social distancing, and handwashing or hand sanitizer use >11 times per day. The lowest mitigation was inconsistent mask wearing, inconsistent social distancing, and handwashing or hand sanitizer use 0-5 times per day. There were no classes that had suboptimal use of only some mitigation strategies but optimal use of others. All participants were categorized into these classes. Two-thirds (n=2656, 67%) practiced optimal mitigation by consistently wearing a mask, consistently following social distancing, and frequently washing their hands or using a hand sanitizer (Tables 5-7). Furthermore, 1 in 5 (n=771, 20.6%) practiced the lowest mitigation by inconsistently or infrequently engaging in all mitigation practices. The final class made up the remainder (n=463, 12.4%) who consistently wore masks and maintained social distance but had the highest frequency of handwashing or sanitizer use (>11 times per day). Compared to optimal mitigation practices, the likelihood of being in the lowest-mitigation class was significantly greater among those who were male, less than 65 years of age, lived in the Midwest (compared to the West), lived outside a metropolitan area, had no health insurance (compared to Medicare, Medicaid, or other public insurance), worked in transportation or warehouse services, or worked somewhere other than completely indoors (Table 8). Compared to just the optimal-mitigation class, the likelihood of being in the class with optimal mask wearing and social distancing but with additional handwashing or sanitizer use was significantly greater among those who were Hispanic or non-Hispanic Black, were less than 65 years of age, had less than a bachelor’s degree, or worked in any of the selected job types (compared to other jobs).

Compared to the optimal-mitigation class, those in the lowest-mitigation class were 20% less likely (PR 0.80, CI 0.79-0.90) to agree that masks provide 95% or better protection against COVID-19 and were twice as likely (PR 2.00, CI 1.27-3.15) to state that it was not necessary for youth to take measures to prevent COVID-19 infection (Table 8). There were no significant differences between the optimal-mitigation class and the class with additional hand hygiene for both the mask-wearing (PR 0.93, CI 0.82-1.06) and youth prevention (PR 1.70, CI 0.92-3.16) questions.

Table 5. “Optimal mitigation” latent class of combined strategies to prevent COVID-19 among a household probability sample of 4090 US adults (August-December 2020).

[g] Among those who were employed and left home for work.

Discussion

Principal Findings

We report the first national probability survey estimates of the prevalence of COVID-19 mitigation strategies among US adults. During the 2020 peak of COVID-19 incidence, nearly three-quarters of adults consistently wore a mask when going out, about half consistently practiced social distancing or frequently washed their hands, and about a quarter frequently used a hand sanitizer. There were 3 distinct patterns of use of these mitigation practices. Two-thirds practiced optimal mitigation, with consistent and frequent use of all mitigation strategies; about 1 in 5 practiced the poorest mitigation practices, with inconsistent or infrequent use of all mitigation strategies; and about 1 in 9 consistently wore a mask and practiced social distancing and may have followed excessive hand hygiene practices. Finally, all mitigation practices and grouping of practices varied substantially among people with different demographic characteristics.

The prevalence of consistently wearing a mask in our population-based study was similar to earlier estimates from polls and convenience samples [5,9,10], but the estimate from our population-based sample was substantially lower than the 89% reported by the online convenience sampling–based COVID Impact Survey in June 2020 [12]. The difference in prevalence could be due to selection bias in the convenience sampling–based COVID Impact Survey if those who were more likely to wear masks were also more likely to respond to the survey. Our survey items were also slightly different, with our survey stipulating mask wearing when going out and asking about the frequency of mask usage, whereas the COVID Impact Survey asked a general question about mask wearing, without regard to context or frequency. It is also possible that mask wearing decreased between June and August 2020 (the beginning of our study), as public facilities reopened and mask requirements in each jurisdiction became more complex and possibly confusing.

There was a similar discrepancy between our findings and those of the COVID Impact Survey for practicing social distancing and washing hands, but for these practices, our estimates were even lower than those of the COVID Impact Survey, which reported >80% prevalence for both [12]. Although the COVID Impact Survey reported a slightly decreased prevalence of social distancing and hand hygiene in June compared to April 2020, a simple extrapolation of that decreasing trend would not explain the difference we found later in 2020. Similar selection biases and differences in survey items for these practices could explain part, but not all, of the difference between the findings of our study and the COVID Impact Survey. ConsumerStyles panel surveys that examined handwashing practices in October 2019 and June 2020 in specific contexts (eg, before eating, after sneezing, or after coughing) also found a substantially higher prevalence of handwashing than we did, providing further evidence that the survey question type (eg, making the questions conditional on situations in which handwashing is recommended even outside of COVID-19 times) can substantially affect prevalence estimates. We structured our questions based on the only published study on the effectiveness of hand hygiene for preventing seasonal coronavirus infection [22]. As we would expect during the COVID-19 pandemic with frequent communications about the importance of hand hygiene, our prevalence estimate of 57.7% who washed their hands 6-10 times in the past 24 hours was substantially higher than the 39.5% reported in the UK study conducted between 2006 and 2009. The prevalence of use of a hand sanitizer in our study was also substantially lower (21.5% vs 70.7%) compared to only 1 other previous paper, by Czeisler et al [14], that reported this as a separate behavior from handwashing. This difference in prevalence was likely due to context-specific differences in behaviors, where Czeisler et al [14] assessed hand sanitizer usage only after contact with high-touch public surfaces.

The distinct sets of mitigation practices (optimal mitigation, lowest mitigation, and optimal mitigation with additional hand hygiene) were also novel findings of our study. Those in the optimal-mitigation and optimal-mitigation-with-additional-hand-hygiene groups frequently wear masks and practice social distancing when they go out in public. Although there was a clear distinction between these groups based on the frequency of handwashing predetermined based on Beale et al’s [22] effectiveness study, there were no differences between these groups in their agreement with the mask-wearing and youth prevention questions. Our findings did indicate that the optimal-mitigation and optimal-mitigation-with-additional-hand-hygiene groups differed on multiple demographic characteristics, which supports the idea that these groups may have fundamental differences in their approaches toward COVID-19 prevention. Further study on the context of hand hygiene practices may clarify some of these issues, and we are now implementing a context-specific set of mitigation practice questions in our 3- and 6-month follow-up surveys with this cohort. The lowest-mitigation group, which was inconsistent in all mitigation practices, comprised an unfortunately large proportion of 1 in 5 US adults. The demographic differences between the optimal- and lowest-mitigation groups were even more pronounced, emphasizing the demographic disparities in COVID-19 mitigation practices.

This heterogeneity in COVID-19 mitigation practices among demographic groups in our study has also been partly reported in other published papers for individual practices [5,9,12,15,20], and those prior published findings are reasonably consistent with the demographic heterogeneity we found. Our study goes a step further to illustrate how persons from various backgrounds combine the individual mitigation recommendations in practice. The demographic heterogeneity in these empirically determined grouping of mitigation practices is even more evident than in individual practices. Compared to men and younger adults, women and older adults are much more likely to optimally use all mitigation practices. These differences in patterns of use may reflect greater risk perception, more exposure to COVID-19 prevention messages, or other contextual factors, such as leaving the home or living in group settings. US adults who were Black or Hispanic (compared to White, non-Hispanic), had no college degree, or worked in service-oriented jobs were more likely to report excessive hand hygiene, while also consistently wearing a mask and maintaining social distancing. These differences might also reflect greater risk perception and prevention message exposure but are more likely due to other contextual factors, such as hand hygiene requirements of their jobs. Finally, US adults who live outside metropolitan areas were likely to engage in all mitigation practices inconsistently. This might be due to differing risk perceptions or exposure to prevention messages in less densely populated areas [28].

Limitations

This study has several limitations. First, there was a lack of contextual information for some mitigation practices that could better clarify whether people are engaging in practices in only some settings or situations but not in others. These situational assessments have been added to our follow-up surveys, which were completed by mid-2021, and will be included in subsequent analyses. Second, some demographic heterogeneity could be explained by confounding, which could be elucidated with additional modeling. Multivariable modeling is planned for follow-up survey analyses. Third, we did not assess the quality of the mitigation behaviors, such as correctly wearing masks, or the effectiveness of those behaviors on preventing COVID-19 infection. The prospective component of the study will directly examine these associations. Fourth, the enrollment and baseline surveys occurred during a 5-month period of substantial changes in the COVID-19 pandemic and response. There may be time frame heterogeneity in the mitigation behaviors during these changes, but we were unable to analyze these baseline data as cross-sectional time series due to sampling method changes and prioritization of the entire survey sample weighting for national estimates [21]. Finally, although household probability sampling methods and weighting allowed for national estimation of these essential mitigation practices, there is likely still selection bias due to nonresponse.

Conclusion

Although the prevalence of consistently wearing a mask was relatively high among US adults, there were still millions who were not doing so during the time of the highest COVID-19 incidence to date in the pandemic. Even greater numbers of US adults did not consistently practice social distancing outside their homes and did not frequently practice hand hygiene. These practices remained crucial to blunting the surge of COVID-19 infections, especially since we had not yet achieved sufficient vaccine coverage to stop the pandemic. Despite clear public health evidence of their importance, the implementation of these practices was further undermined by a confusing array of local jurisdiction messages about mask requirements and restrictions on public gatherings. In future infectious disease outbreak responses, monitoring mitigation practices in a context of changing mandates and messages will help us refine communication strategies to increase the adoption and persistence of effective mitigation behaviors. This monitoring will also help ensure that disparities in mitigation practices do not widen further, leading to even greater disparities in infectious disease incidence and continuation of high-level community transmission.

Acknowledgments

The study was funded by a grant from the National Institutes of Health (3R01AI143875-02S1).

Conflicts of Interest

Abstract

Background: Nosocomial infections are infections incubating or not present at the time of admission to a hospital and manifest 48 hours after hospital admission. The specific factors contributing to the risk of infection during hospitalization remain unclear, particularly for the hospitalized population of the United Kingdom.

Objective: The aim of this systematic literature review was to explore the risk factors of nosocomial infections in hospitalized adult patients in the United Kingdom.

Methods: A comprehensive keyword search was conducted through the PubMed, Medline, and EBSCO CINAHL Plus databases. The keywords included "risk factors" or "contributing factors" or "predisposing factors" or "cause" or "vulnerability factors" and "nosocomial infections" or "hospital-acquired infections" and "hospitalized patients" or "inpatients" or "patients" or "hospitalized." Additional articles were obtained through reference harvesting of selected articles. The search was limited to the United Kingdom with papers written in English, without limiting for age and gender to minimize bias. The above process retrieved 377 articles, which were further screened using inclusion and exclusion criteria following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. The retained 9 studies were subjected to critical appraisal using the Critical Appraisal Skills Programme (cohort and case-control studies) and Appraisal Tool for Cross-Sectional Studies (cross-sectional studies) checklists. Finally, 6 eligible publications were identified and used to collect the study findings. A thematic analysis technique was used to analyze data extracted on risk factors of nosocomial infections in hospitalized patients in the United Kingdom.

Results: The risk factors for nosocomial infections that emerged from the reviewed studies included older age, intrahospital transfers, cross-infection, longer hospital stay, readmissions, prior colonization with opportunistic organisms, comorbidities, and prior intake of antibiotics and urinary catheters. Nosocomial infections were associated with more extended hospital stays, presenting with increased morbidity and mortality. Measures for controlling nosocomial infections included the use of single-patient rooms, well-equipped wards, prior screening of staff and patients, adequate sick leave for staff, improved swallowing techniques and nutritional intake for patients, improved oral hygiene, avoiding unnecessary indwelling plastics, use of suprapubic catheters, aseptic techniques during patient care, and prophylactic use.

Conclusions: There is a need for further studies to aid in implementing nosocomial infection prevention and control.

KEYWORDS

hospital-acquired infections; nosocomial infections; infection risk; systematic review; hospitalized patients; public health

Introduction

Nosocomial infections are recognized public health issues worldwide with a prevalence of 3.0%-20.7% and an incidence rate of 5%-10% [1]. These infections are not present or incubating at the time of admission to a hospital but are acquired after hospitalization and manifest 48 hours after admission; 30% of nosocomial infections are estimated to be preventable [2]. Nosocomial infections are a potential risk to the patients, staff, and community, with many of the microorganisms isolated known to be drug-resistant, resulting in increased admissions associated with a longer hospital stay, mortality, and increased hospital expenses [3]. A recent study [4] found that nosocomial infections account for 80% of all hospital infections, which include catheter-associated urinary tract infections (UTIs), surgical site infections (SSIs), ventilator-associated pneumonia, hospital-acquired pneumonia, and *Clostridium difficile* infections. Major symptoms of nosocomial infections are productive cough, abdominal pain, shortness of breath, altered mental status, rebound tenderness, palpitations, suprapubic pain, dysuria, polyuria, and costovertebral angle tenderness [2].

The risk factors associated with nosocomial infections are dependent on infection control procedures at the facility, the prevalence of pathogens in the community, and patients' immune status [1]. Research-based known risk factors include immunosuppression, older age, period of hospitalization, underlying comorbidities, frequency of hospital visits, mechanical ventilator support, invasive procedures, indwelling devices, longer stay in the intensive care unit (ICU), lack of infection control measures, and environmental hygiene [5]. The increased risk of nosocomial infections in older patients is due to frailty, suppressed immunity, and preexisting conditions [6].

Nosocomial outbreaks can be a cause of hospital closure, increased morbidity, and mortality. Therefore, to prevent and minimize nosocomial infections, several hospitals have implemented infection control procedures such as disinfection, steaming, proper waste management, isolation of affected staff until 48 hours after recovery, and aseptic hand washing before and after patient care, alongside prior identification of patients at risk of nosocomial infections and multidrug resistance [5].

Freeman and McGowan [6] found that risk factor identification allows for evaluating per-patient component risk, epidemiologic comparisons between hospital populations, and cost-effectiveness of infection prevention and control interventions. Calculation of risk per admission justifies findings on length of hospital stay as an increased risk for nosocomial infections [7]. This calculated per-day risk will account for the daily overall risk of infection per patient [6].

This systematic review was conducted to fill the gap in the absence of reviews on risk factors for nosocomial infections in hospitalized patients in the United Kingdom without limiting age and gender. The unique health care system in the United Kingdom funded by the National Health Service (NHS) is always at the frontline of adopting innovations and technologies in health care, which provides a guide to the international community on emerging innovations around infection control and prevention. Therefore, understanding predisposing factors of nosocomial infections in the United Kingdom can help inform local policies and practices, serving as a reference point for other countries considering revising their health care guidelines and policies.

The aims and objectives of this systematic review were focused on exploring the risk factors of nosocomial infections in hospitalized patients in the United Kingdom, the population at risk of nosocomial infections, impacts associated with nosocomial infections, and organisms associated with the spread of nosocomial infections.

Methods

Search Strategy

The search strategy was formulated based on the Population, Exposure, and Outcome framework, which is suitable for investigating the likelihood of developing a condition in the presence of a factor and providing practical strategies for controlling the outcome [8].

The PubMed and Google Scholar databases were searched for any existing or ongoing systematic reviews published between 2017 and 2021 regarding risk factors of nosocomial infections in hospitalized patients. Although systematic reviews were identified, none of these focused on the risk factors of nosocomial infections in hospitalized patients.

The review was focused on a comprehensive search using the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines for systematic reviews of 2020 [9]. Headings and keywords were used through a database search, including the PubMed, EBSCO CINAHL Plus, and EBSCO Medline databases. Although searching multiple databases identified duplicate studies, this approach reduced the chances of missing out on important publications.

Boolean operators "OR" and "AND" were utilized to translate the research question into research strings to retrieve relevant and focused results. Medical Subject Headings in databases and keywords from other research papers were used to identify synonyms of the keywords for obtaining more focused results. The keywords included "risk factors" OR "contributing factors" OR "predisposing factors" OR "cause" OR "vulnerability factors" AND "nosocomial infections" OR "hospital-acquired infections" AND "hospitalized patients" OR "inpatients" OR "patients" OR "hospitalized." Additional articles were obtained through reference harvesting of selected articles. The search was limited to the United Kingdom with papers in English, without limiting for age and gender to minimize bias.

Study Selection

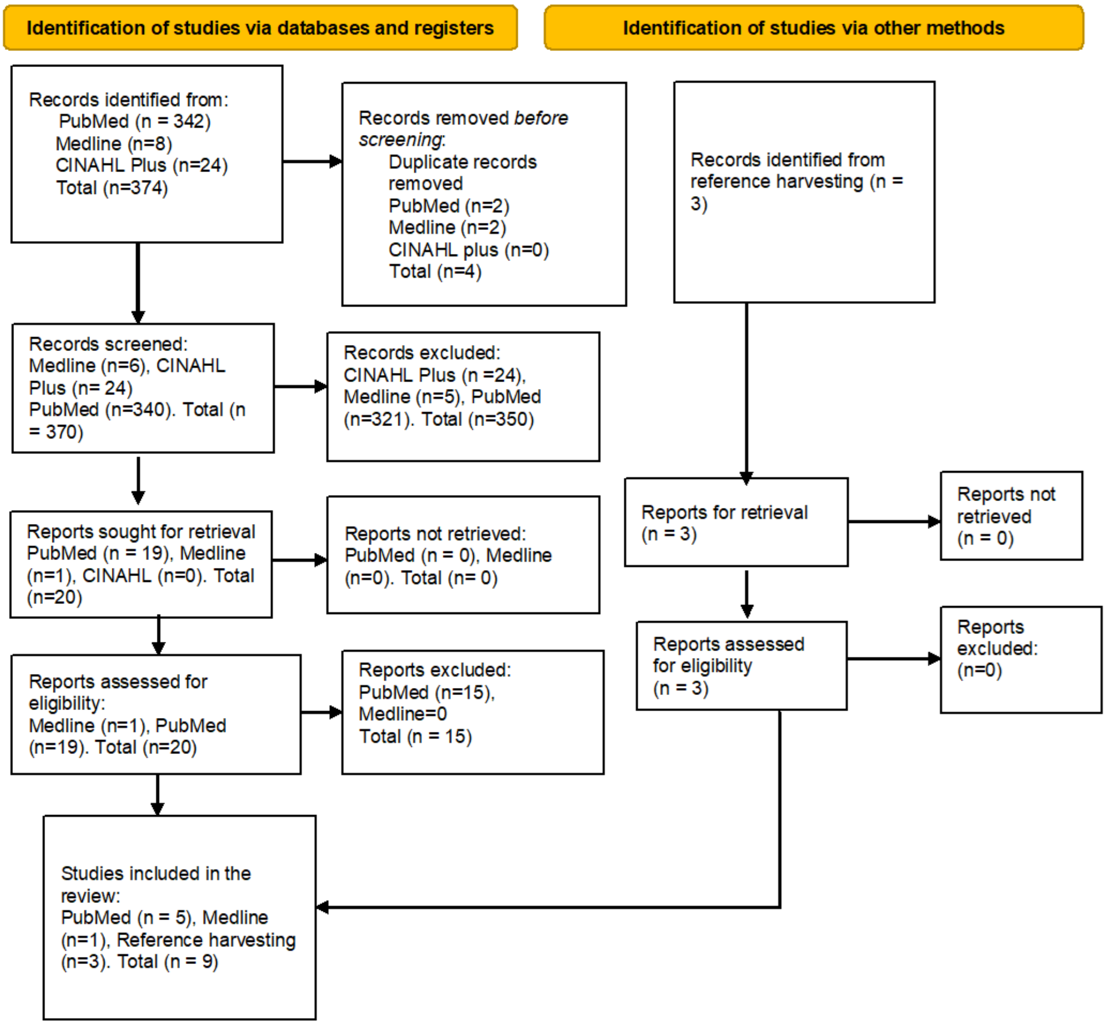
The inclusion and exclusion criteria for the systematic review are shown in Table 1.

The database search resulted in 374 articles plus 3 articles retrieved from reference harvesting (Figure 1).

Table 1. Inclusion and exclusion criteria.

Category	Inclusion criteria	Exclusion criteria
Study type	Primary research studies, 2011-2021 time frame, peer-reviewed articles, English language, full-text articles, qualitative and quantitative studies	Systematic reviews, non-English language, articles published before 2011, not peer-reviewed articles, abstract only
Population	Hospitalized patients/patients/inpatients in the United Kingdom	Hospitalized patients outside the United Kingdom
Exposure	All hospitals in the United Kingdom	Hospitals outside the United Kingdom
Outcome	Nosocomial infections in the United Kingdom	Any other articles that did not collect information on nosocomial infections in the United Kingdom

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram for study selection.



RefWorks software was used to remove duplicate articles and titles were read manually to avoid duplication bias, resulting in 370 articles from all databases.

Title and abstract screening based on the inclusion and exclusion criteria resulted in 20 included articles and 350 excluded articles. The reasons for exclusion were that titles and abstracts were not giving relevant information on risk factors of nosocomial infections, guidelines, providing information on community-acquired infections in non-UK countries, or systematic reviews. Full-text article screening resulted in zero articles being excluded. In addition, 15 studies were excluded because of providing inadequate information on risk factors of nosocomial infections. After applying these criteria, nine articles, including the three obtained from reference harvesting, were subject to critical appraisal. A scoping review was carried out and no relevant papers were identified before 2011.

Data Extraction

The data extracted were tabulated using Microsoft Word. The data drawn out included authors' details, study design, the context of the study, sample size, aim of the study related to the risk of nosocomial infections, key findings, limitations, and conclusions of the identified studies.

Data Analysis

Thematic analysis was conducted on the included studies following the Braun and Clarke [10] guidelines, who describe a thematic analysis as a useful and flexible method for qualitative research. Thematic analysis classifies themes and patterns that connect to data, enabling researchers to identify and detect variables influencing any issues in study participants [10]. The themes were identified by one author and then agreed upon via discussion with all authors.

Critical Appraisal

Critical appraisal was applied to the selected 9 articles to check for the validity of the research if the results provided answers to the research question and the relevance of the information while minimizing bias, with the answers being either yes (+), no (–), or can't tell (+/–). Included case-control (Table 2) and cohort (Table 3) studies were appraised using the Critical Appraisal Skills Programme (CASP) tool and cross-sectional studies (Table 4) were appraised using the Appraisal Tool for Cross-Sectional Studies (AXIS) checklist. The CASP tool is a checklist that uses focused questions to help researchers evaluate the validity and reliability of identified research articles. This provides appraisal skills and tools that facilitate checking research resources for trustworthiness, relevance, and results [11]. The AXIS tool was used to evaluate the reporting quality, study design, and risk of bias in cross-sectional studies [12]. This tool focuses on presented methods and results of studies, which helps researchers assess whether the findings are reliable and credible and whether they relate to the aims, methods, and analysis of what is reported in identified studies. Following critical appraisal, three articles were excluded due to lack of ethical approval, low internal validity, or reliability of results, resulting in a total of six included articles.

Table 2. Critical appraisal of the selected case-control studies using the Critical Appraisal Skills Programme tool [11].

Critical appraisal questions	Boncea et al [13]	Alrawi et al [14]	Ousey et al [15]
Did the study address a clearly focused issue?	+[a]	+	+
Did the authors use an appropriate method to answer their question?	+/–[b]	+	+/–
Were the cases recruited acceptably?	+	+	+/–
Were the controls selected acceptably?	+	+	+/–
Was the exposure accurately measured to minimize bias?	+/–	+	+
Aside from the experimental intervention were the groups treated equally?	+	+/–	+/–
Have the authors taken into account the potential confounding factors in the design and/or in their analysis?	+/–	–[c]	+/–
How large was the treatment effect?	+	–	+/–
How precise was the estimate of the treatment effect?	+	–	+
Do you believe the results?	+/–	–	+/–
Can the results be applied to the local population?	–	+/–	+/–
Do the results of this study fit with other available evidence?	+	+	+/–

[a] +:Yes.

[b] +/–:Unclear.

[c] –:No.

Critical appraisal questions	Mo et al [16]	Behar et al [17]	Ewan et al [18]	Melzer and Welch [19]	Wloch et al [20]
Did the study address a clearly focused issue?	+[a]	+	+	+	+
Was the cohort recruited acceptably?	+	+/–[b]	+/–	+	+
Was the exposure accurately measured to minimize bias?	+/–	+	+	+	+
Was the outcome accurately measured to minimize bias?	+/–	+	+/–	+	+/–
Have the authors identified all important confounding factors?	+	+	+	+	+
Have they taken into account the confounding factors in the design and/or analysis?	+	+	+	+	+/–
Was the follow-up of subjects complete enough?	+	+	+	+	+
Was the follow-up of subjects long enough?	+	+	+	+	+/–
What are the results of the study?	+	+	+	+	+
How precise are the results?	+	+	+	+	+
Did you believe the results?	+	+	+	+	+
Can the results be applied to the local population?	+	+	+/–	–[c]	+
Do the results of this study fit with other available evidence?	+	+	+/–	+	+
What are the implications of the study for practice?	+	+	+	+	+

[a] +:Yes.

[b] +/–:Unclear.

[c] –:No.

Table 4. Critical appraisal of the selected cross-sectional study using the Appraisal Tool for Cross-Sectional Studies [12].

Critical appraisal questions	Ledwoch et al [21]
Was the aim/objective of the study clear?	+[a]
Was the study design appropriate for the stated aim?	+
Was the sample size justified?	+
Was the reference population clearly defined? (Is it clear who the research was about?)	+
Was the sample frame taken from an appropriate population to closely represent the reference population under investigation?	+
Was the selection process likely to select subjects/participants that were representative of the target/reference population under investigation?	+
Were measures undertaken to address and categorize nonresponders?	–[b]
Were the risk factor and outcome variables measured appropriate to the aim of the study?	+
Were the risk factor and outcome variables measured correctly using instruments/measurements that had been trialed, piloted, or published previously?	+
Were the methods (including statistical methods) sufficiently described to enable them to be repeated?	–
Were the basic data adequately described?	+
Does the response rate raise concerns about nonresponse bias?	+
If appropriate, was information about nonresponders described?	–
Were the results internally consistent?	+
Were the results presented for all the analyses described in the methods?	+
Were the authors' discussion and conclusions justified by the results?	+
Were the limitations of the study discussed?	+
Was there funding or conflicts of interest that may affect the authors' interpretation of results?	+
Was ethical approval or consent of participants attained?	–

[a] +:Yes.

[b] –:No.

Results

Characteristics of Included Studies

This systematic review identified 5 cohort studies [16-20], 3 case-control studies [13-15], and 1 cross-sectional study [21]. After critical appraisal, 5 cohort studies [16-20] and 1 case-control study [13] were included for analysis. The included studies covered countries within the United Kingdom, with the majority covering England. Most of the studies identified older adults and patients with preexisting conditions at increased risk of nosocomial infections. The organisms associated with increased nosocomial infections according to the majority of the included studies were *C. difficile*, *Escherichia coli*, *Pseudomonas aeruginosa*, *Enterococcus* spp, *Klebsiella pneumoniae*, *Staphylococcus aureus*, coliform species, anaerobic cocci, methicillin-resistant *S. aureus* (MRSA), coagulase-negative *Staphylococcus*, Enterobacteriaceae, and streptococci (Table 5).

Table 5. Data extracted from the included studies.

Reference	Study design	Context	Sample size	Study aim	Key findings	Limitations	Conclusion
Alrawi et al [14]	Case-control study	United Kingdom	Adult patients admitted to a burn center over 12 months	Determine the presence of different microbes in a UK burn center, and examine the relationships between bacterial colonization, burn size, length of hospital stay, and delayed referral	*Staphylococcus aureus* was common with 79% positive patients, and a direct link was found between an increased incidence of bacteria colonization, delay in referral >24 hours, length of hospital stay, and large burn size	None	A burn wound creates a good medium for bacteria colonization and proliferation; in understanding the sources of bacteria and patients' susceptibility, wound care clinicians can form better management and treatment to reduce mortality and morbidity from burn wound sepsis
Behar et al [17]	Cohort study	England	727 patients admitted to an elderly medicine ward	Establish the risk factors for *Clostridium difficile* in hospitalized patients	9.8% of patients carried toxigenic *C. difficile* and ribotype 027 was not identified, while ribotype 106 was identified 3 times and in 7 others twice. Independent factors of colonization included previous *C. difficile* infection (OR[a] 4.53, 95% CI 15.48) and malnutrition (OR 3.29, 95% CI 1.47-7.35)	Overestimation of carriers because of a higher rate in sampled patients than in unsampled patients. No certainty whether the infection was community-acquired or hospital-acquired. The study may be prone to type 2 errors. Failure to calculate sample size due to lack of information on the frequency of colonization before the start of the study.	The study identifies the common carriage of *C. difficile* in older patients. Patients with previous *C.difficile* infections are to be evaluated as a cost-effective intervention to reduce symptomatic *C. difficile* infection in hospitalized patients.
Boncea et al [13]	Case-control study	United Kingdom	3 hospitals with 24,240 older patients (>65 years)	Explore how intrahospital transfer influences the odds of developing an HAI[b] in an urban hospital network	72.2% of the hospital transfer cases had at least one intrahospital transfer and each additional transfer increased the odds of acquiring a nosocomial infection by 9% in older patients (OR 1.09, 95% CI 1.05-1.13)	Lack of physiological data. Use of OPCS-4[c], which lacks hierarchy in the invasiveness of procedures and failure to record minor medical devices. Unavailable information on prescribed antibiotics and proton pump inhibitors may result in confounding effects. Lack of staffing level; unclear if infection spread is due to staff or patient casual movement. Missing symptom information. Findings not generalizable to the younger population. Lack of time stamp inaccuracies and diagnostic coding errors.	Intrahospital transfers increased the odds of developing nosocomial infections. Strategies for minimizing transfer should be considered. Further studies needed to identify unnecessary transfers.

Reference	Study design	Context	Sample size	Study aim	Key findings	Limitations	Conclusion
Ewan et al [18]	Cohort study	Northeast England	90 patients with lower limb fractures aged 65-101 years in a general hospital	Investigate the association between hospital-acquired pneumonia preceding heavy dental plaque and oral carriage of respiratory pathogens in older patients with limb fractures to determine the target for intervention studies	Hospital-acquired pneumonia was not associated with dentate, tooth number, or heavy dental plaques, but was associated with increased hospital stay and prior oral carriage of *Escherichia coli/S. aureus/Pseudomonas aeruginosa*/MRSA[d] (OR 9.48, 95% CI 2.28-38.78; *P*=.002)	Results are not generalizable to medical patients. Biased sample toward "well patients," leading to underestimation of exposure and outcome variables. Overestimated hospital-acquired pneumonia incidence. Overprediction of significance when the colonization index was larger than zero.	Lower limb fracture patients colonized with *E. coli*, *S. aureus*, MRSA, or *P. aeruginosa* after 5 days in hospital were at greater risk of hospital-acquired pneumonia (*P*=.002). Methods to implement and deliver good oral hygiene at the ward level in the health system need to be investigated to minimize the use of antibiotics and length of hospital stay.
Ledwoch et al [21]	Cross-sectional study	Wales, Scotland, England	3 hospitals and 1 dental practice	Investigate the presence of DSBs[e] on 52 routinely cleaned keyboards from 4 hospitals across the United Kingdom	Hospital keyboards outside the patient area harbor DSBs, representing potential reservoirs for transferrable pathogens with 31% vancomycin-resistant *Enterococcus*, 17% MDR[f]*Acinetobacter* spp, and 72% MRSA recovered from almost half of the 45 samples	Selective plates and quality control were not selective to a single species from the DSB	Hospital keyboards are a source of infection for HAIs with a need for further studies on DSBs to find products that can control DSBs while effectively preventing bacteria transfer
Melzer and Welch [19]	Cohort study	London	500 patients in Royal London Hospital	To determine host factors that can predict severe sepsis in a bacteremic cohort	Bacteremia largely occurred in patients aged over 50 years (64.3%) and in men (58.2%); common isolates were *E. coli* (34.8%) and MRSA (9.6%). In the multivariable logistic regression, the site of infection was associated with severe sepsis and catheter-associated UTIs[g], significant after adjustment of age, sex, Charlson comorbidities index, and where the infection was acquired	Findings are not generalizable to other severe sepsis cohorts with bacteremia	Urinary catheter increases the risk of severe sepsis; if clinically indicated, should be used and removal dates indicated unless long-term use is required

Reference	Study design	Context	Sample size	Study aim	Key findings	Limitations	Conclusion
Mo et al [16]	Cohort study	Oxfordshire, United Kingdom	4 teaching hospitals	Quantify the importance of different transmission pathways of SARS-CoV-2 in a hospital setting	For susceptible patients, 1 day in the same ward with another patient with nosocomial SARS-CoV-2 infection was associated with 7.5 infections per 1000 susceptible patients per day, while exposure to a patient with community-acquired SARS-CoV-2 infection or to an infectious health care worker had a lower risk of 2 per 1000 susceptible patients	No clarity during phase 3 onward when weekly screening was implemented. Recall bias from staff self-reporting. Staff were assumed to be absent after the first positive PCR[h] result. Genomic sequencing of SARS-CoV-2 is not considered to confirm the transmission pathway.	Exposure to patients with nosocomial SARS-CoV-2 infection poses a risk to health care workers and hospitalized patients. Further investigation to enhance infection control and prevention around these patients is required.
Ousey et al [15]	Case- control study	England	206 patients with emergency cesarean section in an acute district general hospital	Assess the incidence risk and factors contributing to an acquired SSI[i] after an emergency cesarean section	BMI was associated with SSI (OR 1.17, 95% CI 1.11-1.24; *P*<.001). Nonsignificant links were identified between SSIs and age and vaginal swab status.	Stigmatization of pregnant women. Use of wound swabs leading to false-positive or false-negative results. Missing or inaccurate recordings. Small sample size. Use of BMI to calculate body composition when its accuracy has been questioned.	BMI was the main risk factor for SSI because of excessive adipose tissue. Diabetes status, age, and preoperative vaginal swab status were not associated with SSI.

[a] OR: odds ratio.

[b] HAI: hospital-acquired infection.

[c] OPCS-4: Office of Population Census and Surveys.

[d] MRSA: methicillin-resistant *Staphylococcus aureus*.

[e] DSB: dry surface biofilm.

[f] MDR: multidrug resistant.

[g] UTI: urinary tract infection.

[h] PCR: polymerase chain reaction.

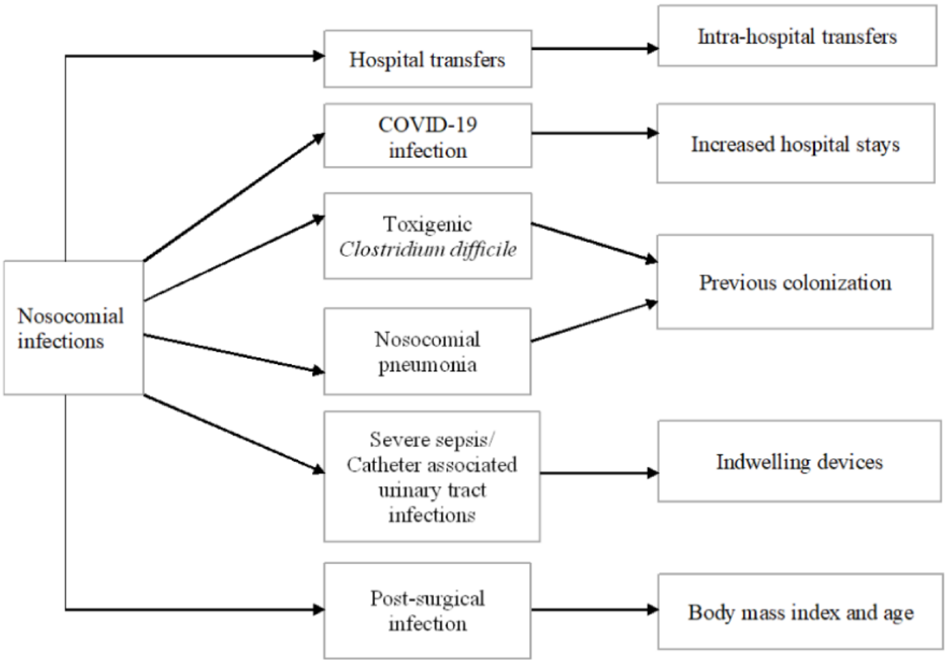
[i] SSI: surgical site infection.

Themes

Overview

The themes identified included intrahospital transfers, increased hospital stay, previous colonization, indwelling devices, and BMI and age, as shown in Figure 2.

Figure 2. Identified themes.



Theme 1: Intrahospital Transfers

According to Boncea et al [13], older patients acquired nosocomial infections associated with ICU admissions and in-hospital deaths (*P*<.001) more frequently than younger patients 48 hours after admission (median 79, IQR 73-86 vs median 79, IQR 72-85; *P*=.004) and also had higher comorbidities (mean 4.0, SD 2.0 vs mean 3.5, SD 1.9; difference=0.5; *P*<.001). The ICU admissions cases (6.7%) and in-hospital deaths (13.3%) were significantly higher (*P*<.001) among patients 48 hours after admission. The findings demonstrated that an additional intrahospital transfer was associated with a 9% increase in the chances of developing a nosocomial infection (odds ratio [OR] 1.09, 95% CI 1.05-1.13).

Overall, 11.9% of the patients developed a nosocomial infection (49.6% men and 50.4% women) with a median age of 79 (IQR 72-86) years and a mean of 3.5 (SD 1.9) Elixhauser comorbidities, an index used to predict hospital length of stay, hospital charges, and in-hospital mortality.

In addition, 76.0% of patients with a positive lab culture collected at least 48 hours after hospitalization experienced at least one transfer compared to 71.7% of controls (patients who remained infection-free throughout the admission), with cardiology patients experiencing more movement (median 2, IQR 1-2). Logistic regression analysis was used to rule out the influence of ethnicity, gender, weekend admissions, and readmissions within 30 days. The most commonly isolated organisms from the patient group were *C. difficile*, *E. coli*, *P. aeruginosa*, *Enterococcus* species, *K. pneumoniae*, *S. aureus*, coliform species, MRSA, and coagulase-negative *Staphylococcus*.

Theme 2: Increased Hospital Stay

Mo et al [16] observed that an increased hospital stay increases the risk of nosocomial infections among health care workers and patients. The evidence indicated that newly admitted COVID-19 patients were associated with a risk of onward transmission to other patients in a hospital setting.

Approximately 62.1% of patients had positive SARS-CoV-2 results after admission and most of them were older. These older patients had more extended hospital stays and more readmissions. Susceptible patients were at a higher risk of acquiring COVID-19 from a patient with nosocomial COVID-19 (adjusted OR 1.76, 95% CI 1.51-2.04) than from a patient with community-acquired COVID-19 (adjusted OR 1.12, 95% CI 0.96- 1.26) or from a health care worker with COVID-19 (OR 1.45, 95% CI 1.22-1.71). These results indicated that the risk of patients transmitting COVID-19 to other patients within the same facility was higher as a result of increased hospital stay. Other infections can also be transmitted because of interacting with the same health care workers and patients for prolonged periods. Mo et al [16] observed that exposure to nosocomial infections was linked with a substantial infection risk to other hospitalized patients.

These findings are consistent with those of Ewan et al [18], who found that increased hospital stay was significantly associated with nosocomial infections (Fisher exact test *P*=.001). Similarly, Boncea et al [13] found that increased length of hospital stay was associated with nosocomial infections even when the researchers controlled for severity of illness.

Theme 3: Previous Colonization

According to Behar et al [17], risk factors for toxigenic *C. difficile* colonization among patients were a previous diagnosis of symptomatic *C. difficile* infection (OR 8.48, 95% CI 2.77-25.96), hospital stay of 3 months, and frailty as assessed by the Malnutrition Universal Screening Tool (MUST) and Barthel score. Multivariable analysis proved colonization to be associated with previous *C. difficile* infection (OR 4.53, 95% CI 1.33-15.48) and a MUST score indicating a higher level of frailty (≥2) (OR 3.22, 95% CI 1.47-7.06); the association with a recent hospital stay was borderline significant (OR 2.18, 95% CI 0.99-4.78).

Overall, 9.8% of the patients were carriers of *C. difficile* after their first stool test presenting with diarrhea. The most isolated ribotypes were 126 (×3), (009, 018, 020, 023, 028, 038, and 039) ×2, and ribotype 027 strains were undetected.

Ewan et al [18] found that prior carriage with opportunistic *S. aureus*, *E. coli*, *P. aeruginosa*, and MRSA (OR 9.41, 95% CI 2.28-38.78; *P*=.002) was significantly associated with nosocomial pneumonia with relative risk of 6.44 (95% CI 2.04-20.34; *P*=.002). A combination of pathogens was identified, and the highest colonization rate was identified with *Streptococcus pneumoniae* (n=27 patients) due to persistent carriage, followed by *Hemophilus influenzae* (n=8), *S. aureus* (n=6), *P. aeruginosa* (n=4), MRSA (n=3), and *E. coli* and *Acinetobacter* spp (n=2). Ewan et al [18] also identified an association between nosocomial pneumonia with admission from the hospital, active cancer, witnessed aspiration episode, increased frailty, antibiotic intake before admission, and reduced mobility.

Theme 4: Indwelling Devices

Melzer and Welch [19] sought to establish whether the presence of a urinary catheter predicts severe sepsis as a nosocomial infection within a bacteremic cohort. The researchers identified 64.3% bacteremic episodes in patients >50 years old, 58.2% of whom were men. The episodes were community-acquired, health care–associated, and hospital-acquired infections, but community-acquired episodes were not associated with severe sepsis (Pitt score≥2). Site of infection, individual patient, critical care admission, and catheter-associated UTI were significantly associated with severe sepsis. After multivariate analysis, the site of infection was significantly associated with severe sepsis, with a stronger association for catheter-associated UTIs (OR 3.87, 95% CI 1.82-8.22), which remained significant after adjustment for age and where the infection was acquired (OR 3.94, 95% CI 1.70-9.11). These results indicate that indwelling devices such as a urinary catheter are a risk factor that can predict nosocomial infections such as severe sepsis.

Theme 5: BMI and Age

Wloch et al [20] found that 10 days following a hospital admission was the median time for all SSIs and 8 days of admission was the median time for deep and organ infections alone. The mentioned risk factors for these nosocomial infections included BMI, which was strongly associated with superficial infections (*P*<.001), and deep organ space (*P*<.003). After multivariate analysis, women with a BMI of 25-30 (overweight) had an estimated OR of 1.6 (95% CI 1.2-2.2) compared to that of women within a normal BMI range. The results also indicated that women with a BMI >30 (obese) had a 2.4-times greater chance of nosocomial infection (95% CI 1.7-3.4).

After multivariate analysis, age had a stronger association for SSIs and women <20 years of age (*P*=.04) had a weaker association for SSIs. *S. aureus* was the commonly associated organism at 40.4%; 17.7% were methicillin-resistant organisms and the rest included anaerobic cocci at 23.2%, Enterobacteriaceae at 13.3%, and streptococci at 7.4%.

Boncea et al [13] observed that increased age was a risk factor for nosocomial infections in a study focused on hospital-acquired infections in an urban UK hospital network. Patients with hospital-acquired infections were older than those who did not acquire the infections (median 79, IQR 73-86 vs median 79, IQR 72-85; *P*<.001). Boncea et al [13] also found that older patients had a higher number of comorbidities than younger patients (mean 4.0, SD 2.0 vs mean 3.5, SD 1.9; difference=0.5; *P*<.001).

Discussion

Principal Findings

The findings of this systematic review provided answers to the study objectives. The main risk factors of nosocomial infections identified in this study include intrahospital transfers, increased hospital stay, previous colonization, indwelling devices, and BMI and age.

Blay et al [22] demonstrated that intrahospital transfers increased the risk of developing nosocomial infections, with the majority of patients in the study undergoing 2.4 transfers per year. This finding has been supported by Boncea et al [13], who reported that an additional intrahospital transfer was associated with a 9% higher risk of acquiring infections in a hospital. Boncea et al [13] also found that older patients were more likely to develop nosocomial infections. The prevalence of nosocomial infections was high in the older population due to frailty and immunosuppression. Intrahospital transfers occurred as a result of lesser equipped wards along with procedure rooms and bed shortages that expose susceptible patients to infectious hospital surfaces, staff, and other patients, thus increasing their risk of nosocomial infection. The findings suggested that minimizing infection risk to be a priority when transferring patients. Kulshrestha and Singh [23] mentioned that patient intratransfers should aim at maintaining patient care to minimize morbidity and mortality. Single-patient rooms can be used to lower pathogen transmission and the number of intrahospital transfers, thereby reducing interactions between staff, hospital surfaces, and patients to eventually reduce the incidence of nosocomial infections [13].

Mo et al [16] observed that COVID-19 transmission between patients and staff had a stronger association for nosocomial COVID-19 than community-acquired COVID-19 [16]. The daily risk of COVID-19 was associated with increased exposure to newly infected patients and staff. Medical professionals can address this challenge by providing adequate sick pay leave for symptomatic staff for better complete recovery and regular screening for early detection to reduce cross-infection and control for the incidence of nosocomial COVID-19. Furthermore, early symptom presentation and regular screening of staff and patients is a better strategy for infection prevention and control, where infected patients and staff should be isolated immediately.

According to Behar et al [17], older patients were largely colonized by *C. difficile* presenting with diarrhea and contributing to transmission to other patients. The risk of colonization with asymptomatic *C. difficile* was due to frailty associated with suppressed immunity, which resulted in increased mortality. The risk of colonization was also associated with previous diagnoses and longer hospital stays. Early detection and isolation upon admission can reduce the further spread of nosocomial *C. difficile*. In a study by Dubberke et al [24], patients showed acquisition of *C. difficile* while hospitalized. The initial intake of antibiotics was associated with disease, whereas susceptibility to colonization with *C. difficile* was associated with suppressed immunity and an altered intestinal flora composition, gender, preexisting comorbidities, and frailty-determined mortality rate [17]. Risks such as previous hospital admission, antibiotic therapy, and immune suppression were well documented and explained in a similar study on *C. difficile* infection in hospitalized children in the United States [25].

Nosocomial pneumonia occurred after admission, with most samples positive for colonization with *S. aureus*, MRSA, *P. aeruginosa*, and *E. coli*, which resulted in extended hospital stays of 30 days, similar to patients with ventilator-associated pneumonia and aspiration pneumonia in medical patients [18]. Colonization was identified as the key risk factor for nosocomial pneumonia.

The results of this systematic review indicate that detection using molecular techniques resulted in a high incidence rate of nosocomial pneumonia in the exposed patient group. Ewan et al [13] failed to identify *K. pneumoniae* and Enterobacteriaceae as prevalent organisms and a risk of nosocomial pneumonia in frailer and unwell patients [26]. Oral colonization began within 72 hours of admission in a majority of the cases, with the possible explanation that some have been acquired from the community or upon admission; therefore, interventions should start within this timeframe. Delivery of better oral hygiene at the ward level in a resource-scarce health system can control for antibiotic use and length of hospital stay associated with nosocomial pneumonia.

Melzer and Welch [19] identified the presence of urinary catheters to be strongly associated with severe sepsis, with a stronger association for gram-negative multidrug-resistant *E. coli*. Furthermore, underlying diseases and obstruction history are also identifiable risks for severe sepsis. *E. coli*, a gram-negative bacterium gastrointestinal colonizer, is known to commonly cause UTIs and septicemia [26], which was also associated with delayed administration of antibiotics. To account for this, patients exhibiting any signs of sepsis should be given immediate admission or management in critical care areas, and implementation of a critical care bundle approach would result in reduced admissions due to severe sepsis. A critical care bundle would aid in the documentation of reasons for catheter insertion, removal dates, and aseptic techniques during and after insertion to control for infection. Medical professionals can increase patient satisfaction and lower infection risks by issuing catheter passports to long-term users, guiding community nurses on the use of prophylactic antibiotics when changing catheters, and using suprapubic catheters.

SSIs were strongly associated with an inpatient stay, readmissions, diabetes, surgeons' grade, and women <20 years and >45 years of age. The most commonly isolated organisms from the skin or genital flora were *S. aureus* (40.4%, 17.1% of which were MRSA), anaerobic cocci (23.2%), Enterobacteriaceae (13.3%), and streptococci (7.4%). BMI was strongly associated with SSIs due to poor prescription techniques that exclude patients' BMI, longer incision time, and slow transit of antibiotics due to thick adipose tissue that result in impaired wound healing and decreased immunity. This view on BMI has been supported by Ousley et al [15]. According to Chu et al [27], younger age in women is associated with an increased risk for SSIs due to underdeveloped immunity to fight infections. Older age is associated with frailty and a suppressed immune system, which has been supported by Boncea et al [13], who also mentioned readmission and increased hospital stay resulting in exposure of patients to hospital surfaces with pathogenic organisms, thereby increasing the risk for nosocomial infections. Another study confirmed diabetes to be a risk of postsurgical infections, which is a marker for other conditions such as vascular changes and white blood cell malfunction, resulting in suppressed immunity that exposes a patient to multiple infections during and after surgery [28]. In general, the analyzed studies identified impacts of nosocomial infections to be associated with increased admissions, increased hospital stay, and costs on health care services. Other studies have reached similar findings and identified that older age, readmissions, and longer hospital stay are associated with increased infection risk due to exposure to infectious pathogens, frailty, and suppressed immunity. Özdemir and Dizbay [29] found that older patients have a higher risk of nosocomial infections resulting from impaired immune defense, long-term hospital stay, immunosuppressive treatments, and underlying chronic illnesses.

Study Strengths and Weaknesses

There were no systematic reviews on risk factors of nosocomial infections in hospitalized patients, and the study identified both qualitative and quantitative data relevant to the research topic. As another strength, this review pointed out key risk factors associated with nosocomial infections and the patient populations at risk, additionally suggesting measures for infection control and prevention, providing an advantage to the NHS whose priority is controlling health care–associated infections [30]. In this review, non-English articles were excluded, which may have limited capturing information in other languages.

Conclusions

Patients with previous colonization and underlying conditions are at increased risk of nosocomial infections due to frailty, extended hospital stay, and suppressed immunity. The use of indwelling devices, increased age, high BMI, and intrahospital transfers increase the susceptibility of patients to nosocomial infections.

Intrahospital transfers expose patients to other infectious patients, staff, and hospital environments, thereby increasing their risk for infection. In addition, the number of staff per patient has been positively associated with an increased risk of infection. Readmissions, underlying conditions and/or active cancer, prior antibiotic intake associated with drug-resistant microorganisms, and colonization with opportunistic organisms contribute to nosocomial infections. Indwelling devices such as urinary catheters increase the risk of sepsis, while obesity and age are strongly associated with SSIs. The most common organisms associated with nosocomial infections included *C. difficile*, *E. coli*, *P. aeruginosa*, *Enterococcus* spp, *K. pneumoniae*, *S. aureus*, coliform species, anaerobic cocci, MRSA, coagulase-negative *Staphylococcus*, Enterobacteriaceae, and streptococci.

Implemented interventions should consider the time frame before and after admission to control for organisms acquired during both periods. Further studies are needed to identify the risk factors of nosocomial infections and drug-resistant pathogens targeting a larger patient group for better infection prevention and control.

Abstract

Background: Telehealth has been widely used for new case detection and telemonitoring during the COVID-19 pandemic. It safely provides access to health care services and expands assistance to remote, rural areas and underserved communities in situations of shortage of specialized health professionals. Qualified data are systematically collected by health care workers containing information on suspected cases and can be used as a proxy of disease spread for surveillance purposes. However, the use of this approach for syndromic surveillance has yet to be explored. Besides, the mathematical modeling of epidemics is a well-established field that has been successfully used for tracking the spread of SARS-CoV-2 infection, supporting the decision-making process on diverse aspects of public health response to the COVID-19 pandemic. The response of the current models depends on the quality of input data, particularly the transmission rate, initial conditions, and other parameters present in compartmental models. Telehealth systems may feed numerical models developed to model virus spread in a specific region.

Objective: Herein, we evaluated whether a high-quality data set obtained from a state-based telehealth service could be used to forecast the geographical spread of new cases of COVID-19 and to feed computational models of disease spread.

Methods: We analyzed structured data obtained from a statewide toll-free telehealth service during 4 months following the first notification of COVID-19 in the Bahia state, Brazil. Structured data were collected during teletriage by a health team of medical students supervised by physicians. Data were registered in a responsive web application for planning and surveillance purposes. The data set was designed to quickly identify users, city, residence neighborhood, date, sex, age, and COVID-19–like symptoms. We performed a temporal-spatial comparison of calls reporting COVID-19–like symptoms and notification of COVID-19 cases. The number of calls was used as a proxy of exposed individuals to feed a mathematical model called "susceptible, exposed, infected, recovered, deceased."

Results: For 181 (43%) out of 417 municipalities of Bahia, the first call to the telehealth service reporting COVID-19–like symptoms preceded the first notification of the disease. The calls preceded, on average, 30 days of the notification of COVID-19 in the municipalities of the state of Bahia, Brazil. Additionally, data obtained by the telehealth service were used to effectively reproduce the spread of COVID-19 in Salvador, the capital of the state, using the "susceptible, exposed, infected, recovered, deceased" model to simulate the spatiotemporal spread of the disease.

Conclusions: Data from telehealth services confer high effectiveness in anticipating new waves of COVID-19 and may help understand the epidemic dynamics.

Introduction

Telehealth encompasses the distinct ways of interaction between patients and their health care providers. The growing popularity of virtual visits stems from the possibility of faster contact, elimination of transportation time [1], and by providing initial care in remote areas without adequate health care [2], making health care more efficient. Telehealth services can be used for diagnosis, treatment, follow-up, and screening purposes [3]. During the COVID-19 pandemic, telehealth services have been widely used for screening suspected cases [4,5], as limited physical contact reduces everyone's exposure to COVID-19. This successful strategy safely provides access to health care services and expands assistance to remote rural areas and underserved communities in situations of shortage of specialized health professionals [3]. Using health information platforms, health care workers can systematically collect qualified data on suspected cases. Such data can be used as a proxy for the spread of infectious diseases for health surveillance [6-11].

The mathematical modeling of epidemics is a well-established field that has been successfully used for tracking the spread of SARS-CoV-2 infection, supporting the decision-making process on diverse aspects of public health response to the COVID-19 pandemic. Such models are usually defined as compartmental models. The population under study is divided into compartments based on qualitative characteristics, with different assumptions about the nature and rate of transfer across compartments. The urgency of the COVID-19 pandemic has motivated the need for more research in this area, with several models for this pandemic outbreak being presented in the last few years [12-18]. The response of the current models depends on the quality of input data, particularly the transmission rate, initial conditions, and other parameters present in compartmental models. Telehealth systems may feed numerical models developed to model virus spread in a specific region.

Here, we report using a high-quality data set obtained from a state-based telehealth service for disease surveillance both for forecasting the geographical spread of new cases of COVID-19 and feeding an advanced computational model that tries to reproduce the virus spread dynamics. We used data from a toll-free telehealth service of the 14.8 million population from the state of Bahia, Brazil [19], to simulate the spatiotemporal spread of COVID-19 using a compartmental model with diffusion in Salvador, the state capital.

Methods

Telehealth

Service and Data Collection

Telecoronavirus was a toll-free phone-teletriage service offered to the population of the state of Bahia, Brazil (population of 14.8 million, 417 municipalities, located in the northeast of the country; Multimedia Appendix 1) [19]. Risk screening was provided for cases suspected of COVID-19 from March 24, 2020, to July 31, 2020, during the first epidemic wave, starting 18 days after the first confirmed case of COVID-19 in the state. This toll-free service operated 7 days a week and was publicized statewide by the state government through television, the internet, social media, billboards, radio, and newspapers. In total, 77% (320/417) of all cities in Bahia and all sanitary districts of the state capital, Salvador, accessed the telehealth service.

Structured data were collected during teletriage by a health team of medical students supervised by physicians. Data were registered in a responsive web application for planning and surveillance purposes. The data set was designed to quickly identify users, city, residence neighborhood, date, sex, age, and COVID-19–like symptoms (fever, cough, breathlessness, rhinorrhea, and gustatory or olfactory disorder). For this study, the call reporting at least one of those symptoms was considered a suspected case of COVID-19.

Strategies to improve the service quality were applied, including educational and technical support for the health care team, updating the online application based on clinical protocols, and monitoring the quality of information registered by the health care team, as previously described [19]. Data of telehealth service were categorized according to the phone call date, the type of COVID-19–like symptom reported by the user, and the city of residence. For Salvador, the state capital, calls were categorized according to the COVID-19–like symptoms and the user's health district. The COVID-19 cases' notification date and their related geolocation in the state of Bahia were obtained through the Brazilian Ministry of Health. For Salvador, notification data were obtained through the Salvador Municipal Health Department. We further quantified the cities of the state of Bahia and the districts of Salvador, where phone calls reporting symptoms of COVID-19 preceded the first notification of the disease. The lag in days between the first call and the first notification dates was also annotated.

Ethical Considerations

Anonymized consolidated data were provided by the Bahia State Health Secretary for research purposes. The ethics committee of the School of Medicine of Bahia approved the project (approval number 4459774, on 12/13/2020). The requirement for obtaining informed consent was waived due to the characteristics of the research.

Data Source and Preparation for Study

We extracted Telecoronavirus data for Salvador inhabitants (population: 2.88 million; surface area: 692.818 km²) for use in the prediction model. The call records were grouped in epidemiological weeks and residential areas informed by Telecoronavirus users. Additionally, they were grouped in sanitary districts using the list of neighborhoods comprising each of the 13 sanitary districts of the city of Salvador. Official numbers of COVID-19 confirmed cases were also obtained by sanitary districts.

Use of Telehealth Data for Feeding Epidemiological Modeling

We further tested the hypothesis that telehealth systems can help feed numerical models developed to predict a virus spread in a specific region using a spatiotemporal model presented in [12,20-22] and explained as follows.

The Susceptible, Exposed, Infected, Recovered, Deceased Model for COVID-19

The COVID-19 dynamics may be modeled as compartmental models, in which the population under study is divided into compartments and has assumptions about the nature and time rate of transfer from one compartment to another [23]. These models have been used extensively in biological, ecological, and chemical applications [24-26]. They allow for an understanding of the processes at work and predict the dynamics of the epidemic. One of the simplest compartmental models is the "susceptible, infected, removed" model proposed in 1927 by Kermack and McKendrick [27], in which the population is divided into susceptible, infected, and recovered compartments. This basic "susceptible, infected, removed" model can be extended in several ways by enriching the number of compartments, as the "susceptible, exposed, infectious, recovered, deceased" model. Here, we work with a spatiotemporal "susceptible, exposed, infectious, recovered, deceased" model, presented in [20-22], given by,

Where $s(x, t)$, $e(x, t)$, $i(x, t)$, $r(x, t)$, and $d(x, t)$ denote the densities of the *susceptible*, *exposed*, *infected*, *recovered*, and *deceased* populations, respectively. The sum of all the compartments, except for $d(x, t)$, is represented by n_{pop}, which is the total living population. β_i and β_e denote the transmission rates between symptomatic and susceptible individuals and asymptomatic and susceptible individuals, respectively (units 1/days), a denotes the incubation period (units 1/days), γ_e corresponds to the asymptomatic recovery rate (units 1/days), γ_i the symptomatic recovery rate (units 1/days), δ represents the mortality rate (units 1/days), and ν_s, ν_e, ν_i, ν_r are the diffusion parameters of the different population groups as denoted by the subscripted letters: units km²/(persons.days).

To use this model, we need to define all parameters that govern the system of equations and the initial population of each compartment. Note that all these parameters can be considered time- and space-dependent. We need to infer several hypotheses about the initial conditions, especially those related to the exposed compartment, consisting of asymptomatic cases, which are more challenging to estimate.

Model Construction for Salvador, Bahia

We define the beginning of the simulation as April 1, 2020, and simulate 180 days. The initial infected population is set according to the 7 days moving average data provided by the Brazilian Ministry of Health, following the procedure in [12] and [28]. The susceptible population is based on the estimation of the population of each Sanitary district, given by the Brazilian Institute for Geography and Statistics. Recovered and deceased populations start with zero assigned cases (ie, we consider that nobody died or recovered from COVID-19 at the beginning of the simulation).

The exposed compartment is the most nontrivial compartment to assign an initial condition. In previous works, the estimation was based on the amount of the infected population. It was considered that the exposed population could be about 10 times the number of the infected [29]. Here, we consider the 7-day moving average data from telehealth on April 1, 2020, as the initial exposed population. The telehealth data indicated rises in cases approximately 2 weeks before the notification system. Therefore, the calls may indicate a better estimation than the relation with the infected, especially at the epidemic's beginning.

Each compartment's population is divided by the area of each sanitary district and distributed in the 12 areas as people/km². Table 1 shows the differences between how the initial exposed population is considered in this work (related to the telehealth system) and how it would be represented when using the old approach (by multiplying the number of infected individuals by 10). Without the need for any calculation, it is possible to see that there is no correlation between the numbers of each approach.

The biological parameters of the simulation are defined based on the literature, as $\alpha = 1/7\ day^{-1}$, $\gamma_i = 1/24\ day^{-1}$, $\gamma_e = 1/6\ day^{-1}$, $\delta = 1/160\ day^{-1}$ [21]. On the other hand, the contact rate and the diffusion coefficient have to be estimated. They are based on the social distancing estimation, representing the homestay rate for Bahia.

Table 1. Initial exposed population (people/km2) based on 10 times the number of infected and the telehealth calls.

Sanitary district	Ten times the number of infected	Telehealth
Barra Rio Vermelho	27.14	53.00
Brotas	8.57	34.57
Centro Histórico	2.86	13.42
Liberdade	4.29	17.70
Boca do Rio	5.71	23.42
Cabula/Beiru	8.57	43.57
Itapuã	10.00	36.14
Pau da Lima	4.29	25.85
Subúrbio Ferroviário	7.14	30.28
Itapagipe	2.86	18.42
São Caetano or Valéria	7.14	26.57
Cajazeiras	2.86	10.28

Results

The telehealth service received a total of 111,795 calls, 83,175 (74%) of which reporting at least one COVID-19 symptom (fever, cough, breathlessness, rhinorrhea, and gustatory or olfactory disorder) during the first 4 months of the COVID-19 epidemic in the state of Bahia (Figure 1). Olfactory or gustatory dysfunction (smell and taste change), considered highly specific for COVID-19 during the first wave of the pandemic [30-32], was reported in 47% of the calls, suggesting a high frequency of COVID-19 cases among users of the telehealth service.

Calls were registered by 320 (77%) out of 417 cities of Bahia State. The majority of these users of the telehealth service were female (48,873, 60%), with a median age of 38 (IQR 28-49) years. The demand for the service progressively increased between the first and ninth week, with a peak in the 23rd week.

In the 4th month of operation, we observed a reduction in the number of daily calls to values close to those at the beginning of the service (Table 2).

During the first month of operation (April 2020), calls reporting COVID-19–like symptoms were registered in 205 cities, including areas from the north and east of the state. By this time, COVID-19 cases were notified in 136 cities (Figure 2). The first call to the telehealth service preceded the first COVID-19 notification in 181 (43%) out of 417 municipalities of Bahia. In these municipalities, the call occurred on average 30 (IQR 11-42) days before the notification. Additionally, for 68 (38%) of these 181 municipalities, the symptoms registered in the telehealth service included olfactory and gustatory disorders. These symptoms specific for COVID-19 were reported on average 14 (IQR 6-31) days before the first notified COVID-19 case (Multimedia Appendix 2).

Figure 1. Flowchart of calls for Telecoronavirus service according to local and presence of COVID-19–like symptoms.

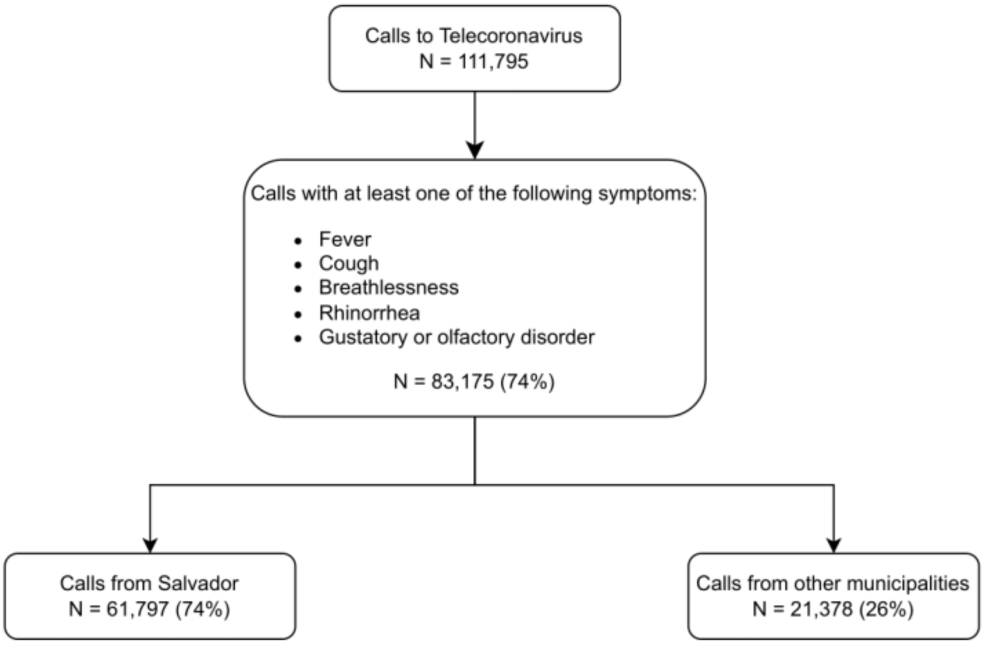

Table 2. Symptoms reported by users and the number of monthly calls.

Characteristic	Salvador (n=61,797)	Other cities (n=21,378)	State (n=83,175)
Age (years), median (IQR)	39 (29, 50)	37 (27, 48)	38 (28, 49)
Month, n (%)			
March	178 (0.3)	49 (0.2)	227 (0.3)
April	10,009 (16)	3464 (16)	13,473 (16)
May	23,227 (38)	4822 (23)	28,049 (34)
June	20,743 (34)	8634 (40)	29,377 (35)
July	7640 (12)	4409 (21)	12,049 (14)
Sex: female, n (%)	36,315 (60)	12,558 (60)	48,873 (60)
Fever, n (%)	30,501 (49)	10,468 (49)	40,969 (49)
Cough, n (%)	30,307 (49)	11,287 (53)	41,594 (50)
Shortness of breath, n (%)	15,518 (25)	6054 (28)	21,572 (26)
Smell or taste change, n (%)	28,741 (47)	9248 (44)	37,989 (47)

We also analyzed the spatial-temporal distribution of calls and notified cases in the districts of Salvador, the state capital. In all districts, an increase in the number of calls reporting COVID-19–like symptoms preceded an elevation in the number of notifications of COVID-19 (Figure 3).

Next, we evaluated if the data obtained with the telehealth service could be helpful in feeding a mathematical model to predict disease spread in Salvador. We simulated 180 days of the epidemic. To validate the results of our model with the available data, we compared the number of notified COVID-19 cases. First, we showed the values obtained for the whole city (Figure 4). Then, we integrated the values of the sanitary districts and plotted them in time. The simulation provides curves of accumulated infection similar to the data of notified cases.

Figure 2. Spatial distribution of calls related to COVID-19–like symptoms (orange) and notifications (green) by months of operation of the Telecoronavirus in Bahia state.

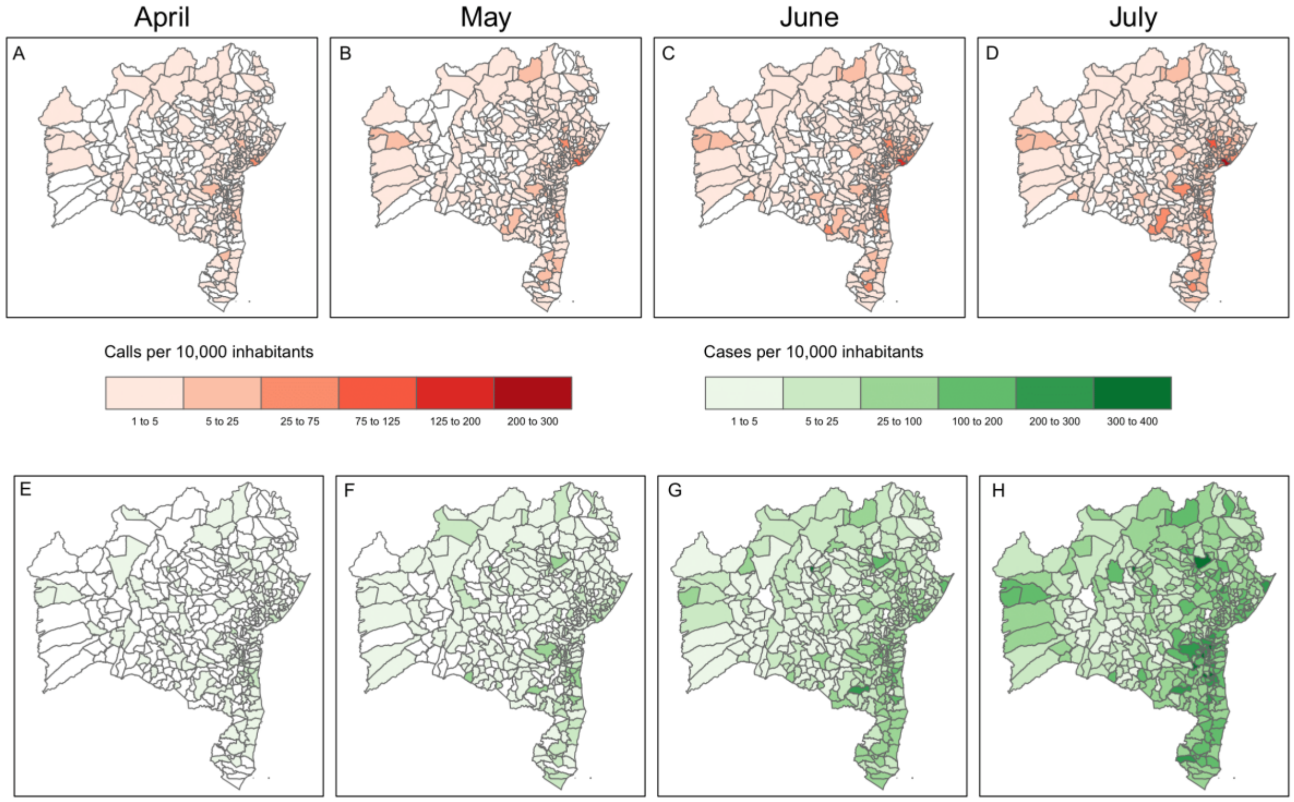

Figure 3. Seven-day rolling average of number of calls reporting COVID-19–like symptoms (blue line) and number of confirmed cases of COVID-19 (red line) in the period of operation of the telehealth service in Salvador, Bahia state, Brazil. (A) All cities. (B) Stratified by sanitary district.

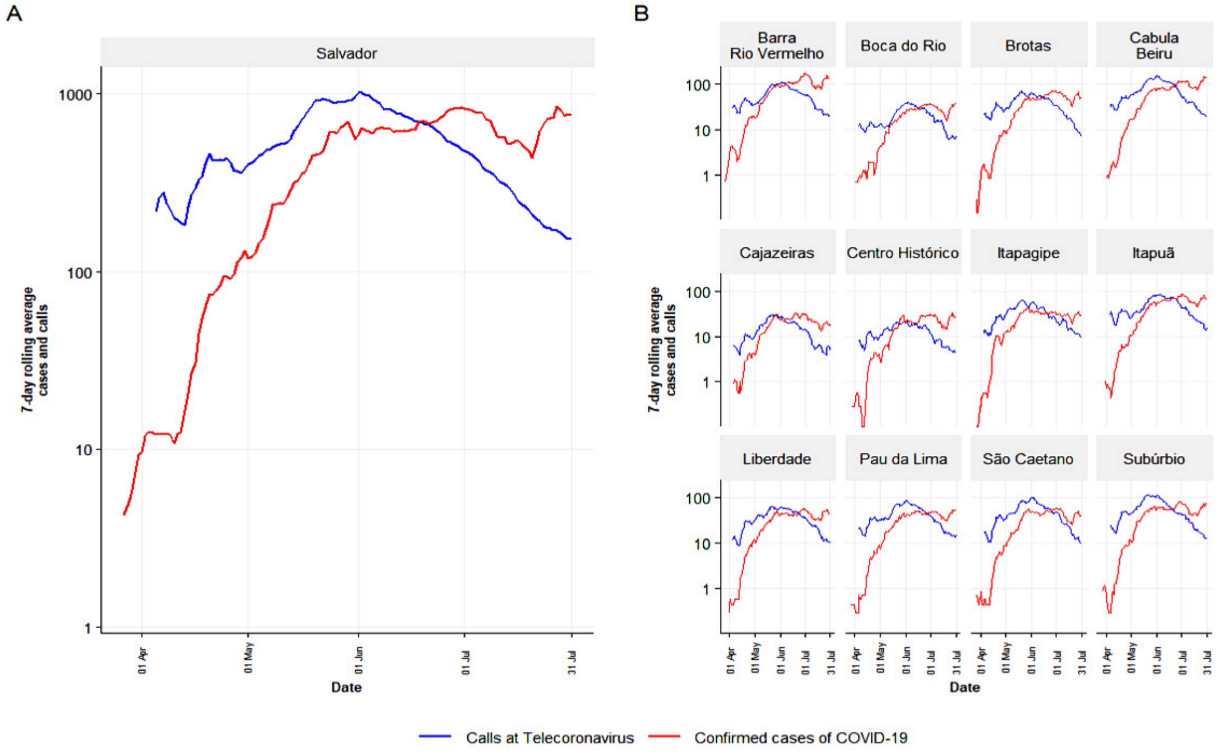

Figure 4. Comparison between simulation and real data of cases at Salvador (total). Dashed blue lines: real data. Pink line: simulation with exposed population based on telehealth calls.

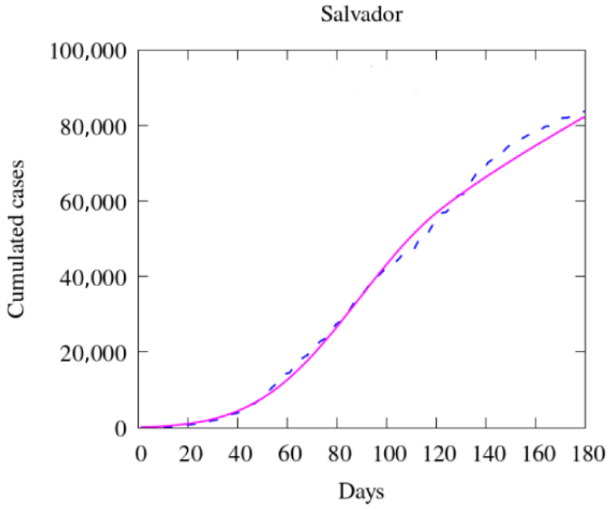

Discussion

Principal Findings

A critical challenge in predicting the spread of cases, especially in locals with a low test rate, is to timely estimate the number of suspected cases. Here, we demonstrated that curated data obtained from a telehealth service could be helpful in anticipating areas with new cases of COVID-19. A rise in calls referring to COVID-19–like illness preceded, in about two weeks, the increase in the notification of COVID-19 in the majority of Bahia state cities demonstrating the potential utility of this instrument for syndromic surveillance in the early phase of the epidemic curve. Additionally, it contains relevant information about the disease under investigation, such as the profile of the affected population, type, and frequency of symptoms, which can help characterize susceptible populations, which is important in the context of epidemics caused by new infectious agents. Calls captured in the telehealth service were also valuable in feeding a numerical disease spread model. Data obtained by a toll-free telehealth service can achieve the goals required for surveillance purposes, such as the following: (1) to be collected early after disease onset, (2) to represent the majority of the population in the covered area, and (3) to be rapidly accessed by the decision-making officials [5,33].

First, in an outbreak caused by a pathogen of airborne transmission, such as COVID-19, the fear of contamination reduces seeking face-to-face medical assistance. The majority of individuals with mild symptoms avoid being exposed in clinical care facilities, reducing the number of individuals who get tested, and therefore confirmed infections may be underestimated. From the patient perspective, telehealth assistance becomes more attractive. Accordingly, a substantial increase in telemedicine service was detected in the first weeks of the pandemic [5,34]. Consequently, data from telehealth services become more suitable for surveillance purposes than laboratory-confirmed infection or electronic medical records obtained from health care units.

Second, telehealth services can cover a population from a wide geographic area. The service offered via telephone dismisses reading or writing skills, digital literacy, or internet access and can be used by all age groups and social strata. If the service is toll-free, most of the population may be covered, which is especially important for low- to middle-income countries, as observed in this case.

Third, data sets containing time-sensitive information collected from telehealth services can be accessed simultaneously by public health authorities for syndromic surveillance. Automating data extraction and real-time interpretation of information in the context of relevant public health emergencies is still challenging. Structured surveys designed for telescreening assistance, as described here, can serve this purpose and offer daily reports for the stakeholders. Although several aspects, such as technical or operational, ethical, and legal points, should be addressed to use these data for disease surveillance, analysis of real-time data obtained from telehealth services is feasible. It has already been performed for contact tracing, screening, and monitoring clinical conditions in emergency response to epidemics [35] and can support decision-making on public health policy.

Our result suggests that the data set from a telehealth service may also be helpful as input to a mathematical model to predict COVID-19 spread. The initial conditions of the exposed and infected populations are essential to short-term predictions. The estimate of exposure may be challenging since this population has no symptoms. Therefore, the hypothesis of assuming the number of exposed as the number of calls might be better than an estimation based on the number of infected, since the telehealth data indicated rises in cases approximately 2 weeks before the notification system.

The simulation for a city of about 2.9 million inhabitants showed that most sanitary districts had a good agreement between the actual data and the simulation. The simulation overestimated the cases in 1 district area and underestimated them in 2 areas. Other districts had an excellent agreement until day 100 and lost accuracy afterward. A loss of accuracy in a fast-changing infectious disease is expected since it is challenging to reproduce long-term predictions. The simulation may still be improved due to several aspects needing to be considered. For example, we used estimates for parameters such as transmission rate and diffusion, and it would be possible to use a machine learning mechanism to find the best ones for this case. Moreover, we define that all sanitary districts would receive the same input parameters, and we know that different regions might have performed differently regarding the population’s behavior and restriction policies. Besides, we used only spatial spread mechanisms due to diffusion and further use of different approaches, as convection and source terms could have offered better estimates. However, the central idea of this report is to show that telehealth data impact a robust algorithm that worked well to simulate the COVID-19 behavior of different regions (Italy, Brazil, and the United States [12]).

Collecting real-time data may help predictors forecast new surges and prepare the population, authorities, and health systems. Moreover, we may infer that our hypothesis works since our simulation with the telehealth data have provided promising results.

Limitations

Our study has some limitations. We used COVID-19–like symptoms as a proxy for confirmed infection. Although this is not accurate, the number of phone calls and the trend in service assessment may suggest the direction and amount of disease spread early on. It shall also be stressed that confirmatory tests may not be available in the early stages of a new epidemic infection. In such cases, the use of the syndromic approach, as employed here, is a critical element for predicting infection spreading. Another significant limitation is that the telehealth service was not equally publicized in all cities, which may have implications for interpreting surveillance data in some areas.

Conclusion

In conclusion, data from telehealth services help model COVID-19 spread and may be helpful in other health situations. Telehealth data and digital health technologies for monitoring disease spread may be especially useful considering the resurgence of new SARS-CoV-2 variants [36]. Data collected from primary health care systems can be used for monitoring the dynamics of COVID-19 cases and the geographic localization of cases. Considering the continuous expansion of telehealth and telemedicine tools in the health care system, the availability of such data may prove a critical tool for modern epidemiology.

Acknowledgments

The authors thank all TeleCoronaVirus volunteers, the Government of the state of Bahia, and all participating institutions.

This study is part of the Alert-Early System of Outbreaks with Pandemic Potential (AESOP) program funded by Fundação Oswaldo Cruz and the Rockefeller Foundation. During the period of analyses, TC-S was a PhD student at the Post-Graduation Program in Health Sciences, Universidade Federal da Bahia, which is supported by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior-Brasil, finance code 001. MBN, VSB, and AC are research fellows from the National Council for Scientific and Technological Development (CNPq).

Data Availability

Our agreement with the Bahia State Health Secretary for accessing the database denies authorization of access to a third party. Request for accessing the database should be addressed to the state government, Secretaria de Saúde do Estado da Bahia.

Conflicts of Interest

None declared.

Multimedia Appendix 1

Brazil’s map showing the state of Bahia and the capital Salvador.

Abstract

Background: Physical activity (PA) and sedentary behavior (SB) have been affected by the COVID-19 pandemic and its restrictive environments, such as social distancing and lockdown measures. However, regional differences in the changes in domain-specific PA and SB in response to the COVID-19 pandemic are not clearly understood.

Objective: This study aimed to examine regional differences in domain-specific PA and SB, as well as sleeping time in response to the COVID-19 pandemic in Japan.

Methods: A web-based cross-sectional nationwide survey and an accelerometer-based longitudinal observation were conducted. In the web-based survey, we recruited 150 Japanese men and 150 Japanese women for each of the following age groups: 20s, 30s, 40s, 50s, 60s, and 70s (n=1800). A total of 1627 adults provided valid responses to web-based surveillance from June to July 2020. Participants were recruited from urban (Greater Tokyo Area, n=1028), urban-rural (regional core cities, n=459), or rural (regional small and medium cities, n=140) areas. They answered sociodemographic and health-related questions and retrospectively registered the PA data of their average day before and during the COVID-19 pandemic in a web-based PA record system. In the accelerometer-based observation, PA and step count data were obtained using a triaxial accelerometer on people living in urban (n=370) and rural (n=308) areas.

Results: Before the COVID-19 pandemic, there were no significant differences between these 3 regions in the time spent sleeping, staying at home, working or studying, and exercising (*P*>.05). By contrast, people living in urban areas had a longer duration of SB and transportation and a shorter duration of moderate-to-vigorous PA and lying or napping time compared with people living in rural areas (*P*>.05). During the COVID-19 pandemic, a significant decrease was observed in transportation time in urban (–7.2 min/day, *P*<.001) and urban-rural (–2.0 min/day, *P*=.009) areas but not in rural (–0.4 min/day, *P*=.52) areas. The moderate-to-vigorous PA was decreased in urban (–31.3 min/day, *P*<.001) and urban-rural (–30.0 min/day, *P*<.001) areas but not in rural areas (–17.3 min/day, *P*=.08). A significant increase was observed in time spent sleeping in urban (+22.4 min/day, *P*<.001) and urban-rural (+24.2 min/day, *P*<.001) but not in rural areas (+3.9 min/day, *P*=.74). Lying or napping was increased in urban (+14.9 min/day, *P*<.001) but not in rural areas (−6.9 min/day, *P*=.68). PA and step count obtained using an accelerometer significantly decreased in urban (*P*<.05) but not in rural areas (*P*>.05).

Conclusions: The effect of the COVID-19 pandemic on PA and SB was significantly dependent on living area, even in a single country. The effects of PA and SB were greater in the Greater Tokyo Area and regional core cities but were not observed in regional small and medium cities in Japan.

Introduction

Human lifestyles have changed in recent years, with an increasing number of people living a sedentary lifestyle, particularly in the countries with higher human development index [1]. Adequate amounts of physical activity (PA), limited sedentary behavior (SB), and proper sleeping time (ST) are essential for maintaining health [2-4]. Physical inactivity increases the risk of many adverse health conditions, such as coronary heart disease, type 2 diabetes, colon and breast cancers, mobility disabilities, and mortality [5].

The COVID-19 pandemic has changed the world and strongly affected the health of the people, with more than 640 million people with COVID-19, causing more than 6.6 million deaths worldwide [6]. Studies have indicated that the COVID-19 pandemic and its restrictive environment induced by the government's statements about social distancing and lockdown measures affect PA, SB, and ST in children, adolescents, and young and older adults worldwide [7-15]. Stockwell et al [16] conducted a systematic review of the changes in PA and SB from before to during the COVID-19 pandemic restrictive environment. Most studies showed a decreased PA and an increased SB in the 66 included studies. They noted that different degrees of *lockdown* in different countries, even regions within a country, make it difficult to objectively assess how different degrees of restrictive environments impact behaviors. They also noted that most studies report PA without investigating in detail the types and durations of PA engaged before and during the lockdown. Thus, it would be beneficial to investigate these because the magnitude of changes will impact the effects on health.

For the Japanese population, a web-based survey using the short version of the International Physical Activity Questionnaire (IPAQ) found that PA decreased in April and recovered in June 2020 in older Japanese adults [7,8]. Another web-based survey using the Global Physical Activity Questionnaire (GPAQ) of Japanese workers found a significant increase in ST and a significant decrease in leisure-related moderate-to-vigorous physical activity (MVPA) during the COVID-19 outbreak (July 2020) compared to before the outbreak (February 2019) [13]. The IPAQ and GPAQ are considered world-standard questionnaires, with the advantage of comparing the results with worldwide data [17]. However, their external validity against the doubly labeled water (DLW) method is poor [18] compared with objective accelerometers [19,20]. The most recent meta-analysis also indicated that the criterion validity of IPAQ and GPAQ against objective smart trackers was low (weighted mean of r=0.23) [17]. Thus, more reliable systems to assess PA and SB in daily life are required for a stronger conclusion. In addition, it is essential to examine regional differences in PA and SB in response to the COVID-19 pandemic.

This study assessed a 24-hour domain-specific PA, SB, and ST in Japanese adults nationwide using a previously validated web-based simplified physical activity record (sPAR) system. In addition, we obtained longitudinal PA and step count data by a triaxial accelerometer on people living in urban and rural areas. We hypothesized that the impact of the COVID-19 pandemic and its restrictions (including government social distancing measures) on domain-specific PA, SB, ST, or step count vary by region of residence, even within a single country.

Methods

Data Source

The web-based surveillance was conducted through an internet research company (Cross Marketing Inc). Cross Marketing Inc and its partner companies have active panels with over 5 million people who registered their sociodemographic information in the company's database and responded to at least one survey within the last year [21]. The company recruited 1800 adults from their active panels from June to July 2020; in total, 150 men and 150 women were recruited for each of the following age groups: 20s, 30s, 40s, 50s, 60s, and 70s. Individuals completed the web-based sPAR system, which was included before and during the COVID-19 pandemic. The company provided the URL via email and requested each participant to complete a survey. All the participants signed a web-based informed consent form. The research company removed participants' names, addresses, contact information, and any other details that might be used to identify individuals prior to transferring the data to researchers from the data. A total of 1627 adults provided valid responses for this web-based survey. Self-reported age, height, and weight data were obtained. The participants were categorized by gender and residential area, which were divided into urban (Greater Tokyo Area), urban-rural (regional core cities), and rural (regional small and medium cities), based on the Fourth National Comprehensive Development Plan, Japanese National Land Agency [22].

Ethical Considerations

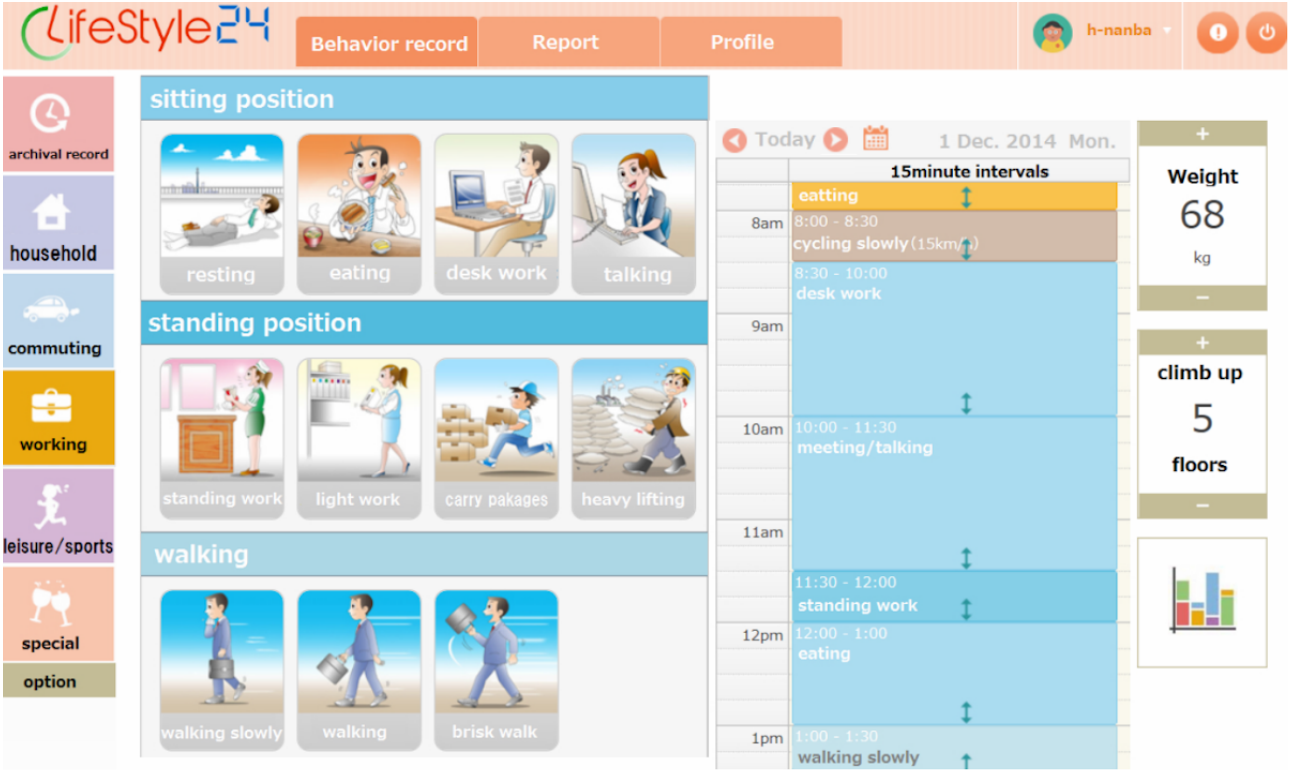
This study was conducted with approval from the ethics committees of Kyoto University of Advanced Science (KUAS no.20-3) and the National Institutes of Biomedical Innovation, Health and Nutrition (NIBIOHN no. 202). Participants were provided with an information sheet on the landing page of the web-based survey. Participants were only allowed to continue participating if they acknowledged that they had read the information sheet and agreed to give informed consent.

Web-Based PA Record

The sPAR is a unique system for assessing 24-hour domain-specific PA, SB, and ST [23]. The external validity is moderate to high (*r*=0.8 for total energy expenditure and *r*=0.63 for PA level) [23-25]. One study developed a web-based sPAR system and found that external and criterion validity were also moderate to high (*r*=0.68 for activity energy expenditure [AEE] measured by DLW and *r*=0.87 for total energy expenditure; *r*=0.77 for AEE; *r*=0.71 for PA level assessed by a validated triaxial accelerometer) [26,27]. The external validity from another study of a triaxial accelerometer and sPAR against the DLW method was similar and high [24].

A representative screenshot of the web-based sPAR system is shown in Figure 1. The system collected recalled activities over 24 hours. The participants were instructed to respond to questions about a typical day that is not a weekend or holiday. The participants selected one of the preset activities performed in each of the four categories (household, transportation, work-related, and leisure or sports) for 15-minute intervals. In this system, 91 activities among the four categories were preset. The details of the web-based sPAR system have been previously described [26,28]. The intensity of each activity was entered into the system as metabolic equivalent of tasks (METs) based on the 2011 Compendium of Physical Activities [29]. MVPA (≥3.0 METs) and SB (1.0-1.5 METs) were calculated based on the MET value of each activity.

Figure 1. Screenshot of the web-based simplified physical activity record (sPAR) system (Namba et al [28]).



eatting

8:00 - 8:30 cycling slowly (15km/h)

8:30 - 10:00 desk work

10:00 - 11:30 meeting/talking

11:30 - 12:00 standing work

12:00 - 1:00 eating

1:00 - 1:30 walking slowly

Weight 68 kg

climb up 5 floors

Accelerometer

In addition to this web-based survey, we also used the data set of a triaxial accelerometer that had been previously published as a short research paper [11]. The original data contained 628,111 observation days from January 1, 2019, to January 1, 2021, from 1167 unique users of the accelerometer nationwide in Japan. From the 1167 unique users' data, people who lived in the Greater Tokyo Area (n=370) and those who lived in rural areas (n=308) were selected to compare urban and rural differences in this study based on the information about the prefecture in which they lived [11]. The average step counts and AEEs for January 2019, April 2019, January 2020, and April 2020 were calculated. Step counts and AEE were monitored using a triaxial accelerometer (EW-NK63; Panasonic). This accelerometer was manufactured based on the Actimarker (EW4800, Panasonic), an accelerometer for research use, as a low-cost version of the one for the general public [30]. Daily step counts and AEE were stored on a server via participants' smartphones. All participants read the explanation of the study and indicated their understanding before providing informed consent. The details of the METs calculations have been previously described [31,32]. The output of the accelerometer was highly correlated (R^2=0.86) with the METs while walking or running at 7 speeds ranging from 40 to 160 m/min^{-1} and during the following 7 daily activities: performing self-care while standing, changing clothes, cooking, simulating eating supper, washing dishes, doing laundry, and using a vacuum cleaner [31,32]. AEE was calculated from 24-hour average METs, and this accelerometer highly correlates with the DLW method [20,24].

Statistical Analyses

Data are shown as means and standard deviations in the tables and as means and standard errors in the figures. One-way ANOVA was performed to compare age, and a chi-square test was conducted to compare the percentage of either gender between residential areas. Socioeconomic status, smoking, alcohol consumption, and health-related information, including medical history, were extracted from the web-based survey. Psychological distress was assessed by the Kessler Psychological Distress Scale (K6) screening scales [33-35]. One-way analysis of covariance was performed to compare other values between residential areas with the variables in Tables 1 and 2. A 2-tailed paired *t* test was conducted to compare values before and during the COVID-19 pandemic. The results were considered significant at a *P*<.05. SPSS version 22 (IBM Corp) was used for all statistical analyses.

Table 1. Physical characteristics of the participants (n=1627).

Characteristics	Urban (n=1028)	Urban-rural (n=459)	Rural (n=140)	*P* value
Men, n (%)	542 (52.7)	267 (58.2)	79 (56.4)	.21

[a] K6: Kessler Psychological Distress Scale.

Results

The physical characteristics of the participants are shown in Table 1. No significant differences were observed in age, gender, height, or weight among the 3 residential area categories (*P*>.05). Table 2 shows the social and health status of the participants. The urban area had a higher percentage of alcohol drinkers, people with higher household income and subjective economic status, and those with higher education than other areas (*P*<.05). However, other variables were not significantly different between areas (*P*>.05).

In Table 3, Before the COVID-19 pandemic, there were no significant differences in sleeping time, time spent at home, working or studying time, and exercise time (*P*>.05) in the 3 regions. By contrast, people living in urban areas had a longer duration of SB and transportation and a shorter duration of MVPA and lying or napping time compared with people living in rural areas (*P*<.05). Significant and negative correlation was observed between work duration and ST (*r*= 0.373, *P*<.001), and between transportation time and ST (*r*= 0.289, *P*<.001).

Table 4 and Figure 2 show changes in ST, SB, transportation, and MVPA before and during the COVID-19 pandemic. A significant decrease was observed in transportation time (−7.2 min/day, *P*<.001) and urban-rural (−2.0 min/day, *P*=.009) areas but not in rural (−0.4 min/day, *P*=.52) areas during the pandemic. The MVPA was decreased in urban (−31.3 min/day, *P*<.001) and urban-rural (−30.0 min/day, *P*<.001) areas but not in rural areas (−17.3 min/day, *P*=.08). A significant increase was observed in time spent sleeping in urban (+22.4 min/day, *P*<.001) and urban-rural (+24.2 min/day, *P*<.001) but not in rural areas (+3.9 min/day, *P*=.74). Lying or napping was increased in urban (+14.9 min/day, *P*<.001) but not in rural areas (−6.9 min/day, *P*=.68).

Figure 3 shows the relationship between the changes in PA and SB during the COVID-19 pandemic. The change in the duration of transportation was significantly and negatively correlated with the change in the duration of staying at home (*P*<.05). The change in MVPA duration was significantly and negatively correlated with the change in the duration of lying or napping and the change of the duration of SB (*P*<.05).

Figure 4 shows the results of the accelerometer monitoring. The step counts and AEE obtained by an accelerometer significantly decreased during the COVID-19 pandemic in urban areas (*P*<.05) but not in rural areas (*P*>.05).

Table 3. Physical activities and sedentary behavior of the participants (n=1627).

Variables	Urban (n=1028), mean (SD)	Urban-rural, (n=459), mean (SD)	Rural, (n=140), mean (SD)	*P* value
Before the COVID-19 pandemic				
Sleeping time (min/day)	453 (139)	462 (145)	460 (137)	.51
Lying or napping time (min/day)	99 (153)	111 (151)	132 (194)	*.045*

Exercise time (min/day)	0.0 (–0.9, 0.9)	.98	–0.6 (–1.3, 0.1)	.09	–0.2 (–0.7, 0.3)	.42

[a] SB: sedentary behavior.

[b] MVPA: moderate-to-vigorous physical activity.

Figure 2. The changes in sleeping time, sedentary behavior, and physical activity from before to during the COVID-19 pandemic were assessed by a web-based physical activity record system (mean and SE). Significant differences were observed between the urban (Greater Tokyo Area) or urban-rural areas and the rural area in changes in the duration of sleeping, lying or napping, transportation, and moderate-to-vigorous physical activity (MVPA). ***Signficantly changed from before the COVID-19 pandemic (*P*<.001).

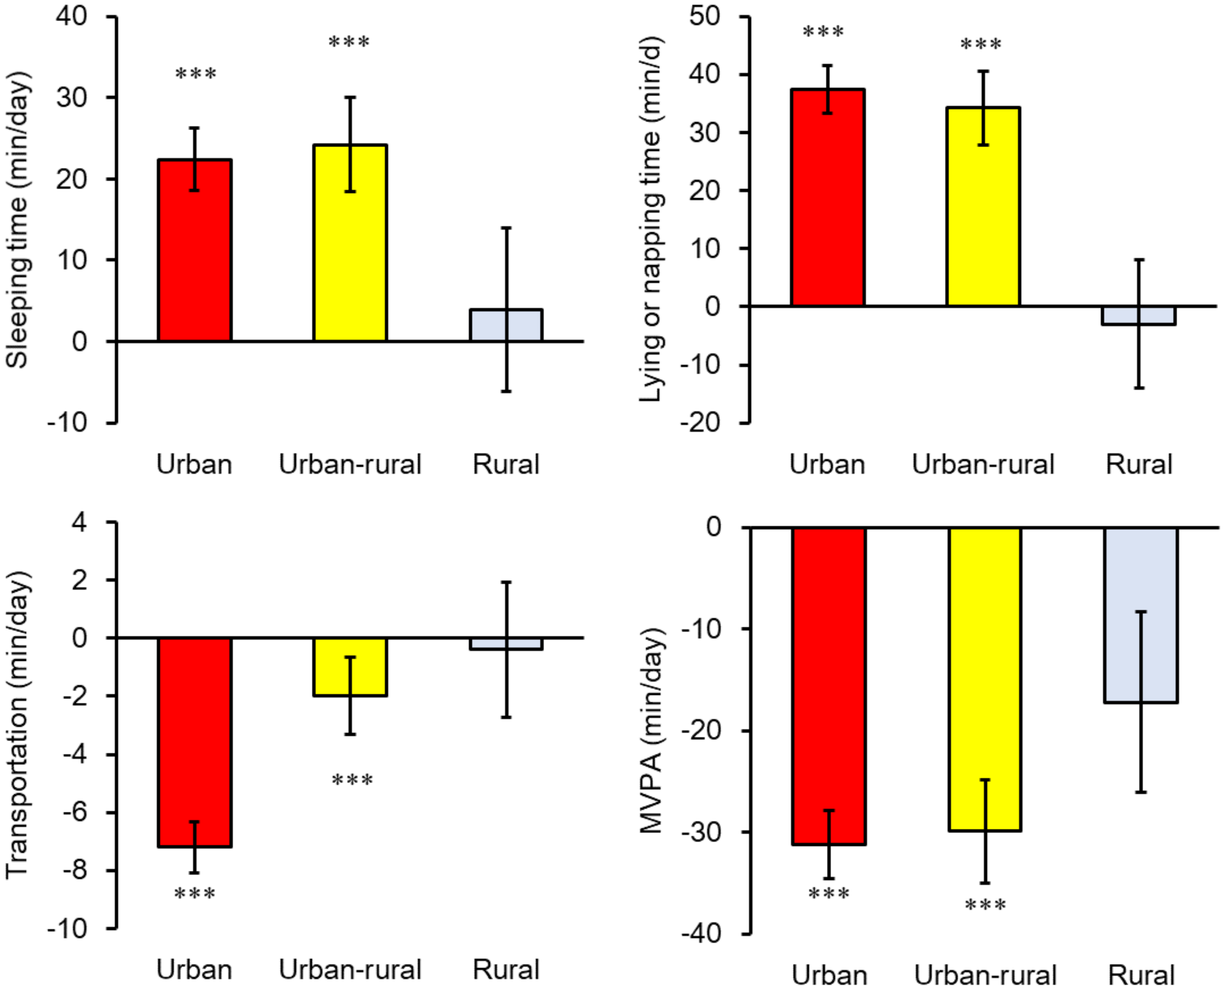

Figure 3. The relationship between changes in physical activity and sedentary behavior (SB) during the COVID-19 pandemic. The change in moderate-to-vigorous physical activity (MVPA) duration was significantly and negatively correlated with the change in the duration of lying or napping and SB. The change in transport duration was significantly and negatively correlated with the change in the duration of staying home.

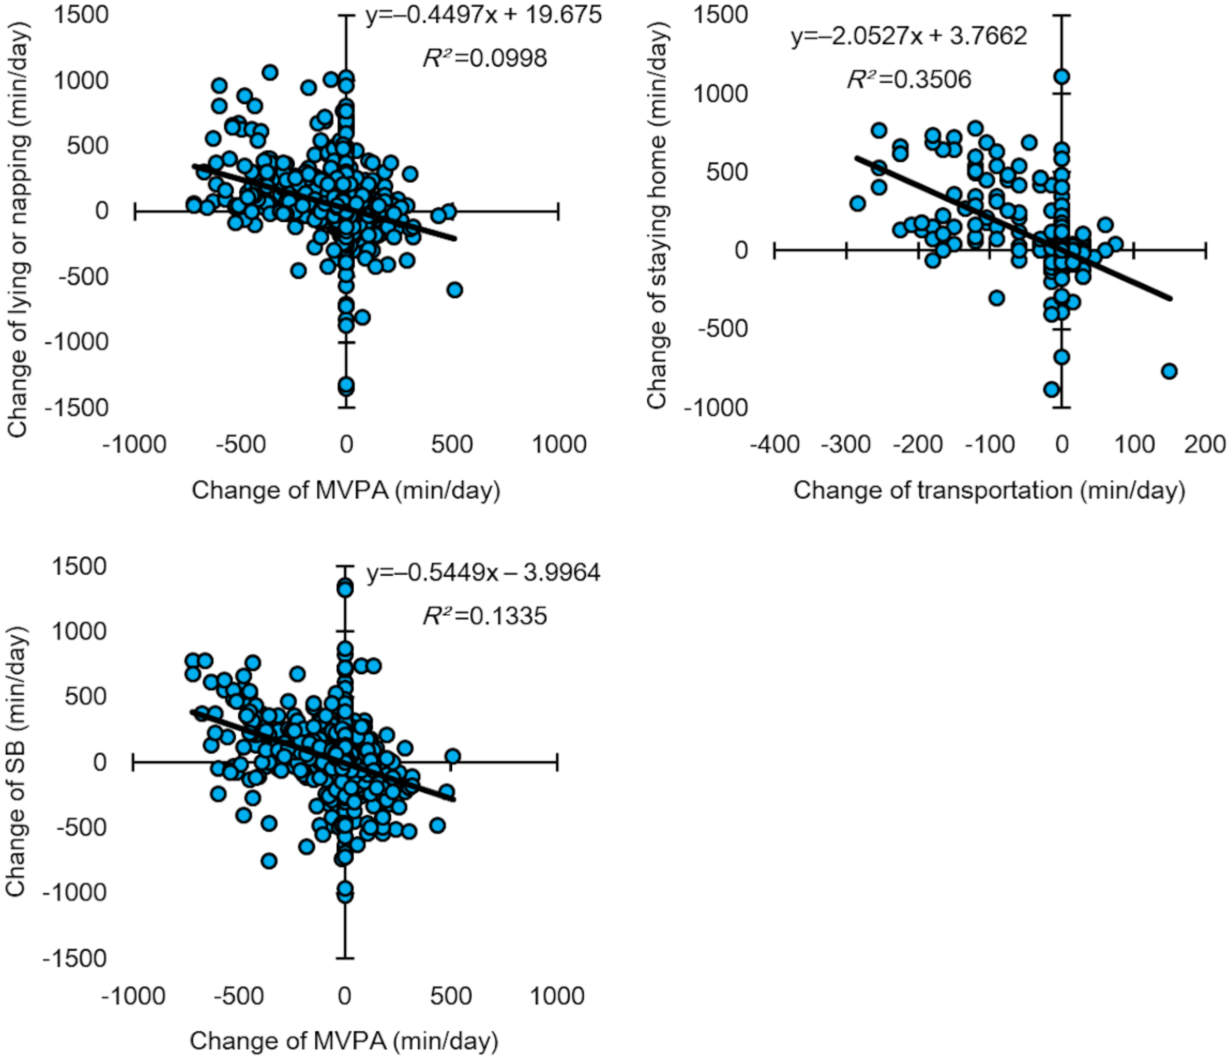

Figure 4. Objectively measured step counts and activity energy expenditure (AEE) by triaxial accelerometer (mean and SE). There is no significant difference between January and April 2019 in step counts and AEE in urban and rural prefectures. The step counts (*P*<.001) and AEE (*P*<.05) in April 2020 were significantly decreased in urban prefectures when January and April 2019 are compared to January 2020.

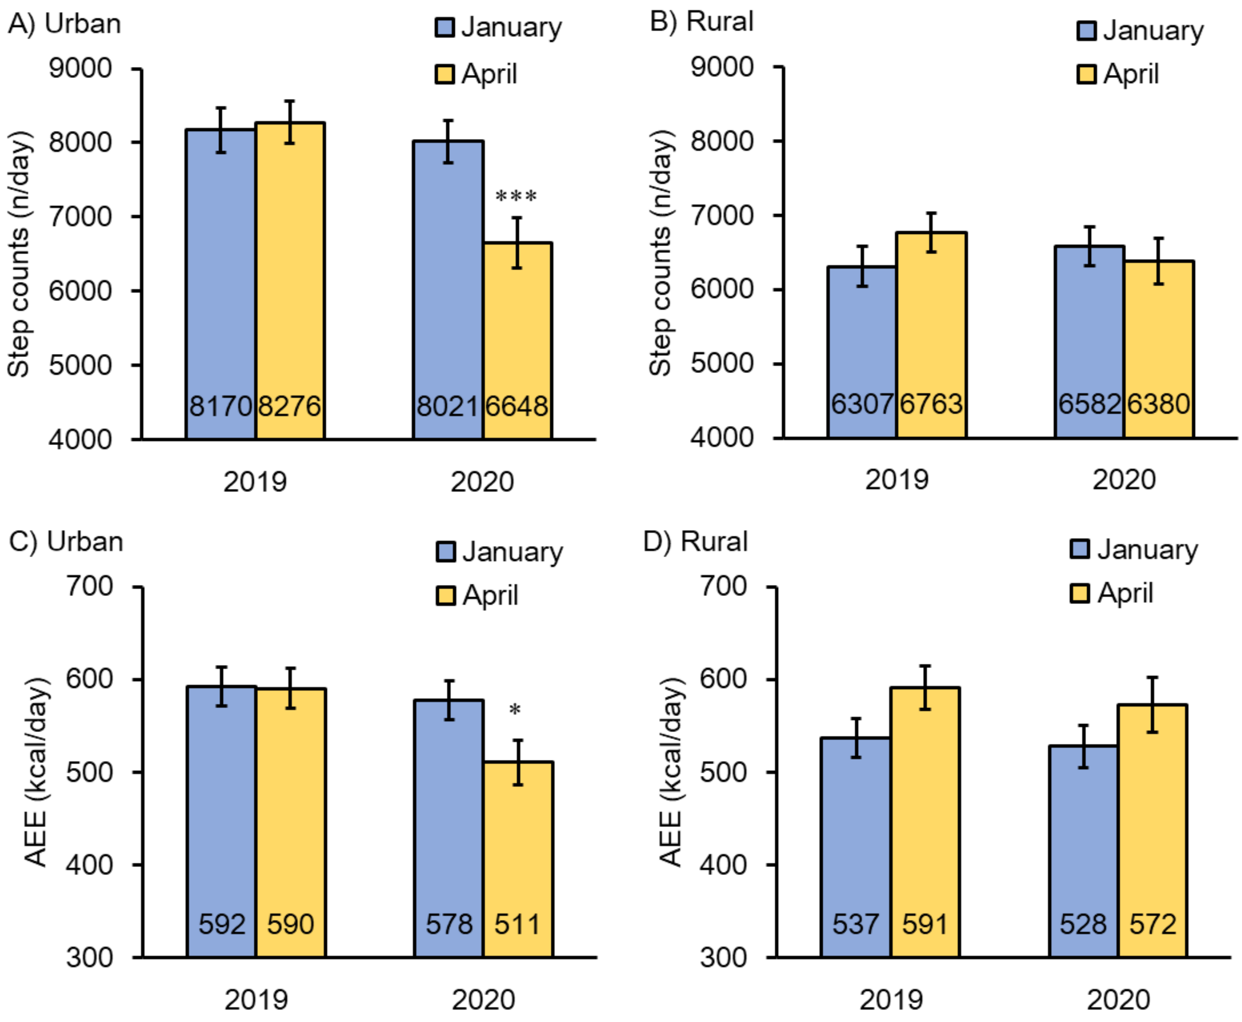

Discussion

Principal Findings

This study clearly shows regional differences in domain-specific PA, SB, and ST changes in response to the COVID-19 pandemic. The Japanese government first declared a state of emergency in response to the COVID-19 outbreak on April 7, 2020 [36,37]. The effects of the COVID-19 outbreak and the government-declared state of emergency were significantly larger in the urban (Greater Tokyo Area) and urban-rural (regional core cities) areas than in rural areas (regional small and medium cities). Particularly, MVPA decreased by 31 min/day (–18.4%), from 168 min/day before to 137 min/day during the COVID-19 pandemic. Sleeping time (+26 min/day on average) and lying or napping time (+36 min/day on average) increased significantly during the COVID-19 pandemic in the urban and urban-rural areas. In addition, the duration of transportation was significantly decreased by 7 min/day, from 65 min/day before to 57 min/day during the COVID-19 pandemic in the urban area. In addition, we confirmed these regional differences using the triaxial accelerometer as an objective method.

Several previous studies have observed similar patterns in other population groups [7,13,38,39]. However, many surveys that addressed domain-specific PA used PA questionnaires, such as the IPAQ and GPAQ. The external and criterion validity of the PA questionnaires was relatively low when compared with a gold standard method, such as the DLW method, or with objective accelerometers [17-20]. Thus, more reliable systems to assess PA and SB in daily life are required for a stronger conclusion. The web-based sPAR system is a unique method for obtaining PA and SB data with moderate or high external validity [23,26,27].

In this study, Japanese living in urban or urban-rural areas were found to have spent more time lying and sleeping during the COVID-19 pandemic than before the pandemic. The average ST of the participants was 455 min/day before the COVID-19 pandemic. This is consistent with the Organization for Economic Co-operation and Development (OECD) statistics in 2019, which shows 442 min/day as the average sleep duration for individuals in Japan [40]. Japan has the shortest ST compared to other countries [40]. OECD Better Life Index stated that “the percentage of employees working very long hours is higher in Japan than the OECD average of 11%, and full-time workers devote less of their day to personal care and leisure than the

OECD average" [41]. This survey found a significant and negative correlation between working duration and ST (P<.05).

In Japan, several companies have introduced and supported some level of teleworking to avoid denseness in response to government statements [18]. Our study found a significant and negative correlation between transportation time and ST. The average transportation time in the Greater Tokyo Area was 65 min/day, which was significantly longer than that in the rural areas. Teleworking leads to less time traveling for work, and people might sleep more than they did before the COVID-19 pandemic. This might be a favorable effect of teleworking. However, people have spent more time in a lying position during the COVID-19 pandemic. A recent study found that an increase in SB was significantly associated with an increase in the motivation and PA aspects of fatigue [18]. Therefore, people who live in urban or urban-rural areas and spend more SB time might experience increased fatigue. However, further research is required [42].

MVPA is defined as any activity ≥3 METs, including sports, exercise, and nonexercise PA, such as walking or bicycling to supermarkets or active periods of childcare. In this study, significantly decreased exercise time was not observed in all areas (P>.05); however, MVPA duration significantly and largely decreased during the COVID-19 pandemic (P<.001). Our study indicated that nonexercise MVPA decreased during the COVID-19 pandemic by about 30 min/day in the urban and urban-rural areas but not in rural areas in Japan.

One of the factors contributing to the regional differences is the difference in population density. The Tokyo metropolitan area has a very high population density. Thus, requests for self-restraint from the government were more severe than in smaller regional cities. It is also likely that a stronger response was seen in terms of people's behavior to avoid crowds. Another factor that may have contributed to the regional differences is the occupational characteristics of the residents. In rural small and medium-sized cities, a smaller percentage of residents are office workers, university faculty, and people from other professional occupations, while a higher percentage comprise blue-collar workers and agricultural and workers in the fishing industry. We believe that differences in population density in the places where they work or live and whether they can be replaced by teleworking also had an impact on the change of PA and SB.

Limitations

Our study has some methodological limitations. First, our web-based survey and accelerometer-based study used convenient samples without random sampling; thus, we did not calculate sample sizes and effect sizes in this study. Those not using the internet or accelerometers, especially older people, could not be included in this study. Therefore, this study's results do not reflect the Japanese population characteristics; participants could be more health conscious than the general population, and our study potentially includes selection bias. Second, possible inconsistency of PA levels on workdays and weekends may exist. That is, the 24-hour sPAR data from a single acquisition may not represent a typical week for the PA level of the study participants. Particularly, the current system cannot examine weekly or monthly exercise habits. In addition, while we obtained the physical and mental health status in the web-based survey, we could not obtain the physical and mental health status in the accelerometer study, which may affect the results. Finally, as the main limitation of this study is based on the study design, it cannot be argued that such differences are based on the COVID-19 pandemic or the aging effect.

Conclusion

This research, using a web-based sPAR system, found several lifestyle changes, indicating that people became less active and spent a longer amount of time in the lying position in urban and urban-rural areas during the COVID-19 pandemic. In addition, we found that Japanese living in urban and urban-rural areas had increased sleeping time during the COVID-19 pandemic. Longer sleep duration during the COVID-19 pandemic may favor the population's health, as Japan has the shortest sleeping time worldwide. However, the less time spent on MVPA and the longer time spent on SB, particularly in the lying position, would have an unfavorable effect on health. The sociopsychological aspects of the effect of such lifestyle change should be examined in future studies.

Abstract

Background: Never before COVID-19 had Canadians faced making health-related decisions in a context of significant uncertainty. However, little is known about which type of decisions and the types of difficulties that they faced.

Objective: We sought to identify the health-related decisions and decisional needs of Canadians.

Methods: Our study was codesigned by researchers and knowledge users (eg, patients, clinicians). Informed by the CHERRIES (the Checklist for Reporting Results of Internet E-Surveys) reporting guideline, we conducted 2 online surveys of random samples drawn from the Leger consumer panel of 400,000 Canadians. Eligible participants were adults (≥18 years) who received or were receiving any health services in the past 12 months for themselves (adults) or for their child (parent) or senior with cognitive impairment (caregiver). We assessed decisions and decisional needs using questions informed by the Ottawa Decision Support Framework, including decisional conflict and decision regret using the Decision Conflict Scale (DCS) and the Decision Regret Scale (DRS), respectively. Descriptive statistics were conducted for adults who had decided for themselves or on behalf of someone else. Significant decisional conflict (SDC) was defined as a total DCS score of >37.5 out of 100, and significant decision regret was defined as a total DRS score of >25 out of 100.

Results: From May 18 to June 4, 2021, 14,459 adults and 6542 parents/caregivers were invited to participate. The invitation view rate was 15.5% (2236/14,459) and 28.3% (1850/6542); participation rate, 69.3% (1549/2236) and 28.7% (531/1850); and completion rate, 97.3% (1507/1549) and 95.1% (505/531), respectively. The survey was completed by 1454 (97.3%) adults and 438 (95.1%) parents/caregivers in English (1598/1892, 84.5%) or French (294/1892, 15.5%). Respondents from all 10 Canadian provinces and the northern territories represented a range of ages, education levels, civil statuses, ethnicities, and annual household income. Of 1892 respondents, 541 (28.6%) self-identified as members of marginalized groups. The most frequent decisions were (adults vs parents/caregivers) as follows: COVID-19 vaccination (490/1454, 33.7%, vs 87/438, 19.9%), managing a health condition (253/1454, 17.4%, vs 47/438, 10.7%), other COVID-19 decisions (158/1454, 10.9%, vs 85/438, 19.4%), mental health care (128/1454, 8.8%, vs 27/438, 6.2%), and medication treatments (115/1454, 7.9%, vs 23/438, 5.3%). Caregivers also reported decisions about moving family members to/from nursing or retirement homes (48/438, 11.0%). Adults (323/1454, 22.2%) and parents/caregivers (95/438, 21.7%) had SDC. Factors making decisions difficult were worrying about choosing the wrong option (557/1454, 38.3%, vs 184/438, 42.0%), worrying about getting COVID-19 (506/1454, 34.8%, vs 173/438, 39.5%), public health restrictions (427/1454, 29.4%, vs 158/438, 36.1%), information overload (300/1454, 20.6%, vs 77/438, 17.6%), difficulty separating misinformation from scientific evidence (297/1454, 20.4%, vs 77/438, 17.6%), and difficulty discussing decisions with clinicians (224/1454, 15.4%, vs 51/438, 11.6%). For 1318 (90.6%) adults and 366 (83.6%) parents/caregivers who had decided, 353 (26.8%) and 125 (34.2%) had significant decision regret, respectively. In addition, 1028 (50%) respondents made their decision alone without considering the opinions of clinicians.

Conclusions: During COVID-19, Canadians who responded to the survey faced several new health-related decisions. Many reported unmet decision-making needs, resulting in SDC and decision regret. Interventions can be designed to address their decisional needs and support patients facing new health-related decisions.

KEYWORDS

health care decisions; decisional conflict; decision regret; shared decision-making; COVID-19; older adults; caregivers; parents; public health decision; health care; health outcome; pandemic preparedness; public health policy

Introduction

During the COVID-19 pandemic, never before had Canadians made health-related decisions in the context of so much uncertainty. Health care decisions were complex, with limited, rapidly changing evidence and evolving public health directives [1,2]. Concurrently, health services shifted from in-person to virtual delivery and emergency department visits increased after the first wave [3-5]. These circumstances are perfectly fit for shared decision-making, a process between patients and clinicians that relies on the best evidence available and what matters most to patients. However, due to unique challenges with communicating risk, lack of nonverbal communication, and less meaningful patient involvement experienced during the pandemic, it may have been possible that Canadians were inadequately involved in health-related decisions [2,6,7]. When patients are inadequately involved in health decisions, there are more harms from choosing ineffective options, health care system waste, poor patient experiences, more litigation, and higher inequities [8,9]. This is why identifying Canadians decision-making needs was of uttermost importance in order to be able to provide person-centered care, achieve improved health outcomes, and inform future pandemic preparedness.

Decisional needs are deficits that can adversely affect the quality of decisions [10]. A quality decision is informed with the best-available evidence and based on patients' values for features and outcomes of options. A previous systematic review of 45 decisional needs assessment studies included 2 population surveys that identified 75 decisions (including 16 social decisions) and 43 clinical studies that focused on 29 specific health decisions [10]. Common decisional needs included decisional conflict, inadequate knowledge of the options (including benefits, harms), unclear values, and limited support and resources [10,11]. Decisional conflict refers to "uncertainty about a course of action when choice among competing options involves risk, regret, or challenge to personal life values" [12]. Those who experience more difficultly with decision-making are living with a serious or chronic illness, are immunocompromised, belong to linguistic minorities, have lower education, are passive in decision-making, or make a decision on behalf of someone else (parents and caregivers) [13-19]. None of the 45 studies from 7 countries were focused on decision-making needs during pandemics [10]. A recent cross-sectional study of 4905 Canadians aged 18-40 years reported that factors associated with vaccine hesitancy are negative attitudes toward vaccines in general; COVID-19 conspiracy theory beliefs; distrust of the government; and a low income, low education, or unemployment [20]. Canada was no exception, as little was known about its health-related decision-making experience during the COVID-19 pandemic. Therefore, we sought to determine the type of decisions and decisional needs of Canadians during the first year of the COVID-19 pandemic.

Methods

Study Design

Our team of researchers and knowledge users (patients, clinicians) conducted 2 population-based cross-sectional surveys using Leger's consumer panel. Having patients and clinicians as equal partners on the team was done to ensure the study yielded relevant findings [21]. Patients were on the executive research team coleading the study (author CL who is immunocompromised), and author MS stimulated the research topic. Both were engaged in all study aspects. Together, we identified the research objectives, outcomes, procedures, and deliverables for the funded proposal. Next, they were involved in guiding the study. We used the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) guideline [22].

Setting

The survey was conducted in Canada during the third wave of COVID-19 [23]. During the first wave of COVID-19 in January-June 2020, 80% of the COVID-19–related deaths occurred in long-term-care homes, and governments issued stay-at-home orders and travel restrictions [24]. Masks became mandated for use in indoor spaces in July 2020. The second wave of COVID-19 started in November 2020 and the third wave in March 2021. When the hospitals became overwhelmed during the third wave, with a high impact on intensive care units, governments reissued a stay-at-home order [23]. COVID-19 vaccines were initially approved by Health Canada in December 2020, with priority for health care workers, Indigenous peoples, the elderly living in group settings, and others at higher risk (eg, people with cancer, with organ transplants, or undergoing dialysis). Vaccination gradually opened to adults in spring 2021 and to children (ages 5-12 years) in fall 2021 [25]. Although the AstraZeneca vaccine was approved for use on February 26, 2021, the rate of vaccine-induced immune thrombotic thrombocytopenia was of concern (1 in 60,000; April 2021). Governments continued to recommend the AstraZeneca vaccine until June 2021 because Canada was in the third wave of infections and there was insufficient supply of messenger RNA (mRNA) vaccines [23].

Recruitment

We recruited 2 groups of participants: (1) adults aged 18 years or older who received or were receiving any health services in the past 12 months for themselves (labeled "adults") and (2) adults aged 18 years or older who were responsible for children or seniors aged >65 years with cognitive impairment who received or were receiving any health services in the past 12 months (labeled "parents/caregivers"). Leger recruited participants through its consumer panel titled "Leger Opinion (LEO) Panel," which has about 400,000 Canadians across 10 provinces and 3 territories. The panel includes data on age, gender, and region that can be used for sampling and quota management. At the onset, specific quotas by age, gender, and region were set based on the Canadian population data published by Statistics Canada [26]. Leger monitored throughout the recruitment phase, and sampling was adjusted to ensure the data collected were representative. For example, if a certain cohort was underrepresented, sampling was adjusted to recruit more respondents falling within that cohort. There was no weighting applied to the data after being collected. Respondents received a personalized email containing a unique URL link to the survey. The email invite said, "LEO wants to hear from you!" and it did not state the exact survey topic.

Survey Instrument

Adapted from previous surveys in Canada [13,14,27], questions were based on the Ottawa Decision Support Framework [11]. Questions from instruments with good reliability and validity included the Decisional Conflict Scale (DCS) [12], the Decision Regret Scale (DRS) [28], and Strull's roles in decision-making [13]. The survey enquired about health-related decisions adults and parents/caregivers faced during the past 12 months, factors influencing decision-making, trusted information sources, and sociodemographics according to the PROGRESS (place of residence, race/ethnicity/culture/language, occupation, gender/sex, religion, education, socioeconomic status, and social capita) framework [29,30]. To collect data on a broader range of participants' characteristics that may stratify health opportunities and outcomes due to discrimination [29,30], we also asked respondents to self-identify if they had lived experience as a member of a marginalized group defined as disabled or caregiver of a person with a disability, gender diverse (eg, agender, nonbinary, transgender, cisgender), intersex, LGBTQ+ (lesbian, gay, bisexual, pansexual, transgender, queer, two-spirited, questioning), Indigenous, racialized (eg, person of color), neurodivergent (eg, attention deficit hyperactivity disorder [ADHD], autism, dyslexia), or a marginalized group not listed. Respondents were initially asked to list all the decisions made in the past year and then pick 1 difficult decision for the remaining questions. A difficult decision was defined as having more than 1 option and no clear best option. The online survey, available in English or French, screened eligibility and included 32 questions (Multimedia Appendix 1). Two random test questions were used to ensure respondents were not trying to speed through the survey, and the survey stopped for those who clicked a wrong response on both.

Respondents received 1 question per screen and pressed "continue" to proceed. They could not return to previous screens to change responses. To avoid missing responses, no questions could be skipped. Up to 3 reminders were sent to those who started but did not complete the survey. To avoid multiple entries, respondents were assigned a unique identifier linked to their LEO account; if they tried to complete the survey again, they received an error message.

The English and French versions were pretested by members of our team, including patient partners. On May 18, 2021, we field-tested the surveys with 139 adults and 26 parents/caregivers to monitor completion time (adults: ~10 minutes; parents/caregivers: ~9 minutes) and potential problems with surveys, including predefined skip logic. Given no changes were made to the surveys based on field testing, the collected data were retained.

Sample Size

Based on our previous research [13,31,32], sample sizes of 1500 adults and 500 parents/caregivers were adequate to estimate proportions with significant decisional conflict (SDC) associated with decision delay. SDC is defined as a total score of >37.5 out of 100 on the DCS based on 253 studies [33] using a 2-sided 95% CI with a margin of error of +1.80% or +3.85% when the estimated proportions are 0.15 or 0.26, respectively [34,35]. This is the most severe cutoff; sensitivity analyses were performed with a more relaxed cutoff of 25, also sometimes seen in the literature (data not shown), but we privileged a more severe cutoff. This means it could have been showing more people with SDC. To account for an anticipated 10% response rate, target sample sizes of adults and parents/caregivers were 15,000 and 5000, respectively.

Statistical Analysis

We classified respondents into adults who made a health-related decision for themselves (adults) or made a decision on behalf of a child or a senior with cognitive impairment (parents/caregivers). Next, we used descriptive statistics to identify decisions and described decisional needs using the Ottawa Decision Support Framework for each group (adults and parents/caregivers) [10]. We classified respondents as having SDC [36], and for those who had made the decision, we classified respondents as having significant decision regret based on a cutoff of >25 out of 100 on the DRS [37].

Ethical Considerations

The University of Ottawa research ethics board approved our study (H-03-21-6752). Invitees provided study consent at the start of the online survey and only initiated the survey questions after clicking the link consenting to participate. Respondents voluntarily answered questions and were guaranteed confidentiality. Leger offered an incentive of 2000 points (equivalent to CA $1.60, or US $1.18) to complete the survey.

Results

Respondent Details

From May 18 to June 4, 2021, 14,459 adults and 6542 parents/caregivers were invited to participate (Figure 1). The view rate (unique survey visitors/unique survey invitees) was 15.5% (2236/14,459) and 28.3% (1850/6542), respectively. The participation rate (unique visitors who consented to participate/unique survey visitors) was 69.3% (1549/2236) and 28.7% (531/1850). The completion rate (users who completed the survey/users who consented to participate) was 97.3% (1507/1549) and 95.1% (505/531), respectively. Among those who completed the surveys, we removed respondents if they did not identify a difficult health decision. After reading open text describing options, 36 were moved to the adult database and 16 were moved to the parent/caregiver database.

There were 1454 adults and 438 parents/caregivers included in the analysis. The survey was completed in English (1598/1892, 84.5%) or French (294/1892, 15.5%). Respondents represented a range of ages, education levels, civil statuses, ethnicities, and annual household income (Table 1). Of 1892 respondents, 541 (28.6%) self-identified as members of marginalized groups.

[a] Examples of other genders specified included bisexual, demiboy, gender fluid, transgender, and 2-spirited.

[b] Respondents sometimes specified more than 1 response option.

[c] Other languages included Arabic, Armenian, Bengali, Croatian, Czech, Danish, Dutch, Filipino, Finnish, Fukien, Friulan, German, Greek, Haitian Creole, Hakka, Hindi, Irish, Italian, Japanese, Kannada, Konkani, Korean, Laotian, Latvian, Macedonian, Malayalam, Mongolian, Norwegian, Pashto, Polish, Portuguese, Punjabi, Romanian, Russian, Serbian, Slovak, Spanish, Tagalog, Taiwanese, Tamil, Teochew, Ukrainian, Urdu, Vietnamese, Yoruba, and Zulu.

[d] Other cultural/ethnic backgrounds included Acadian, African, Canadian, Caribbean, Fijian, Guyanese, Jewish, mixed, and West Indian.

[e] Other reasons respondents indicated having lived experience as a member of a marginalized group included intersex, their gender (eg, "a woman"), occupation, social capital, socioeconomic status, religion, philosophical or political beliefs, physical or mental health condition, and not specified.

[f] LGBTQ+: lesbian, gay, bisexual, pansexual, transgender, queer, two-spirited, questioning.

[g] ADHD: attention deficit hyperactivity disorder.

[h] CA $1=US $0.74.

[i] Overall quality of life was measured on a 7-point scale: from 1 (life is very distressing, and it is difficult to imagine how it could get much worse) to 7 (life is great, and it is difficult to imagine how it could get much better); 4, life is so-so, neither good nor bad.

Decisions

Health-related decisions, in order of frequency, were about COVID-19 vaccination, managing a health condition, social COVID-19 decisions (masking, limiting contacts), mental health care or addiction treatment, medication, surgery, pain management, health care for COVID-19 (testing, seeking care for symptoms), stay at home or move to an assisted care facility (eg, nursing home), pregnancy, birth control, staying safe at home (eg, adapt or retrofit home), and end-of-life care (Table 2). Decisions were similar when respondents were asked to pick a single decision described as more difficult, with the exception of health care for COVID-19, which a few rated as difficult. Other single decisions for caregivers were about moving a family member to/from a retirement or nursing home and stopping them from driving a car. Decisions (adults vs parents/caregivers) were within the past month (318/1318, 24.1%, vs 70/366, 19.1%), 1-6 months (524/1318, 39.8%, vs 134/366, 36.6%), 6-12 months (307/1318, 23.3%, vs 97/366, 26.5%), or no response (169/1318, 12.8%, vs 65/366, 17.8%).

Decisional Needs

Of 1454 adults and 438 parents/caregivers, 323 (22.2%) and 95 (21.7%), respectively, had SDC (Tables 3 and 4). Decisions, in order of frequency, for adults with SDC were mental health care, managing a health condition, taking medications, pain management, and COVID-19 vaccination (Figure 2). Decisions for parents/caregivers with SDC were COVID-19 vaccination, managing a health condition, health care for COVID-19, and mental health care.

Table 3. Decisional needs and factors influencing decision-making of Canadian cross-sectional survey respondents during the COVID-19 pandemic (DCS[a]).

Variables	Adults (N=1454)	Parents/caregivers (N=438)

[b] Respondents sometimes specified more than 1 response option.

[c] Q1: quartile 1; Q3: quartile 3.

Table 4. Decisional needs and factors influencing decision-making of Canadian cross-sectional survey respondents during the COVID-19 pandemic (DRS[a]).

Variables	Adults who made a decision (N=1318)	Parents/caregivers who made a decision (N=366)
Decisional regret[b]		
Mean (SD)	18.8 (18.2)	21.3 (18.4)
Median (Q1, Q3)[c]	20.0 (0.0, 35.0)	25.0 (5.0, 40.0)
No decisional regret=0, n (%)	367 (27.8)	89 (24.3)
Low decisional regret=1 to ≤25, n (%)	598 (45.4)	152 (41.5)
Decisional regret>25, n (%)	353 (26.8)	125 (34.2)
Decision made alone, n (%)	843 (58.0)	185 (50.5)
Preferred option chosen, n (%)	996 (75.6)	289 (79.0)

[a] DRS: Decision Regret Scale.

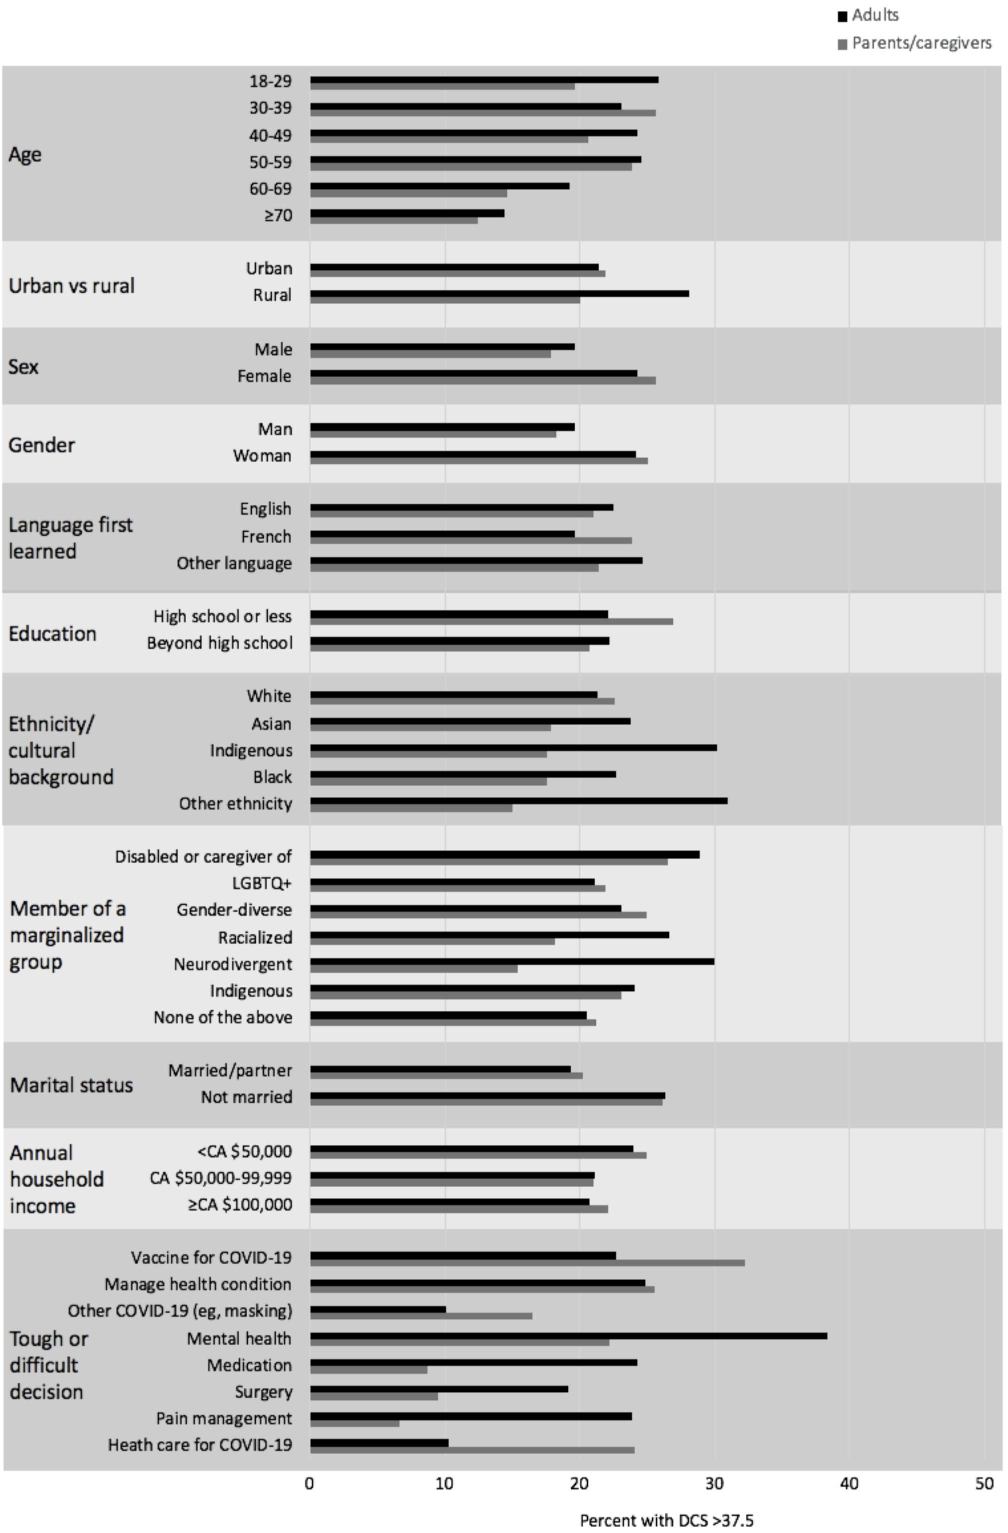
[b] Values were standardized out of 100.

[c] Q1: quartile 1; Q3: quartile 3.

Respondents experiencing SDC were more likely to feel uninformed (mean 44, SD 18.6, vs mean 18, SD 14.3, out of 100), have unclear values (mean 45, SD 20.3, vs mean 18, SD 14.6), feel they made an ineffective decision (mean 48, SD 16.1, vs mean 16, SD 13.3), and have decision regret (mean 41, SD 17.5, vs mean 16, SD 15.7) compared to those not experiencing SDC. In addition to feeling worried about choosing the wrong option (193/418, 46.2%), respondents experiencing SDC identified the following factors as making the decisions more difficult: public health restrictions due to COVID-19 (133/418, 31.8%), difficulty separating misinformation from scientific evidence (113/418, 27.0%), information overload (107/418, 25.6%), and no or limited access to information on the decision (97/418, 23.2%); see Table 3 for all respondents. Adults identified difficulty discussing the decision with clinicians (85/323, 26.3%). Parents/caregivers identified difficulty discussing the decision with significant others (eg, family, friends; 22/95, 23.2%).

Of 1318 (90.6%) adults and 366 (83.6%) parents/caregivers who made a decision, 353 (26.8%) and 125 (34.2%), respectively, had decision regret (Table 4). Those facing mental health care decisions had higher decision regret (mean 32.0%, SD 46.8%). Adults (322/1318, 24.4%) and parents/caregivers (77/366, 21.0%) reported not getting their preferred option.

Figure 2. Proportion of Canadian cross-sectional survey respondents with clinical SDC>37.5 out of 100 during the COVID-19 pandemic. CA $1=US $0.74. DCS: Decisional Conflict Scale; LGBTQ+: lesbian, gay, bisexual, pansexual, transgender, queer, two-spirited, questioning; SDC: significant decisional conflict.



Role in Decision-Making

Most respondents indicated an active role in making the decision either alone (768/1318, 58.3%, adults vs 181/366, 49.5%, parents/caregivers) or after considering the opinion of their clinician (348/1318, 26.4%, adults vs 105/366, 28.7%, parents/caregivers). Few decided together with their clinician (148/1318, 11.2%, adults vs 63/366, 17.2%, parents/caregivers) or deferred to their clinician (54/1318, 4.1%, adults vs 17/366, 4.6%, parents/caregivers). If asked to make the decision again, most preferred an active role (1067/1318, 81.0%, adults vs 264/366, 72.1%, parents/caregivers) or together with their clinician (218/1318, 16.5%, adults vs 83/366, 22.7%, parents/caregivers).

Trusted Information Sources

Respondents indicated that trustworthy information sources were health professionals (1190/1454, 81.8%, adults vs 323/438, 73.7%, parents/caregivers), Health Canada (931/1454, 64.0%, adults vs 273/438, 62.3%, parents/caregivers), and provincial health departments (755/1454, 51.9%, adults vs 211/438, 48.2%, parents/caregivers). Fewer respondents trusted information from specific health organizations (583/1454, 40.1%, adults vs 167/438, 38.1%, parents/caregivers), consumer/patient organizations (265/1454, 18.2%, adults vs 79/438, 18.0%, parents/caregivers), companies that produce health information (199/1454, 13.7%, adults vs 49/438, 11.2%, parents/caregivers), or health insurance companies (99/1454, 6.8%, adults vs 43/438, 9.8%, parents/caregivers). Those experiencing SDC and decision regret were less trusting of these sources (Table 5).

Table 5. Trusted information sources for Canadian cross-sectional survey respondents during the COVID-19 pandemic.

[b] DRS: Decision Regret Scale.

Discussion

Principal Findings

In the first year of the pandemic, the most frequent decisions identified by Canadians were about COVID-19 vaccination, managing a health condition, social COVID-19 decisions, mental health care, medication treatments, and caregiver decisions about moving family members to or from residential facilities. One in five respondents had SDC, and a third reported decision regret. Factors making decisions more difficult were public health restrictions due to COVID-19, information overload, difficulty separating misinformation from scientific evidence, and difficulty discussing decisions with clinicians. Demographics of and the types of decisions made by respondents indicating iniquities above a level of 30% differences were ethnicity and mental health, respectively. The most trusted information sources were health care professionals and governmental sources. Our results led to the following observations:

- Respondents described 2 broad types of decisions, COVID-19–specific decisions and "routine" health-related decisions influenced by the pandemic or pandemic-related changes to health care services (eg, virtual care). When respondents were asked to focus on 1 difficult decision, some COVID-19–related decisions were selected less often and these decisions were more likely to have been influenced by mandatory public health regulations (eg, mask wearing in public indoor spaces, COVID-19 testing before an exposed child goes to school) [1,6]. However, the common decision about COVID-19 vaccination, selected by those experiencing SDC, would have been influenced by emerging scientific evidence and changing recommendations from Canadian public health officials [38]. COVID-19 vaccination became available to Canadian adults 5 months prior to the survey, with priority for frontline health care workers, the elderly in residential care, and Indigenous peoples [39]. In addition, 2 months prior to the survey, 4 vaccines were approved in Canada and public health officials recommended vaccination for adults and encouraged pregnant or breastfeeding persons to make shared decisions with their clinicians [38]. Decisions were being made when COVID-19 misinformation was spreading rapidly on social media, health care services were mostly virtual, and risk communication was also challenged with reports that the AstraZeneca vaccine caused rare blood clots [2-4,40-43]. In fact, misinformation also influenced uptake of the influenza vaccine in the United Kingdom [43].
- Many respondents reported decisional conflict and were worried about choosing the wrong option, a known manifestation of decisional conflict [33,44]. The 22.2% who reported SDC in our survey using the 16-item measure of decisional conflict were less than the 59% who reported being unsure about what to choose (1-item measure of decisional conflict) in the 1999 population-based study of 635 Canadians [17]. Another study conducted in March 2020 prior to the COVID-19 pandemic reported that 14.6% of 460 Canadian adults aged 65 years and older receiving home care services had SDC and common difficult decisions were about housing [14]. The highest proportion of respondents experiencing SDC in our study were making mental health care decisions. This was not surprising, given mental health has been impacted the most during COVID-19 [45,46]. Respondents reporting SDC highlighted unmet

decisional needs requiring targeted support to address underlying modifiable factors [11]. Effective interventions for addressing decisional conflict are patient decision aids [11,47]. During our survey, 3 publicly available decision aids specific to COVID-19 were available (eg, moving a loved one from a retirement or nursing home, vaccination for persons who were pregnant or breastfeeding) [48-50]. However, not all information is accessible. Racialized and Indigenous Canadians described that the barriers to understanding COVID-19 public health information were the use of unfamiliar medical terminology, limited to English or French, and requiring technology to access the information (eg, the internet, television) [51]. Hence, our findings indicate the importance of monitoring and better supporting those experiencing SDC with plain-language interventions designed to ensure accessibility for all Canadians.

- For respondents who made a decision, a third reported decision regret. Decision regret was previously reported in 54% of 932 Canadian caregivers of seniors receiving health care services in their home in February 2020 [27]. Those with decision regret in both studies had SDC as well as a mismatch between their preferred option and the decision made. Decision regret is associated with lower satisfaction, lower quality of life, and decisional conflict [28]. Although regret can be managed by using interventions to ensure a realistic understanding of options and expectations of outcomes [11,52], our findings showed that respondents who were experiencing decision regret had lower levels of trust in the information provided by national, provincial, or local organizations. In addition, their decisions were influenced by information overload, difficulty separating misinformation from scientific evidence, and difficulty believing scientific evidence. Another survey reported that vaccine-hesitant Canadians aged 18-40 years were influenced by conspiracy theories and a distrust of governments [20]. Furthermore, protests against public health regulations indicate high levels of distrust of COVID-19 information [53]. This highlights the need to find ways to correct misinformation and help people make informed decisions [42,43]. More importantly, as we know that decision regret may lead to more litigation/complaints, we cannot completely exclude that this may be a mechanism by which there is an increasingly fractured society, with increasingly more Canadians feeling deceived by public officials, including public health officials.
- Our surveys found more patient-controlled decision-making compared to previous surveys [6,17]. We are unsure whether these findings are related specifically to the context of the COVID-19 pandemic or a change in Canadians' roles. Half of the respondents made their decisions alone, but some preferred a more collaborative role with their clinicians. Our findings are higher than the 29% who decided alone in the 1999 Canadian survey [17] and different from a survey of 1061 Germans who preferred clinician-led decisions for hypothetical COVID-19 situations [6]. A few respondents (<6%) in our study had their clinicians make the decision for them or their clinicians make the decision after considering the respondents' opinion. Another consideration is that most health care services were virtual during the pandemic [3,7] and likely impacted roles in decision-making.
- Lastly, we found demographics and types of health-related decisions showing iniquities among Canadians, mostly ethnicity and mental health. As our health care system is espousing the quintuple objective (better patient outcomes, better patient experiences, better efficiency, better health team well-being, and more equity [54,55]), this should be resonating in public health policies in terms of future interventions targeting the most vulnerable people in our society.

Strengths and Limitations

The involvement of knowledge users on the study team was beneficial, and they guided all aspects of this study, including survey design, interpretation of findings, and drafting of results. No negative effects of involving knowledge users were encountered. Our view rate of 15.5% for adults and 28.3% for parents/caregivers was comparable to the typical rate for online surveys of 10%-20% [27,56-58]. In addition, the geographic distribution across provinces and territories was consistent with Canadian distribution [59].

With regard to limitations, our data may be subject to recall bias, given respondents were asked to identify a difficult decision made within the previous year. Second, it would have been easier to compare findings with the 1999 survey had we used "facing a complex health decision" as an eligibility criterion [17]. However, we were interested in all decisions (including those with any level of SDC or decision regret) for those who had interactions within the health care system. Compared to Canadian census data, fewer respondents had high school education or less (33.7% invited, 20.5% participated, 44.8% census) and were from the Canadian territories (0.2%-0.4% invited, 0.5% from Yukon participated, 0.1% census); see Multimedia Appendix 2. Finally, the question about costs influencing the decision preceded the question asking to list options, and some only listed options related to costs.

Conclusion

Our survey of Canadians identified COVID-19–related decisions that emerged during the first year of the pandemic and how the pandemic influenced other health-related decisions. Many adults, parents, and caregivers had unmet decision-making needs, resulting in SDC and decision regret. Factors making decisions more difficult were public health restrictions due to COVID-19, information overload, difficulty separating misinformation from scientific evidence, and difficulty discussing decisions with clinicians. Most Canadians made the decisions on their own, with few sharing the decisions with others. Canadians need their decision-making needs recognized for providing person-centered care to achieve improved health outcomes and to inform future pandemic preparedness.

Abstract

Background: Community pharmacists confronted dual burdens in response to the COVID-19 pandemic by expanding the scope of pharmaceutical practices.

Objective: This study aimed to assess the perceived roles and functions of community pharmacies during the pandemic and to explore their updated roles after the pandemic began.

Methods: We conducted a self-reported web-based survey in October 2022. Based on Korean census data, we recruited the study participants (n=1000) through quota sampling stratified by age, sex, and region, yielding a 7.45% (1000/13,423) response rate. The questionnaires were composed of 3 sections: demographics, the roles and functions of community pharmacies during the pandemic, and the updated roles of community pharmacies during disasters. Each question in the second and third sections was rated on a 5-point Likert scale from 1 (strongly disagree) to 5 (strongly agree), and each item's mean scores and SDs were reported. The study participants were categorized into 2 groups: individuals who had a family pharmacy and those who did not. A chi-square test and ordered logistic regression analyses were conducted.

Results: Out of 1000 respondents, 418 (41.8%) had a history of COVID-19, and 639 (63.9%) had a family pharmacy. Assigning specific roles and functions to community pharmacies during the pandemic contributed to positive assessments. Respondents gave higher scores to community pharmacies that had responded appropriately (a mean Likert score of 3.66, SD .077 out of 5) and provided continuous pharmaceutical services (mean 3.67, SD 0.87) during the pandemic. The pandemic served as an opportunity to positively recognize the role of community pharmacies (mean 3.59, SD 0.83). In the ordered logistic model, having a family pharmacy was consistently associated with positive perceptions. Respondents perceived that community pharmacies collaborated with general practitioners and health authorities. However, community pharmacies need to function appropriately in terms of knowledge. The mean score of the 4 domains of community pharmacy functions was the highest for collaboration (mean 3.66, SD 0.83), followed by communication (mean 3.57, SD 0.87), responsiveness (mean 3.54, SD 0.87), and knowledge (mean 3.41, SD 0.91).

Conclusions: The pandemic resulted in interprofessional collaboration between community pharmacists and general practitioners. Family pharmacies could be a valuable asset to the comprehensive case management of patients. However, community pharmacists should have the expertise to build solid interprofessional collaborations and fulfill their expanded and updated roles.

KEYWORDS

community pharmacy; pharmaceutical practice; COVID-19; South Korea; pandemic; survey; pharmacists; pharmacy; primary care; medicine-centered services

Introduction

Background

Pharmacists are the third-largest group of health care professionals after nurses and physicians [1,2]. The most common type of pharmacy is a community pharmacy [3]. Community pharmacies include retail pharmacies that provide over-the-counter drugs and other health-related products to a specific community [4] and outpatient pharmacies that are considered an essential part of the primary care system [5]. Community pharmacists are the most accessible and visited health care professionals, and community pharmacies are the public's first access to their medication. Given their roles and functions, community pharmacists are integral health care professionals. However, community pharmacies are not integrated into the current primary care system [6,7]. Community pharmacists operate in a retail environment, selling or dispensing medications independently [8], and remain underestimated in their roles and functions as an integral part of the health care system [9].

In an aging population, community pharmacies are increasingly required to expand the scope of traditional pharmaceutical practices [10-12]. The health care demands of patients exceed physicians' capacity to address them [13]. Pharmaceutical practices can be categorized into medicine-centered services, patient-centered care, and public health services [14-16]. Medicine-centered services indicate traditional pharmaceutical care, such as promoting the safe use of medicines, providing information on medicines, and dispensing prescriptions. Patient-centered care emerged as an essential element of high-quality health care [17], and patient-centered pharmaceutical care includes counseling services and managing specific disease states [18-20]. Public health services may include pharmacovigilance, monitoring infectious diseases, and education in disease prevention [15,21]. Several policies have been implemented to expand the scope of pharmaceutical practice care from medicine-centered services to patient-centered care and public health services [12-15].

Community pharmacies are currently compelled to be on the frontline against COVID-19 [22,23], and the expanded role of community pharmacies has gained momentum within a short time frame [24]. As the spread of the COVID-19 pandemic continues, unprecedented measures, such as social distancing restrictions, mandated stay-at-home rules, and business closures, have been implemented to contain the transmission of the virus, control people who have been infected, and prevent overwhelming the health system [25-28]. The increased number of people with COVID-19 has caused a surge in the demand for health care services [29-31]. Further, the need for pharmaceutical services during the pandemic is beyond the scope of pharmaceutical services in the nonpandemic situation. According to the 4 disaster phases, the updated need for pharmaceutical services could be divided into prevention, preparedness, response, and recovery [32,33]. The public needs to be informed about adequate personal protection against the infection and community transmission of COVID-19. Patients must be treated for the disease and other related symptoms at home with rational medication use.

Pharmaceutical Practice in South Korea

Pharmacy practice in South Korea needs to catch up to practices in other countries. The concept of pharmaceutical care was first introduced in 1994 [34]. However, pharmacy practices are still limited to medicine-centered services. Pharmacists in South Korea do not have the authority to direct refill reviews and approvals and administer vaccinations [11]. South Korea introduced a law separating prescribing and dispensing medicine in 2000 [35]. Under the law, only physicians could prescribe medicines, and pharmacists could dispense the medicine by prescription. The law aimed to enhance the rational use of medicine and manage pharmaceutical expenditures [36]. However, the separate systems relegated community pharmacies to delivering medicine-centered services, only dispensing medicines rather than performing other pharmacy practices [11]. Thus, community pharmacies are located near clinics or hospitals where they receive and dispense prescriptions [37]. Patients visit community pharmacies near clinics or hospitals to fill prescriptions; they usually receive prescriptions when they visit clinics or hospitals and then fill those prescriptions at different community pharmacies. Thus, providing centralized and consistent pharmaceutical practices is difficult in South Korea. The Korean Pharmaceutical Association has suggested a family pharmacy system to the government to provide effective and comprehensive pharmaceutical services [37]. However, a family pharmacy is still not a legally established concept in the Korean health care system.

In South Korea, the COVID-19 pandemic has changed the roles and functions of community pharmacies in 2 ways. The expanded role of traditional community pharmacies requested by the community has been accelerating quickly. Furthermore, community pharmacies must develop new functions to address the pandemic, particularly in their preparedness and responses to COVID-19. We considered the interaction between the 2 burdens—increased and updated demand for pharmaceutical practice—placed on the current community pharmacies. The primary objective of this study was to assess the perceived roles and functions of community pharmacies during the pandemic and explore their updated roles, not to test a hypothesis but to measure the public perceptions toward community pharmacies. The secondary objective was to investigate the role of family pharmacies in the public perceptions of community pharmacies.

Methods

Overview

We conducted this study as part of a more extensive study on the public perceptions of the roles and functions of community pharmacies in South Korea. Public perceptions before the COVID-19 outbreak have been published elsewhere [11]. This study investigated the changes in the public perceptions of community pharmacies during the pandemic. To this end, we developed a self-reported web-based survey. The survey was conducted from October 2 to October 4, 2022, with technical support from Realmeter, a survey agency. The characteristics of the previous and current studies are provided in Multimedia Appendix 1.

Study Design and Participant Recruitment

Assuming a 95% CI, 3.1% margin of error, and 0.5% SD, a representative sample size (n=1000) for the entire population was obtained. A quota sampling method was implemented to recruit study participants. The participants were registered in the survey agency's panel and agreed to respond to the survey in advance. Quotas for the sample were stratified by sex, age, and region based on Korean census data. The study population was Korean individuals aged 19 years or older. For the quota sampling process, regions were categorized into *Si* and *Do*. *Si* indicates an urban area in South Korea and includes 8 regions: Seoul, Busan, Daegu, Incheon, Kwangju, Daejeon, Ulsan, and Sejong. Do indicates a rural area in South Korea and includes 9 regions: Gyeonggi, Gangwon, Chungbuk, Chungnam, Jeonbuk, Jeonnam, Gyeongbuk, Gyeongnam, and Jeju. *Do* indicates a rural area in Korean and includes 9 regions: Gyeonggi, Gangwon, Chungbuk, Chungnam, Jeonbuk, Jeonnam, Gyeongbuk, Gyeongnam, and Jeju. Invitations were sent randomly for the stratified quotas until the number of completed surveys reached the predetermined percentage.

The survey was conducted as follows. We explained the purpose of the study. Study participants who consented to participate in this study were directed to the encrypted website to complete the survey. Those who completed the survey received a voucher worth US $4. Out of 13,423 invitations, 1000 completed the survey, yielding a 7.45% response rate.

Ethics Approval

The study protocol was reviewed and approved by the Hanyang University Institutional Review Board (HYIRB-202209-006).

Questionnaires

The survey comprised 3 sections: demographics, the roles and functions of the community pharmacy during the pandemic, and the updated roles of the community pharmacy during disasters. The questions in the second and third sections were derived from the literature on pharmaceutical care, pharmacy practice, and the role of pharmacies during disasters. They were also modified to reflect the Korean context. The content of the developed questionnaire was pretested with members of the public, registered pharmacists, and researchers.

The demographic variables were sex, age, education, occupation, and region. For the statistical analyses, regions (8 *Si*s and 9 *Do*s) were recategorized into metropolitan, urban, and rural areas. Metropolitan areas included South Korea's capital city, Seoul, and its surrounding areas, Incheon and Gyeonggi. Urban areas included the 6 *Si*s excluding Seoul and Incheon. Rural areas included the 8 *Do*s excluding Gyeonggi. Two additional items were added to the demographics: experience with COVID-19 and having a family pharmacy. In this study, *a family pharmacy* was defined as a pharmacy where a respondent would usually fill a prescription or ask for advice about his or her health problem [38-40]. The second section was composed of 28 questions regarding the roles and functions of community pharmacies during the pandemic. We presented 12 questions to assess the roles of community pharmacies. For the functions of community pharmacies, we categorized 16 questions into 4 domains: communication, knowledge, responsiveness, and collaboration. The third section includes 19 questions regarding the roles of community pharmacies during disasters. To clarify the updated roles of the community pharmacy during disasters, 4 disaster phases—prevention, preparedness, responses, and recovery—were used. Questions in the second and third sections were rated on a 5-point Likert scale from 1 (strongly disagree) to 5 (strongly agree). Detailed survey questions are provided in Multimedia Appendix 2.

Statistical Analyses

Two types of analysis were applied: descriptive analysis and ordered logistic regression. Descriptive analysis was used to present the distribution of rated scores, mean scores, and SDs. A chi-square test compared categorical variables, including having a family pharmacy and experiencing COVID-19 [41]. Cronbach α was calculated to measure the internal consistency of survey items. An ordered logistic regression was conducted to elucidate the association between having a family pharmacy and positive perceptions toward community pharmacies. In the ordered logistic model, the dependent variable was ordinal scale data, and the independent variables were having a family pharmacy, experiencing COVID-19, sex, age, region, and education. We tested the proportional odds assumption using the Brant test, and if it was not satisfied, we conducted a generalized ordered logistic regression [42]. The results of the ordered logistic regression presented adjusted odds ratios (aORs) with 95% CIs. Statistical significance was considered at a 2-sided *P* value <.05. All statistical analyses were performed using Stata software (version 16; StataCorp).

Results

Survey Respondents

Table 1 presents the basic characteristics of the 1000 respondents to this study. Of the respondents, 418 (41.8%) had a history of COVID-19, and 639 (63.9%) had a family pharmacy. We separated the respondents into 2 groups: those with or without a family pharmacy. The distribution of respondents in the 2 groups was not significantly different in terms of sex, age, region, education, occupation, or COVID-19 infection (all *P*>.05).

Table 1. Characteristics of the survey respondents.

Characteristics	Total respondents (n=1000), n (%)	Respondents with a family pharmacy (n=639), n (%)	Respondents without a family pharmacy (n=361), n (%)	*P* value
Sex				.39
Male	496 (49.6)	324 (50.7)	172 (47.6)	
Female	504 (50.4)	315 (49.3)	189 (52.4)	
Age range (years)				.07
19-29	162 (16.2)	89 (13.9)	73 (20.2)	
30-39	151 (15.1)	94 (14.7)	57 (15.8)	
40-49	188 (18.8)	120 (18.8)	68 (18.8)	
50-59	198 (19.8)	131 (20.5)	67 (18.6)	
60 and older	301 (30.1)	205 (32.1)	96 (26.6)

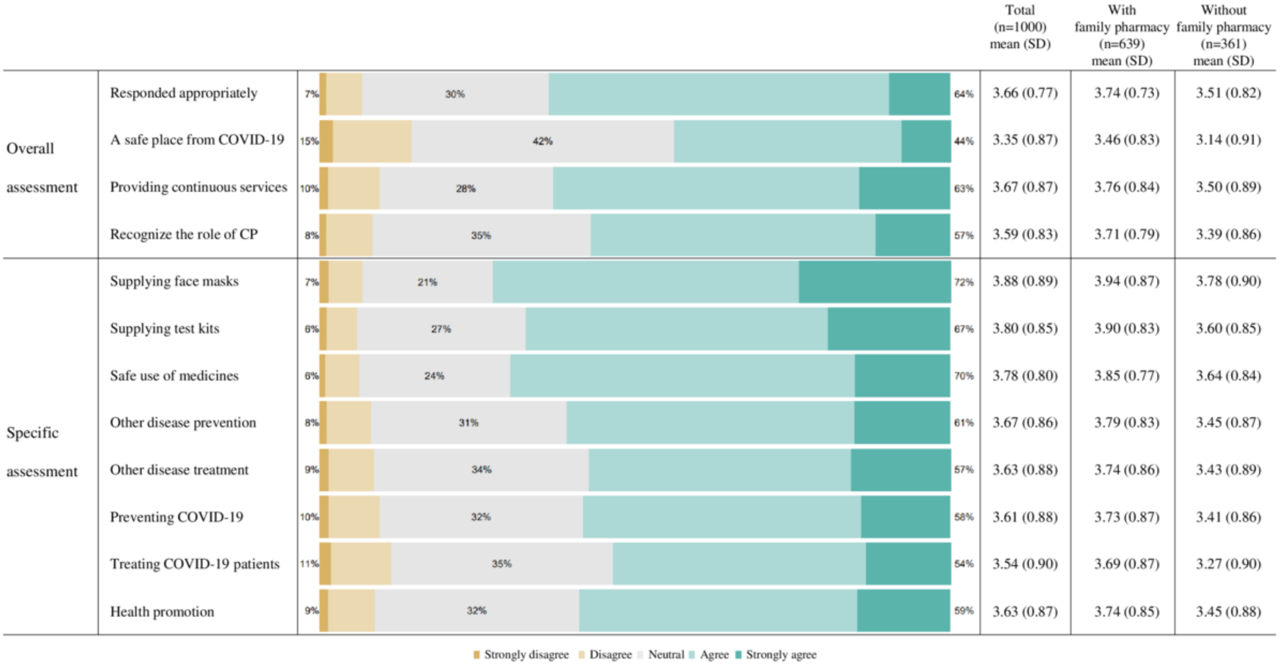
COVID-19 infection				.65
Yes	418 (41.8)	271 (42.4)	147 (40.7)	
No	582 (58.2)	368 (57.6)	214 (59.3)	

Assessment of the Roles of Community Pharmacies During the Pandemic

Figure 1 describes the overall and specific assessments of the roles of community pharmacies during the pandemic. We reported the distribution of rated scores, mean scores, and SDs. A higher score indicates that the roles of community pharmacies are perceived as positive by the respondents. Regarding the overall assessment, respondents gave higher scores for community pharmacies that had responded appropriately (a mean Likert score of 3.66, SD 0.77 out of 5) and provided continuous pharmaceutical services (mean 3.67, SD 0.87). The pandemic served as an opportunity to positively recognize the roles of community pharmacies (mean 3.59, SD 0.83). However, respondents gave lower scores for community pharmacies as a safe place from COVID-19 (mean 3.35, SD 0.87). Respondents gave higher scores for community pharmacies playing an essential role in the supply of publicly distributed face masks (mean 3.88, SD 0.89) and COVID-19 rapid antigen test kits (mean 3.80, SD 0.85) and in the safe use of medicines (mean 3.78, SD 0.80). However, respondents gave lower scores for community pharmacies playing an essential role in treating patients with COVID-19 (mean 3.54, SD 0.90) and preventing COVID-19 (mean 3.61, SD 0.88). When we separated the respondents into 2 groups, higher scores were observed consistently in the subgroup of those with a family pharmacy than those without one.

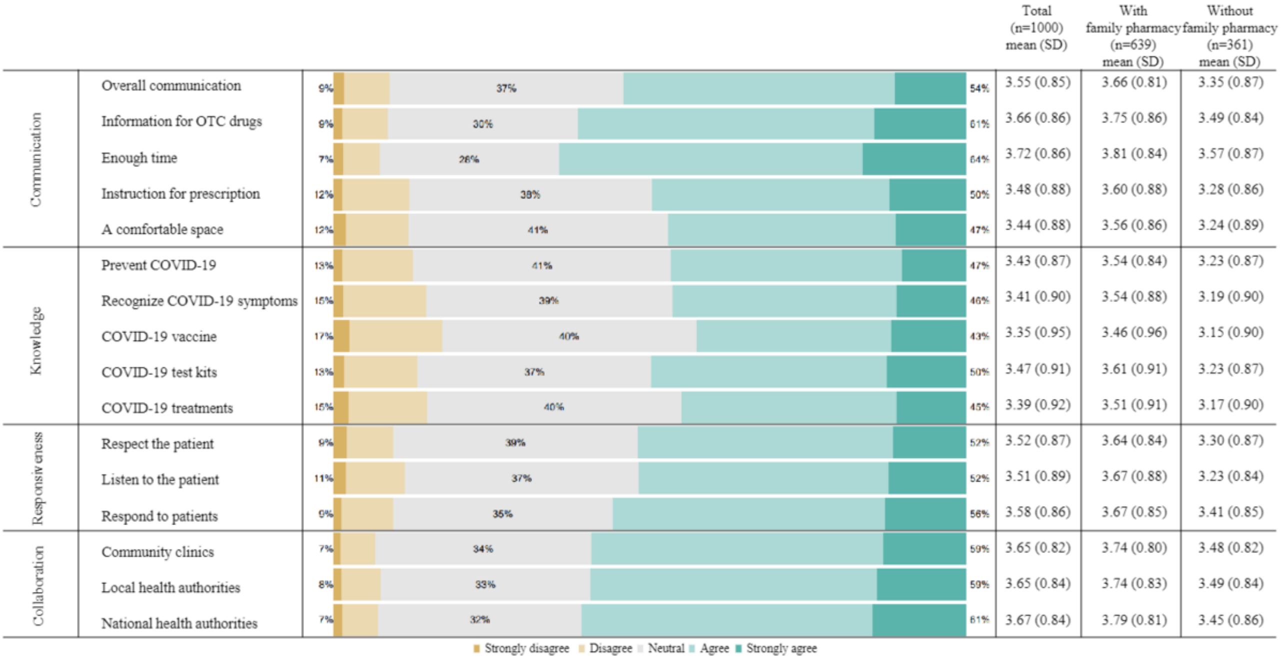
Figure 1. The assessment of the roles of community pharmacies (CP) during the pandemic.



Perceived Functions of Community Pharmacies During the Pandemic

Figure 2 presents the perceived functions of community pharmacies during the pandemic. The mean score of the 4 domains was the greatest for collaboration (mean 3.66, SD 0.83), followed by communication (mean 3.57, SD 0.87), responsiveness (mean 3.54, SD 0.87), and knowledge (mean 3.41, SD 0.91). Respondents gave higher scores for community pharmacies collaborating with community clinics and hospitals (mean 3.65, SD 0.82), local health authorities (mean 3.65, SD 0.84), and national health authorities (mean 3.67, SD 0.84). However, respondents gave lower scores for the expertise of community pharmacies regarding the COVID-19 vaccine (mean 3.35, 0.95), COVID-19 treatment (mean 3.39, SD 0.92), and recognizing COVID-19 symptoms (mean 3.41, SD 0.90). Cronbach α values for the communication, knowledge, responsiveness, and collaboration domains were .88, .92, .83, and .85, respectively. When we separated the respondents into 2 groups, higher scores were observed consistently in the subgroup of those with a family pharmacy than those without one.

Figure 2. The perceived functions of community pharmacies during the pandemic. OTC: over-the-counter.



Updated Roles of the Community Pharmacy During Disasters

Figure 3 describes the updated roles of community pharmacies during disasters. The 4 phases in descending order according to mean scores were preparedness (mean 3.72, SD 0.88), responsiveness (mean 3.70, SD 0.87), recovery (mean 3.58, SD 0.92), and prevention (mean 3.52, SD 0.92). Respondents gave higher scores for the items belonging to the preparedness phase: an inventory of quarantine supplies (mean 3.81, SD 0.89), other medicines, including over-the-counter drugs (mean 3.80, SD 0.87), and medicines used for treating COVID-19 (mean 3.76, 0.88). Respondents gave higher scores for pharmacies supplying COVID-19 rapid antigen test kits (mean 3.74, SD 0.89) under the responsiveness phase and managing safe medication use after infection (mean 3.75, SD 0.90) under the recovery phase. However, respondents gave lower scores to pharmacies for providing education to prevent infectious disease (mean 3.46, SD 0.93) and education for infectious disease management (mean 3.46, 0.95) under the prevention phase. Cronbach α values for the prevention, preparedness, responsiveness, individual recovery, and social recovery domains were .86, .88, .81, .87, and .88, respectively. Higher scores were consistently observed in the subgroup of those with a family pharmacy than those without one.

Figure 3. The updated roles of community pharmacies during disasters.

					Total (n=1000) mean (SD)	With family pharmacy (n=639) mean (SD)	Without family pharmacy (n=361) mean (SD)
Prevention	Information on diseases	9%	32%	60%	3.63 (0.87)	3.73 (0.83)	3.46 (0.91)
	Education to prevent diseases	13%	38%	49%	3.46 (0.93)	3.61 (0.90)	3.20 (0.93)
	Education for disease management	14%	37%	49%	3.46 (0.95)	3.59 (0.94)	3.22 (0.94)
Preparedness	Inventory of quarantine supplies	7%	26%	67%	3.81 (0.89)	3.89 (0.86)	3.67 (0.92)
	Inventory of COVID-19 medicines	8%	27%	65%	3.76 (0.88)	3.84 (0.84)	3.61 (0.92)
	Inventory of other medicines	7%	25%	68%	3.80 (0.87)	3.90 (0.83)	3.64 (0.91)

Having a Family Pharmacy and Positive Perceptions

Table 2 presents factors associated with a positive assessment of the roles of community pharmacies during the pandemic. Having a family pharmacy was consistently associated with a positive assessment of all items about the roles of community pharmacies during the pandemic. In particular, having a family pharmacy (aOR 1.67, 95% CI 1.23-2.15) and higher educational attainment (aOR 1.40, 95% CI 1.02-1.93) were associated with a positive assessment that community pharmacies responded appropriately during the pandemic.

Table 2. Ordered logistic regression analysis for each item in the assessment of the roles of community pharmacies (CP) during the pandemic.

Dependent variable[a]	Independent variable (reference), odds ratio (95% CI)						
	Family pharmacy: yes (no)	COVID-19 infection: yes (no)	Sex: female (male)	Age (years)	Education: ≥13 years (<13 years)	Region: metropolitan (rural)	Region: urban (rural)

Discussion

Study Overview

This study assessed the perceived roles and functions of community pharmacies during the pandemic and explored their updated roles after the pandemic. The expanded roles of community pharmacies requested by the community accelerated quickly during the pandemic. Furthermore, community pharmacies began to develop new functions to address the pandemic. Findings from this study highlight how to expand and update the roles and functions of community pharmacies in countries where pharmacies are still limited to medicine-centered services.

Principal Findings in Pharmacy Practice

Three findings are noteworthy. First, in the overall assessment, more than 50% of participants agreed that community pharmacies responded appropriately, and the pandemic served as an opportunity to recognize the role of community pharmacies. When we asked for specific assessments, the proportion of participants who agreed was the highest for the question that pharmacies that had played an essential role in supplying face masks, followed by COVID-19 test kits and advice about the safe use of medicines. Assigning specific roles and functions to community pharmacies would contribute to the public's positive assessment of community pharmacies. Similarly, community pharmacies in other countries have shown effort and courage in providing face masks and COVID-19 test kits and administering vaccinations [6,43,44]. The public assessed effort and courage positively.

Second, we conducted this study as part of a more extensive study on the public perceptions of community pharmacies in South Korea. By comparing the previous and current studies, we could evaluate the changed roles and functions of community pharmacies before and during the pandemic. As explained earlier, these 2 studies implemented a quota sampling method stratified by age, sex, and region. Both studies conducted a self-reported web-based survey for 1000 adults aged older than 19 years. Furthermore, the questionnaires in the 2 studies were closely related. We provided 4 domains to understand the functions of community pharmacies. Changes in the public perceptions toward the functions of community pharmacies were noted. In this study, the mean Likert scores of the 4 domains in descending order were collaboration (3.66), communication (3.57), responsiveness (3.54), and knowledge (3.41). In contrast, the mean Likert scores of the 4 domains in descending order were knowledge (3.73), responsiveness (3.47), communication (3.45), and collaboration (3.44) in the previous study [11]. The mean Likert score for collaboration, communication, and responsiveness increased by 0.22, 0.12, and 0.07 points, respectively, whereas the score for knowledge decreased by 0.32 points. Knowledge has been essential to interprofessional collaboration between community pharmacists and general practitioners [45,46]. However, community pharmacists still need to develop their knowledge, particularly about COVID-19, during the pandemic. In contrast, the public responded that community pharmacies collaborated with community clinics and health authorities during the pandemic. The expertise of community pharmacists is required to build solid interprofessional collaboration between community pharmacists and general practitioners after the pandemic.

Third, we asked about the updated roles of community pharmacies in 4 disaster phases—prevention, preparedness, responsiveness, and recovery. Respondents gave higher scores for the items in preparedness and responsiveness, whereas they gave lower scores for the items in prevention and recovery. The preparedness and responsiveness phases were key areas during the pandemic [47]. However, community pharmacies' role in prevention and recovery should not be underestimated [48,49]. The role of community pharmacies in the infection prevention phase is to take measures to reduce the health risk of disasters, including providing information and education about infections and ensuring that patients are aware of the increased risk of adverse health outcomes [24,32]. The role of community pharmacies in the recovery phase involved checking on the local community's health needs, identifying and prioritizing susceptible patients, and participating in postdisaster reports [32,47]. In European countries, a comprehensive range of pharmacy practices, from prevention to recovery, has been implemented to address the demands during a pandemic [24]. By doing so, community pharmacies in other countries could be a bridge between medical care and broader community services. Furthermore, community pharmacies could be embedded in the comprehensive case management of patients with COVID-19 and other susceptible groups [50,51]. In this study, having a family pharmacy was consistently associated with positive assessments by the public. The consistent effect implies that family pharmacies could be a platform for embedding community pharmacies into the comprehensive case management of patients.

Policy Implications: Barriers and Facilitators in Expanding the Roles of Community Pharmacies

It is necessary to review the mean score of each survey item. The scores ranged from 3.35 to 3.88 points, implying that they were less than "agree" or "positive." The government and researchers in South Korea praised the roles of community pharmacies in distributing face masks in the early phase of the pandemic [52-54]. However, in the survey, respondents gave ratings of less than "agree (4.00 pts)" when asked if community pharmacies had played an essential role in the supply of publicly distributed face masks. Which factors caused the difference in assessment between the public and the government and researchers? In addition, what caused the public to perceive the roles of community pharmacies during the pandemic as less than positive?

First, we should note the timing factor. We conducted this survey in October 2022, and community pharmacies supplied face masks from March 2020 to July 2020. A more than 2-year gap between the 2 events could have caused the public's neutral stance. The lack of expertise is another factor. Similar to retailers, community pharmacies supplied face masks to the public. Pharmacies, post offices, and Nonghyup Hanaro Mart—a grocery store—supplied face masks during the initial stage of the pandemic. However, the public did not expect the distribution of face masks to be a substantial role of community pharmacies. The public also responded that community pharmacies needed to gain knowledge. In the questionnaire, the public gave the lowest score to community pharmacists who provided expertise on the COVID-19 vaccine. Community pharmacists in Egypt expressed an unmet need for pandemic-related knowledge as a barrier to the expanded roles of community pharmacies [44]. The lack of expertise requires measures such as providing continuous guidance on the pandemic and educational materials to community pharmacists. Space is the final factor. Our previous research raised time and space issues in the communication between pharmacists and patients [11]. Before the pandemic, we noted the availability of private and comfortable spaces within community pharmacies as barriers to expanding the roles of community pharmacies. During the pandemic, the public raised space issues regarding coronavirus transmission within the pharmacy and responded that community pharmacies were unsafe from COVID-19. Improper infection control measures in community pharmacies, reported in Australia, provided clues to interpret this finding [55]. In South Korea, approximately 60% of community pharmacies had a total space of less than 66 m^2, implying that a separate space for infection control was impossible in most cases [56].

This study also highlights the association between community pharmacies' roles and functions and pharmacists' expertise. Pharmacists in South Korea do not have the authority to direct refill reviews and approvals and administer vaccinations [11]. During the pandemic, the roles of community pharmacists were limited to supplying face masks and COVID-19 test kits. Their roles did not expand to more active and professional ones, such as vaccinating the public and finding, preventing, and treating COVID-19 cases. In this context, the public might not expect the expertise of community pharmacists in areas they have yet to experience. Similarly, community pharmacists have not been incentivized to develop their expertise in those areas [57]. Assigning new roles to community pharmacies would contribute to developing the expertise of community pharmacists. Similarly, developing the expertise of community pharmacists would successfully link to expanding the roles and functions of community pharmacies.

Strengths and Limitations

This study has several strengths. First, we analyzed public perceptions toward the roles and functions of community pharmacies. Many studies have captured the roles and functions of community pharmacies from the perspective of health care providers. However, public perceptions are essential in designing patient-centered community pharmacies. Second, we conducted a large-scale (n=1000) web-based questionnaire that represented the entire population in South Korea in terms of sex, age, and region. Third, we conducted this study as part of a more extensive study on the public perceptions of the roles and functions of community pharmacies. Before the COVID-19 pandemic, we studied the public perceptions of the roles and functions of community pharmacies in South Korea. This study analyzed the public perceptions of the roles and functions of community pharmacies during the COVID-19 pandemic. By comparing the different study results between the prepandemic and pandemic periods, we could investigate the effect of the pandemic on the public perceptions of the roles and functions of community pharmacies.

This study has several limitations. First and foremost, this study used a web-based survey and applied a stratified sampling method to obtain samples that represented the entire population in South Korea. The response rate was low for some quotas, and the total response rate was 7.45%. A low response rate implies that the study participants are a self-selected minority, and their participation might be linked to other personal characteristics. There would be selection bias in the sampling process, and the conclusion would be biased. Second, we investigated public perceptions to assess the roles and functions of community pharmacies during the pandemic and to explore the updated roles of community pharmacies after the pandemic began. However, measuring perceptions is problematic when allowing respondents to rate different items on the questionnaire. Third, this study was a cross-sectional survey, which may hinder the interpretation of the findings as a causal relationship. Longitudinal design and qualitative studies are needed to understand the contexts and mechanisms of public perceptions.

Conclusions

The COVID-19 pandemic has changed the roles and functions of community pharmacies. Assigning specific roles and functions to community pharmacies contributed to the public’s positive assessment. Furthermore, having a family pharmacy was consistently associated with the public’s positive assessments. The pandemic resulted in interprofessional collaboration between community pharmacists and general practitioners. In particular, family pharmacies could be a valuable platform in which to embed community pharmacies in the comprehensive case management of patients. However, community pharmacists should have the expertise to build solid interprofessional collaborations and fulfill their expanded and updated roles.

Abstract

Background: Following the recent COVID-19 pandemic, returning to normalcy has become the primary goal of global cities. The key for returning to normalcy is to avoid affecting social and economic activities while supporting precise epidemic control. Estimation models for the spatiotemporal spread of the epidemic at the refined scale of cities that support precise epidemic control are limited. For most of 2021, Hong Kong has remained at the top of the "global normalcy index" because of its effective responses. The urban-community-scale spatiotemporal onset risk prediction model of COVID-19 symptom has been used to assist in the precise epidemic control of Hong Kong.

Objective: Based on the spatiotemporal prediction models of COVID-19 symptom onset risk, the aim of this study was to develop a spatiotemporal solution to assist in precise prevention and control for returning to normalcy.

Methods: Over the years 2020 and 2021, a spatiotemporal solution was proposed and applied to support the epidemic control in Hong Kong. An enhanced urban-community-scale geographic model was proposed to predict the risk of COVID-19 symptom onset by quantifying the impact of the transmission of SARS-CoV-2 variants, vaccination, and the imported case risk. The generated prediction results could be then applied to establish the onset risk predictions over the following days, the identification of high–onset-risk communities, the effectiveness analysis of response measures implemented, and the effectiveness simulation of upcoming response measures. The applications could be integrated into a web-based platform to assist the antiepidemic work.

Results: Daily predicted onset risk in 291 tertiary planning units (TPUs) of Hong Kong from January 18, 2020, to April 22, 2021, was obtained from the enhanced prediction model. The prediction accuracy in the following 7 days was over 80%. The prediction results were used to effectively assist the epidemic control of Hong Kong in the following application examples: identified communities within high–onset-risk always only accounted for 2%-25% in multiple epidemiological scenarios; effective COVID-19 response measures, such as prohibiting public gatherings of more than 4 people were found to reduce the onset risk by 16%-46%; through the effect simulation of the new compulsory testing measure, the onset risk was found to be reduced by more than 80% in 42 (14.43%) TPUs and by more than 60% in 96 (32.99%) TPUs.

Conclusions: In summary, this solution can support sustainable and targeted pandemic responses for returning to normalcy. Faced with the situation that may coexist with SARS-CoV-2, this study can not only assist global cities in responding to the future epidemics effectively but also help to restore social and economic activities and people's normal lives.

Introduction

After more than a year of the COVID-19 pandemic, people are beginning to look forward to the return of normalcy in the forms of no masks, no isolation, and no social distancing [1]. A global normalcy index has been compiled by the Economist to measure the current daily activities relative to the prepandemic level in the 50 largest economies in the world [2]. The index comprises 8 indicators, split into 3 domains, as follows: transport and travel, recreation and entertainment, and retailing and work [2]. According to the data as of December 31, 2021, Hong Kong is at the top of the normalcy index [2]. Hong Kong is one of the most densely populated cities and ranks one of the top 5 territories for population density in the world. The high population density together with the highly developed international transportation networks make it vulnerable to importation as well as the local spread of SARS-CoV-2 variants [3-5]. Despite the severe challenges [6-8], Hong Kong's figures on confirmed and fatal cases are among the lowest in the world [9]. Even in the face of the rapidly spreading variant of Omicron, the local epidemic situation in Hong Kong has remained stable, and no local cases have been recorded for 80 consecutive days [9,10]. Hong Kong's economy is exhibiting major signs of recovery with people's lives subsequently being back to normal [11].

It is of note that from the outbreak of the COVID-19 epidemic on January 18, 2020, only strict social distancing and crowd control measures were adopted in Hong Kong, as opposed to extreme measures, such as citywide lockdowns or curfews [12]. The overall aim of this new direction was to formulate sustainable and targeted pandemic responses and hence more effectively enable better control of the epidemic situations [13]. A spatiotemporal solution has been developed to enable the prediction of COVID-19 symptom onset risk and provide support for Hong Kong's new direction of pandemic prevention.

The improved intercity-scale [14,15] and urban-community–scale [16] weighted kernel density estimation (WKDE) models have been applied to predict spatiotemporal COVID-19 symptom onset risk [17,18]. The above extended WKDE models provide competitive advantages based on high viral load around the date of symptom onset [19,20] as well as the delay between the onset dates and subsequent confirmation report dates [21-23]. Thus, the tracking of the COVID-19 symptom onset risk better reflects the COVID-19 transmission at the urban-community scale. However, the urban-community–scale WKDE model needs further improvement regarding the new normal of long-term coexistence with SARS-CoV-2 [24]. Consequently, the urban-community–scale WKDE model has been further enhanced by introducing the reproduction number for local cases, the number of passenger arrivals at all ports of entry, time-varying vaccination rate, and vaccination efficiency.

The enhanced urban-community–scale WKDE model has been used to predict the risk of COVID-19 symptom onset in each of the 291 tertiary planning units (TPUs) in Hong Kong. It generates the following urban-community–scale prediction results: the daily onset risk prediction results during the following few days and the daily onset risk prediction enhanced by the population distributions within 291 TPUs during the following few days. Hence, these applications are able to be implemented to support precise prevention and control as well as the recovery of socioeconomic activities in Hong Kong. A web-based visualization platform has been further developed to present the above prediction and application results. The study was conducted based on a spatiotemporal data set of 7184 local onset cases [25] with community-level locations in Hong Kong from January 18, 2020, to April 22, 2021, including, so far, all four epidemic waves of COVID-19 epidemics in Hong Kong [26].

Methods

Data Sources

In addition to asymptomatic cases, imported cases under mandatory quarantine, and cases with unknown location information, a total of 7184 local onset cases from January 18, 2020, to April 22, 2021, have been used in this study. These local onset cases include information regarding the date of the symptom onset and consequent report as well as the community-level location of these onset cases prior to diagnosis. Currently, the main COVID-19 vaccines used in Hong Kong are mRNA (BNT162b2) vaccines [27] and inactivated (CoronaVac) SARS-CoV-2 vaccines [28]. Thus, to measure the impact of vaccination on the COVID-19 epidemic, daily data [29] on people with full vaccination were selected, including the daily number of people receiving the second dose of the BNT162b2 vaccine [29] and the daily number of people receiving the second dose of the CoronaVac vaccine [29]. The daily traffic flow data covering all Hong Kong strategic routes from January 18, 2020, to April 22, 2021, were used in this study [30]. To enable the measurement of the risk of the imported cases, the daily number of passenger arrivals at all 16 ports of entry during the same period was also obtained [31]. Moreover, the reproductive number for local cases during the same period was generated by an enhanced Susceptible-Infectious-Removed model [22].

An Enhanced Urban-Community–Scale WKDE Model for Predicting the Onset Risk of COVID-19 Symptoms

As a further development of the original urban-community–scale WKDE model, the enhanced urban-community–scale WKDE model was used in this study [14-16]. The details of this model are presented in Multimedia Appendix 1. Finally, the original onset risk prediction in each location was divided by the city's maximum predicted risk, on a specific date, and thereby, standardized to a value between 0 and 1 [14-16]. Following the idea of a hit rate, the accuracy of the enhanced urban-community–scale WKDE model is set as the percentage of onset cases, on the date of prediction, that occur in the areas with predicted onset risk higher than 0.8 (known as hotspots) [14-16]. The population distributions in different communities were further used to enhance the original onset risk (details are presented in Multimedia Appendix 1).

Ethical Considerations

For this study, no ethics approval was required because the granularity of the data was at the city level.

Results

Daily Spatiotemporal Risk Prediction of COVID-19 Symptom Onset by the Enhanced Urban-Community–Scale WKDE Model

Based on the onset cases data in 291 TPUs of Hong Kong from January 18, 2020, to April 24, 2021, the daily spatiotemporal onset risk predictions of COVID-19 symptoms were obtained by the enhanced urban-community–scale WKDE model developed in this study. During the following first week after predicting the onset risk, the median prediction accuracy of the urban-community–scale WKDE model was over 80% (Figure 1). The prediction accuracy during the following second week, as possibly could be expected, was lower due to the accumulation of prediction errors over time.

In all four epidemic waves caused by different SARS-CoV-2 variants, the daily spatiotemporal distributions of urban-community–scale COVID-19 symptom onset risk from January 18, 2020, to April 24, 2021, were used to measure urban-community–scale heterogeneity (Figure 2). Communities with the onset risk higher than 0.8 were always concentrated in Central and Western, Wan Chai, Kowloon City, and Yau Tsim Mong, all of which are central shopping and commercial areas with a very high traffic flow. Conversely, the onset risk was relatively low in suburban communities, far away from the main transportation network. The Q statistic results conducted by Geodetector showed that the variations in mobility had a very strong effect on variations in onset risk in 291 TPUs, with a Q value of 0.98 (*P*=.005). Technological details of Geodetector is presented in Multimedia Appendix 1. Moreover, the trend on the daily regional shift regarding different onset risk levels could be visually displayed.

Identification of High–Onset-Risk Communities in Three Epidemiologic Setting Scenarios

From the identified results of high–onset-risk communities based on the daily prediction of the original onset risk, the number of TPUs within high–onset-risk areas always only accounted for 2%-25% under the two epidemiologic setting scenarios of no cases and sporadic and clusters of cases. This enabled only the most stringent measures needing to be implemented in a very limited area within the high onset risk to reduce the impact on normal activities in other areas. In addition, such an identification of high–onset-risk communities also supports the allocation of limited COVID-19 medical supplies in Hong Kong.

However, in the community transmission scenario, the high–onset-risk communities identified directly from the original symptom onset risk prediction did not seem to be controlled in a small area. For example, on July 15, 2020—the peak of the third wave of the epidemic in Hong Kong—the high–onset-risk communities identified accounted for 155 (53.26%) of all 291 TPUs (Figure 2F). Limited COVID-19 medical supplies and human resources for health could not be allocated to the communities that needed them most. Based on the enhanced identification of high–onset-risk communities by population distributions, even during the peak period of the four epidemic waves, communities within the high onset risk could be reduced to a limited area (Figure 3A-C).

Assistance in the Effect Analysis and Implementation of COVID-19 Response Measures

During the early stages of the epidemic, a series of previously untried COVID-19 response measures were implemented to suppress the spatiotemporal spread of SARS-CoV-2, including stringent border control measures to guard against imported cases and social distancing measures to prevent the local spread of the virus. Thus, it was necessary to evaluate the effect of these COVID-19 response measures on the spatiotemporal onset risk so as to adjust the COVID-19 response measures during subsequent stages. Thus, the effects of border control measures and social distancing measures already implemented in the first and second waves during the early stage of the epidemic were evaluated by the overall onset risk variations in 291 TPUs of Hong Kong within one week of the implementation (Figure 4). For border control measures, barred entry of all non-Hong Kong residents seemed to be the most effective during the peak period of the epidemic caused by imported cases. After its implementation, the overall onset risk was reduced by 28.82% within one week (Figure 4C). For local social distancing measures, prohibiting public gatherings of more than 4 people achieved the most significant reduction effect, by reducing the overall onset risk by 45.91% (Figure 4C). Other effective measures have been the closure of bars, the closure of leisure venues, the restriction of restaurant capacity, and the strengthening of laboratory virus surveillance, enabling the overall onset risk to be reduced by 33.33%, 30.17%, and 16.26%, respectively (Figure 4).

As the epidemic enters the normalization stage of prevention and control, COVID-19 response measures need to be more targeted than during the early stage of the pandemic. For the new response measures to be implemented, it is necessary to analyze the effects of new measures and assist in a more targeted implementation. For example, during the peak period of the recent fourth epidemic wave, the new measure—compulsory testing—was planned to be adopted from January 23, 2021. Before the implementation of the compulsory testing measures, based on the results of symptom onset risk prediction before January 23, 2021, “specified areas” with medium-high risk and “restricted areas” with high risk were quickly delineated by identifying the presence of TPUs within areas with medium-high onset risk and high onset risk (Figure 5). Moreover, in response to the public’s possible doubts about the controlling effects of the new measures, the simulation of the spatiotemporal effects of the new measures could also be provided, such as the simulation of the effect of the compulsory testing measure. The comparison of simulation results (Figure 6) showed that the compulsory testing not only suppressed the spread of SARS-CoV-2 in 291 TPUs but also reduced the onset risk related to each TPU. The onset risk was reduced by more than 80% in 42 (14.43%) TPUs and by more than 60% in 96 (32.99%) TPUs (Figure 6E; Table 1). Moreover, the compulsory testing was the most significant regarding the risk of those TPUs that had been originally at low or medium risk.

0-20	108 (37.11)
20-40	40 (13.75)
40 60	47 (16.15)
60-80	54 (18.56)
>80	42 (14.43)

The Developed Web-Based Platform to Inform Governmental Agencies and Populations Based on the Symptom Onset Risk Predictions

The precise prevention and control in Hong Kong rely on effective government response and public cooperation. Based on the above onset risk prediction and analysis results, a web-based platform has been developed in this study. Through the services of this platform, the government and the public can obtain the prediction and analysis results of the risk of COVID-19 symptom onset within the next three days. Advanced deployment of epidemic prevention measures can be achieved especially when large-scale events are held. In addition, for the public cooperation, an intuitive understanding of the onset risk predictions in the surrounding communities and potential travel communities helped in the adjustment of their daily activity plans in advance.

Discussion

Principal Findings

Global cities are taking swift actions in regard to building a sustainable postpandemic recovery [32]. COVID-19 is likely to stay with us as an endemic disease and cannot be eradicated globally or even eliminated regionally [33]. Thus, it is crucial for the recovery to identify resource mobilization needs, strengthening targeted measures and public cooperation in the new normalcy of long-term coexistence with SARS-CoV-2. Preemptively estimating the virus spread trend should become part of future epidemic prevention. Hence, in line with this aim, a spatiotemporal solution that supports more sustainable pandemic responses for returning to normalcy in the context of living with COVID-19 has been developed and is presented in this study. Since the COVID-19 epidemic outbreak, the proposed spatiotemporal solution has been supporting precise prevention and control in Hong Kong.

Firstly, the daily onset risk prediction results enables the spread of SARS-CoV-2 in communities to be timely assessed. It can therefore support the implementation of targeted and differentiated measures, especially at large events such as university entrance exams.

Secondly, under three main epidemiologic setting scenarios, high–onset-risk communities could be identified from the original daily onset risk prediction result and daily onset risk prediction enhanced by population distributions. It could limit the high–onset-risk communities in a small area in all three epidemiologic setting scenarios. The strictest COVID-19 response measures were only implemented in limited high–onset-risk communities to reduce the impact on normal social and economic activities.

Third, the effect of COVID-19 response measures already implemented by the government could be analyzed. These proven effective measures in this study have been playing a key role in Hong Kong's epidemic prevention. This was important in the early stage when the characteristics of the spread of SARS-CoV-2 variants were not clear. This could help the government adjust previous measures in subsequent stages.

Fourth, the implementation of the new COVID-19 response measures could be assisted, such as the new compulsory testing measure in the fourth epidemic wave. Before this measure was implemented first, the high–onset-risk restriction area could be determined through onset risk prediction results.

Fifth, in response to the public's possible doubts about the effects of the new COVID-19 response measures, the effects of the new COVID-19 response measures could be simulated. This is important with respect to the enhancement of policy transparency and also in building public trust in epidemic prevention.

Sixth, the prediction and set of analysis results related to onset risk have been integrated into a web-based visualized platform. Visualized information of spatiotemporal prediction and analysis enables the government and people to more easily and even more intuitively understand the nature of the potential spread of onset risk, leading to further understanding of symptom onset risk information related to each community. Logically, such understanding can better strengthen the appropriate response.

Comparison With Prior Work

To the best of our knowledge, this is the first attempt to use spatiotemporal onset cases data to explore the spatiotemporal variations of onset risk at the urban-community scale in the context of the emergence of different variants since the epidemic outbreak. It can further support effective epidemic control at the urban-community level for returning to normal. The Space-Time Scan Statistical Analysis Method [34], the improved Susceptible Exposure Infection and Recovery model [35-37], the spatiotemporal Bayesian inference model [38], and the hierarchical clustering analysis [39] were used in the previous studies to investigate the impact of the spatiotemporal spread of COVID-19. Consistent with the conclusions of these studies, results of this study also show that precise epidemic prevention and control measures can help effectively control the epidemic. Similarly, when epidemic prevention and control measures are relaxed, high-risk areas will also expand significantly, especially in the early stages of the epidemic. However, the vast majority of previous modeling studies have focused on the national, state, and regional levels [40]. The strength of this study is that building an onset risk prediction model at the urban-community level can facilitate accurate and differentiated public health responses at the finer spatial scale [40]. This allows the vast majority of areas in the city to maintain normal social and economic activities while maintaining strict prevention and control measures in a very small number of areas. Meanwhile, it can also facilitate the more effective allocation of limited medical resources to the limited areas with high onset risk that need it. In addition, this study simulates and predicts the spatiotemporal spread of COVID-19 under different measures or population mobility based on the symptom onset risk model. Hence, epidemic prevention measures and people's daily travel can be adjusted in advance in a timely manner. The proposed solution in this study can be used to support the enhancement need for community-based interventions and services in a multinational Delphi consensus to end the COVID-19 public health threat [41].

Limitations

We acknowledge the following potential limitations: First, limited by the information of the current official data, the location information of the cases used in this study only includes community-level locations of residence. If more information about the work locations and visited locations are combined, urban-community–level onset risk associated with their spatiotemporal activities can be estimated more comprehensively. Second, the applied data of human mobility mainly include the traffic flow data on the main roads, which fails to more comprehensively reflect the population flow under multiple modes of transportation. In addition, various data that can reflect viral load of SARS-CoV-2 at different locations, such as sewage monitoring, can be incorporated into our proposed solution in the future.

Conclusions

In the new normalcy of long-term coexistence with SARS-CoV-2, it is crucial to explore how to take the necessary response actions to reduce the impacts of the future epidemics and increase urban pandemic resilience for global cities [32]. Therefore, based on the enhanced prediction of COVID-19 symptom onset risk, a spatiotemporal solution has been proposed in this study. Such a solution has been used to support healthier and more sustainable pandemic responses in 291 communities of Hong Kong. The related web-based platform has served both the government agencies and Hong Kong residents. This solution not only assists global cities in responding to the future epidemic effectively but also helps to restore the social and economic activities and people’s normal lives. Based on this solution, we hope to make global cities more sustainable and hence promote the United Nations Sustainable Development Goals [42].

Abstract

Background: Digital surveillance tools and health informatics show promise in counteracting diseases but have limited uptake. A notable illustration of the limits of such tools is the general failure of digital contact tracing in the United States in response to COVID-19.

Objective: We investigated the associations between individual characteristics and the willingness to use app-based contact tracing in Detroit, a majority-minority city that experienced multiple waves of COVID-19 outbreaks and deaths since the start of the pandemic. The aim of this study was to examine variations among residents in the willingness to download a contact tracing app on their phones to provide public health officials with information about close COVID-19 contact during summer 2020.

Methods: To examine residents' willingness to participate in digital contact tracing, we analyzed data from 2 waves of the Detroit Metro Area Communities Study, a population-based survey of Detroit, Michigan residents. The data captured 1873 responses from 991 Detroit residents collected in June and July 2020. We estimated a series of multilevel logit models to gain insights into differences in the willingness to participate in digital contact tracing across a variety of individual attributes, including race/ethnicity, degree of trust in the government, and level of education, as well as interactions among these variables.

Results: Our results reflected widespread reluctance to participate in digital contact tracing in response to COVID-19, as less than half (826/1873, 44.1%) of the respondents said they would be willing to participate in app-based contact tracing. Compared to White respondents, Black (odds ratio [OR] 0.45, 95% CI 0.23-0.86) and Latino (OR 0.32, 95% CI 0.11-0.99) respondents were significantly less willing to participate in digital contact tracing. Trust in the government was positively associated with the willingness to participate in digital contact tracing (OR 1.17, 95% CI 1.07-1.27), but this effect was the strongest for White residents (OR 2.14, 95% CI 1.55-2.93). We found similarly divergent patterns of the effects of education by race. While there were no significant differences among noncollege-educated residents, White college-educated residents showed greater willingness to use app-based contact tracing (OR 6.12, 95% CI 1.86-20.15) and Black college-educated residents showed less willingness (OR 0.46, 95% CI 0.26-0.81).

Conclusions: Trust in the government and education contribute to Detroit residents' wariness of digital contact tracing, reflecting concerns about surveillance that cut across race but likely arise from different sources. These findings point to the importance of a culturally informed understanding of health hesitancy for future efforts hoping to leverage digital contact tracing. Though contact tracing technologies have the potential to advance public health, unequal uptake may exacerbate disparate impacts of health crises.

KEYWORDS

COVID-19; contact tracing; surveillance; informatics; trust; racial disparities

Introduction

Throughout the COVID-19 pandemic, public health authorities have engaged in contact tracing to inform those exposed to COVID-19, monitor for signs and symptoms of the virus, aid in access to testing, and promote self-quarantine as necessary [1]. While these efforts generally involve traditional direct outreach by public health workers, technologists and public health advocates have highlighted the potential of smartphone-based digital technologies to assist in contact tracing [2,3]. A May 2020 guidance from the Centers for Disease Control and Prevention (CDC) acknowledged that digital contact tracing tools for COVID-19 can function as a “supplement to traditional public health contact tracing with the use of voluntary opt-in proximity or exposure notification tools” [4].

The proliferation of digital contact tracing apps in response to COVID-19 builds on advancements in health informatics and the rise of health apps and eHealth over the past decade [5,6]. This expansion of digital health surveillance tools has a variety of potential benefits, including aiding in managing health conditions [7-9], modifying health behaviors [5,10], and helping facilitate racial equity in health information and health care [11,12]. Additionally, recent studies have found that digital health tools with exposure notifications are effective in decreasing infections from the coronavirus [13,14].

Despite the promise of digital surveillance tools to mitigate the spread of COVID-19, app-based contact tracing has had limited success in the United States [15,16]. As with all contact tracing approaches, the success of app-based contact tracing depends on individuals’ willingness to participate. Such willingness appears to be low [17,18]. In late 2020, Pew Research Center found that about 40% of Americans said they were unlikely to talk to contact tracers, and 50% said they were uncomfortable sharing location data from their phones [19].

Studies on public engagement with digital contact tracing around the world have proliferated since the start of the COVID-19 pandemic [13,20-24]. However, fewer studies have focused on the United States and drawn on representative survey samples. A notable exception is the work of Camacho-Rivera et al [18], who conducted a representative survey of US households between April and June 2020 to examine attitudes toward mobile health tools for COVID, including location-based exposure tracking. They found that although more than half of the respondents reported they were not likely to use mobile health tools for COVID, some sociodemographic and health-related factors were associated with more willingness to engage with digital contact tracing. For example, non-White respondents were more likely than their counterparts to say they were willing to use app-based location exposure tracking for COVID [18]. Additionally, systematic reviews of engagement with contact tracing during COVID (and some other contagious health outbreaks) across various countries have observed a number of barriers to uptake, including concerns about privacy and surveillance, mistrust of the government, and mistrust of technology [20,21]. Thus, while past research has pointed to several factors that influence contact tracing, limited research has considered how these factors interact in meaningful ways.

Gaining insights into differences regarding who is willing to participate in contact tracing may be especially consequential given the disproportionate impact of COVID-19 on racial/ethnic minority populations in the United States [25]. Greater willingness or hesitancy to participate in contact tracing among minoritized groups could affect the ability to stop the virus’ localized spread and could heighten the risks of morbidity and mortality in communities of color. Related research on the limited uptake of digital health technologies suggests that differences in uptake, especially along racial/ethnic and socioeconomic lines, can exacerbate health disparities [26,27]. For example, some studies on the adoption of telehealth technologies indicate that Black and Latino patients are less likely to use telehealth than White patients, limiting their access to care [28,29]. However, other studies have reported opposite findings, with Black and Latino patients being more likely to use telehealth than White patients [30,31]. Additionally, there is evidence that individuals with lower levels of education are less likely to use digital health platforms and services compared to those with more than a high school education [18,26,32].

As noted in other studies, willingness to use digital health technologies in general and app-based contact tracing in particular is likely undermined by issues of trust. Studies have demonstrated that individuals’ trust in the medical system influences their use of health services [33,34]. Lack of trust among racial/ethnic minorities, including lower trust toward medical providers, research, and treatments, is commonly cited as a key mechanism underlying disparities in health care [24,35-37]. Such differences in trust in the health care system may be further exacerbated by concerns around privacy and security, which can adversely affect patients’ willingness to use eHealth tools and provide accurate health information to providers [38,39]. Prior research shows that there are socioeconomic differences in trust, as adults with a college degree are more likely than those with lower educational attainment to report avoiding products or services because of privacy concerns [40]. Further, widespread uptake of contact tracing may be hampered by concerns regarding data privacy and trust in the government [20-22,41]. Recent evidence suggests that contact tracing efforts face greater resistance in communities where people have low levels of trust in public officials or are worried about state surveillance [42,43].

Given previous findings regarding the role of trust and mixed findings on the differential uptake of health technologies, including COVID-19 apps, we set out to determine the individual factors associated with the willingness to participate in digital contact tracing in response to COVID-19 in the US city of Detroit, Michigan. By focusing on Detroit, we highlight the attitudes of residents in a majority-minority city that experienced multiple waves of COVID-19 outbreaks and deaths since the start of the pandemic. In Detroit, Black residents have been disproportionately impacted by COVID-19, representing over 75% of known diagnoses and 90% of deaths, and they are 10 times more likely than White residents to have friends or family who have died from COVID-19 [44]. Using data from a population-based survey of Detroit, Michigan residents, we examined not only how the factors of race/ethnicity, education, and trust are associated with individuals' willingness to download a contact tracing app during summer 2020, but also how those factors are intertwined in important ways. The findings of this study can help shed light on what factors need to be considered to encourage use of digital public health tools in the future, including how various subpopulations may respond to messages about or sources of those tools.

Methods

Data Source

To examine individual willingness to participate in app-based contact tracing, we analyzed data from 2 surveys conducted by the Detroit Metro Area Communities Study (DMACS) in 2020 (one in June and the other in July). DMACS is a panel study designed to regularly capture the perspectives and behaviors of a representative sample of Detroit adults [45,46]. DMACS launched in 2016 and recruited respondents from an address-based probability sample of Detroit households. It has refreshed its sample approximately once a year through additional address-based probability sampling. In response to the March 2020 declaration of COVID-19 as a national emergency and the emergence of Detroit as a "hotspot" of coronavirus cases, DMACS initiated a series of rapid response surveys on residents' experiences with COVID-19 [44,47,48]. Due to restrictions on human subject interactions during the pandemic, participation in these surveys was limited to survey panelists who had provided email addresses or phone numbers prior to the COVID-19 pandemic. In the June survey (fielded between May 28 and June 11, 2020), 1802 panelists were invited and 1173 completed surveys (66.1% response rate). In the July survey (fielded between July 15 and July 29, 2020), 1772 panelists were invited and 1137 completed surveys (64.2% response rate). In both waves, surveys were either self-administered online by respondents or interview administered by telephone. We limited the current analysis to panelists who provided complete responses to the items measuring key independent and dependent variables in the June and July surveys. In total, our results reflected 1873 responses from 991 Detroit residents.

Ethics Approval

Human subjects research was approved by the University of Michigan Health Sciences and Behavioral Sciences Institutional Review Board (HUM00187155).

Measures

Our dependent variable captured respondent willingness to participate in app-based contact tracing with the item, "Would you be willing to download an app on your cell phone that would provide information to public health officials about close contact you have with other people?" Respondents could answer yes, no, don't know, or "I do not own a cell phone." Because our primary interest was to examine what distinguishes those who are willing to participate in app-based contact tracing, we dichotomized responses to compare those who said yes to those who said no or don't know. We dropped the small number (n=18) of respondents who reported not owning a cell phone.

We examined the willingness to engage in app-based contact tracing in relation to self-reported race/ethnicity, gender, age, education, and income. We used multiple imputation with chained equations (MICE, implemented with Stata 17 software, StataCorp) and Rubin's combination rules to fill in missing values of these and other independent variables to avoid dropping respondents from the analyses [49,50]. To ensure sufficient data coverage, we restricted our analyses to Detroit's 3 largest racial/ethnic groups: non-Latino Black (hereafter Black), non-Latino White (hereafter White), and Latino. We defined "Latino" as any respondent who self-identified as being of "Hispanic, Latino, or Spanish origin," including those who selected another racial identity and Latino. "White" and "Black" refer to respondents who selected only those respective categories (and no other ethnoracial categories) and who did not identify as Latino. Respondents who identified on the survey using other ethnoracial categories alone or in combination (Asian, Native American, Hawaiian or Pacific Islander, multi-race, or other) were omitted from this analysis owing to their small sample sizes and to avoid combining segments of unlike populations. Age was captured as a continuous variable. Categories were created for annual household income (<US $10,000, US $10,000-29,999, US $30,000-49,999, US $50,000-100,000, and >US $100,000). Because income was commonly missing and unwillingness to provide income information may be associated with data privacy concerns and unwillingness to provide other personal information relevant to contact tracing, we included a dummy variable in our analysis that captured whether the respondents withheld their income data. Education level (less than college degree, or college degree or higher) and gender (male or female) were captured as binary variables.

Finally, we included in our analyses several measures of respondents' beliefs about and experiences with COVID-19. Specifically, we included a measure of respondent trust in the government (adapted from the ICF COVID Monitor Survey of US Adults [51]). The question asked was as follows: "How much do you trust the Michigan state government to deal with the COVID-19 pandemic, on a scale of 1 to 10, where 1 is not at all and 10 is entirely?" Responses were captured on a 10-point Likert scale and were mean-centered for interpretability. We focused on this measure of trust in the state government because our outcome variable made reference to sharing information with "public health officials," and most local COVID health efforts and digital contact tracing tools were coordinated at the state level at this time. We also included, as dichotomous variables, measures of whether the respondent had a close friend or family member who died from the coronavirus; had a close friend or family member who got ill from the coronavirus; had been diagnosed with COVID-19; and would say the COVID-19 pandemic is very serious for them personally. Because our outcome variable was focused on the use of a contact tracing app, we included a binary variable for the availability of reliable internet access as a proxy for technological use and access. We also controlled for the effect of time by including a binary variable for survey wave. We did not use sampling weights because they are incompatible with the multiple imputation package of Stata 17 when estimating multi-level models, but we controlled for survey sampling strata and individual characteristics used in the creation of sample weights.

Statistical Analyses

Because we were analyzing panel data with multiple observations per person, we used random effects logit models, which introduce a random intercept to help correct for person-level unobserved heterogeneity. We estimated a series of models to gain insights into respondents' willingness to engage in app-based contact tracing. Our first model examined differences in the willingness to contact trace across a variety of individual attributes, including race/ethnicity, degree of trust in the government, and education. Our second and third models added interactions among these key variables to examine if the effects of trust and level of education vary by race/ethnicity of the respondent. We tested a 3-way interaction between race/ethnicity, education, and trust in the government but found that the results were substantively similar to the results for the interaction between education and race/ethnicity, and thus, we omitted these results for parsimony.

Results

Descriptive Statistics

Summary statistics for respondents are presented in Table 1. Less than half (826/1873, 44.1%) of the respondents reported they would be willing to participate in app-based contact tracing. Black residents comprised the majority of our sample (1486/1873, 79.3%), while 14.2% (265/1873) of our sample was White and 6.5% (122/1873) was Latino, similar to the proportions in the city of Detroit. On average, DMACS respondents reported a relatively high degree of trust in the state government to deal with COVID-19 (7.25 out of 10 points). The majority of respondents did not attend college (1301/1873, 69.5%) and had an annual household income below US $50,000 (1219/1772, 68.8%). The average respondent was 49 years old. Like many surveys, our sample had a higher proportion of female respondents (1372/1873, 73.3%). Our respondents reflected the severe impact of the COVID-19 pandemic on those living in Detroit, with 71.4% (1337/1873) saying that the pandemic was very serious for them personally and many saying that they had a close friend or family member who got ill (1088/1870, 58.2%) or died (745/1871, 39.8%) from COVID-19. However, only 5.5% (102/1868) of respondents said that they had been diagnosed with COVID-19 as of July 2020. In general, respondents were technologically connected, with 86.6% (1622/1873) reporting that they had reliable access to the internet at home.

Table 1. Descriptive statistics of the analytical sample.

Variable	Value (N=1873)
Willing to participate in contact tracing, n (%)	826 (44.1)
Race/ethnicity, n (%)	
White	265 (14.2)
Black	1486 (79.3)
Latino	122 (6.5)
Trust in the state government (score range 0-10), mean (SD)	7.25 (0.25)
Education, n (%)	
Less than college	1301 (69.5)
College	572 (30.5)
Gender, n (%)	
Male	501 (26.8)

July 2020 (wave 10)	886 (47.3)

[a] Variable imputed with multiple imputations. Within the data set of 1873 observations, income was missing in 101 cases, age was missing in 18 cases, information on whether a family member died from COVID was missing in 2 cases, information on whether a family member got ill from COVID was missing in 3 cases, and information on diagnosis of COVID was missing in 5 cases.

Analytic Results

Results from our models are presented in Table 2. Model 1 examined the relationships of individuals' demographics, trust in the government, and COVID-19 experiences with their willingness to download a contact tracing app. The results showed that individual characteristics were strong predictors of the willingness to participate in app-based contact tracing. Compared with White respondents, Black (odds ratio [OR] 0.45, 95% CI 0.23-0.86) and Latino (OR 0.32, 95% CI 0.11-0.99) respondents had significantly lower odds of being willing to participate in contact tracing. Similarly, the odds of women saying they would participate in app-based contact tracing (OR 0.44, 95% CI 0.27-0.70) were about half of the odds of men. The willingness to participate in contact tracing was associated with trust, whereby higher levels of trust in the state government's management of COVID-19 were associated with greater odds of downloading a contact tracing app (OR 1.17, 95% CI 1.07-1.27). Furthermore, respondents who reported their household income had roughly 4 times the odds of being willing to participate in contact tracing as those who elected to not report their income (OR 0.24, 95% CI 0.09-0.63), which is perhaps a measure of the wariness about sharing one's personal information. While it might be expected that individual experience with COVID-19 (being sick, having friends or family who have gotten sick or died from the virus, or feeling the pandemic is personally very serious) would increase the willingness to participate in preventative measures, including contact tracing, we found that only those who lost a close friend or family member to COVID-19 showed significantly greater odds of participating in app-based contract tracing (OR 1.72, 95% CI 1.12-2.62). Age, level of income, access to the internet, and time were not significant predictors of an individual's willingness to participate in contact tracing via an app.

Table 2. Predictors of the willingness to participate in app-based contact tracing among the respondents.

[a] Results from multilevel logistic regression with random effects. We controlled for sampling strata in our models, but we have not presented the nonsignificant effect of these strata to keep the table short. Data reflect 1873 responses nested within 991 respondents across 2 survey waves.

[b] OR: odds ratio.

[c] N/A: not applicable.

[d] Variable imputed with multiple imputation. Sensitivity analyses without imputation reach substantively similar conclusions as those of the imputed models.

To understand what may be driving racial/ethnic differences in the willingness to participate in contact tracing, subsequent models estimated interactions between race/ethnicity and trust (Model 2), and race/ethnicity and education (Model 3). By allowing the effects of race to differ by the degree of trust and level of education, we can better understand whether resistance to contact tracing among racial/ethnic groups is uniform or varies within subgroups.

Examining the interaction between race/ethnicity and trust (Model 2), we found that for White respondents, higher levels of trust in the state government's management of COVID-19 were associated with greater likelihood of being willing to participate in contact tracing via an app (OR 2.14, 95% CI 1.55-2.93). This relationship was significantly weaker for Black and Latino respondents (Black: OR 0.51, 95% CI 0.37-0.71; Latino: OR 0.56, 95% CI 0.36-0.87). Figure 1 illustrates the relationship between race/ethnicity, trust, and contact tracing, showing the strong positive relationship between trust and the willingness to participate in contact tracing for White respondents and the negligible effect of trust on the willingness to participate in contact tracing for other respondents. Model 2 results also show that the effect of trust does not fully explain differences in the willingness to participate in contact tracing by race/ethnicity. Black respondents with an average degree of trust in the government remained significantly less likely than White respondents to be willing to engage in app-based contact tracing (OR 0.47, 95% CI 0.24-0.92). We also continued to find that women and those who did not report income were less likely to participate in contact tracing, while those who had a close acquaintance die of COVID remained more likely to participate.

Turning to the interaction between race/ethnicity and education (Model 3), the main effects showed no significant difference in the willingness to participate in contact tracing among noncollege-educated respondents by race. However, the interaction showed that the effect of college education differs significantly depending on whether the respondent is Black or White. The diverging effect of education on the likelihood to engage in app-based contact tracing among White and Black respondents is illustrated in Figure 2. Among White respondents, the probability of participating in app-based contract tracing was significantly higher among college-educated respondents (predicted probability 0.63, 95% CI 0.53-0.73) compared to noncollege-educated respondents (predicted probability 0.39, 95% CI 0.28-0.50). However, among Black respondents, college-educated respondents were less likely to participate in app-based contact tracing (predicted probability 0.36, 95% CI 0.30-0.41) compared to noncollege-educated respondents (predicted probability 0.46, 95% CI 0.42-0.50). There was no significant difference between college- and noncollege-educated Latino respondents in the probability of participating in app-based contact tracing.

Figure 1. Predicted probability of the willingness to participate in app-based contact tracing by race and trust in the government.

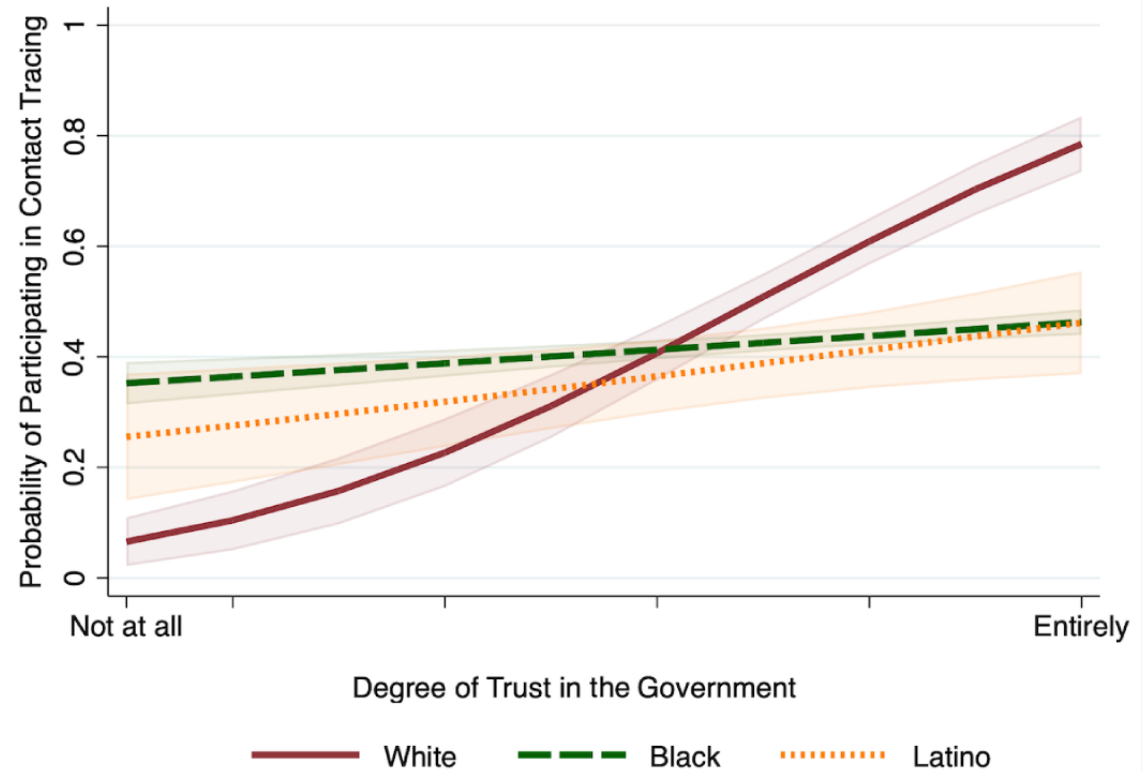

Figure 2. Predicted probability of the willingness to participate in app-based contact tracing by race and education level.

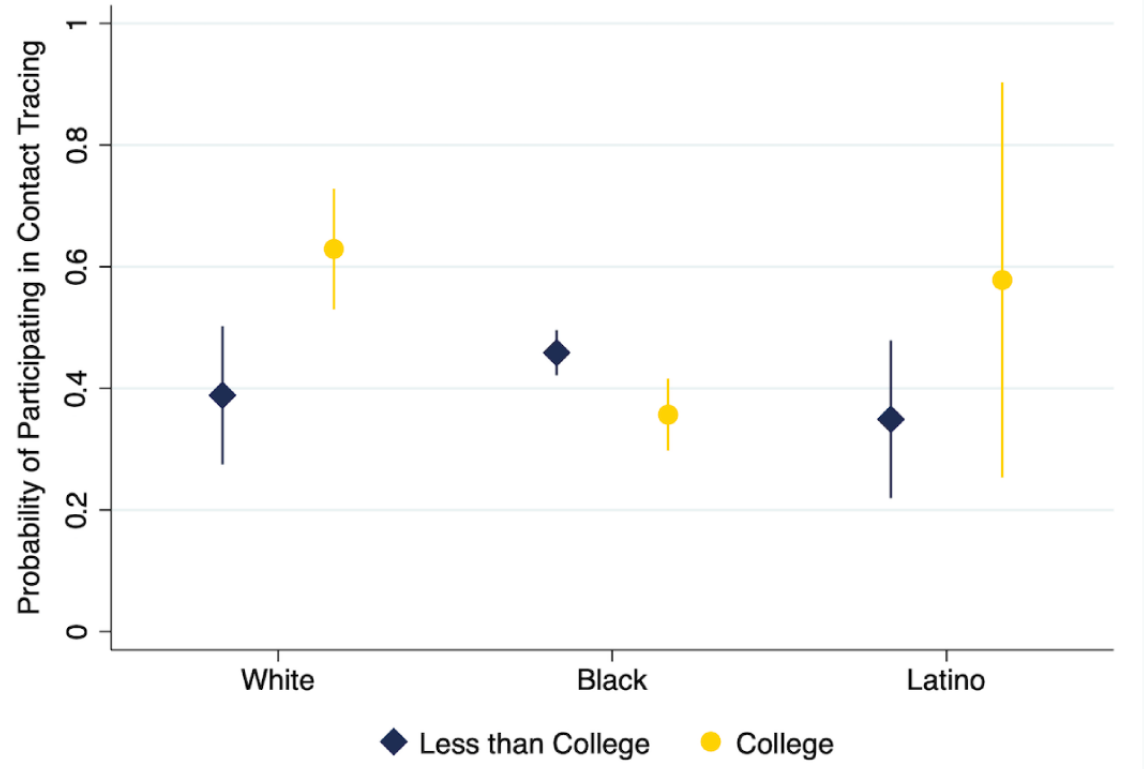

Discussion

Principal Findings

In this study, we found several factors that were associated with respondents' willingness to participate in contact tracing using a digital app. Black and Latino respondents were significantly less likely than White respondents to say they are willing to use an app for contact tracing, while those with higher trust in the government as well as those who had a close family member or friend die of COVID-19 were significantly more willing to use a contact tracing app than those with low trust or no close experiences. We also found that the relationship between trust in the government and willingness to participate in contact tracing was much stronger for White respondents than for Black and Latino respondents among whom trust in the government does not matter as much for predicting the willingness to participate in contact tracing. Given the widespread evidence of mistrust in the medical system among racial/ethnic minorities [35-37], this lack of association between trust in the government and willingness to adopt app-based contact tracing among Black and Latino respondents may reflect a general apprehension around digital health care that cannot be moderated by the level of trust. At the same time, the effect of trust in the state government on White residents' willingness or unwillingness to participate in contact tracing may reflect the partisan divide apparent nationally in response to COVID-19 [19].

In addition to our findings on trust, we also found that willingness to engage in app-based contact tracing varies substantially among racial/ethnic subpopulations depending on the level of education. While the likelihood of contact tracing among noncollege-educated respondents was relatively uniform across racial/ethnic groups, college-educated White respondents were substantially more likely to participate in contact tracing than noncollege-educated White respondents, and college- and noncollege-educated Black respondents. Moreover, for Black respondents, a college education significantly decreased the willingness to participate in contact tracing. In light of existing research indicating that education may influence one's use of digital health platforms [26,32] and online products or services because of privacy concerns [40], the interaction between race and education regarding the willingness to participate in app-based contact tracing suggests an understudied phenomenon whereby education may amplify the fears of minority populations when it comes to public health and may mitigate the fears of White populations.

Comparison to Prior Work

Our findings are consistent with prior research on public health and contact tracing apps, which has shown that factors, including personal experience with COVID-19, trust in the government, education level, and race and ethnicity, affect the willingness to use digital health tools [18,20,21]. Unlike previous work, however, we showed that some of these factors intersect in important ways. For example, while greater trust in the government was associated with increased willingness to use these digital tools among White respondents in our study, it had no significant effect among Black and Latino respondents.

Lower trust among racial and ethnic minorities is often linked to experiences of discrimination that reveal power imbalances and systemic inequalities in the practices of social institutions [52,53]. For example, systemic racism in health care is associated with disparities in access, quality of care, and health outcomes, as well as mistrust [54-59]. It is often racial minority individuals with higher levels of socioeconomic status who report more instances of discrimination in health care and in other institutions [52,55,60]. Upwardly mobile young adult Black and Latino individuals, for example, not only experience higher levels of discrimination than White individuals, but also are significantly more likely to experience acute and chronic discrimination compared to their socioeconomically stable counterparts [61]. Such research is consistent with our findings of an interaction between race/ethnicity and education, with college-educated Black respondents being significantly less willing to use a contact tracing app than either similarly educated White respondents or Black respondents with less than a college education. Awareness of and concerns about the extent of racial bias in digital technologies generally [62-66] may further contribute to reluctance to use these particular technologies among highly educated minoritized individuals.

Our findings are important because they suggest that factors that matter for some individuals and groups do not operate in the same way for others. Although trust in the government matters for the use of public health technologies for some individuals, it is likely to be interconnected with other social factors and conditions that must be considered. For most White individuals, trust in the government matters greatly, so understanding what influences that trust may be important for influencing the use of public health tools. For minoritized individuals, unequal experiences across social institutions may influence not only levels of trust but also more general opinions about and use of digital technologies. Future work must be attentive to not only how opinions, behaviors, and outcomes differ across minoritized groups, but also how actions and outcomes are associated with the lived experiences of individuals, stemming from institutionalized racism and other systems of inequality.

Limitations

A number of limitations should be considered when interpreting our findings. First, because the data were drawn from a single city, the findings may not be generalizable to digital contact tracing efforts in other communities or in the United States more broadly. Additional research is needed to understand the extent to which our findings on the willingness to participate in contact tracing extend to other communities with different demographic and socioeconomic compositions, including larger populations of other racial and gender minorities. As Detroit is a majority Black city in a majority White state, the effect of trust in the state government on individuals' decisions to participate in contact tracing may be more pronounced here than in other communities. At the same time, Detroit's experience, particularly early in the pandemic, as a COVID-19 hotspot may mean that residents are more willing to engage in contact tracing than other populations. Future research should investigate whether the patterns captured in our analysis hold in other communities and in the national population. Second, because our measure of contact tracing focused specifically on the willingness to download an app, it is possible that respondents' hesitancy is shaped more by discomfort with or privacy concerns regarding phone apps or access to smartphones and not contact tracing specifically. Though we controlled for internet access as a proxy for technology access and use, and only examined responses among cell phone owners, future research would benefit from examining the willingness to participate in digital contact tracing across a variety of modalities. Finally, our data were collected within the first 4 months of the coronavirus pandemic being declared a national emergency in the United States. In the ensuing months and years, COVID-19 has continued to spread and people's personal experiences of being infected with or knowing others infected with the coronavirus have changed. While digital contact tracing efforts in the United States have generally waned over time, it is possible that perspectives on contact tracing have shifted since the data were collected in response to the evolving nature of the pandemic and perspectives on public health generally.

Conclusions

The impact of COVID-19 has been disproportionately experienced by people of color [25]. In Detroit, Black residents experienced extremely high levels of disease, death, and loss of loved ones as a result of the pandemic [44]. Contact tracing is an important public health tool to limit the spread of infectious diseases like COVID-19, and digital contact tracing apps can positively contribute to such efforts [3]. Yet, throughout the COVID-19 pandemic, people's willingness to engage with digital contact tracing has varied [19].

Contact tracing technologies have the potential to advance public health efforts during the COVID-19 pandemic and beyond, but unequal uptake of these platforms across racial/ethnic groups and socioeconomic status may exacerbate the disparate impacts of health crises. Our findings show that residents' wariness of participating in contact tracing is associated with trust in the government and education levels, suggesting that distrust and concerns about systemic inequality and surveillance may drive reluctance to use such tools, especially among people of color [24]. These results point to the importance of being attuned to the ways intersectional identities influence public health behaviors and the need to develop culturally informed advocacy when promoting these platforms in the future [23,67].

Acknowledgments

We would like to thank the Detroit residents who took part in the survey. We would also like to acknowledge the staff of the Detroit Metro Area Communities Study and the funding for data collection from The Knight Foundation, The Ballmer Group, and Poverty Solutions at the University of Michigan. Additional support was provided though a Eunice Kennedy Shriver National Institute of Child Health and Human Development training grant to the Population Studies Center at the University of Michigan (T32 HD007339).

Conflicts of Interest

Abstract

Background: Case investigation and contact tracing are core public health activities used to interrupt disease transmission. These activities are traditionally conducted manually. During periods of high COVID-19 incidence, US health departments were unable to scale up case management staff to deliver effective and timely contact-tracing services. In response, digital contact tracing (DCT) apps for mobile phones were introduced to automate these activities. DCT apps detect when other DCT users are close enough to transmit COVID-19 and enable alerts to notify users of potential disease exposure. These apps were deployed quickly during the pandemic without an opportunity to conduct experiments to determine effectiveness. However, it is unclear whether these apps can effectively supplement understaffed manual contact tracers.

Objective: The aims of this study were to (1) evaluate the effectiveness of COVID-19 DCT apps deployed in the United States during the COVID-19 pandemic and (2) determine if there is sufficient DCT adoption and interest in adoption to meet a minimum population use rate to be effective (56%). To assess uptake, interest and safe use covariates were derived from evaluating DCTs using the American Psychological Association App Evaluation Model (AEM) framework.

Methods: We analyzed data from a nationally representative survey of US adults about their COVID-19–related behaviors and experiences. Survey respondents were divided into three segments: those who adopted a DCT app, those who are interested but did not adopt, and those not interested. Descriptive statistics were used to characterize factors of the three groups. Multivariable logistic regression models were used to analyze the characteristics of segments adopting and interested in DCT apps against AEM framework covariates.

Results: An insufficient percentage of the population adopted or was interested in DCTs to achieve our minimum national target effectiveness rate (56%). A total of 17.4% (n=490) of the study population reported adopting a DCT app, 24.7% (n=697) reported interest, and 58.0% (n=1637) were not interested. Younger, high-income, and uninsured individuals were more likely to adopt a DCT app. In contrast, people in fair to poor health were interested in DCT apps but did not adopt them. App adoption was positively associated with visiting friends and family outside the home (odds ratio [OR] 1.63, 95% CI 1.28-2.09), not wearing masks (OR 0.52, 95% CI 0.38-0.71), and adopters thinking they have or had COVID-19 (OR 1.60, 95% CI 1.21-2.12).

Conclusions: Overall, a small percentage of the population adopted DCT apps. These apps may not be effective in protecting adopters' friends and family from their maskless contacts outside the home given low adoption rates. The public health community should account for safe use behavioral factors in future public health contact-tracing app design. The AEM framework was useful in developing a study design to evaluate DCT effectiveness and safety.

Introduction

Background

During periods of high COVID-19 incidence, US health departments were unable to scale up case management staff to deliver effective and timely contact-tracing services [1]. This is expected considering that prior to the COVID-19 outbreak, US health departments were grossly understaffed and needed a minimum of 80,000 more full-time equivalent positions to provide adequate infrastructure and a minimum package of public health services [2].

Digital contact tracing (DCT) apps are intended to supplement health department case managers by automatically and more efficiently estimating the proximity and duration of an individual's exposure to patients diagnosed with COVID-19. A model developed to predict the impact of conventional and mobile DCT apps on the SARS-CoV-2 pandemic estimated that the disease transmission rate could be reduced by adding either contact tracers or effective widely used DCT apps (eg, Bluetooth, GPS) [3]. DCTs reduce disease spread by alerting the user if they have been near an infected person who is also using DCT, followed by user isolation and testing for infection. However, a key DCT effectiveness assumption is that there are sufficient people adopting the app to signal disease exposure. Ongoing monitoring of population uptake is necessary to address concerns that users are relying on DCT apps that have not met minimum population-level app adoption rates [4,5].

Health Technology Assessments

Health technology assessments (HTAs) of public health applications are uncommon and challenged by lack of data, conflicting stakeholder priorities, and methodological issues [6]. The surge in COVID-19 cases in the United States in the summer of 2021 (ie, the "third wave") driven by the SARS-CoV-2 Delta variant marks an urgent time to perform an assessment of DCT apps to inform future public health contact-tracing programs and app design [7]. By 2020, an estimated 2.6 billion people globally were expected to use mobile health (mHealth) apps, generating an estimated US $31 billion in revenue [8].

Despite the large market of mHealth apps, there is no US regulatory authority in place to evaluate if DCT apps are safe and beneficial [9]. Section 522 of the Federal Food, Drug, and Cosmetic Act provides the Food and Drug Administration (FDA) with the authority to require manufacturers to conduct postmarket surveillance to address important public health questions on the effectiveness and safety of a health device [10]. However, the FDA generally does not regulate products that are intended solely to track locations or contacts associated with public health surveillance [11]. Public health DCT developers could voluntarily implement HTAs using the FDA Software Precertification Program; however, the FDA guidance does not provide a framework to conduct the postmarket evaluations [12].

There are a wide variety of frameworks available for evaluating health applications, but they may not be suitable for HTAs [13,14]. The clinical applications marketplace conducts HTAs, but they have not been frequently performed in the public health market [6]. This study adapted the American Psychological Association (APA) App Evaluation Model (AEM) hierarchical rating system because it was developed by harmonizing application evaluation questions from 45 frameworks [15]. The AEM provides a comprehensive evaluation framework for clinicians and patients to identify high-quality mHealth apps. The framework may work well at a population level with hierarchical layers to explain adoption decisions [16,17].

DCT only functions when all people near each other are using the app. Individuals install DCT apps on their own mobile devices, and these apps must be adopted by a sufficient percentage of a population to be effective [16,17]. In this study, we set the adoption effectiveness rate at 56% of the national population [18]. We define our DCT adoption as the percentage of the population using a DCT plus those that are interested in using a DCT but have not yet adopted it. Our assumption is that public health campaigns could convert many of the interested users into adopters through public health communication campaigns.

Following public health safety guidance while using DCT is important, and the AEM framework provides health and technology evaluation elements to evaluate functional use. For example, DCT requires users to voluntarily report their positive COVID-19 test results to public health authorities; therefore, user behavior is part of DCT functionality. After DCT adoption, users should not cease their social distancing behaviors in a way that increases disease exposures.

DCT represents a new technology with a short research history, and the AEM provides a structure for measure selection [19]. The AEM has five categories for evaluation: Access and Background, Privacy and Safety, Clinical Foundation, Usability, and Data Integration Toward a Therapeutic Goal. The AEM provides a way to critically assess mHealth and does not include a minimum or maximum score to be considered "good" or "useful" [15,20].

Objective

The main objective of this study was to evaluate COVID-19 DCT apps deployed in the United States during the COVID-19 pandemic under the hypothesis that DCT requires a minimal level of uptake by a population to be effective and DCT users should follow social distancing policies. Accordingly, the specific study aims were as follows.

Aim 1: Determine if there is a sufficient percentage of people using or interested in DCT to reach the minimum critical mass (56%) [18].

Aim 2: Assess the effectiveness and safety of DCT apps using the APA AEM hierarchical rating system [16].

The AEM is a conceptual framework for developing key study measures and was used to select variables. The measures derived from the framework assess adoption rate characteristics and behaviors necessary for the safe use of DCT apps.

Methods

Data Source

We approximated a nationally representative sample of US adults (aged 18+ years), with a stratified nonprobability sample to survey 3853 online panel participants between December 22, 2020, and January 2, 2021. Respondents were recruited by Climate Nexus Polling, using several market research panels as described elsewhere [21]. Participants were recruited using stratified sampling methods [21]. Compensation for participants depended on the specific market research panel and respondents' preferences (eg, cash, gift cards, reward points) and was valued below US $4.00. Quotas were set to match the US Census Bureau's Voting and Registration Supplement to the Current Population Survey parameters for age, gender, race, educational attainment, census region, and Hispanic ethnicity. Sampling weights were used to account for small deviations from the preselected census parameters. The participation rate of the survey was 68.5% (qualified respondents that completed the survey). The 95% credibility interval for this survey was ±1.7%. The survey data are provided in Multimedia Appendix 1.

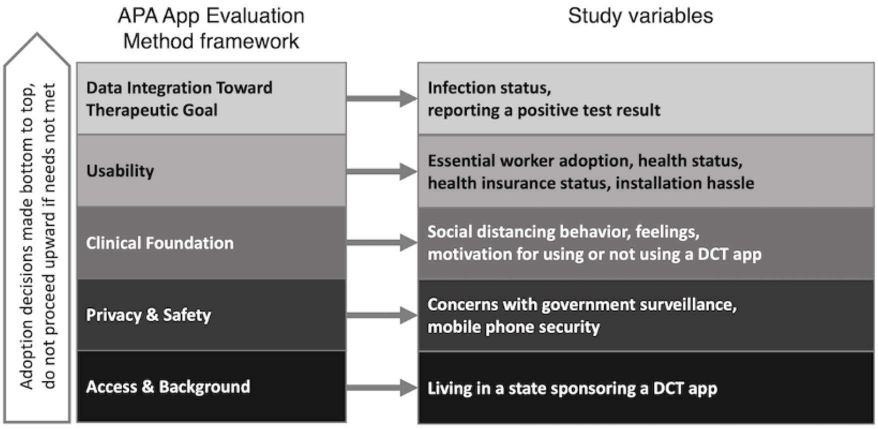
DCT apps are new technology and there were no established and validated survey instruments to measure their use; therefore, Climate Nexus Polling developed DCT app survey questions based on a previous Pew Research survey on digital privacy [22].

Key Study Measures Aligned to the APA AEM

Model Variable Selection

Demographic measures were based on a literature review to assess if app adoption applied to a diverse range of people [23,24]. The following background for each category links the AEM to the study's DCT postmarket evaluation. The AEM framework was used to select variables a priori from data available in the survey (Figure 1). The detailed process is described in Multimedia Appendix 2.

Figure 1. App Evaluation Model (AEM) with study variables. APA: American Psychological Association; DCT: digital contact tracing.



Access and Background

This category is concerned with the transparency of app governance and ensuring that the benefits of mHealth apps are available to a diverse range of people, regardless of background. The US DCT apps are based on mobile phone Bluetooth proximity tracking using the Google/Apple Exposure Notification (GAEN) platform [25], and are cosponsored by US state government public health organizations [25]. Adoption of DCT apps in the United States is voluntary, and varies by demographics and behavior [23]. Furthermore, DCT app adoption may be subject to health equity issues since mHealth adoption is generally associated with younger, educated populations [23,26].

The "state of residence" measure was used to demonstrate the role of a person's state government in driving local adoption [25,27,28].

Privacy and Safety

There is an expectation of confidentiality by DCT users, and privacy policies should ensure that COVID-19 exposure proximity measurement is accurate. Concern over privacy and data breaches is a genuine concern. Experts collaborated to develop secure decentralized contract-tracing platform architectures [29]; however, some GAEN implementations may have exposed user data. A class action lawsuit was filed in April of 2021 against Google, claiming that their COVID-19 contact-tracing platform exposed unwitting Android adopters' sensitive personal information [30].

Concerns over government surveillance and mobile device hacking measures were selected from the survey [23,28,30].

Clinical Foundation

There is no agreed-upon definition of effectiveness for measuring the clinical foundation of DCT. In January 2021, the National Institute of Standards and Technology held a workshop to discuss successes and challenges associated with implementing proximity detection technologies [31]. For public health, effectiveness is defined as reducing transmission and quicker notification of exposure. From an adopter perspective, effectiveness lies in addressing privacy concerns and finding a value proposition. From a technology perspective, effectiveness is how well the DCT apps measure proximity and if they can function at current adoption rates. A systematic review of DCT also found this lack of definition for effectiveness [18].

Also of potential concern is the "risk compensation" theory, which suggests that individuals will increase risky social distancing behavior after a COVID-19 public health intervention is implemented [32,33]. Researchers are concerned that DCT app adoption could create a false sense of security and safety, leading to behavior that increases infections [34]. Additionally, the personality of the adopter may be an issue because the extroversion personality type is associated with lower compliance with social distancing [35].

Clinical foundation measures were selected to inform future work on the definition of DCT public health effectiveness. Measures were selected to assess social distancing behavior (mask, visiting friends/family, attending religious services) [23,35]. Psychological distress that could impact adoption and measures were included to assess a user's worry about COVID-19 [36]. Measures on motivations for adoption and interest were selected from the survey [23,24].

Usability

Grounded in the principle of autonomy, an mHealth app should enable the user to take an educated and active role in their health decisions. For example, DCT apps could help essential workers take an active role in managing their exposures. However, a German study showed that there was not greater uptake of DCT apps by people working during the early pandemic [23]. In addition, the readability of DCT apps is higher than US reading levels and potentially less accessible for the general population [27]. There is also little known about DCT use by people in good versus poor health. Studies show that older people with chronic diseases adopt self-care and vitals mHealth apps [26]; however, their chronic disease management is a very different purpose than tracking infectious disease exposure.

Usability is especially important for populations with high exposure risk or at high risk of poor outcomes. Measures were selected for essential worker, health, and health insurance status [23,24].

Data Integration Toward a Therapeutic Goal

This category is related to the principle of shared decision-making through appropriate information sharing with public health departments and health care systems. Some DCT apps do offer adopters links to testing resources, local health department resources, and quarantine social support [27]. In the US GAEN DCT systems, adopters are solely in control of reporting their positive test results through the app; therefore, designers have limited ability to automate the contact-tracing reporting data path. Unfortunately, a Morbidity and Mortality Weekly Report found that 35% to 48% of individuals with COVID-19 did not report any of their contacts to public health department contact tracers [37]. DCT apps provide anonymous COVID-19–positive lab test reporting capability, but there is no evidence showing that DCT adoption improves the likelihood of reporting.

User infection status and sharing a positive test result measures assess if apps ultimately provide exposure data to public health authorities [24,37].

Statistical Analysis

Market segments of the survey population were divided into three categories: (1) the "adopted" category includes the population self-declaring use of a DCT app; (2) the "interested-not-adopted" category includes the population self-declaring interest in, but not using a DCT app; and (3) the "not interested" category describes the remaining population. All three categories were included in the descriptive statistics table using frequencies and survey weighted percentages. Only the adopted and interested-not-adopted ("interested") categories were included in the statistical analysis because these populations would be targets for uptake communications campaigns. Logistic regression models were applied to the adopted and interested-not-adopted segments to compare against the key measures. Regression results for the two models are presented with unweighted percentages and adjusted odds ratios (ORs) with 95% CIs. Both model results and key measures are presented in tables with variables organized by AEM categories. Health care workers (n=1029) were excluded from the analysis because health systems had contact-tracing protocols in place before the COVID-19 pandemic to meet health care–acquired infections regulations. Health care workers may answer survey questions inconsistently because they follow workplace infection contact-tracing protocols that are not applicable to the general public. Multicollinearity of adopted and interested-not-adopted models were checked through correlation analysis. Descriptive and statistical analyses were conducted using STATA version 16.1 (StataCorp, College Station, TX).

To mitigate the risk of model overfitting given the large number of measures, variables were selected a priori through a literature review and allocated to the APA framework as described in the Key Measures section above and Multimedia Appendix 2. By using measures with statistical significance from other data sets, we reduced the likelihood that our results were based on overfitting in our survey sample. Results were also analyzed for overfit risk by setting a minimum measure subsample frequency threshold (n>15) [38].

Ethical Considerations

This project was considered exempt for review by the George Mason University Institutional Review Board (1684418-3).

Results

Descriptive Analysis

Out of 3853 respondents, 2824 were included in the analysis, with 1029 excluded because they self-identified as health care workers. Among the total sample of 2824 people, 490 (17.4%) reported using a DCT app, 697 (24.7%) reported interest, and 1637 (58.0%) were not interested (Table 1). All measures exceed the minimum frequency threshold for assessing the risk of overfitting, with most of the measures having over 100 survey respondents.

Older age groups adopted the apps less frequently, where the ≥65-year-old group are at higher risk of poor COVID-19 outcomes but represent a lower rate of adoption (10.2%). Those not interested in adopting the app were disproportionately concerned with government surveillance postepidemic (43.2%).

Table 1. Frequencies of survey population and survey segments.

Survey segment	Study population (N=2824), n (wt%[a])	Adopted (n=490), n (%)	Interested-not-adopted (n=697), n (%)	Not interested (n=1637), n (%)
Access and background: State of residence offers a DCT[b] app (yes)	1534 (55.3)	310 (63.3)	376 (54.0)	848 (51.8)

[a] wt%: weighted percentage.

[b] DCT: digital contact tracing.

[c] N/A: not applicable.

DCT app adopters more frequently visited friends and family outside the home each week (61.6%) compared to the overall survey rate (47.6%). Those interested in the app visited friends and family outside the home less frequently (43.0%). Adopters also had high rates of concern about losing their home (43.3%), being lonely (41.2%), and feeling afraid (41.6%). Despite having a higher rate of thinking they have or had the coronavirus infection (28.6%), their rate of telling neighbors and friends was similar to that of the base population (67.4%).

There was also a difference in the rate of wearing masks in the overall study population (84.5%) versus a lower rate in the adoption segment (74.9%). Adopters showed a higher rate of very good/excellent health (54.3%) compared to the overall population and other categories.

Logistic Regression Analysis

There were differences in the frequency and association between the adopted and interested segment populations across all five AEM categories (Table 2). Covariate-adjusted ORs show how the adoption and interest vary by study subject characteristics. The OR is interpreted as the odds of a covariate being the same (OR=1.0) for adopted versus not adopted groups. For example, people who live in a state that offers a DCT adopt the apps 1.47 times more often (OR>1.0) than people in states not offering DCTs. People who wore a mask in public to help protect themselves or others from getting sick adopt DCT apps 0.52 times less often (OR<1.0) than people that do not wear masks.

Table 2. Logistic regression results for adopted and interested-not-adopted segments.

[a] Frequency is presented as a percentage of adopted or interested-not-adopted against the total population of each variable.

[b] OR: odds ratio.

[c] DCT: digital contact tracing.

[d] Statistically significant associations are in italics.

[e] N/A: not applicable.

[f] Removed from model due to collinearity with being in the interested-not-adopted segment.

Essential worker status was not associated with being in the adoption or interest segments, and education was not a significant factor. Being an adopter was negatively associated with having health insurance (16.1%; OR 0.65, 95% CI 0.48-0.89) and being interested was associated with being in fair to poor health (31.0%; OR 1.42, 95% CI 1.08-1.85). Older age was negatively associated with both adoption and interest. Having an annual income over US $100,000 was associated with both adoption and interest. Political party affiliation was not a statistically significant factor in adoption, although those self-declared as Democratic party members had the highest adoption frequency.

Not adopting a DCT app due to concerns about government surveillance (25.0%; OR 0.65, 95% CI 0.52-0.81) and that their phone will be hacked (27.7%; OR 0.78, 95% CI 0.62-0.99) was negatively associated with interest. Adoption was positively associated with visiting friends and family (22.9%; OR 1.63, 95% CI 1.28-2.09), whereas interest was negatively associated with visits (28.1%; OR 0.81, 95% CI 0.66-0.99). Religious services attendance was associated with interest (32.5%; OR 1.29, 95% CI 1.06-1.58). Adopters tended to express feeling lonely (24.9%; OR 1.31, 95% CI 1.00-1.70), while being interested was positively associated with feeling afraid (39.3%; OR 1.38, 95% CI 1.10-1.73). Motivation measures showed the highest frequencies in the adoption (38.3%-41.3%) and interest segments.

Adopters were more likely to think they have or had the coronavirus (28.6%; OR 1.60, 95% CI 1.21-2.12). Adoption was not positively associated with telling friends and neighbors about a positive COVID-19 lab result.

Discussion

Principal Findings

Overall, each layer of the hierarchical AEM framework shows barriers to the ability of DCT to effectively and safely supplement understaffed manual contact tracers and protect the public. With respect to aim 1, we found that a small percentage of the eligible population reported adoption of the app (17.4%), which is lower than estimated adoption rates in the United Kingdom (28%) [39] and New Zealand (31%) [40]. Programs to encourage adoption among those interested in a DCT app (24.7%) could increase adoption, but still fall well below the minimum target threshold of adoption. The not-interested segment is large enough (58.0%) to prevent DCT apps from reaching the population adoption minimum. Low adoption and interest rates are problematic because in order for DCT apps to be effective, high population uptake is needed alongside other control measures [18]. With respect to aim 2, inconsistent associations across prior DCT studies may be due to variable selection differences, which shows the benefit of using the AEM framework to develop study measures a priori [19]. Our results show that DCT apps may not be clinically effective in protecting adopters' friends and family from their frequent maskless contact outside the home given low adoption rates and DCT technology false-negative detection issues. Adopter and interested segments were positively associated with motivations to protect friends and family, community, and the older population; however, this study found several areas of concern regarding beneficence.

Essential workers are at greater risk of exposure as part of their employment, but they adopted DCT apps at a low rate (23.6%). Essential workers were not associated with being part of either the adoption or interest segment, and other studies also found that they had lower intent to adopt and report positive COVID-19 lab tests [24]. Future DCT app design should consider that infection risk varies across subpopulations, and DCT solution design should focus on adoption with higher-risk subpopulations. A study on DCT app user sentiment suggested that DCT apps are largely passive in nature, and could be improved by adding features such as proactive reminder notifications and links to detailed disease-spread information [30].

The US public health department sponsorship of DCT apps was considered a positive attribute in the AEM Access and Background category; however, in the not-interested segment, this was a negative attribute due to the association with distrust of government surveillance. Other studies indicated concerns about privacy that varied by political affiliation [28], whereas concerns about postpandemic surveillance and hacking were not associated with adoption hesitancy in the interested segment. Resolving this conundrum requires further study of the not-interested segment.

DCT apps are available for free on Google Play and Apple Store, and the adoption rate is higher in the 26 US states sponsoring apps [25]. Early studies before DCTs were deployed could only survey people about their intent to adopt [24], and our findings show differences in adoption versus interest subpopulations across the AEM categories. The influence of age, gender, race, and income was found to be inconsistent across studies [24] and variation in culture is suggested to play a role [23]. Our results support previous findings that DCT adoption is associated with a younger population, but did not support the association with well-educated populations [23,26].

Safe use of DCT apps after adoption is a concern. The high volume of social visits warrants further investigation into the influence of risk compensation behavior and an extraversion personality trait. The COVID-19 pandemic has resulted in ongoing related psychological stress accompanying DCT exposure monitoring, reporting, quarantine, and isolation [41]. Adoption and interest are associated with mental health stressors, with worries of losing a home and feelings of loneliness. More research is needed to determine if there are causal links with loneliness, extroversion personality type, DCT adoption, and poor social distancing compliance [35]. Our study suggests that DCT apps should not be considered as passive public health infection reporting tools because of the psychological and behavioral associations [36]. Our findings support a prior recommendation to investigate DCT adoption psychological impacts [36].

Neither adoption nor interest was associated with telling neighbors or friends about testing positive for COVID-19. This is concerning considering that adoption was associated with adopters thinking they had been infected with the coronavirus. DCTs may not be an effective addition to manual contact tracing given that they are not associated with improving upon the rate of infected people sharing contacts with public health contact tracers. Lessons from other stigmatized diseases such as HIV may offer DCT designers insight to encourage the sharing of exposure information to slow transmission [42]. Findings from an HIV mHealth prevention and testing study recommended using evidence-based methods for app development, including links to geospatial prevention information and the ability to access self-testing kits [43]. There is a clinical trial underway for an HIV mHealth app that may produce useful information to DCT developers [44].

Limitations

Adoption and interest were measured by self-described use at the time of the survey and did not include questions about duration of use. The survey was national and did not ask the respondents which of the DCT apps they considered when answering survey questions, although most states use the same GAEN proximity detection platform. The study results occasionally varied from those reported by international DCT deployments, which suggests that local culture can play a role in adoption. The data are representative of the US adult population but not of all app adopters, and we were able to identify important differences between adopters and nonadopters. Importantly, this study is the first to create a postmarket assessment approach for DCTs, and points to the need to prioritize development of multidisciplinary teams at each step of the development, implementation, and evaluation continuum.

This study did not assess the political party control of DCT sponsoring states, which controls if a DCT is offered and how energetically it is marketed. An individual's political party affiliation was not associated with adoption, but political party in control of a regional government is likely a different factor than individual user political affiliation.

Conclusions

With low adoption rates nationally, the DCT apps may only be useful as part of pandemic management programs in smaller, more targeted populations such as company employees, university employees and students, or health system workers and clients.

The AEM highlighted key clinical foundation issues that should be addressed in exposure contact-tracing system design. For example, DCT app adoption is associated with frequent visits with friends and family members outside the home, not wearing masks, not having health insurance, feeling lonely, and adopters thinking they have/had the coronavirus. Designing for behavioral risks requires public health and technology organizations to codevelop multidisciplinary definitions of DCT effectiveness along with measurement methods.

The APA AEM framework combined with observational data analysis is suited to assess end-user mobile app experience and can help with future study measure selection. This postmarket beneficence and safety evaluation approach using the AEM and observational data could be applied to other COVID-19 pandemic public health applications that manage disease exposure, promote personal health tracking, monitor health, and raise awareness [45].

Acknowledgments

The authors wish to thank our colleagues at Climate Nexus for their support, including James Wyatt, Molly Fisch-Friedman, and Reece Rushing, and Dr. Gary Kreps for his insights on health communication. The authors would like to thank the Institute for Biohealth Innovation at George Mason University and the TD Charitable Foundation for financial support.

Data Availability

A subset of survey data that were used in this study and the data dictionary are available in Multimedia Appendix 1.

Authors' Contributions

KEC and AAR had full access to all the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis. Study concept and design: KEC. Acquisition, analysis, and interpretation of data: KEC, AAR. Drafting of the manuscript: KEC. Critical revision of the manuscript for important intellectual content: AAR. Statistical analysis: KEC. Abstract

Background: There are regional gaps in the access to medical services for patients with chronic kidney disease (CKD), and it is necessary to reduce those gaps, including the gaps involving medical costs.

Objective: This study aimed to analyze regional differences in the medical costs associated with CKD in the South Korean population.

Methods: This longitudinal cohort study included participants randomly sampled from the National Health Insurance Service-National Sample Cohort of South Korea. To select those who were newly diagnosed with CKD, we excluded those who were diagnosed in 2002-2003 and 2018-2019. A total of 5903 patients with CKD were finally included. We used a marginalized two-part longitudinal model to assess total medical costs.

Results: Our cohort included 4775 (59.9%) men and 3191 (40.1%) women. Of these, 971 (12.2%) and 6995 (87.8%) lived in medically vulnerable and nonvulnerable regions, respectively. The postdiagnosis costs showed a significant difference between the regions (estimate: –0.0152, 95% confidence limit: –0.0171 to –0.0133). The difference in medical expenses between the vulnerable and nonvulnerable regions showed an increase each year after the diagnosis.

Conclusions: Patients with CKD living in medically vulnerable regions are likely to have higher postdiagnostic medical expenses compared to those living in regions that are not medically vulnerable. Efforts to improve early diagnosis of CKD are needed. Relevant policies should be drafted to decrease the medical costs of patients with CKD disease living in medically deprived areas.

Introduction

Chronic kidney disease (CKD) has been known as a causative factor for early death and is being recognized as a global health problem [1]. In the United States, 1 in 7 adults are known to have CKD, and recent data show that the number of deaths due to CKD in the past 2 decades has increased. With the increased incidence of CKD, the cost of health care has increased substantially [2]. The most severe phase of CKD, which is end-stage renal disease (ESRD), has cost Medicare US $32.9 billion [2], with earlier stages costing Medicare approximately US $48 billion in 2010 [3]. This phenomenon is also evident in South Korea. In South Korea, the number of patients with CKD has increased by 8.7% annually over the last 5 years (from 2013 to 2017), and CKD was estimated to affect approximately 4.6 million patients as of 2017. The annual medical fee per patient with CKD is 8,361,000 won (US $6367.04), and the annual total medical cost of these patients exceeds 1.7 trillion won (1.2 billion dollars), which makes the per-patient treatment cost for CKD the highest compared with that for other diseases, such as dementia or cancer [4].

In the case of chronic diseases, the effective implementation of medical care, management, and prevention of these diseases are important for social integration [5]. However, in South Korea, despite the need for more medical help in provincial areas, resources and medical expenditure are concentrated in big cities. As of 2009, Seoul was home to 27.6% of the country's medical specialists and 52.4% of its physicians and dentists. In addition, medical expenditure is concentrated in the capital region. As of 2008, Seoul accounted for 26.9% of all insured medical bills, while regions outside Seoul and the capital region accounted for 36.2% and 14.5% of insured medical bills, respectively [6]. Patients with CKD living in rural areas have a higher risk of morbidity, hospitalization, and mortality compared to those living in urban areas [7]. In addition, rural residents are likely to have low income levels and need to travel farther to seek medical care, which can result in further disparities in CKD care [8]. As South Korea becomes an aging society, rural areas are observed to be aging more rapidly than urban areas [9]. Considering that age is an important factor for CKD [10], its treatment is even more challenging in rural areas with high aging rates. Since there are clear economic and regional gaps in access to services in the health system, it is necessary to make efforts to improve access to essential medical services for CKD.

Kim et al [11] studied the cost-utility data among patients with ESRD, although their analysis was limited due to the data being collected from a specific hospital. Another study [12] on the economic burden of CKD in South Korea used a national sample cohort; however, they found no regional differences. Therefore, our study aimed to estimate the regional differences using the position value for relative composite index of the medical costs of CKD in the South Korean population. We used the data available from the Korean Health Insurance Service.

Methods

Data and Study Population

The data for this study were obtained from the National Health Insurance Service- National Sample Cohort (NHIS-NSC). The NHIS-NSC data were collected by random sampling of medical claims, covering 2% of the South Korean population. The period during 2002 to 2003 was designated as a washout period to account for the effects of other existing diseases that might influence the results associated with the hypothesized relationship. To select those who were newly diagnosed with CKD, we excluded those who were diagnosed with CKD in 2002-2003 and 2018-2019. From these data, we extracted 10,019 cases diagnosed with CKD (International Classification of Diseases, 10th revision; code: N18). After excluding patients who were diagnosed with CKD during the excluded period, a total of 7966 individuals were included in the final study (vulnerable regions: n=971, 12.2%; nonvulnerable regions: n=6995, 87.8%).

Ethical Consideration

This study was reviewed and approved by the International Review Board of Yonsei University's Health System (Y-2020-0031) and adheres to the tenets of the Declaration of Helsinki. The NHIS-NSC data do not contain any identifying information; thus additional approval was not required.

Variables

The variable of interest in this study was the region. Position value for relative composite (PARC) indicators were used to categorize the health care level by region in South Korea; the analysis methods have been explained in detail in previous studies [13-18]. PARC is an objective indicator that identifies the relative health care level of a location compared with other regions. The PARC value ranges from −1 to 1, with a value of 1 as the best, 0 as the average, and −1 as the worst value, compared with the mean value of the entire region; the closer the value is to −1, the lower the health care level in the region compared with the average; on the other hand, the closer the value is to 1, the higher the level is compared with the average. In this study, when the PARC value was less than −0.33, the region was classified as a medically vulnerable region.

The dependent variable of this study was the total medical cost. Based on the time of diagnosis, the medical expenses were calculated monthly for 24 months before diagnosis and 24 months after diagnosis. Medical expenses before death were also included.

In addition, analyses that included sex, age, income, and social security type as independent variables were performed. Social security was categorized into health insurance (eg, corporate or regional) and medical aid. One of the social security systems in South Korea, National Health Insurance Service (NHIS), covers the entire population except for medical aid beneficiaries. Since the South Korean government provides insurance for the poor, it offers a medical aid program to people unable to pay for their own health care coverage. The medical aid program beneficiaries are financed by both the local and central government and are a part of the South Korean public assistance system [19].

Statistical Analyses

Marginalized Two-Part Longitudinal Model

To overcome the limitations posed by a conventional two-part model, we used a marginalized two-part (MTP) longitudinal model that directly parameterizes the marginal mean of Y_{ij} with covariates [20]. The MTP model has the same two-part structure as the conventional model, but instead of parametrizing the model with a conditionally positive-valued log-scale location parameter μ_{ij}, it models the marginal mean ν_{ij} that is conditional expectation value of Y_{ij} on b_i for medical users and nonusers combined. Thus, we take the following equation:

We redefined b_i to now have b'_i vector that includes a'_i and d'_i, the random effects are assumed to jointly follow a multivariate normal distribution; this allows cross-part correlation among random effects. Under the MTP parameterization, β_k is the incremental effect in the log of the overall mean, $E(Y_{ij} |b_i)$, that comprises the entire population, including both medical users and nonusers, $E(Y_{ij} |b_i)$, and corresponds to a unit increase in the *k*th covariate, x_{2kij}.

Model Details

The percentage of the study population with 0 expenditure over the study period was 29%, creating the need for a two-part model. To assess the effect of the regional difference on medical costs, we fit the MTP model with explanatory variables in the binary and overall mean components. In addition, we used segmented regression analysis for powerful estimation of intervention effects in an interrupted time series. The full model was constructed as follows:

In the above, $0 \leq time_{ij} \leq 48$ and $0 \leq After\ time_{ij} \leq 24$.

We fit the MTP model using the %MTPmle SAS macro program that correctly estimates model parameters through the likelihood function and can be maximized using SAS PROC NLMIXED. In addition, we chose a model type that used a continuous distribution in the second part of the MTP model: the gamma distribution.

Results

We analyzed the descriptive statistics of the medical costs of CKD by region (Table 1). The people living in the vulnerable region comprised 12.2% (971/7966) of participants, and those in the nonvulnerable region comprised 87.8% (6995/7966).

We analyzed the summary statistics for the semicontinuous outcome at each time point (Table 2). After the diagnosis of CKD, significant differences were found in region, sex, income, and Charlson comorbidity index between the groups.

We calculated the overall means and 95% confidence limits of the MTP model parameters (Table 3). There was a significant difference in difference in pre- and postdiagnosis medical costs between the regions (estimate: –0.0152, 95% CI 0.0171 to –0.0133).

We mathematically expressed the MTP model–estimated slope effects of differences in diagnosis and region (Table 4).

We used the MTP model to estimate the effect of region on medical expenses over time (Table 5). The first 2 years are the estimates, and the following years are predictions. The difference in medical expenses between vulnerable and nonvulnerable regions increased every year.

The overall mean of the values with log scale in Table 2 was calculated (Figure 1). Before the CKD diagnoses, there was a significant difference in the slope or intercept. There was also a clear difference in both the slope and intercept after the diagnosis.

Table 1. Descriptive statistics of the medical costs of chronic kidney disease analyzed by region.

Characteristics	Region			*P* value

Discussion

In this study, we examined the differences in medical costs of CKD among the regions of South Korea. The study results demonstrated that there were differences in postdiagnosis medical costs for patients with CKD depending on the region. Patients living in medically vulnerable areas had higher medical costs than patients living in nonvulnerable areas.

These findings are consistent with those of previous studies on chronic obstructive pulmonary disease, as our analysis on this disease (Multimedia Appendix 1), which found that deprivation of health care resulted in an increase in medical costs, emergency health care use, and mortality [21]. As shown in our results, people in medically vulnerable areas were likely to spend more in terms of medical costs. This could be because people living in vulnerable areas discover their symptoms only when conditions have become severe, which results in higher medical costs. Since social deprivation has been found to affect the development of a kidney condition, it is likely that the stage of CKD may worsen [22]. Diagnosis of CKD tends to happen at later stages, resulting in treatment delay and poorer outcomes [23]. Many studies, including those conducted in Canada [24], have found that rural residents with CKD are likely to have less access to specialty care and are provided with low-quality care, which results in a higher prevalence of severe stages of CKD in these areas. As previous studies have shown [3,25], more severe symptoms cause a rapid increase in medical expenses.

Geographical location plays an important role in the treatment of CKD. Some treatments, such as hospital-based hemodialysis, may not be feasible in rural areas. For patients who are dependent on ambulance service, transportation also becomes an important issue [26]. There are many indicators, such as Index Multiple Deprivation, that are used in the United Kingdom to evaluate deprivation within a geographic area [27]. The PARC indicators measure many aspects of the health care level by region in South Korea, rather than simply classifying regions as rural or urban; therefore, they might provide more accurate indicators for evaluation of the actual deprivation of health care regarding the medical cost of CKD.

Since there is an increase in postdiagnosis medical expenses for CKD in vulnerable areas, necessary policies should be implemented to lower the burden of this condition. In addition, efforts to increase early diagnosis of CKD are needed. Currently, most cases of CKD are detected during the course of treating other health problems rather than because of any CKD symptoms. Often, the early stages of CKD show no symptoms, and discovery is made only when conditions become severe. As shown previously [3], early detection of CKD is needed to lower the medical expenses of the patient.

Our study has some important limitations. First, we were not able to perform a random slope analysis in the study because SAS software does not currently provide the necessary program. In future studies, using another statistical program would avoid this issue. Second, since the data set is a collection of medical-claim bills, it is highly likely that the actual number of patients with CKD and their actual burdens are higher than the reported numbers. In general, the number of patients with CKD can be said to represent a pyramid with ESRD at its peak, although the number of patients with CKD based on their treatment performance with health insurance and medical benefits shows the opposite picture [28]. In addition, data on socioeconomic costs that could affect medical expenses, such as transportation, privately hired caregivers, private health insurance, and health supplements, were not available for this study.

However, there are some major strengths to our study. To the best of our knowledge, this study is the first to investigate the regional differences in the medical costs of CKD in the South Korean population using a TPM model. In addition, since all South Korean citizens are obligated to enroll in the NHIS, the NHIS data sets provide nationally representative data.

Our findings suggest that patients with CKD living in medically vulnerable regions are more likely to have increased postdiagnosis medical expenses compared with those living in medically nonvulnerable regions. Over time, the differences in medical expenses are likely to increase substantially. Policies are needed to decrease the medical bills of patients with CKD living in medically deprived areas.

Acknowledgments

This research was supported by a grant (HI20C1130) of the Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health and Welfare, South Korea. This work was also supported by the National Research Foundation of Korea (NRF; grant 2022R1F1A1062794) funded by the Korea government (Ministry of Science and ICT [information and communication technology]).

The funding organizations had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and decision to submit the manuscript for publication.

Data Availability

All data are available in the database of the Korean National Health Insurance Sharing Service and can be accessed upon reasonable request.

Authors' Contributions

MP and CY conceptualized and designed the study; CY contributed to the acquisition, analysis, and interpretation of data as well as statistical analysis; MP drafted the manuscript; SIJ, ECP, and CMN were in charge of the administrative, technical, or material support of the study; YH and SIJ supervised the study; all authors contributed to the critical revision of the manuscript for important intellectual content.

Conflicts of Interest

None declared.

Abstract

Background: Alcohol consumption during pregnancy is associated with a range of adverse birth-related outcomes, including stillbirth, low birth weight, preterm birth, and fetal alcohol syndrome (FAS). With more than 10% of women consuming alcohol during pregnancy worldwide, it is increasingly important to understand how racial/ethnic variations affect FAS onset. However, whether race and ethnicity inform FAS risk assessment when daily ethanol intake is controlled for remains unknown.

Objective: This study aimed to assess racial/ethnic disparities in FAS risk associated with alcohol consumption during pregnancy.

Methods: We used data from a longitudinal cohort study (the Collaborative Initiative on Fetal Alcohol Spectrum Disorders) at 5 hospital sites around the United States of 595 women who consumed alcohol during pregnancy from 2007 to 2017. Questionnaires, in-person interviews, and reviews of medical, legal, and social service records were used to gather data on average alcoholic content (AAC) during pregnancy. Self-reports of maternal race (American Indian/Alaska Native [AI/AN], Asian, Native Hawaiian or other Pacific Islander, Black or African American, White, more than one race, and other) and ethnicity (Hispanic/Latino or not Hispanic/Latino), as well as FAS diagnoses based on standardized dysmorphological criteria, were used for analysis. Log-binomial regression was used to examine the risk of FAS associated with each 1-gram increase in ethanol consumption during pregnancy, stratified by race/ethnicity.

Results: A total of 3.4% (20/595) of women who reported consuming alcohol during pregnancy gave birth to a baby with FAS. Women who gave birth to a baby with FAS had a mean AAC of 32.06 (SD 9.09) grams, which was higher than that of women who did not give birth to a baby with FAS (mean 12.07, SD 15.87 grams). AI/AN mothers with FAS babies had the highest AAC (mean 42.62, SD 8.35 grams), followed by White (mean 30.13, SD 4.88 grams) and Black mothers (mean 27.05, SD 12.78 grams). White (prevalence ratio [PR] 1.10, 95% CI 1.03-1.19), Black (PR 1.13, 95% CI 1.04-1.23), and AI/AN (PR 1.10, 95% CI 1.00-1.21) mothers had 10% to 13% increased odds of giving birth to a baby with FAS given the same exposure to alcohol during pregnancy. Regardless of race, a 1-gram increase in AAC resulted in a 4% increase (PR 1.04, 95% CI 1.02-1.07) in the chance of giving birth to a baby with ≥2 facial anomalies (ie, short palpebral fissures, thin vermilion border of the upper lip, and smooth philtrum) and a 4% increase (PR 1.04, 95% CI 1.01-1.07) in the chance of deficient brain growth.

Conclusions: The risk of delivering a baby with FAS was comparable among White, Black, and AI/AN women at similar levels of drinking during pregnancy. Regardless of race, a 1-gram increase in AAC resulted in increased odds of giving birth to a baby with facial anomalies or deficient brain growth.

Introduction

Alcohol consumption during pregnancy is associated with a range of adverse birth-related outcomes, including stillbirth, low birth weight, preterm birth, and fetal alcohol spectrum disorders (FASDs) [1]. FASDs range from physical defects to cognitive, social, behavioral, and emotional impairments [2]. Fetal alcohol syndrome (FAS) is the most severe form of FASDs, which are defined as a range of lifelong congenital anomalies, pre- or postnatal growth restrictions, and dysmorphic facial features originating from prenatal alcohol exposure [3].

Globally, around 10% of women consume alcohol during pregnancy, of whom 1 in 13 will deliver a child with a FASD, and 1 in 67, a child with FAS [4]. Previous studies have reported racial/ethnic variations in alcohol consumption during pregnancy [4]. Black, Asian/Pacific Islander, and Hispanic women drink less than White women during pregnancy [5], while non-Hispanic Black women are up to 48% and 62% less likely to drink alcohol during pregnancy and binge drink, respectively, compared to non-Hispanic White women [6]. Controlling for socioeconomic background, social support, paternal health behaviors, and maternal medical history, Black and Hispanic mothers are 41% and 58% less likely to drink during pregnancy, respectively, compared to White mothers [7].

However, although White women may drink more alcohol than Black/African American or Hispanic women before and during pregnancy [8], they are less likely than their counterparts to be at risk of adverse birth-related outcomes [9]. The fetal mortality rate among Black women (11.2%) is nearly twice that of White (5.9%) and Hispanic (5.1%) women in the United States [9]. Black women are also known to be at greater risk of both unintended pregnancies and poor pregnancy outcomes, such as preterm birth or low birth weight [10].

Concerning FAS and FASDs, Black infants have been reported to have a 7-fold higher risk of FAS compared to White infants, while infants born in some Southwestern Native American communities have prevalence rates of up to 17.9 per 1000 individuals [11] (US average: 2-7 per 1000 infants) [12]. To date, there is uncertainty regarding the racial disparities in FASDs, as there is a possibility of misestimation of prevalence. Black infants and children are more likely to be misdiagnosed or receive a later diagnosis due to limited access to care, stigmas, or lower socioeconomic status [13]. Contrastingly, concerns have been raised that clinician racial bias results in higher reports of prenatal substance exposure among Black children and lower reports among Hispanic children than White children [13]. Racial and ethnic differences in facial morphology will also result in an overestimation of FASDs among certain African American populations, especially in the absence of a race-specific lip/philtrum guide and 3D evaluations of philtrum height [14].

Advances in technology such as 3D ultrasound allow accurate assessment of dysmorphic facial features among fetuses with FASD [15]. Nevertheless, researchers are questioning whether the current reference standards for facial measurements in assessing FASDs account for such biases and racial/ethnic variations [16]. Current Institute of Medicine (IOM) diagnostic guidelines recommend that ethnic phenotypes should be considered, as what may seem dysmorphic in one racial/ethnic context (ie, lip/philtrum abnormalities or growth retardation, that is, height or weight ≤10th percentile) may be normal in another [17]. Hence, we sought to examine racial/ethnic variations in the prevalence of FASDs using high-quality diagnostic data in which each instance of a FASD was assessed using uniform criteria rather than an administrative assessment (eg, discharge codes on electronic health records).

Methods

Study Protocol

As part of a multisite research study of patients with FASD and mothers worldwide conducted since 2003, we analyzed data collected by the Collaborative Initiative on FASDs [18]. We restricted our analyses to sites within the United States, including (1) the Center for Behavioral Teratology at San Diego State University (San Diego, CA); (2) Emory University (Atlanta, GA); (3) 7 Northern Plains communities, including 6 Indian reservations; (4) the University of California, Los Angeles (UCLA; Los Angeles, CA); and (5) the University of Minnesota (Minneapolis, MN) [18]. Methods for obtaining information about prenatal alcohol exposure varied by site and ranged from questionnaires and in-person interviews to reviews of medical, legal, or social service records [18]. For all locations, histories of prenatal alcohol exposure were verified retrospectively [19]. At all sites, the participants were examined for FAS using standardized methodology, as reported by Mattson et al [18,20].

Although the Collaborative Initiative on Fetal Alcohol Spectrum Disorders (CIFASD) also included some women with no alcohol consumption during pregnancy or with unverified prenatal alcohol exposure histories, these samples were not representative of the source populations. Therefore, reliable estimates for average alcoholic content (AAC) could not be calculated. Hence, our analyses were restricted to subjects with at least one incident of verified alcohol consumption during pregnancy. Our objective was to estimate the risk of FASD per gram of pure ethanol intake among women who reported drinking during pregnancy.

Study Sites

Center for Behavioral Teratology Study Site

At this site, children suspected of alcohol exposure were referred to the principal investigator and local professionals for participation in this project [18]. Many patients were already attending this center before the initiation of the CIFASD project, including patients referred to the investigative team for meeting the traditional diagnostic criteria for FAS (eg, facial anomalies, growth retardation, evidence of central nervous system dysfunction (eg, microcephaly, mental retardation, or attentional deficits) [20]. Alcohol exposure histories were obtained via self-reports or professional reviews of medical, legal, or social service records of the biological mother. Parents or primary caregivers completed questionnaires regarding the children’s behavior, while the children were examined for facial features of FAS (ie, 2 of the 3 key facial features: short palpebral fissures [≤10th percentile], a thin vermilion border on the upper lip [rank 4 or 5 on a racially normed lip/philtrum guide], a smooth philtrum [rank 4 or 5 on a racially normed lip/philtrum guide], and signs of pre- or postnatal growth deficiency [head circumference, height, or weight ≤10th percentile]) [19].

Emory University Study Site

At Emory University, the Fetal Alcohol and Drug Exposure Clinic gathers data on a large sample of patients with FASDs while providing clinical services and facial evaluations at the Emory University Marcus Institute [21]. In the absence of direct reports, documentation of alcohol abuse or dependence by the biological mother in the form of medical, social services, or court records was reviewed [18]. Recruitment took place via clinical and community referrals. Parents or primary caregivers completed questionnaires and interviews, while patients with FASD were administered various neuropsychological tests over a 3-hour session [22].

Northern Plains Study Site

Seven communities, including 1 urban and 6 reservation sites throughout North Dakota, South Dakota, and Montana, participated in this study [21]. Children with FASDs were recruited via active case ascertainment methods and advertisements in tribal and community health centers [19]. Data on prenatal alcohol exposure were obtained from in-person interviews with the parent or primary caregiver to retrospectively obtain exact exposure histories and were also confirmed via reviews of medical records when available [19].

University of Minnesota Study Site

The Department of Psychiatry at the University of Minnesota collected data on prenatal alcohol exposure histories through several modalities, including medical reports, birth records, social service records, and, when available, maternal self-reports [21].

UCLA Study Site

Data were collected from children attending the Fetal Alcohol and Related Disorders Clinic at UCLA [23]. Participant recruitment was through local FASD clinic referrals, online advertisements, and word of mouth in caregiving communities [23]. All alcohol exposure histories were confirmed via in-person interviews and maternal reports of prenatal substance exposure or reviews of maternal medical records by a licensed medical doctor [23].

Study Participants

Among children with confirmed prenatal alcohol exposure, a diagnosis of FAS was made if 2 of the 3 key facial features of FAS (ie, short palpebral fissure, smooth philtrum, and thin vermillion border) were accompanied by either microcephaly or growth retardation [18]. Children were excluded when there were reports of known causes of mental deficiency, such as congenital hypothyroidism, neurofibromatosis, or chromosomal abnormalities [18].

Ethical Considerations

This study was approved by the institutional review board of the Harvard TH Chan School of Public Health (IRB21-1261). Primary data collection at each clinical location of the CIFASD received IRB approval, and informed consent was obtained from all adult participants or their legal guardians [24]. For secondary analysis of the data, our research team was provided with deidentified and anonymized data upon request and approval from CIFASD’s data committee. As a multisite study across several locations and time periods, compensation amount and type varied by collection site; for example, at Emory University, participants were given US $50 as monetary compensation [24,25], while at the University of Southern California and University of Minnesota, participants were compensated for their time with gift cards [26].

Measures

Alcohol Consumption

To calculate the grams of ethanol consumed per day during pregnancy for each pregnant woman, maternal reports of alcohol consumption frequency, quantity, and preferred alcoholic beverage were used. All women were asked to report the frequency (1-2 times during pregnancy, 3-5 times, once/month, 2-3 times/week, almost daily, or daily) and quantity (eg, 2) of alcohol exposure during pregnancy, as well as their preferred alcoholic beverage (eg, beer). Only cases of confirmed exposure were included. Each beverage was converted to grams of ethanol based on average alcoholic content (AAC), that is, 13.6 grams of pure alcohol or one standard drink: 340 mL of regular beer (approximately 5% alcohol), 150 mL of wine (approximately 12% alcohol), and 45 mL of distilled spirits (approximately 40% alcohol) [18]. Upon converting all frequency measures to a daily dose (eg, 1.5/280 days throughout the gestational period, with 1 to 2 incidents of consumption during their entire pregnancy), quantity and AAC were multiplied to determine the grams of pure ethanol consumed by each woman daily.

Race/Ethnicity

All participants were asked to self-report their ethnicity as Hispanic/Latino or not Hispanic/Latino. Then, they were asked to self-report their race as American Indian/Alaska Native (AI/AN), Asian, Native Hawaiian or other Pacific Islander, Black/African American, White, more than one race, or other. Owing to the limited number of participants in this investigation for whom there were available data on AAC, they were divided into White, Black, AI/AN, or other.

Outcome Assessment

At 4 of the sites (excluding the Northern plains), a dysmorphologist was trained to accurately diagnose FAS based on physical features as defined by the CIFASD dysmorphology core [27]. The CIFASD dysmorphology core has been tested in previous studies and has good interrater agreement for height and head circumference, moderate-to-fair agreement for facial anomalies, and poor agreement for the thin vermilion border on the upper lip [28]. Site differences for demographic variables including race, ethnicity, and age group were assessed via a 4-way interaction multivariate analysis of variance (MANOVA) but are not reported, as the effects of demographic variables varied by site [27].

Contrastingly, for the Northern Plains site, a team of physicians, teachers, and other representatives was trained to identify children with certain morphological characteristics of FASDs and other birth defects, as well as IQ and neuropsychologic traits; however, a pediatric dysmorphologist could not be consulted for verification. As “a single generalized set of nonspecific normative physical measures” was often insensitive to local ethnic variations in FASD morphology, syndromic features of FASDs were sometimes compared to normal controls within the same population in terms of weight, head circumference, fissure length, and other facial characteristics (eg, ptosis, and intercanthal distance) [29].

For all CIFASD sites, physical growth and dysmorphology features were recorded on a standardized and weighted checklist, and the IOM criteria for FASDs were used for FAS diagnosis: (1) evidence of a characteristic pattern of minor facial anomalies including at least ≥2 key facial features of FAS (palpebral fissures ≤10th percentile, thin vermilion border, or smooth philtrum), (2) evidence of pre- or postnatal growth retardation (height or weight ≤10th percentile), (3) evidence of deficient brain growth (structural brain anomalies or occipitofrontal circumference ≤10th percentile), and, if possible, (4) confirmation of maternal alcohol consumption directly from the mother or a knowledgeable collateral source [30].

For FAS severity, the IOM-recommended Diagnostic Criteria for FAS and Alcohol-Related Effects were used to determine severity of symptoms in terms of the number of FASD features and type of features (ie, facial anomalies, pre- or postnatal growth deficiency, deficient brain growth, and neurobehavioral impairment) for each patient [30]. FAS was considered the most severe form of FASD, with characteristic facial patterns, growth retardation, and neurodevelopmental abnormalities of the central nervous system (CNS). This was followed by partial FAS, defined as the presence of some components of FAS facial patterns and any of the aforementioned characteristics of FAS [30]; alcohol-related birth defects, which result from congenital defects and malformations or dysplasias of the heart, bone, kidney, vision, or hearing systems; and alcohol-related neurodevelopmental disorders, which include CNS neurodevelopmental abnormalities and complex behavioral and cognitive deficits [30].

Likewise, across all sites, the Child Behavior Checklist (CBCL) was completed by caregivers to collect information regarding child psychopathology and behavioral or emotional functioning [31]. All scores were compiled as a parent-completed survey assessment of their child to determine whether prenatal alcohol exposure affected the child’s ability to internalize or externalize difficult situations; adhere to rules and guidelines; and avoid social, thought, and attention problems [32].

Statistical Analysis

Descriptive statistics of the overall sample for mean AAC were calculated for participants according to race/ethnicity, maternal age at childbirth, tobacco and substance use (ie, marijuana, amphetamine, cocaine, hallucinogens, heroin, and methadone) during pregnancy, child sex, CBCL score, and clinical location of investigation. To examine the association between race/ethnicity and FAS, as well as FASDs, such as facial anomalies, growth retardation, and deficient brain growth, a log-binomial regression analysis was used while adjusting for child sex, child age, maternal age, and clinic location (as a dummy variable). Analyses were further stratified by race/ethnicity while accounting for a 1-gram unit increase in AAC. All analyses, including the GPLOT SAS procedure for displaying graphs, were performed using SAS software (version 9.4; SAS Institute).

Results

Table 1 shows the general characteristics of our sample by FAS diagnosis. Overall, 3.4% (20/595) of women who reported consuming alcohol during pregnancy gave birth to a baby with FAS. Women who gave birth to a baby with FAS had a mean AAC of 32.06 (SD 9.09) grams, which was higher than women who did not (mean 12.07, SD 15.87 grams). AI/AN mothers with FAS babies had the highest AAC (mean 42.62, SD 8.35 grams), followed by White (mean 30.13, SD 4.88 grams) and Black mothers (mean 27.05, SD 12.78 grams).

As seen in Figure 1, there was a dose-response relationship between AAC and FAS for exposure during different pregnancy trimesters. For women who only consumed alcohol in the first trimester, there was a 25% probability of giving birth to a baby with FAS when they consumed more than 40 grams of pure ethanol (ie, approximately 2.9 standard drinks). Contrastingly, for women who kept drinking alcohol throughout all 3 trimesters of their pregnancy, there was a 25% probability of giving birth to a baby with FAS when they consumed around 30 grams of pure ethanol (ie, approximately 2.1 standard drinks).

Table 1. General characteristics of sample by fetal alcohol syndrome diagnosis.

Characteristics	Gave birth to a baby with fetal alcohol syndrome		Did not give birth to a baby with fetal alcohol syndrome	
	Participants, n (%)	AAC[a] (grams/day), mean (SD)	Participants, n (%)	AAC (grams/day), mean (SD)

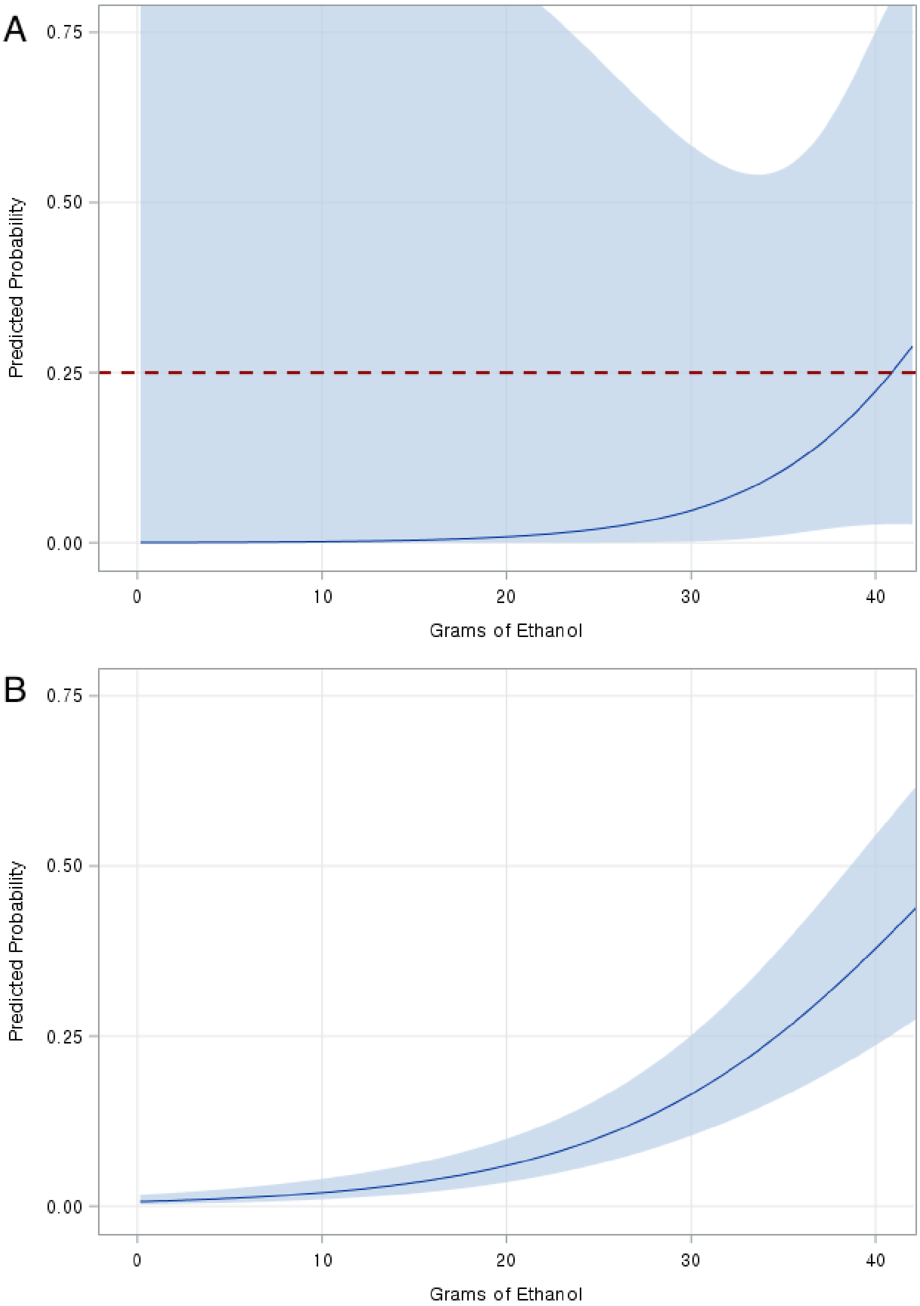
[a] AAC: average alcoholic content.

[b] SD values missing due to the number of participants being too low.

[c] N/A: not applicable.

Figure 1. Dose-response effect of average alcoholic content from 0 grams to 45 grams per day on predicted probability of fetal alcohol syndrome. (A) First-trimester drinking only; (B) drinking throughout all trimesters.



As seen in Table 2, AI/AN (PR 9.44, 95% CI 1.78-50.09) mothers and mothers who used tobacco during pregnancy (PR 13.78, 95% CI 4.18-45.35) had significantly increased odds of giving birth to a baby with FAS relative to their counterparts.

As seen in Table 3, when accounting for a 1-gram increase in alcohol consumption during pregnancy, White (PR 1.10, 95% CI 1.03-1.19), Black (PR 1.13, 95% 1.04-1.23), and AI/AN (PR 1.10, 95% CI 1.00-1.21) mothers had 10% to 13% increased odds of giving birth to a baby with FAS given the same exposure to ethanol during pregnancy.

Regardless of race/ethnicity, as seen in Table 4, every 1-gram increase in alcohol consumption during pregnancy was associated with an 11% increased risk of FAS (PR 1.11, 95% CI 1.07-1.15) and 7% increased risk of alcohol-related brain damage (PR 1.07, 95% CI 1.02-1.13). Each 1-gram increase in AAC was also associated with a 4% increase in the chance of giving birth to a baby with ≥2 facial anomalies (ie, short palpebral fissures, thin vermilion border of the upper lip, or a smooth philtrum; PR 1.04, 95% CI 1.02-1.07) or deficient brain growth (PR 1.04, 95% CI 1.01-1.07).

Table 2. Log-binomial regression analysis of association between sociodemographic variables and fetal alcohol syndrome, adjusted for child sex, child age, maternal age, and clinical location.

Sociodemographic variables	Prevalence ratio (95% CI)	*P* value

Neurobehavioral impairment	148 (36.6)	1.00 (0.28-3.53)	.83

[a] FASD: fetal alcohol spectrum disorder.

[b] FAS: fetal alcohol syndrome.

[c] Not available.

[c] Facial anomalies included short palpebral fissures (≤10th percentile), a thin vermilion border on the upper lip (rank 4 or 5 on a racially normed lip/philtrum guide) and a smooth philtrum (rank 4 or 5 on a racially normed lip/philtrum guide).

Discussion

Principal Results

Our results suggest that although the average quantity of alcohol consumed during pregnancy varied by race/ethnicity, the risk of delivering a baby with FAS or FASDs did not vary by more than 3% among White, Black, and AI/AN women when equal doses of ethanol were consumed. There is a consensus that "for unclear reasons, there is an increased risk of FAS in those who belong to African American or Native American ethnicities" [33]. Some researchers have attributed this to genetic polymorphisms that result in an increased risk of FAS among certain races [34,35]. African American race/ethnicity is believed to increase FAS risk due to the ADH1B*3 functional polymorphism—found in approximately 33% of those with African ancestry and almost exclusively in this group, which has a 70-to-80-time higher conversion rate of ethanol to acetaldehyde [36]. However, a previous study attributed to the maternal CIF*3 allele found among African Americans a protective effect against adverse prenatal effects of alcohol [37]. The high prevalence of FAS in certain communities (eg, the Indigenous) is likely due to more intensive screening or other social and environmental risk factors (eg, lead exposure or poor diet) than innate racial characteristics [38].

Our findings also suggest that innate racial characteristics are likely unassociated with the risk of FASDs for any race, especially when AAC is controlled for. Regarding Hispanic/Latino women, our study also found no statistically significant association between ethnicity and risk of FAS when AAC was accounted for, and this was in alignment with a previous study reporting that the pattern of early-pregnancy alcohol consumption in Latinas of childbearing age residing in the United States was similar to that of other racial/ethnic groups [39].

As data on patients with FAS or FASDs and their exposure histories have remained sparse [40], it was difficult to adjust for AAC accurately before the public release of the CIFASD data. While existing nationally representative data sets, such as the National Birth Defects Prevention Study (NBDPS) [41] and Pregnancy Risk Assessment Monitoring System (PRAMS) [42] have some information on women's health-related behaviors during pregnancy, they do not have a detailed assessment of drinking behaviors, such as the exact type of alcoholic beverage consumed (eg, beer, wine, or distilled spirits) [43], which makes it impossible to calculate exact AACs.

Limitations
