Abstract

Background: Chlamydia and gonorrhea cases continue to rise in Illinois, increasing by 16.4% and 70.9% in 2019, respectively, compared with 2015. Providers are required to report both chlamydia and gonorrhea, as mandated by public health laws. Manual reporting remains a huge burden; 90%-93% of cases were reported to Illinois Department of Public Health (IDPH) via electronic laboratory reporting (ELR), and the remaining were reported through web-based data entry platforms, faxes, and phone calls. However, cases reported via ELRs only contain information available to a laboratory facility and do not contain additional data needed for public health. Such data are typically found in an electronic health record (EHR). Electronic case reports (eCRs) were developed and automated the generation of case reports from EHRs to be reported to public health agencies.

Objective: Prior studies consolidated *trigger* criteria for eCRs, and compared with manual reporting, found it to be more complete. The goal of this project is to pilot standards-based eCR for chlamydia and gonorrhea. We evaluated the throughput, completeness, and timeliness of eCR compared to ELR, as well as the implementation experience at a large health center–controlled network in Illinois.

Methods: For this study, we selected 8 clinics located on the north, west, and south sides of Chicago to implement the eCRs; these cases were reported to IDPH. The study period was 52 days. The centralized EHR used by these clinics leveraged 2 of the 3 case detection scenarios, which were previously defined as the *trigger*, to generate an eCR. These messages were successfully transmitted via Health Level 7 electronic initial case report standard. Upon receipt by IDPH, these eCRs were parsed and housed in a staging database.

Results: During the study period, 183 eCRs representing 135 unique patients were received by IDPH. eCR reported 95% (n=113 cases) of all the chlamydia cases and 97% (n=70 cases) of all the gonorrhea cases reported from the participating clinical sites. eCR found an additional 14 (19%) cases of gonorrhea that were not reported via ELR. However, ELR reported an additional 6 cases of chlamydia and 2 cases of gonorrhea, which were not reported via eCR. ELR reported 100% of chlamydia cases but only 81% of gonorrhea cases. While key elements such as patient and provider names were complete in both eCR and ELR, eCR was found to report additional clinical data, including history of present illness, reason for visit, symptoms, diagnosis, and medications.

Conclusions: eCR successfully identified and created automated reports for chlamydia and gonorrhea cases in the implementing clinics in Illinois. eCR demonstrated a more complete case report and represents a promising future of reducing provider burden for reporting cases while achieving greater semantic interoperability between health care systems and public health.

Introduction

Background

Burden of Sexually Transmitted Infections in Illinois

Based on 2019 surveillance data, the disease burden for chlamydia and gonorrhea has increased by 16.4% and 70.9%, respectively, in Illinois since 2015 [1]. Public health laws mandate that these sexually transmitted infections be reported to Illinois Department of Public Health (IDPH) by health care providers and clinical laboratories within 7 business days [2]. Health care providers in Illinois generally report sexually transmitted infection cases via a web-based data entry platform; health systems and laboratories generally report their case results by electronic laboratory reporting (ELR). For many health care providers, reporting via the web-based platform poses an enormous workforce burden, and many report barriers to reporting such as lack of capacity, difficulty extracting relevant information, confusing vocabulary standards, etc [3]. Consequently, case reporting via electronic health records (EHRs) is a welcome prospect for all parties—reporting entities and public health agencies.

Public Health Surveillance and Informatics

Public health surveillance as a distinct discipline of public health was described by Langmuir [4] with the emphasis of ongoing and systemic collection of relevant data, consolidation, and analysis, followed by regular dissemination to all who need to know and can take public health action [5]. The role of public health informatics in facilitating surveillance is: “1) to improve timelines and completeness of data collection and analysis and 2) to free human resources to focus on the areas that require the most creative thought and to do the work that technology cannot” [6]. The Centers for Disease Control and Prevention (CDC) published the agency’s vision for public health surveillance in the 21st century [7] and recognized an opportunity to improve data quality and timeliness by accessing EHRs [8].

ELR and electronic case reporting (eCR) are creating a paradigm shift in public health surveillance. ELR is the automated messaging of laboratory reports of notifiable cases and has been widely adopted in the United States [9]. eCR is the automated generation of case reports from EHRs and subsequent reporting to public health agencies [10,11]. Both eCR and ELR were found to be more complete and timelier than paper-based reporting [12,13]. These approaches represent an advancement toward better semantic interoperability to support public health surveillance [14], greatly reducing the burden of reporting from clinical providers and improving the completeness and timeliness of those reports [15]. However, further evaluation and consideration is required to achieve a greater level of success and widespread implementation.

Prior Work in eCR Architecture for Chlamydia and Gonorrhea

The Council of State and Territorial Epidemiologists determines the case definition of notifiable conditions and maintains position statements for these conditions, including for chlamydia and gonorrhea [16-18]. An earlier study by Mishra et al [12] leveraged these position statements to develop the case detection logic for chlamydia and gonorrhea in EHRs. As an outcome of this study, value sets were created using national health care data standards (eg, International Classification of Diseases, Tenth Revision, Clinical Modifications; Logical Observation Identifiers Names and Codes [LOINC]; and Systematized Nomenclature of Medicine – Clinical Terms [SNOMED-CT]) [19] and Health Level 7 (HL7) [20]. Mishra et al [12] also compared eCR reporting with manual reporting and found that eCR increased provider reporting and improved the completeness of those case reports [12]. This study further consolidated the *trigger* for eCRs (when the case-detection logic is met in the EHR) based on the following three scenarios: (1) when an individual is diagnosed, (2) when a confirmatory laboratory result (named organism) is returned, or (3) a combination of laboratory test performed and result indicating the presence of infection is found (without the organism named in the result) [21]. Subsequently, this eCR architecture was implemented in Oregon simultaneously to our implementation in Illinois. In both the Oregon implementation and this study reporting the Illinois findings, the eCRs were generated via the HL7 electronic initial case report (eICR) standard [20,22]. The Oregon implementation found that this eCR architecture successfully reported cases of chlamydia and gonorrhea to public health while at the same time improving on the completeness compared to ELRs for the same cases [22].

Objective

The primary goal of this project was to pilot standards-based eCR for chlamydia and gonorrhea in 2 participating jurisdictions (public health agencies of the states of Illinois and Oregon), study the completeness of data between ELRs and eCRs, and disseminate the findings to promote adoption. In this process, we not only furthered the previous work by Mishra et al [12] but also learned about local variations while implementing the same architecture of eCR in 2 separate state health departments [12,22]. We recognize that local codes in EHRs are very common, and mapping them is a challenge [14]. Due to the challenges posed by variations in nonstandard codes used in EHRs, every implementation of eCR becomes an exercise of local implementation with some degree of customization. We further evaluated this implementation experience at a large health center–controlled network in Illinois. Additionally, we evaluated the completeness of eCR and compared it to ELR.

Methods

Ethical Review and Study Duration

For this evaluation, case-related information was sent from the EHR to IDPH, the State of Illinois's public health agency. An internal review committee of the participating clinics deemed that an Institutional Review Board review was not necessary for this project. The study period was a little over 7 weeks (or 52 days), which began on August 12, 2020, and ended on October 2, 2020.

Implementation Partners and Clinical Setting

Clinical Site and EHR Platform

We sought a network of clinics that shared a common platform of centrally hosted EHR. This would allow for scaling up across multiple clinical sites using a single implementation of the eCR architecture. AllianceChicago is a health center–controlled network that supports 45 ambulatory primary care practices in 19 states. For this evaluation, we selected 8 clinics operated by Near North Health, a federally qualified health center, located on the north, west, and south sides of Chicago [23]. In 2019, the selected clinical sites served 37,223 patients for a total of 122,277 visits. These clinical sites used AthenaHealth as the EHR [24] and QVERA as the interface engine [25].

Public Health Department

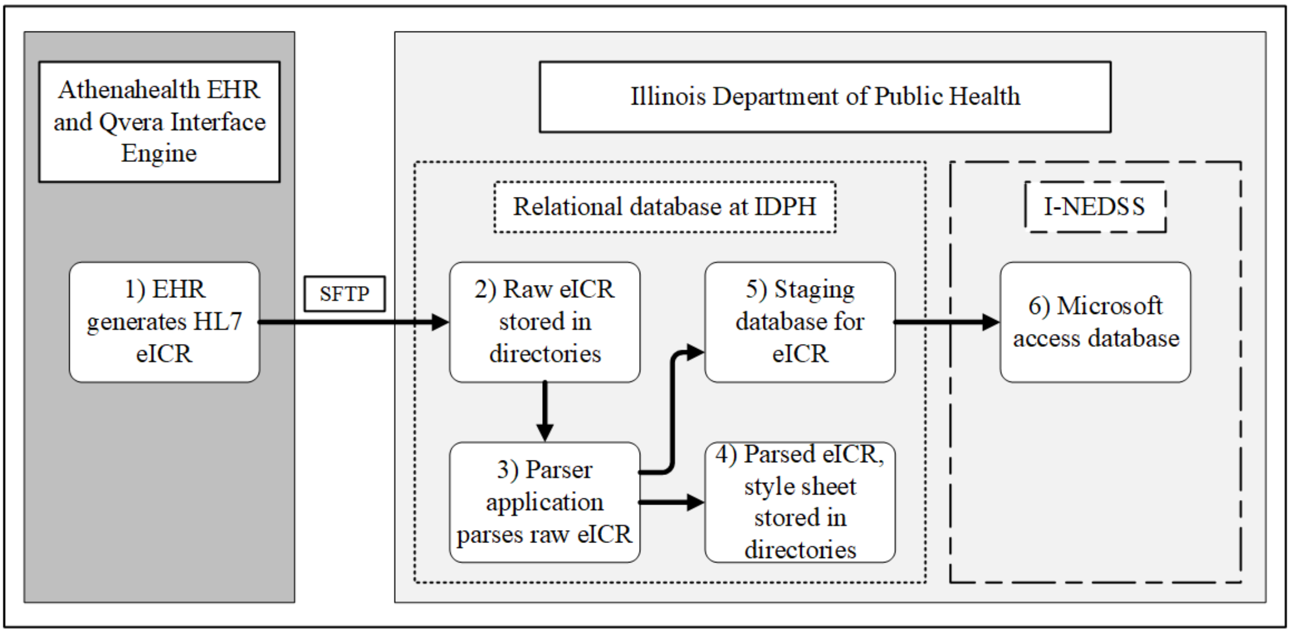
IDPH has a centralized IT infrastructure that uses the Illinois National Electronic Disease Surveillance System (I-NEDSS), a home-grown person-based and event-based system [26]. Health care providers and clinical laboratories are required to report all cases of chlamydia and gonorrhea within 7 working days [2,27]. Prior to this project, IDPH accepted reports via ELR, electronic provider report (a custom flat file generated by the health care provider), provider reports via a web-based data entry platform, faxes, and in rare instances, phone calls. An internal review (unpublished) of IDPH's I-NEDSS surveillance system revealed that in 2020, 90%-93% of the chlamydia and gonorrhea cases originated from ELRs.

Implementation of eCR Architecture and Method of Receiving Case Reports

Implementing eCR Architecture at Clinical Sites

The reference eCR implementations were defined in the previous study [12]. Some degree of customization was necessary to accommodate existing public health workflows, available code terminologies, and data parsing. The EHR leveraged 2 of the 3 case-detection scenarios [21]—scenario 1 (encounter diagnoses) and scenario 3 (name of the laboratory test performed and abnormal result flag), but not scenario 2 (name of the microorganism identified). While the case detection value sets include standard code concepts and terminologies, a given EHR instance may not have equivalent codes that reflect all 3 scenarios. This was the case for the Illinois implementation where the EHR in use contained codes aligned with Scenarios 1 and 3 only. The case detection logic is designed to work in the background of the EHR to detect chlamydia and gonorrhea cases using a predefined case detection algorithm consisted of value sets using industry standard terminologies (eg, International Classification of Diseases, Tenth Revision, Clinical Modifications; LOINC; and SNOMED-CT) [21], with no need for additional action on the part of the patient care team. Once the case detection logic was met, the EHR created XML documents in accordance with the HL7 eICR [28] and delivered them to IDPH via Secure File Transfer Protocol (Step 1, Figure 1).

Figure 1. Workflow depicting electronic case report (eCR) generation, transportation, and ingestion. EHR: electronic health record; eICR: electronic initial case report; HL7: Health Level 7; I-NEDSS: Illinois National Electronic Disease Surveillance System; IDPH: Illinois Department of Public Health; SFTB: secure file transfer protocol.



Receiving and Ingesting eCR at Public Health Agency

Directly ingesting eCRs into I-NEDSS was deemed out of scope due to project timeline and the extent of invasive intervention required to make modifications in the surveillance system. The raw eCRs were, instead, stored in a directory at IDPH (Step 2, Figure 1) and parsed by XML Harvester [29], an open-source XML parser application (Step 3, Figure 1). The parser application was housed in a relational database and passed the reformatted records to the staging database (Step 5, Figure 1). Relevant tables were identified by mapping data elements to the I-NEDSS and ingested into a Microsoft Access database for analysis (Step 6, Figure 1).

Data Collection and Analysis Methods

AllianceChicago tallied a count of eCRs generated daily throughout the pilot period and extracted data directly from the EHR. In some instances, manual inspection was performed on the captured data. Once the eCRs were received at IDPH, they were evaluated for the following: (1) compliance with the trigger logic for confirmed chlamydia and gonorrhea laboratory results or diagnosis, (2) completeness of key data elements, (3) timeliness of reporting, and (4) the degree to which eCR laboratory results matched ELR reporting during the study period. We compared the timeliness of eCR to ELR by calculating the median time from documented patient encounter to the time the public health agency received eCR and ELR for an individual.

Results

Case Report Throughput and Case Detection Metrics

eCR Throughput

During the study period, 11,192 encounters were logged in the EHR across all 8 clinical sites for various types of clinical care. During the study period, IDPH received 202 eCRs which were valid as per the HL7 requirements and stored in the staging database. Of these 202 eCRs, 19 (9.4%) did not meet the Council of State and Territorial Epidemiologists case definition and were not tallied. They were rejected because a manual review determined that they were not positive chlamydia or gonorrhea eCR tests or diagnosis. Therefore, a total of 183 eCRs representing 135 unique patients (some patients had both chlamydia and gonorrhea) were deemed valid and met the case definitions.

Case Detection Metrics

There were 113 instances where the case detection logic was satisfied for chlamydia; 80% (90/113) were based on scenario 3 (name of the laboratory test performed and abnormal result flag) and 20% (23/113) were based on both scenario 1 (encounter diagnoses) and scenario 3 (Table 1). Similarly, for the 70 instances where the case detection logic was satisfied for gonorrhea, 61% (43/70) were based on scenario 3, and 39% (27/70) were based on scenarios 1 and 3. Of note, there were no instances when scenario 1 (encounter diagnoses) alone was met, but instead, all of them had a corresponding confirmatory laboratory test (Table 1). eCR reported 95% (n=113 cases) of all the chlamydia cases that were reported from the participating clinical sites (Table 1). However, ELR reported 6 additional cases of chlamydia, which were not reported via eCR. eCR reported 97% (n=70 cases) of all the gonorrhea cases found by ELR, finding an additional 14 cases (19%) that were not reported via ELR (Table 1). ELR reported 2 additional cases of gonorrhea not detected by eCR. ELR reported 100% (119/119) of chlamydia cases but only 81% (58/72) of gonorrhea cases.

Table 1. Case detection metrics for electronic case reporting (eCR) and electronic laboratory reporting (ELR).

Variables	Chlamydia (n=119), n (%)		Gonorrhea (n=72), n (%)	
	Reported by ELR		Reported by ELR	
	Yes	No	Yes	No
Reported by eCR				
Yes				
Scenario 1 (encounter diagnoses) only	0	0	0	0
Scenario 3 (name of the laboratory test performed and abnormal result flag) only	90 (76)	0	33 (57)	10 (71)
Both scenarios 1 and 3	23 (19)	0	23 (40)	4 (29)
No				
No eCR was generated	6 (5)	0	2 (3)	0
Total, n	119	0	58	14

eCR Data Completeness and Timeliness

Key elements for public health reporting such as patient and provider names were complete in all eCRs and ELRs (Table 2). Race and ethnicity were slightly lower in eCR (n=113, 95%) than ELR (n=119, 100%; Table 2). However, eCR was found to report additional clinical data such as social history information, which is important for portraying a more complete epidemiologic picture but was beyond the scope of this evaluation. History of present illness and reason for visit were both reported on 82% (97/119) of eCR in this study; symptoms, diagnosis, and medications were reported on 33% (39/119), 23% (27/119), and 22% (26/119) eCRs, respectively (Table 2). While pregnancy is supported in the HL7 eICR standard [21], total absence of pregnancy information is due to the configuration of the EHR and is specific to this implementation.

The median time from the documented patient encounter to the time IDPH received ELR was 4 days. Similarly, the median time for scenario 1 (encounter diagnosis) was 11 days, and for scenario 3 (laboratory result) was 6 days.

Table 2. Comparison of the completeness in electronic case reporting (eCR) and electronic laboratory reporting (ELR).

eCR data element	Complete, n (%)	ELR data element	Complete, n (%)
Provider name	119 (100)	Ordering provider	119 (100)
Provider phone	119 (100)	Oder callback phone number	119 (100)
Provider fax	0 (0)	N/A[a]	N/A
Provider email	90 (76)	N/A	N/A
Patient name	119 (100)	Patient name	119 (100)
Patient phone	119 (100)	Phone number (home); phone number (business)	119 (100)
Patient email	29 (24)	N/A	N/A
Street address	119 (100)	Patient address	119 (100)

Discussion

Principal Findings

We implemented an approach to case reporting that automated and provided more complete, timely, and relevant information to public health authorities for chlamydia and gonorrhea in Illinois. This approach furthered data exchange between health care providers and public health by using health care data standards (SNOMED-CT, LOINC) to meet case detection logic in the EHR [12,21] and messaging standards (HL7 eICR) as the transport mechanism [20]. This method could facilitate better public health surveillance and inform public health practice. While ELRs comprised 90% of all cases of notifiable conditions reported to IDPH in 2020, eCR can provide better clinical information than the ELR is capable of reporting. Additionally, we demonstrated that eCR can be configured to retrigger at a later date to capture information not available at the time the initial case definition was met.

In this study, ELR detected 6 additional chlamydia cases and 2 additional gonorrhea cases, and eCR detected 14 additional cases of gonorrhea. These 14 cases were detected via scenarios where laboratory results were present in the EHR. We did not investigate why these were missed by ELRs, but some hypotheses include as follows: (1) specimen was collected toward the end of the study period (median time for receipt of ELR by IDPH was 4 days), (2) laboratory where the test was done could have had problems leading to delayed reporting, (3) specimens could have been tested by out-of-jurisdiction labs, and (4) other unknown reasons. Similarly, eCR detection logic missed 6 chlamydia and 2 gonorrhea cases. Potential reasons include the following: (1) faulty local code mapping; (2) if patient was seen toward the end of the study period, eCR may not have triggered yet (could take up to 11 days for IDPH to receive eCR, compared to ELR, which took 4 days); and (3) other unknown reasons. Of note, among all the cases reported by the clinical sites, eCR reported 95% and 97% of all chlamydia and gonorrhea cases, respectively. We also found that eCR contains more complete information compared to ELR and allowed for the collection of additional data such as diagnoses, treatment, and other clinical information that are typically not available in ELR. However, these additional data elements were not available on all eCRs. Some records reflect clients who were tested or diagnosed at external locations whose records were subsequently scanned into the EHR system as PDF files with no accompanying lab records. More work needs to be done to explore whether these were not available at the time of the case report generation or if this information was present in some other unstructured format not represented as a standard vocabulary such as SNOMED-CT.

An earlier study by Mishra et al [12] had developed the case detection logic, curated the value sets needed for this eCR architecture, and collaborated with a clinical partner to demonstrate the case detection and eCR efficacy. Another study in Oregon, simultaneously conducted with this evaluation, also implemented this approach with clinical sites reporting to the Oregon Health Authority. They reported on the local customization required for that implementation and differed from this study in that the Oregon Health Authority had existing infrastructure to consume eCR via its interface engine into its proprietary surveillance system [21]. A broader adoption of eCR will be a step toward bridging the information gap between health systems and public health. Such steps toward improved semantic interoperability will allow a timely and better understanding of epidemiology, will inform the development of effective policy and most relevant updates to treatment guidelines, and will reduce burdens for both health systems and public health agencies by automating case reporting and investigating cases for more information.

Limitations

The EHR had limited Fast Healthcare Interoperability Resources capability. The health centers had to collaborate with the EHR vendor to develop, test, and release a beta version of eCR that could be specifically used for this project. eCR standards allow for data elements that are above and beyond those that have been received through traditional reporting. This information may be present in an unstructured format without any semantic representation. An eCR triggered by laboratory results (scenario 3) would contain information in a structured format with semantic representation, while for scenario 1, diagnoses may not be available in a structured format but may be represented in an unstructured, narrative format, resulting in a lower number of triggers. Some additional examples of unstructured data elements include those found in the “Problems,” “History of present illness,” “Reason for visit,” “Social history,” and so on, and could explain why symptoms, diagnosis, and medications were reported only on 33%, 23%, and 22% of the eCRs, respectively.

I-NEDSS, the surveillance system at IDPH, required additional resources to consume eCR. Any addition to the surveillance system’s capability would require extensive modification. Due to the constraint of project timeline and lack of dedicated resources for this activity, we elected not to reconfigure the surveillance information system to receive eCR. Instead, we used a parser application and created a staging database that could be mapped to the data elements of the surveillance information system. This challenge of ingesting eCRs into surveillance information systems is likely to be far more common across health departments in the United States and needs additional work to create a standardized and scalable approach. We did not quantify the burden of manual reporting, and how much of that burden was potentially alleviated via automated case reporting via eCR. Future studies could provide insight into the resources saved via such automated reporting methods.

Conclusions

The eCR approach to public health surveillance successfully identified and created automated case reports for chlamydia and gonorrhea cases in the selected Illinois clinics. This approach also demonstrated a more complete case report with additional demographic, clinical, and treatment information. eCR reduced the burden of reporting cases on clinical providers and represents a promising future of greater semantic interoperability between health care systems and public health by automating the case report using health care data standards in a scalable manner.

Abstract

Background: With the increased availability of data, a growing number of studies have been conducted to address the impact of social determinants of health (SDOH) factors on population health outcomes. However, such an impact is either examined at the county level or the state level in the United States. The results of analysis at lower administrative levels would be useful for local policy makers to make informed health policy decisions.

Objective: This study aimed to investigate the ecological association between SDOH factors and population health outcomes at the census tract level and the city level. The findings of this study can be applied to support local policy makers in efforts to improve population health, enhance the quality of care, and reduce health inequity.

Methods: This ecological analysis was conducted based on 29,126 census tracts in 499 cities across all 50 states in the United States. These cities were grouped into 5 categories based on their population density and political affiliation. Feature selection was applied to reduce the number of SDOH variables from 148 to 9. A linear mixed-effects model was then applied to account for the fixed effect and random effects of SDOH variables at both the census tract level and the city level.

Results: The finding reveals that all 9 selected SDOH variables had a statistically significant impact on population health outcomes for ≥2 city groups classified by population density and political affiliation; however, the magnitude of the impact varied among the different groups. The results also show that 4 SDOH risk factors, namely, asthma, kidney disease, smoking, and food stamps, significantly affect population health outcomes in all groups ($P<.01$ or $P<.001$). The group differences in health outcomes for the 4 factors were further assessed using a predictive margin analysis.

Conclusions: The analysis reveals that population density and political affiliation are effective delineations for separating how the SDOH affects health outcomes. In addition, different SDOH risk factors have varied effects on health outcomes among different city groups but similar effects within city groups. Our study has 2 policy implications. First, cities in different groups should prioritize different resources for SDOH risk mitigation to maximize health outcomes. Second, cities in the same group can share knowledge and enable more effective SDOH-enabled policy transfers for population health.

Introduction

Overview

Social determinants of health (SDOH), defined by the World Health Organization, encompass economic policies, social and physical environments, and access to health services and shapes the conditions "in which people are born, grow, work, live, and age" [1].

It is well established that SDOH factors, such as health behaviors, clinical care, social and economic status, and physical environment, account for 30% to 55% of health outcomes [2]. There is considerable literature examining the association between SDOH factors and various health outcomes, among which most studies used patient-level and hospital-level data. For example, prior studies have found that SDOH factors are associated with medication adherence [3], care use [4], readmission risk [5,6], length of stay [7,8], postoperative surgical outcomes [9], mortality risk [10,11], and risk of exposure to and subsequent health outcomes after contracting the SARS-CoV-2 virus [12,13].

Understanding the ecological association between SDOH factors and population-level health outcomes is vital. Such an understanding is particularly relevant for researchers, clinicians, and policy makers in assessing new SDOH-enabled programs or policies to improve population health, enhance quality of care, and reduce health inequities [14,15]. Several frameworks have been developed to understand the impact of SDOH risk factors on population health outcomes [16-19]. Among these frameworks, the County Health Ranking (CHR) model has been widely applied to explicate the relationship between SDOH factors and population health outcomes in the United States [17,20].

The CHR model uses >30 ranking criteria to measure the impact of SDOH factors on the current and future population health outcomes at the county level [17]. However, this model is not always accurate at the state level or lower-than-state level (eg, county, city, and census tract level) because it uses a predetermined set of weights for the SDOH factors. Two recent empirical studies of the CHR found that the influence of SDOH factors on health outcomes varies among different states in the United States [21,22]. In addition, existing CHR studies are limited to either the county level or the state level. Analysis at a lower level is desired by local policy makers because local governments need to derive insights into the SDOH and health outcomes within their administrative delineation [23]. For instance, Corburn et al [23] showed substantial results in reducing health inequities by examining all policies adopted by the city of Richmond, California, at the zip code level.

This study investigates the ecological associations between the SDOH and population health outcomes at the city level to support health policy decisions using the CHR as the foundation. For this purpose, we curated data from 5 different sources and integrated them at the census tract level from 29,126 census tracts within 499 cities across all 50 states in the United States. With such smaller geographical delineations, researchers, policy makers, and other relevant parties can aggregate data into larger administrative divisions to make more impactful and effective decisions.

After grouping cities through 2 factors, namely, population density and political affiliation, we formalized measures for SDOH factors and population health outcomes and used a voting-based feature selection approach to reduce the original 148 sociodemographic and SDOH-related variables to 9. We then used a linear mixed-effects model to examine the ecological associations between the SDOH factors and population health outcomes. At the census tract level, the goodness of fit ranges from 0.65 to 0.75. At the city level, the total variance explained by the model was high, ranging from 0.86 to 0.90. The effect size of variables is different across groups. Noticeably, asthma, kidney disease, smoking, and food stamp variables were significant in all groups. Post hoc analysis was later conducted using predictive margin to assess group differences in health outcomes for the 4 behavioral health indicators that majorly affect health outcomes across all groups.

Background

Social Determinants of Health

SDOH encompass a wide set of dimensions such as socioeconomics, education, physical environment, food access, health care system condition, health behaviors, community status, and politics [1,24,25]. The importance of the SDOH is apparent to both academia and policy makers. Research on SDOH is impactful and prominent, especially in the context of this research, that is, linking health outcomes and disparities [2,3,12,26,27].

In the United States, the CHR model is a widely applied model that describes how SDOH factors contribute to population health [17,20]. The CHR model uses >30 ranking measures to understand the current population health outcomes and health factors (ie, health behaviors, clinical care, social and economic status, and physical environment) that would affect future health in the United States [17]. Both the health outcomes and health factors are weighted by a panel of national experts on population health in the CHR model [17].

Although the CHR model makes health outcomes and factors easy to calculate and be understood by the general public and policy makers, it has 2 major drawbacks. First, the weights proposed by experts in the CHR may not be applicable to the entire population because different locations may have various population characteristics and dissimilar social and policy environments. Two recent studies that empirically tested the CHR [21,22] revealed that the influence of health factors on health outcomes varies among the US states. In other words, the CHR model performed better in some states than in others. Second, previous studies used SDOH through CHR at either the county level or the state level. A more granular level of data is needed to comprehensively understand the SDOH factors that affect population health and to provide insights for local policy makers, such as governments at the city level. In this study, we use census tract data, a geographical delineation of a county that encompasses approximately 4000 population, with relatively well-maintained and updated demographic information [28]. Using census tracts as the unit of analysis, researchers and policy makers can aggregate the data into larger administrative divisions.

Generally, SDOH research has both breadth and depth. Research can be found using study sites worldwide, with different takes on what SDOH are, and using a diverse range of research methods. The same perspective can be gleamed when focusing on the relationship between health outcomes and the SDOH. Owing to the divergent and seemingly agglomeration research that explores the relationship between health outcomes and SDOH factors, researchers need to be careful when defining (1) the health outcomes measurement, (2) the SDOH factors, (3) the population and study sites, and (4) the research methods. These definitions set up the phenomenon for research while providing concrete findings to help promote population health, which in turn affects policy changes.

SDOH Factors and Health Outcomes

Health outcomes and SDOH factors are interlinked. For instance, poverty, education, and income are known to be closely related to health outcomes [12,26,29-32]. Specifically, Washington et al [30] identified low income to be related to the higher unmet needs for health care, whereas Bauer et al [33] found a major association between income and health literacy. Several studies have associated income and insurance status with risk of readmission [6,34]. Similarly, studies have found that income, age, and vulnerable populations have worse postoperative surgical outcomes or higher mortality risk [9-11]. Furthermore, when present alongside SDOH, disadvantaged racial and ethnic groups are negatively affected in several health outcomes areas, including COVID-19 [35], stroke [36], and kidney transplant [37].

Health behavior is another essential component of SDOH [38,39]. It is related to people's health practices such as smoking, diet, exercise, and alcohol habits. According to Healthy People 2020, individuals' healthy behaviors can substantially influence their health needs and outcomes [40]. Likewise, it was estimated that approximately 443,000 Americans die annually of smoking-related diseases, such as cancer, stroke, lung disease, and heart disease [41]. Lack of physical activities and high-calorie food intake can lead to obesity, which majorly affects people's health conditions.

Population Density

At any location, the population can be delineated into living in 3 areas: urban, suburban, and rural. Although the general public could easily discern the differences between the 3, in research, this has been proven as not as clear-cut as it may seem [42]. Generally, there is a decision framework, along with several decision criteria, to designate a location to be either urban, suburban, or rural. This designation separates the way in which people live. Unfortunately, owing to the nature of our research inquiry that examines census tracts at the city level, the abovementioned delineation cannot be definitively justified. However, based on the simple criteria of population density, we were able to dissect cities into different segments, each of which had different health behaviors and outcomes.

Indeed, population density is closely related to health service delivery and further influences health outcomes. On the one hand, health care institutions located in low population–density places may need to manage small-scale operations and handle financial losses owing to low volume, whereas people who live in low population–density locations may have difficulties accessing health care facilities and services because of human service and resource deficiency. For example, in less populated areas, ambulance response time is likely to be longer [43].

Furthermore, these low population–density locations usually have an increasingly aging population, demanding more health services and resources [44,45]. Government-supported health programs are often limited in low population–density areas because of the high rate of poverty and limited tax in such areas [45], and high population–density areas may cause congestion in major hospitals [46], suggesting a complex relationship between population density and health outcomes. The interplay between the supply and demand of health care is greatly influenced by the availability of services and the needs of the population. Naturally, the denser the population, the more health care is needed. In contrast, low population–density areas require fewer health care services but suffer from scarcity.

Previous studies have found that population density is associated with various health outcomes, such as mortality rate [47,48], survival outcome [49], and morbidity in certain diseases [48]. To account for the complex relationship between population density and health outcomes, we examined the relationship between SDOH and health outcomes by grouping cities based on their population density.

Political Affiliation

Local governments and their political leaning greatly affect health policy. The US political system is a constant wrestle between 2 major political parties: the Democratic Party (often colorized as blue) and the Republican Party (often colorized as red). Contention exists throughout the United States and at various levels of the government. At the state level, the differences between the parties encompass both health policy and social issues (eg, attitude and policy regarding abortion and substance use) and the preferred role of the government (eg, big vs small government) in addressing health-related problems [50]. For example, Pagel et al [51] painted a stark contrast in the priorities of health care policy between Democratic and Republican state legislators. Republicans prioritize reducing health costs and smaller government, whereas Democrats prioritize improving health and equity and reducing disparities over other goals [51].

At the individual level, partisan polarization in public attitudes shapes individuals' health behaviors. For example, studies found that there are diverging attitudes between Republicans and Democrats toward influenza and the COVID-19 vaccine, in which Republicans displayed a negative attitude and intention toward vaccine, whereas attitudes and intentions of Democrats remained largely stable [52,53]. Given the importance of how political affiliation can affect both policies and attitudes toward health outcomes, we surmise that the identification of political parties would also influence the relationship between health outcomes and SDOH.

Despite the research outcomes suggesting linkages between health outcomes and SDOH, policy makers do not view SDOH as a priority, as is evident in the absence of SDOH in the general government policy agenda, despite earlier emphasis [54,55]. Instead, current health policy in the United States still focuses on "medicalizing" health problems, assuming that the solution to health is medical care [55,56]. For example, policy makers often emphasized health access policies to increase geographic and financial access to health services for vulnerable populations [56] but neglected other important social and economic factors that are associated with health disparities [56]. Prior studies also pointed out that even with universal health care access, rich populations are more likely to have healthier lives because they can afford advanced health care; thus, the most important policy issues in health care are largely dependent on the overall allocation of resources to health care rather than merely on the distributive justice within health care [57,58].

Furthermore, Embrett and Randall [54] suggested that extant SDOH policy studies appear to be focused on advocacy rather than analysis. To promote "healthy public policies" based on SDOH factors, health disparities need to be examined so that the government can develop specific policy responses with their tools at hand such as regulation, legislation, taxation, and financing [59]. Health care professionals, researchers, and governments can work together to empirically examine the extent to which SDOH factors contribute to disparate health outcomes so that policies can be developed to solve health disparities in a more effective and efficient manner [13].

This study makes the following contributions to research and practice. First, the study divulges additional insights into how different SDOH factors affect health outcomes by curating related data in census tracts. In contrast to the county level, targeted but limited SDOH data are available at the census tract level. Our study presents a novel data curation process that creates additional SDOH variables that are otherwise not readily available. At the census tract level, data could be aggregated to the city level, allowing policy makers to devise policy more effectively. Second, city is a living and emergent ecosystem, and each city presents its own opportunities and challenges in terms of population health [60]. Despite these differences, our study sheds unique insights through 5 distinct groups with 2 prevailing properties: the city's population density and its political affiliation. The analysis results showed that the health effectiveness intragroup was similar, whereas the effects diverged intergroup. Therefore, it is prudent for cities from different groups to prioritize resource allocations to address SDOH factors based on their group properties so that population health outcomes can be maximized.

Methods

Study Design

The study design includes 4 considerations. First, to perform the ecological analysis at the city level, we need to identify data sources for SDOH factors and health outcomes at the group level. Second, we need to determine the unit of analysis, that is, how to define the study population and the method of grouping. Third, we need to formalize the measures for SDOH factors and population health outcomes. Finally, we need to determine the appropriate data analysis method. In the subsequent sections, we describe each consideration in detail.

Data Collection

We curated and integrated a data set from 5 different sources: the PLACES program [61], the National Center for Health Statistics, Census Data portal, Simply Analytics, and the Massachusetts Institute of Technology Election Laboratory [62]. The data obtained from the PLACES program included population health outcomes, such as mental and physical health days, as well as population health behaviors, such as the percentage of the population with asthma or kidney disease. Additional data were collected at the census tract level for a selected 500 cities in the United States, which serves as the basis of the data for analysis. Life expectancy data for each census tract were obtained from the National Center for Health Statistics [63]. These data were later used to measure the health outcomes. Population-related variables such as age, income, ethnicities, and education levels were obtained through the Census Data portal, supplemented by data from the Simply Analytics platform. We used data from the Massachusetts Institute of Technology Election Laboratory to determine the political affiliation to which each census tract belongs. Political affiliation is proxied by the 2020 presidential election. In the United States, voting for a presidential candidate happens in the general election every 4 years, in which most of the population votes, and it solidifies the general political direction of the country, whether it will lean toward Democratic or Republican policies. Election data are reported at the precinct level, which is a larger spatial delineation than census tracts, is smaller than US counties, and overlaps with US cities. When precincts have more votes for the Democrats presidential candidate, we code the census tracts to reside within it as blue. Similarly, we coded red for census tracts that reside in precincts that have more votes for the Republican presidential candidate. census tract data from Washington, District of Columbia, were dropped because they did not have a life expectancy measure. The final data set included 29,126 census tracts within 499 cities across all 50 states in the United States, all obtained in 2021.

Determining Unit of Analysis

The results of our data collection process yielded the census tract as the default unit of analysis. We further examined whether this unit of analysis was sufficient or whether an additional grouping mechanism was warranted. As the census tracts resided within the city boundary, a natural grouping was to coalesce tracts based on the city itself. However, this type of grouping did not help explain the relationship between cities. Rather, additional grouping of cities was required. Therefore, we used political affiliation and population density, as discussed in the previous sections with the same name.

To determine the political affiliation of a city, we revisited the political affiliation of each census tract, which was determined using the abovementioned description. With a simple majority rule, if a city has more census tracts that are red, we assign red as the city's political affiliation. Similarly, a city will be coded blue as its political affiliation if a majority of the census tracts residing within it are blue. Correspondingly, the population density of a tract was calculated by dividing the total population by its area in square miles [44,49]. Each city was then sorted and classified into 3 quartiles: sparsely populated cities were below the 25th percentile (denoted low), medium-populated cities were between the 25th and 75th percentiles (denoted mid), and highly populated cities were above the 75th percentile (denoted high). The final grouping included 73 cities in blue-low, 198 cities in blue-mid, 120 cities in blue-high, 53 cities in red-low, 51 cities in red-mid, and 4 cities in red-high. As red-high had a small number of cities, it was combined with the red-mid category, making the final number of cities in the combined category, red-high, 55. Multimedia Appendix 1 includes the list of cities in each classification.

Formalizing Measurements

Formalizing Health Outcome Measurement

After integrating and cleaning the data, we then formulated the health outcomes measurements for our research based on the CHR model [17]. In the CHR model, health outcome measures the current state of population health and can be further divided into 2 categories: length of life and quality of life. Length of life can be measured by life expectancy and quality of life by poor physical health days and poor mental health days. Specifically, the health outcome measure was based on the CHR model, as shown in the following equation:

$$\text{Health outcome} = 50\% \times (\text{life expectancy}) - 25\% \times (\text{poor physical health days}) - 25\% \times (\text{poor mental health days}) \quad (1)$$

Similar to the CHR model, our proposed health outcome measure assigns equal weightage to the length of life (through life expectancy) and quality of life (through poor physical health days and poor mental health days). The subtraction signs signify the negative effects of having poor physical health days and poor mental health days on health outcomes.

Formalizing SDOH Measurements

To formalize the measurements for SDOH factors, we first standardized the different scales such as rates, percentages, and averages of the survey responses. We also followed the CHR model by standardizing all measures with *z* scores, in which the standardized variables had a mean of 0 and a SD of 1 [17,22]. The initial SDOH data comprised 148 variables (Multimedia Appendix 2), including some highly correlated features. Thus, a feature reduction is required. As different feature selection techniques may result in a different set of features and no standardized rules on which technique might be better than the others, we experimented with the following 5 feature selection methods: Pearson correlation, recursive feature elimination, backward stepwise regression, XGBoost, and random forest. Independent variables were then ranked into 4 quartiles from highest to lowest, based on their feature importance or effect size against the dependent variable health outcome. We then applied a majority voting method, retaining variables that were placed in the top quartile based on at least 3 methods. The final data set included 9 variables for SDOH risk factors (Table 1).

Table 1. Metadata of the final data set[a].

Variable name	Type	Description
Health outcome	DV[b]	Health outcome of the population (refer to equation 1)
Asthma	IV[c]	Percentage of the population aged >18 years and with asthma
Kidney disease	IV	Percentage of the population aged >18 years and with chronic kidney disease
Smoking	IV	Percentage of the population aged >18 years who has smoked >100 cigarettes in their lifetime and currently smoke
Teeth lost	IV	Percentage of the population aged ≥65 years who has lost all their natural teeth
Annual checkup	IV	Percentage of the population aged >18 years who has visited a physician for a routine checkup
Lack of sleep	IV	Percentage of the population aged >18 years who sleeps <7 hours over a 24-hour period
Lack of health insurance	IV	Percentage of the population aged between 18 and 64 years who does not have health insurance
Below poverty	IV	Percentage of the population below the federal poverty level
Food stamps	IV	Percentage of households using food stamps or other cash public assistance programs
Group	Grouping	Grouping of tracts based on the city's population density and political affiliation (5 groups in total)

[a] The final data set included 1 dependent variable, 9 independent variables, and 1 grouping variable. Metadata applies for all 29,126 census tracts within 499 cities in the United States in 2021.

[b] DV: dependent variable.

[c] IV: independent variable.

Data Analysis

For data analysis, a linear mixed-effects model [64] was used to analyze the statistical parameters that varied at the census tract level and the city level. Observations in census tracts were hypothesized to have a systematic and predictable influence on health outcomes. Thus, the census tract data were modeled as a fixed effect, nonrandom, or nonindependent. As different cities are expected to have unpredictable and nonsystematic effects, they were modeled as random effects.

Ethical Considerations

The data used in this study are secondary data, which do not involve human participants, and are collected and aggregated by the respective organizations mentioned in the *Data Collection* section, most of which are curated from the US Census Bureau as the primary source. No additional data were collected specifically for this study.

Results

All the linear mixed-effects models converged. We present the results of the linear mixed-effect models for 5 groups: blue-low (model 1), blue-mid (model 2), blue-high (model 3), red-low (model 4), and red-high (model 5) in Tables 2-4. The R^2 results from the 5 models indicated that the overall fit of each model was adequate. Specifically, the conditional R^2 represents the variance of the variables explained by both fixed and random effects within the model. The conditional R^2 value ranging from 0.86 to 0.90 in models 1 to 5 indicated that the grouping at the city level exemplifies the intertwined relationship between population density and political affiliation grouping against health outcomes. Furthermore, the marginal R^2 represents the variance affected by the fixed effects. The marginal R^2 value ranging from 0.60 to 0.75 in models 1 to 5 indicates that the set of variables at the census tract level also has high goodness of fit to health outcomes.

Our results suggest that all the groups examined in the study have an equipotential baseline, as evidenced by the comparable intercepts across all 5 city groups classified by population density and political affiliation. Furthermore, the results showed that all SDOH variables had a statistically significant impact on population health outcomes for ≥2 or city groups, but the magnitude of the impact varied among the different groups. For example, an increase in the proportion of the population with asthma, kidney disease, smoking, or using cash assistance programs (such as food stamps) is associated with a decline in population health outcomes across all groups, consistent with the SDOH literature [65-68]. However, the magnitude of the impact of these variables on population health outcomes varied among different groups. The impact of asthma on population health outcomes is highest for cities classified as red-high (model 5: red-high) and lowest for cities classified as blue-low (model 1: blue-low), whereas the impact of kidney disease or smoking is higher for blue cities (as observed in models 1-3). The impact of food stamps on population health outcomes is higher for red cities with high population density (model 5: red-high) and blue cities with medium population density (model 2: blue-mid).

Some SDOH variables were statistically significant for a subset of the city groups. For instance, the percentage of the population having an annual checkup does not have a statistically significant impact on population health outcomes for red cities with low population density (model 4: red-low), whereas the impact of the percentage of the population below the federal poverty level is not statistically significant only for red cities with high population density (model 5: red-high). Similarly, the impact of the percentage of the population without health insurance is not statistically significant for blue cities with low density (model 1: blue-low). Finally, the impact of lack of sleep is only statistically significant for rural cities, and the impact of teeth loss is statistically significant for cities with a high population density (model 3: blue-high and model 5: red-high), regardless of their political affiliation.

To further investigate these findings, a post hoc analysis was conducted using predictive margins to assess group differences in health outcomes for the 4 SDOH variables, namely, asthma, kidney disease, smoking, and food stamps, that substantially affected health outcomes across all groups (as shown in Figure 1). Figure 1 illustrates that each group had a better health outcome with low asthma, low smoking, low kidney disease, or low food stamps and a worse health outcome with high asthma, high smoking, high kidney disease, or high food stamps. One exception was the red-low group, which had a slightly better health outcome with a high food stamp. Overall, the blue-low and red-low groups had better health outcomes than the other 3 groups, whereas blue-high had the lowest health outcome compared with the other 4 groups. Furthermore, asthma, kidney disease, smoking, and food stamps had larger impacts on the red-high and blue-high groups than the other 3 groups.

Discussion

Principal Findings

In this study, we have demonstrated that, with the use of census tracts as the unit of analysis, more insights are extracted regarding how SDOH factors would affect the health outcomes of a diverse population. Furthermore, aggregating data into city jurisdictions enables a more targeted examination of how each city operates and influences health outcomes with an eye on policy generation and implementation at the city level.

Using a unique grouping method for cities based on population density and political affiliation, we reveal that cities are similar in many ways yet exhibit remarkable differences in public health. Specifically, we observed a major divide in public health and the different impacts of SDOH factors on population health outcomes between different political support in the United States, which contains only 2 main political parties. The results reinforce the current political climate in the United States, namely, the polarization between the 2 parties and how it affects health care outcome [69-71]. These findings add complexity for city officials who are monitoring and maintaining the quality of public health while upholding the political ideals and expectations through policy enforcement. Similarly, population density, which substitutes urban-rural designations, adds to the dichotomy of health. When cities are in the same grouping, they share many aspects of SDOH effects on health outcomes, although there is a distinct difference among members of different groups.

Our research yielded several interesting findings related to different SDOH factors. For example, we found that the number of adults who lost all their natural teeth before age 65 contributed to health outcomes in an oscillating manner. Although there is an established link between oral health and quality of life, there seems to be a disconnect between oral health and population health outcomes in the literature [72,73]. In addition, we observed the interrelationship between access to health services and annual checkups, highlighting the importance of health insurance for improving health outcomes. The health care system in the United States is complex, and obtaining health insurance for the disadvantaged group has been a major roadblock. Having health insurance is not enough; with it alone, there is only a negligible uptick in annual checkups [74]. These findings strongly support the need to establish incentives for having more individuals perform annual checkups. For example, the Preventive health Evidence-based Recommendation Form is a program that can potentially fulfill such a need [75].

This study has several implications for public health. First, we highlight that public health policies should differ among cities with different population densities and political affiliations. For instance, policies targeting the population with asthma, such as promoting environmental cleanliness, reducing pollution particles, and reducing the costs of asthma treatment and medication, would have a much stronger effect in red-leaning cities with a high population density than in cities in other groups. Likewise, smoking affects the blue-leaning cities the most, so a policy to discourage smoking and promote quitting would be more beneficial to population health outcomes in those cities. As resources are scarce, cities should allocate their resources according to the effectiveness of the proposed solutions. Therefore, each devised policy could target different SDOH factors for policy interventions to optimize health outcomes based on the categorization of each city. Second, our findings provide additional variables of interest for invigorating public health policy transfer possibilities among cities. Policy transfer is a well-studied phenomenon worldwide, especially in the European Union, but it has been much less studied in the United States. This study indicates that policy transfer between cities in the same group is possible. For example, a blue-leaning city with low population density might try to focus more on reducing smoking by perusing policies from health care offices residing in other blue-leaning rural cities. Similarly, cities may be able to pool resources together and procure a repository containing all related health policies. This repository could help facilitate faster and more efficient knowledge transfer between cities across the United States.

Limitations

This study has several limitations. First, the curated data were not equivalent to those of the CHR. Only a handful of equivalent variables are available at the census tract level. Second, data normalization in the CHR encompasses all counties in the United States, although this study limits the data set to 499 cities, potentially skewing the results. Third, although the cities may represent many populations, sparse suburban areas and rural areas are largely neglected owing to data availability. Fourth, as an ecological study, there are possible confounders that existed outside our data set. Finally, the ecological nature of the study prohibits generalization of conclusions such as giving more food stamps to an individual, which could result in a change in personal health outcomes. Future research should continue to explore the relationship between SDOH and health outcomes in other delineations suitable for policy decision making.

Conclusions

This study aimed to investigate the impact of SDOH factors on population health outcomes using a large data set comprising 29,126 census tracts within 499 cities across all 50 states in the United States. Our results identified 4 SDOH factors, namely, asthma, kidney disease, smoking, and food stamps, that have major effects across cities with different population densities and political affiliations. In addition, this study highlights the need for differentiated public health policies among cities with different population densities and political affiliations. The analysis of data at the city level, in which policies and decisions directly affect its citizens, promotes an understanding of how SDOH factors affect population health outcomes. The grouping mechanism, based on the combination of population density and political affiliation, provides a useful framework for separating and comparing different census tracts in different cities. To that end, this study adds to the existing literature on various ways to improve health equity among geographic areas or demographic and socioeconomic groups.

Abstract

Background: Multimorbidity and frailty are characteristics of aging that need individualized evaluation, and there is a 2-way causal relationship between them. Thus, considering frailty in analyses of multimorbidity is important for tailoring social and health care to the specific needs of older people.

Objective: This study aimed to assess how the inclusion of frailty contributes to identifying and characterizing multimorbidity patterns in people aged 65 years or older.

Methods: Longitudinal data were drawn from electronic health records through the SIDIAP (Sistema d’Informació pel Desenvolupament de la Investigació a l’Atenció Primària) primary care database for the population aged 65 years or older from 2010 to 2019 in Catalonia, Spain. Frailty and multimorbidity were measured annually using validated tools (eFRAGICAP, a cumulative deficit model; and Swedish National Study of Aging and Care in Kungsholmen [SNAC-K], respectively). Two sets of 11 multimorbidity patterns were obtained using fuzzy c-means. Both considered the chronic conditions of the participants. In addition, one set included age, and the other included frailty. Cox models were used to test their associations with death, nursing home admission, and home care need. Trajectories were defined as the evolution of the patterns over the follow-up period.

Results: The study included 1,456,052 unique participants (mean follow-up of 7.0 years). Most patterns were similar in both sets in terms of the most prevalent conditions. However, the patterns that considered frailty were better for identifying the population whose main conditions imposed limitations on daily life, with a higher prevalence of frail individuals in patterns like *chronic ulcers &peripheral vascular*. This set also included a dementia-specific pattern and showed a better fit with the risk of nursing home admission and home care need. On the other hand, the risk of death had a better fit with the set of patterns that did not include frailty. The change in patterns when considering frailty also led to a change in trajectories. On average, participants were in 1.8 patterns during their follow-up, while 45.1% (656,778/1,456,052) remained in the same pattern.

Conclusions: Our results suggest that frailty should be considered in addition to chronic diseases when studying multimorbidity patterns in older adults. Multimorbidity patterns and trajectories can help to identify patients with specific needs. The patterns that considered frailty were better for identifying the risk of certain age-related outcomes, such as nursing home admission or home care need, while those considering age were better for identifying the risk of death. Clinical and social intervention guidelines and resource planning can be tailored based on the prevalence of these patterns and trajectories.

multimorbidity; frailty; clustering; electronic health record; primary care; trajectory

Introduction

Aging is associated with the development of complex conditions, such as multimorbidity and frailty [1,2], which need to be assessed at the individual level. Frailty is a holistic state defined by the biological age-related loss of homeostasis and resistance to stressors, not by particular conditions, and it increases vulnerability to adverse outcomes [2-5]. Frailty can be measured either through the frailty phenotype [5] or cumulative deficit models that consider physical, psychological, and social domains [2,6,7]. On the other hand, multimorbidity is defined as the simultaneous presence of two or more chronic diseases [8]. There is a 2-way causal relationship between multimorbidity and frailty [4,9], and both are associated with higher health care utilization and expenditure [10-14]. Health systems thus need to characterize and monitor the older population to estimate health care and social resource demand.

Electronic health records (EHRs) are essential nowadays to monitor and evaluate patients [15]. Real-world studies use EHRs to obtain a large quantity of observational data from diverse populations. These data sources allow studies to be conducted at a lower cost than traditional epidemiological studies or randomized clinical trials [16,17] and can achieve similar results to randomized clinical trials [18]. Most multimorbidity studies in recent years have used EHRs [19], while EHR-based tools have also been recently developed to measure frailty [20,21].

Clustering is an unsupervised exploratory data analysis technique used for identifying and characterizing population groups. It has already been extensively used to find subgroups of people based on the similarity, in terms of co-occurrence, of their concurrent chronic disease [22-28]. Several systematic reviews [27-29] describe different clustering techniques used to group patients based on multimorbidity, including hierarchical clustering, exploratory factor analysis, multiple correspondence analysis, network analysis, and k-means. K-means and fuzzy c-means are the most common approaches [22-26]. K-means is a hard clustering algorithm that forces each record to belong to a single cluster, while fuzzy c-means is a soft clustering technique that allows records to be simultaneously assigned to multiple clusters through membership probability [30]. In our study, this fuzziness allowed individuals to belong to several clusters, thus creating clusters characterized by broader disease combinations. These techniques have also been applied to identify subgroups of people based on their frailty [31,32]. Although multimorbidity and frailty are strongly associated [4], our review identified only 1 study that considers both simultaneously to build clustering-based patterns [33]. Other authors have related multimorbidity clusters to frailty-related outcomes using regression models [10,26]. However, to our knowledge, no study has assessed whether frailty may influence well-established multimorbidity patterns.

Considering frailty in analyses of multimorbidity is important for tailoring health and social care to the specific needs of the ever-expanding population of elderly people [34]. Moreover, frailty and multimorbidity evolve as people age, and these patterns can change over time, defining a trajectory. Only a few studies have been found that explored these trajectories [19], using hidden Markov models [23,35], latent class growth analysis [36], and descriptive statistics [37]. Furthermore, identifying changes in multimorbidity patterns and trajectories when considering frailty can enrich our understanding of patients' complex care needs and inform social and health care service strategies [38]. Therefore, our primary aim was to assess how the inclusion of frailty contributes to identifying and characterizing multimorbidity patterns in people aged 65 years or older. Moreover, we described the trajectory of the multimorbidity patterns of individuals as they aged.

Methods

Study Design, Setting, Data Source, and Participants

This observational study followed a dynamic cohort from primary care services in Catalonia (Spain) from January 1, 2010, to December 31, 2019. The cohort was drawn from the Information System for Performing Primary Care Research (SIDIAP [Sistema d'Informació pel Desenvolupament de la Investigació a l'Atenció Primària]) database [39]. The SIDIAP database collects pseudoanonymized EHRs from 328 primary care centers in Catalonia managed by the Catalan Health Institute (CHI) since 2005, and it currently has EHRs on more than 8 million patients. This represents almost 80% of the Catalan population and is a reliable representation of the region in terms of age, sex, and geographic distribution [40].

Participants were included at baseline if they were aged 65 years or older in 2010, or were added over the study period as they turned 65 years or arrived in the catchment area (if already aged 65 years or older). They were followed until death, transfer out of the catchment area (lost to follow-up), or end of the study (December 31, 2019). Individuals with no available information, those who did not attend a primary care center over the study period, and those who were aged 100 years or older in 2010 were excluded. Of the initial sample of 1,702,062 individuals, 1,456,052 were finally included.

The CHI linked primary care data with hospital admission data from public health care providers to maintain the pseudoanonymization of the data for researchers. Data included (1) sociodemographic information (ie, sex, age, and socioeconomic status [41]), (2) visits to primary care (ie, date of visit, health professional, and institution visited), (3) clinical measures (eg, BMI, blood pressure, frailty, and dependency questionnaires), (4) all diagnoses made in primary care (using International Classification of Diseases, 10th revision [ICD-10]), (5) laboratory results (eg, cholesterol and glycated hemoglobin), (6) emergency admission episodes (ie, date, number of diagnoses at admission, and length of stay), (7) medications dispensed in pharmacies (using Anatomical Therapeutic Classification [ATC] 5th level), and (8) inclusion in social assistance programs. Socioeconomic status was analyzed by census tract according to a 5-category classification, which considers 22 indicators, for instance, the proportion of the population with a manual occupation or dependency, households without internet access, and single-parent households.

This study complied with the RECORD (Reporting of Studies Conducted using Observational Routinely-collected Data) statement [42] (Multimedia Appendix 1).

Measurement of Multimorbidity and Frailty

Multimorbidity was measured using the operational definition of the Swedish National Study of Aging and Care in Kungsholmen (SNAC-K), which defined 60 categories of chronic conditions using more than 900 ICD-10 codes, along with clinical, laboratory, and drug-related parameters for assessing certain conditions [43]. The SNAC-K definition of multimorbidity is widely used in studies on older populations, so our results are amenable to comparisons with other studies. Frailty was measured using eFRAGICAP, a validated tool that uses EHRs from Catalan primary care centers [21]. This index considers 36 possible deficits that can be extracted from the EHRs, with 20 related to diseases and 16 related to signs, symptoms, laboratory results, and disabilities. According to the proportion of deficits a person has, their frailty status can be obtained using the cutoff points proposed by Clegg et al [20] (ie, fit, <0.12; mild, 0.12-0.24; moderate, 0.24-0.36; and severe ≥0.36). The complete list of codes considered in both multimorbidity and frailty definitions can be found in [43] and [21], respectively.

Statistical Analysis

Following study approval, data were obtained from SIDIAP. All authors had access to the database. Diagnoses with inconsistent dates and wrong sex-specific diagnoses were excluded. Duplicated diagnoses and clinical measures (same person, same day, and same code) were also excluded. The presence of each of the 60 disease groups and 36 deficits was calculated annually for each participant, according to which conditions were active and which laboratory results or clinical measures were out of range in the participants' EHRs [21,43]. There were no missing values related to diagnoses or frailty, as a lack of information was interpreted as the absence of the condition or frailty deficit, not as a loss of information. Continuous variables were described using medians and IQRs, as testing for normality showed a nonparametric distribution in all cases, and categorical variables were expressed as absolute and relative frequencies. Clustering and Cox regressions were performed on R v4.1 (R Project for Statistical Computing). Statistical significance was defined as $P<.05$ (2-sided).

Clustering Analysis

In this study, the information for each included person and year was used to group people based on the similarity of their combined concurrent chronic diseases. Each individual in the clustering analysis contributed records for each year they were included in the study. These groups represented multimorbidity patterns and were found using fuzzy c-means and 2 sets of data. Fuzzy c-means is a fuzzy form of clustering in which records for each individual can be assigned to more than one cluster, or multimorbidity pattern, through fuzzy membership, allowing the pattern definition to be more diverse. Both sets considered chronic conditions, as defined by SNAC-K; however, *multimorbidity & age* also included the age associated with the record, while *multimorbidity & frailty* considered the number of frailty deficits. A detailed description of the clustering analysis can be found in Multimedia Appendix 2 [21,43-47].

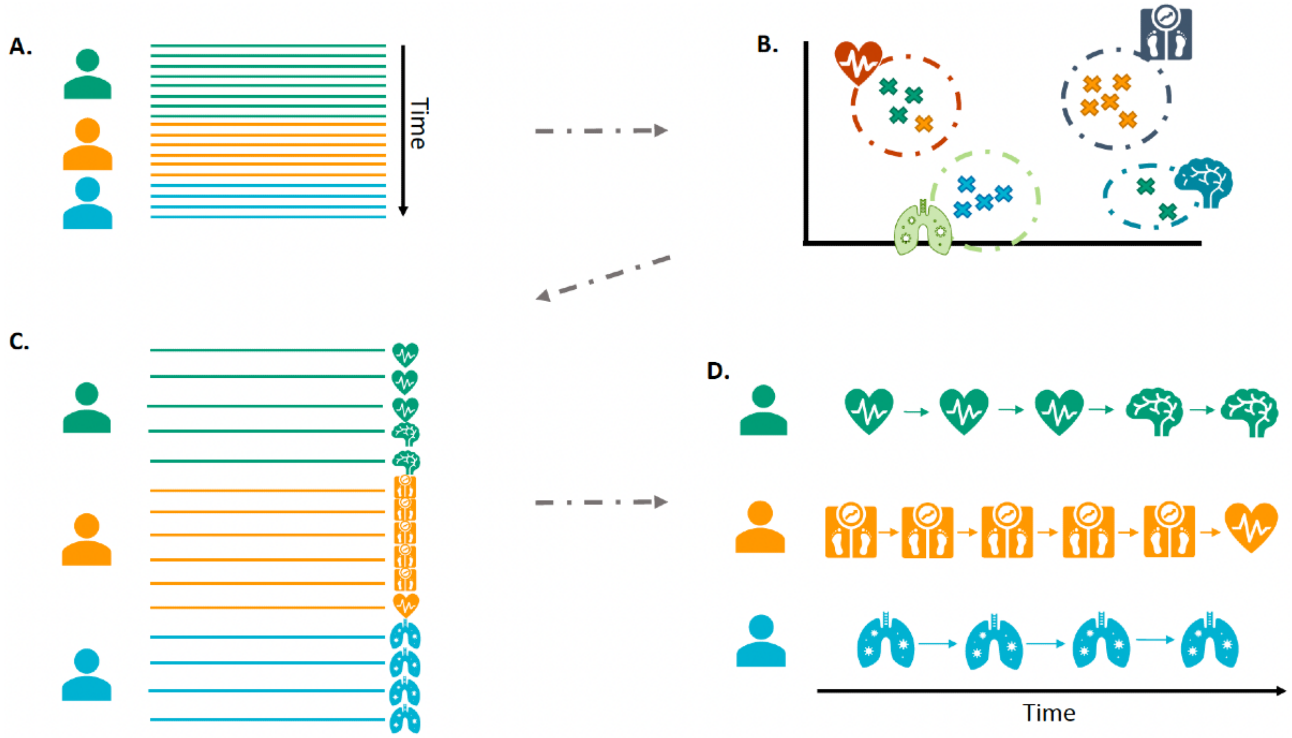
Dimensionality was reduced before clustering to simultaneously reduce computational cost and obtain more meaningful variables. First, chronic conditions with a low mean annual prevalence (<2%) were removed. Second, a PCAmix transformation [44], which is a mixture of the well-known Principal Component Analysis (PCA) and Multiple Correspondence Analysis (MCA), was applied, and a dimension reduction was performed using the Karlis-Saporta-Spinaki rule [45]. The choice of both the number of clusters (k) and the degree of fuzziness (m) was validated between $k \in (2, 15)$ and $m \in (1.1, 1.2, 1.4, 1.8)$, calculating analytical indexes using a subset of 100,000 randomly selected participants and 100 repetitions to account for random initialization of the cluster centroids. In addition to the analytical indexes, the opinion on the clinical usefulness and validity of the different sets of patterns of the research team was also considered to select the final k. This approach has been used in other studies [22-24,26].

Description of the Identified Patterns and Trajectories

To characterize the patterns, each person's annual record was assigned to the pattern with the highest membership probability. The observed/expected (OE) ratio, that is, the ratio between the condition prevalence in the pattern and the condition prevalence in the overall population, and exclusivity, that is, the ratio between the number of individuals in the pattern with the condition and the total number of individuals in the population with the condition, were calculated (see Multimedia Appendix 2 [21,43-47]). Conditions were considered associated with a specific pattern when the exclusivity was ≥25% or the OE ratio was ≥2. The patterns were named in line with these conditions by consensus within the research team (2 general practitioners, 1 nurse, and 2 statisticians), aiming to maximize their clinical utility and consistency with previous literature. In addition, each pattern was described in terms of age, sex, socioeconomic status, multimorbidity and frailty prevalence, smoking and alcohol intake, and health care service use.

The clustering model demonstrated the probability of every record and person belonging to each pattern, showing which pattern was most likely for each person each year. Therefore, the evolution among patterns over the study period could be followed as shown in Figure 1. Alluvial and chord plots were used to describe the trajectories, focusing on their evolution with aging, and a transition matrix showed the probability of change from the pattern assigned in the first year of inclusion to that in the last year.

Figure 1. Visual summary of the process of obtaining multimorbidity patterns and trajectories. A: Electronic Health Records (EHR) for three subjects, represented as a line per year of follow-up. B: Clustering gathers each year of each patient. C: Multimorbidity Pattern Assignment. D: Multimorbidity Trajectory.



Cox Regression

The association between the patterns identified for each data set and the following outcomes was calculated: all-cause mortality, nursing home admission, and home care need. The last 2 outcomes were measured using ICD-10 codes (Z59.3 and a Z74 starting code, respectively). The time to event was defined as the interval between cohort entry and the event. Patients were followed until censored (event, lost to follow-up, or end of observation). Cox proportional hazard regression models were fitted to test the association between the patterns and mortality. Similarly, cause-specific Cox models were calculated for nursing home admission and home care need, considering the competing risk of death through a multistate definition. For each model, the Akaike Information Criterion (AIC), R^2, and c-statistic (area under the receiver operating characteristic curve [AUC]) were calculated to assess the goodness of fit, the explained variation, and the predictive capacity of each set of patterns. The only covariate for building these models was the assigned pattern, and was considered time-varying, as each person was assigned to a pattern every year. The proportional hazard assumption was assured in all cases by checking the distribution of the Schoenfeld residuals.

Ethical Considerations

This study was approved by the Scientific and Ethical Committees of IDIAP (19/518-P) on December 18, 2019. The SIDIAP database is based on optout presumed consent. If a patient decides to opt out, their routine data are excluded from the database. Regarding the hospital admission data, the CHI acts as a trusted third party to execute the linkage and provide the pseudoanonymized data set, without needing informed consent. More information about the management of the SIDIAP database can be found in a previous report [40].

Results

Description of the Population

During the follow-up period, 1,456,052 unique participants were included in the study population (Figure 2 and Multimedia Appendix 3), with a mean follow-up of 7.04 (SD 3.15) years. The median age at cohort entry was 69.0 years, and 55.8% (813,074/1,456,052) were women. Most (1,297,810/1,456,052, 89.1%) joined the study with at least two chronic conditions; by the end of follow-up, this proportion was 94.5% (1,376,367/1,456,052). Frailty prevalence increased from 33.4% (486,320/1,456,052) to 60.3% (877,861/1,456,052) (Table 1). The prevalence of each chronic condition is presented in Table S2 in Multimedia Appendix 2.

Figure 2. Flow chart of the study population. The figure reports the number of individuals who met each exclusion criterion, as well as the number of individuals who met all the criteria simultaneously (unique IDs). CHI: Catalan Health Institute; SIDIAP: Sistema d'Informació pel Desenvolupament de la Investigació a l'Atenció Primària.

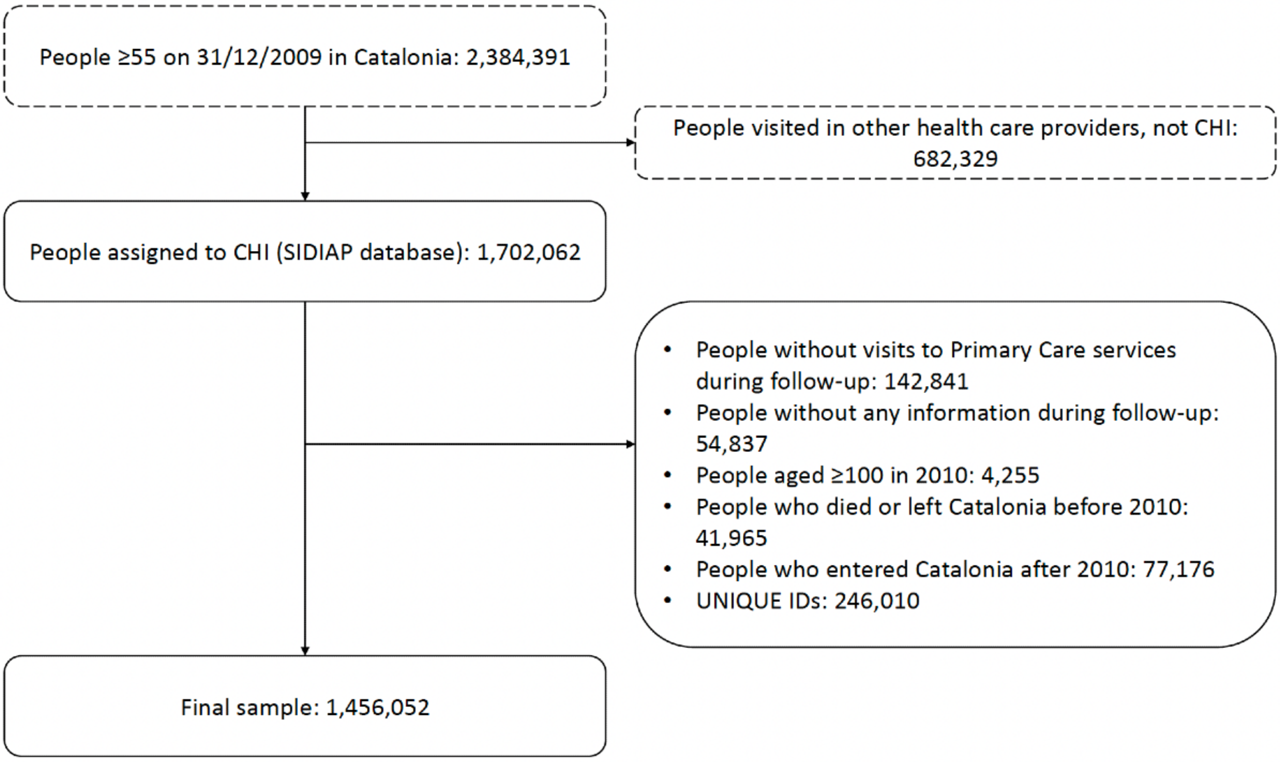


Table 1. Characteristics of the included individuals in their first and last years of follow-up (N=1,456,052).

[a] Follow-up began in 2010 for individuals aged 65 years or older who were in the catchment area, or the year when they turned 65 years or arrived in the catchment area. The end of follow-up was 2019, the year of death, or the year they left the catchment area. The characteristics were calculated at the end of each year, using the records from that year.

[b] For categorical variables, missing values, if any, are excluded from the calculation of the percentage.

[c] SNAC-K: Swedish National Study of Aging and Care in Kungsholmen.

[d] SSLD: signs, symptoms, laboratory results, and disabilities.

[e] The number of distinct drugs was calculated using the first 5 digits of the Anatomical Therapeutic Classification (ATC) code.

Description of the Identified Multimorbidity Patterns

Two sets of 11 multimorbidity patterns were identified (*multimorbidity & age* and *multimorbidity & frailty*). The most prevalent chronic conditions in each pattern were similar between sets in most patterns, regardless of whether frailty was included (see Multimedia Appendix 4 for the complete description; a demonstration is shown in Table 2) and the characteristics of their members (see Multimedia Appendix 5 for the complete description; a demonstration is shown in Table 3). The following patterns were identified in both data sets: *allergy & migraine*, *chronic ulcers & peripheral vascular*, *diabetes & obesity*, *genitourinary & respiratory*, *heart & circulatory*, *mental & neurodegenerative*, *neuromusculoskeletal*, *nonspecific*, *peripheral vascular & respiratory*, and *respiratory*. The prevalence of all chronic conditions in *nonspecific* was lower than in the general population. On the other hand, *dementia & motility digestive* appeared only in *multimorbidity & frailty*, while *autoimmune & metabolic* appeared only in *multimorbidity & age*.

Some patterns were female-dominant, such as *allergy & migraine*, *neuromusculoskeletal*, *chronic ulcers & peripheral vascular*, *dementia & motility digestive*, and *mental & neurodegenerative*. On the other hand, *autoimmune & metabolic*, *respiratory*, *genitourinary & respiratory*, and *peripheral vascular & respiratory* were male-dominant, with the latter 2 patterns having the highest rates of smokers and high-risk drinkers. *Allergy & migraine*, *diabetes & obesity*, *genitourinary & respiratory*, *neuromusculoskeletal*, and *nonspecific* included younger individuals, while *chronic ulcers & peripheral vascular*, *dementia & motility digestive*, *heart & circulatory*, and *mental & neurodegenerative* were more common in older individuals. These, together with *peripheral vascular & respiratory*, were the patterns with the highest prevalence of frailty. All patterns, except *nonspecific*, had a high prevalence of multimorbidity.

The emergence of the *dementia & motility digestive* pattern in *multimorbidity & frailty* significantly changed the definition of *mental & neurodegenerative* between sets. As shown in Table 3, in *multimorbidity & frailty*, it comprised younger, less frail individuals with more chronic conditions, such as Parkinson disease and other neurological diseases (ie, Huntington disease or myasthenia), rather than dementia (see Multimedia Appendix 4), while in *multimorbidity & age*, this pattern comprised older and frailer individuals. On the other hand, the *dementia & motility digestive* pattern was made up of older individuals, mostly women, with moderate and severe frailty and a high prevalence of dementia.

Table 2. Top 10 conditions in terms of the observed/expected ratio and exclusivity for the heart & circulatory and mental & neurodegenerative patterns.

Pattern and disease	Multimorbidity & frailty		Multimorbidity & age	
	OE[a] ratio	Exclusivity, %	OE ratio	Exclusivity, %
Heart & circulatory

[a] Each column reports the information of all individuals and years included in each pattern. The description of the rest of the patterns can be found in Multimedia Appendix 5.

[b] For categorical variables, missing values, if any, are excluded from the calculation of the percentage.

[c] SNAC-K: Swedish National Study of Aging and Care in Kungsholmen.

[d] SSLD: signs, symptoms, laboratory results, and disabilities.

[e] The number of distinct drugs was calculated using the first 5 digits of the Anatomical Therapeutic Classification (ATC) code.

Effect of Considering Frailty

Compared to the *multimorbidity & age* patterns, the *multimorbidity & frailty* grouping assigned more frail individuals to the patterns defined by chronic conditions imposing greater limitations on daily life. For example, severe frailty was more prevalent in the *heart & circulatory* pattern and a lack of frailty was more common in the *nonspecific* pattern in *multimorbidity & frailty* than in *multimorbidity & age* (Table 3). In addition, the *dementia & motility digestive* pattern appeared only in *multimorbidity & frailty*, and the definition of *mental & neurodegenerative* changed considerably, as described above.

Each set of patterns behaved differently in terms of the associated outcomes (Table 4). *Multimorbidity & age* patterns had a better goodness of fit (AIC) with mortality than *multimorbidity & frailty*, while *multimorbidity & frailty* patterns had a better or similar goodness of fit with nursing home admission or home care need. A similar behavior was observed for R^2, while both sets of patterns achieved similar results in all outcomes in terms of AUC. Regarding the hazard ratios, they were very similar between *multimorbidity & age* and *multimorbidity & frailty* in all patterns and outcomes, except *mental & neurodegenerative*, which were lower in *multimorbidity & frailty*. *Chronic ulcers & peripheral vascular*, *dementia & motility digestive*, *heart & circulatory*, *mental & neurodegenerative*, and *peripheral vascular & respiratory* showed the highest risk of death. All patterns had a higher risk of nursing home admission than *nonspecific*, with *dementia & motility digestive*, *chronic ulcers & peripheral vascular*, and *mental & neurodegenerative* standing out. These latter patterns, together with *heart & circulatory*, also had a higher risk of home care need.

Table 4. Data for the unadjusted survival models using the multimorbidity patterns as the time-varying covariate.

[c] HR: hazard ratio.

[d] N/A: not applicable.

[e] AIC: Akaike Information Criterion.

[f] The set of patterns that achieved better performance for each metric and outcome.

[g] AUC: area under the receiver operating characteristic curve.

Study of the Trajectories

Over the follow-up, individuals changed patterns an average of 1.75 (*multimorbidity & age*) and 1.85 (*multimorbidity & frailty*) times, while 45.1% (656,778/1,456,052) of the individuals remained in the same pattern. Multimedia Appendix 6 shows that these values depended on the length of the trajectory. For example, people with 5 years of follow-up had an average of 1.55 different patterns in their trajectory, while around 54.5% (52,634/96,578, 54.5% in *multimorbidity & age*; 52,586/96,578, 54.4% in *multimorbidity & frailty*) remained in the same pattern. In those with 10 years of follow-up, these values changed to 2.15 and 26.6%, respectively. The prevalence of most patterns varied with age, as shown in Figure 3. The prevalence of *nonspecific* showed the largest reduction, as most of its members developed diseases as they aged and shifted to more disease-specific patterns. On the other hand, *heart & circulatory* and *mental & neurodegenerative* for *multimorbidity & age*, and *dementia & motility digestive* for *multimorbidity & frailty* showed the highest increases in prevalence with age.

Figure 4 shows the transition matrices for both *multimorbidity & age* and *multimorbidity & frailty*. *Chronic ulcers & peripheral vascular*, *heart & circulatory*, *mental & neurodegenerative*, and *dementia & motility digestive* were the multimorbidity patterns most closely associated with mortality, as more than 55% of the individuals who started in them died during follow-up (Figure 4). On the other hand, the *allergy & migraine*, *neuromusculoskeletal*, and *nonspecific* clusters showed the lowest mortality. When considering frailty, the number of individuals transitioning to *mental & neurodegenerative* from any pattern was reduced. Nevertheless, considering the general stability of the trajectories, a relatively high percentage of individuals transitioned to *dementia & motility digestive*. Multimedia Appendix 7 (*multimorbidity & age*) and Multimedia Appendix 8 (*multimorbidity & frailty*) show the evolution of 3 subsets of 50 random individuals aged 65, 75, and 85 years, respectively, in 2010 to illustrate how multimorbidity trajectories vary with age. These figures show that the percentage of individuals starting in *nonspecific* decreased inversely with age at cohort entry, as did the percentage of individuals remaining in this pattern throughout follow-up.

Discussion

This study aimed to assess how frailty contributes to the characterization of multimorbidity patterns, as identified through clustering techniques. In a Mediterranean cohort of 1,456,052 people aged over 65 years, 2 sets of 11 multimorbidity patterns were identified based on the presence of chronic conditions. One considered age and the other considered the number of frailty deficits. The consideration of frailty modified multimorbidity patterns, revealing patterns with better goodness of fit to the outcomes related to frail aging, such as nursing home admission and home care need, and gathering more frail individuals in patters characterized by more limiting conditions. The better fit to aging-related outcomes when considering frailty has been previously reported [48]. Moreover, the trajectories of multimorbidity patterns were different when considering frailty. When considering only conditions and age, and not frailty, the patterns showed better goodness of fit with the outcome of death, and described an additional disease-related pattern.

When considering frailty, an additional pattern more specific to aging was identified (*dementia & motility digestive*). Distinguishing this pattern from *mental & neurodegenerative* can enable more personalized clinical treatment. In the former case, palliative care would be appropriate, while the latter would call for active treatments to delay disease progression. Patterns defined by less limiting conditions for daily life, such as *diabetes & obesity*, had a lower prevalence of frailty when frailty was considered, in contrast with more limiting patterns such as *heart & circulatory*. For this same reason, the *genitourinary & respiratory* pattern also had a higher proportion of men when frailty was considered, as it included more individuals with prostate diseases, which usually lead to more frailty [49,50], while the same pattern included more women when frailty was not considered, as it involved addictions (ie, drug, alcohol, or tobacco use), which usually involve less frailty than prostate diseases.

Most of the 11 multimorbidity patterns were similarly described whether frailty was considered or not and could be classified into concordant or discordant multimorbidity patterns depending on whether the conditions defining the pattern shared pathophysiology or approaches to clinical management [51,52]. For example, *heart & circulatory*, *chronic ulcers & peripheral vascular*, *respiratory*, and *diabetes & obesity* are patterns of concordant multimorbidity, while *genitourinary & respiratory* and *peripheral vascular & respiratory* are patterns of discordant multimorbidity. Discordant conditions might be grouped together because of shared risk factors, such as smoking or alcohol intake, rather than shared pathophysiology. This is the case for *genitourinary & respiratory* and *peripheral vascular & respiratory*, which mainly included men, with a higher prevalence of smokers and high-risk drinkers. Another risk factor these individuals may share could be their genetics, which can also influence the development of multimorbidity [53]. This discordance makes treatment more complex [52]; thus, identifying patients who follow a discordant multimorbidity pattern can signal a need for integrated care.

Regarding the trajectories of multimorbidity patterns, the *heart & circulatory* and *mental & neurodegenerative* patterns (when not considering frailty), and the *dementia & digestive motility* pattern (when considering frailty) showed the most changes over time. Their prevalence increased the most with aging, and the patients in these groups had the highest probability of transitioning to death at the end of their follow-up. This may be due to the high prevalence of frailty in these patterns, and the association of frailty with death [54]. The *nonspecific* pattern also had a high probability of transition, as it included healthier individuals who transitioned to other patterns as diseases appeared with age. *Peripheral vascular & respiratory* involved a burden of heart conditions, which could lead the trajectory toward *heart & circulatory*. However, many of these individuals died, possibly before the onset of the cardiac diseases could be recorded in the EHRs. On the other hand, *neuromusculoskeletal* and *respiratory* were the patterns with the fewest transitions during follow-up, with more than 50% of the individuals remaining in the same pattern throughout the study period. This may be because both patterns tended to evolve toward disability rather than death or the development of other comorbidities, and nowadays, treatments are more effective in maintaining the status of patients. In our study, trajectories included a mean of 1.8 different multimorbidity patterns. Even people who had 10 years of follow-up did not make 3 changes on average; thus, the trajectories can be considered quite stable. This result is similar to that found in previous research in this same population, albeit with slightly different methods, where 59% of individuals did not change their pattern [23] over 5 years of follow-up (54.5% in this study).

In terms of patient-based multimorbidity patterns reported in the literature, the substantial variability [55] could be attributed to differences in the populations or to the lack of consensus on how many and which diseases should be considered in determining multimorbidity [9]. However, the most commonly reported patterns from multimorbidity data include cardiac, cognitive, psychiatric, musculoskeletal, respiratory, and genitourinary system diseases [27,28], and these patterns have also been found in this work. Few studies have described multimorbidity trajectories [19], and none considered frailty in their definition; thus, our study is pioneering in this line of research. Only 1 scoping review on multimorbidity trajectories compiled evidence from 34 studies, finding significant associations between multimorbidity and adverse outcomes [56]. However, the heterogeneity of the described methods and the long-term conditions considered in each study preclude a robust comparison.

This study has strengths and limitations. We used a large high-quality database [57] along with standardized and validated tools to identify both multimorbidity [43] and frailty [20,21]. EHRs are a representation of real-world data and may, despite cleaning, contain mistakes inherent to daily clinical practice. This could represent an information bias, but SIDIAP has implemented several standardized quality protocols to avoid it [40]. In addition, we considered the absence of any condition or frailty information in the EHRs to indicate an absence of that condition or frailty status in the individual. Therefore, some chronic conditions or frailty deficits could be underreported among patients who visit primary care centers less frequently, constituting an information bias. Consequently, only data available in the EHRs were considered, and to avoid the creation of unreal records, no missing values were imputed. The SIDIAP database is representative of the population of Catalonia [40], so its use does not imply a selection bias. We excluded people who did not visit primary care during the entire study period in order to eliminate those with private health insurance; however, we cannot rule out that some were healthy individuals. After the first filtering, a criterion based on the predominance of diseases in the identified patterns had to be defined and used to make the final selection. The inclusion of all potential diagnoses would have entailed greater complexity, which would have hindered both the interpretation of findings and the comparison with other studies. Other studies have proceeded in the same way [22,23]. Clustering is an unsupervised exploratory technique whose results depend on the population. Therefore, different patterns could be identified from a database in another region. However, the variables used to generate the patterns were obtained using electronic tools based on routine EHR data, such as SNAC-K and eFRAGICAP, so their acquisition is reproducible in information systems in other countries. This increases the international applicability of this study, helping to establish multimorbidity management worldwide. In addition, clustering techniques can suffer from dependency on random initialization, and there is no guarantee of optimal clustering. To minimize this disadvantage, 100 repetitions with different seeds were performed when optimizing the choice of the number of clusters. Particularly in fuzzy clustering techniques, the membership probability in the heuristic global cost function depends on the number of clusters, and specifying a wrong number of clusters may affect the clustering solution [58]. However, we have validated the number of clusters both analytically and clinically.

Care for older people requires holistic patient-centered care plans that are effectively coordinated and minimally disruptive, considering the social and family context in which health care activities are managed, decisions are made, and care is experienced. As a future line of work, these multimorbidity patterns could be used as adjustment covariates in prediction models for outcomes, such as those reported here, or others, such as emergency admission. Similarly, artificial intelligence–based models that predict the timing and direction of transitions between patterns can be developed. These models could help to improve and anticipate decision-making regarding end-of-life management. More work can be done on the study of trajectories, such as the development of care and treatment guidelines that simultaneously consider the current individual’s multimorbidity pattern and the trajectory over time. Sequence analysis, which combines longitudinal analysis and clustering, could also be used to identify trajectories [59]. The relationship between genetics and concordant and discordant multimorbidity patterns could also be studied.

This study took a person-centered approach, offering relevant information about the multimorbidity patterns and trajectories in the aging population based on age, frailty, and other health determinants. Multimorbidity and frailty can define aging, so both characteristics are relevant considerations made when designing and developing tools, such as multimorbidity patterns, to characterize the aging population. When considering the frailty of individuals, the estimation of outcomes, such as nursing home admission and home care need, improved, as did the characterization of the patterns themselves in terms of how limiting their main chronic conditions can be. The consideration of both multimorbidity and frailty can help to improve treatment guidelines, social assistance, and decision-making in primary care. If most patients in a primary care center follow patterns associated with frailty, increased spending on home-based care services and integrated care programs may be warranted, while a higher burden of multimorbidity would imply higher spending on physician visits. Therefore, and echoing other studies, we recommend that future research involving older populations consider frailty [60].

Acknowledgments

The project received a research grant from the Carlos III Institute of Health, Ministry of Economy and Competitiveness (Spain), awarded in 2019 under the Health Strategy Action 2013-2016, within the National Research Programme oriented to Societal Challenges, within the Technical, Scientific and Research National Plan 2013-2016 (reference PI19/00535), and the PFIS Grant FI20/00040, co-funded with European Union ERDF (European Regional Development Fund) funds. The funder had no role in the study design, data collection, data analysis, data interpretation, or writing of this work. The authors thank Meggan Harris for her role in editing and proofreading the manuscript.

Data Availability

The data used in this study are only available to the participating researchers, in accordance with current European and national laws. Thus, distribution of the data is not allowed. However, researchers from public institutions can request data from SIDIAP. Further information is available online [61].

Authors' Contributions

CV, MCB, ARL, and LACR participated in the study conceptualization, investigation, funding acquisition, and methodology definition. LACR and ARL performed the data curation, formal analysis, and visualization. LACR, MDC, and CV drafted the manuscript, and all authors participated in the review and editing of the final manuscript.

Abstract

Background: Hemophilia A is a chronic condition that requires meticulous treatment and management. Patient preferences for prophylactic treatment can substantially influence adherence, outcomes, and quality of life, yet these preferences remain underexplored, particularly in China.

Objective: This study aimed to investigate the preferences for prophylactic treatment among Chinese adult patients with hemophilia A without inhibitors, considering clinical effectiveness, side effects, dosing mode, and dosing frequency.

Methods: A discrete choice experiment was used to elicit patient preferences for prophylactic treatment of hemophilia. The study was conducted across 7 provinces in China with socioeconomic and geographical diversity. Subgroup analysis was performed according to education level, geographic location, and treatment type, alongside the exploration of benefit-risk trade-offs.

Results: A total of 113 patients completed the discrete choice experiment questionnaire, and we included 102 responses for analysis based on predetermined exclusion criteria. The study found that patients prioritized reducing annual bleeding times and avoiding the risk of developing inhibitors over treatment process attributes. Subgroup analysis revealed that lower-educated patients and those from rural areas attached more importance to the dosing mode, likely due to barriers to self-administration. Patients demonstrated a clear understanding of benefit-risk trade-offs, exhibiting a willingness to accept an increased risk of developing inhibitors for improved clinical outcomes.

Conclusions: This study provides valuable insights into the preferences of patients with hemophilia A for prophylactic treatment in China. Understanding these preferences can enhance shared decision-making between patients and clinicians, fostering personalized prophylactic treatment plans that may optimize adherence and improve clinical outcomes.

KEYWORDS

benefit-risk assessment; discrete choice experiment; hemophilia A; patient preference; prophylactic treatment

Introduction

Hemophilia, an infrequent hemorrhagic disorder, is primarily triggered by the absence or deficiency of specific coagulation factors in the blood [1]. According to the World Federation of Hemophilia's 2018 global survey, China was found to have the second highest incidence of confirmed hemophilia cases globally [2]. With a prevalence of 2.73 per 100,000 individuals, hemophilia A (ie, classical hemophilia) constituted more than 80% of these instances [3]. The ensuing joint deformities and disabilities resulting from bleeding into tissues, joints, and muscles critically impair the quality of life for these patients [1].

Factor replacement therapy, classified into on-demand treatment (administered during bleeding episodes) and prophylactic treatment (routine administration to prevent bleeding), is the prevailing treatment modality [4]. However, the development of inhibitors, or an immune response to the therapy, constitutes the most severe adverse effect of this approach [5]. Patients with hemophilia A who have developed inhibitors undergo hemostasis and the removal of inhibitors [4]. In contrast, for patients with hemophilia A devoid of inhibitors, prophylactic treatment remains the optimal care strategy [4].

China has actively pursued and advocated prophylactic treatment measures appropriate to its national context, fostering comprehensive health management of patients with hemophilia [6,7]. Nevertheless, a key impediment remains low adherence to prophylactic treatment. Alarmingly, the rates of prophylactic treatment and treatment compliance are substantially lower in China compared to developed nations (4.1% vs 36.8% and 6.2% vs 40.5%, respectively) [8]. Previous studies have indicated that various factors, such as age, health status, annual bleeding times, infusion methods, dosing regimens, and cost, significantly influence the uptake of prophylactic treatment among adult patients with hemophilia [9,10]. Patients with hemophilia A receiving prophylactic treatment experience a reduction in annual bleeding times, yet they face an associated risk of developing inhibitors. This makes establishing a benefit-risk balance challenging. Therefore, assessments of potential benefits and harms can aid stakeholders, regulators, health technology assessors, and health professionals in understanding and communicating treatment-risk balance, ultimately enhancing adherence to prophylactic treatment [11].

The discrete choice experiment (DCE) is an established stated preference method, extensively used to quantify patients' preferences concerning health care [12-16]. Several DCEs have been conducted to elicit the treatment preferences of patients with hemophilia [17-23]. However, evidence regarding the preference for prophylactic treatment among adult patients with hemophilia A without inhibitors, particularly in terms of benefit-risk assessment, remains sparse in mainland China. This study endeavors to address this research gap by using a DCE as a patient decision aid. It aims to identify the preferences of adult patients with hemophilia A without inhibitors in China concerning the risk and benefit attributes when selecting prophylactic treatment.

Methods

Overview

The DCE is a renowned tool used to simulate the influence of diverse attributes of a service or commodity on individual preference [15,16]. In the scope of a DCE, participants are presented with the task of deciding between 2 or more hypothetical incentive scenarios, differentiated by several relevant dimensions, termed *attributes*. These attributes present varied configurations, referred to as *levels*, across the proposed alternatives [15].

Identification of Attributes and Levels

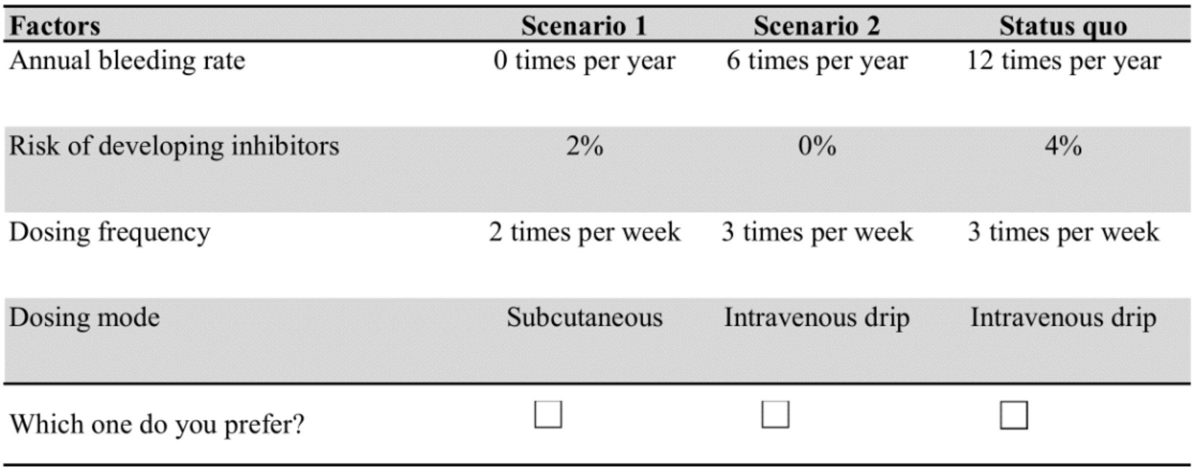
The onset of the DCE involved pinpointing relevant attributes. In accordance with research guidelines, a combination of qualitative and quantitative methods was applied to derive attributes and levels [24]. A total of 7 attributes were ascertained through literature reviews and expert consultations, including the annual bleeding times [21-23,25-28], the risk of developing inhibitors [17-21,27], dosing frequency [18,19,21,23,26-30], dosing mode [26,27,30], storage temperature [21,29], dosage form [18,20,22,26], and the risk of virus infection [17-20]. Following face-to-face patient interviews and expert focus group discussions, 3 attributes (storage temperature, dosage form, and virus infection risk) were dismissed. Due to its complexity, cost was also discarded as a function of individual factors such as weight, the type and specification of medication, and regional health insurance reimbursement rates (varying from 40% to 90%) [31]. Consequently, 4 attributes were selected for inclusion in this study: annual bleeding times, dosing frequency, dosing mode (these 3 represent benefits), and the risk of developing inhibitors (this represents risk). The levels of the 4 DCE attributes were sourced from drug instructions and clinical prophylactic treatment studies [5,32-35]. The chosen attributes and their corresponding levels are detailed in Table 1.

Table 1. Attributes and levels for discrete choice experiment questions.

Attributes	Levels
Annual bleeding times	• 0 times per year • 6 times per year • 12 times per year
Risk of developing inhibitors	• 0% • 2% • 4%
Dosing frequency	• 1 time per week • 2 times per week • 3 times per week
Dosing mode	• Intravenous drip • Intravenous push • Subcutaneous

Questionnaire and DCE Instrument Design

The D-optimal design approach was used to produce 18 choice tasks in SAS (version 9.2; SAS Institute). To alleviate cognitive load, these tasks were divided into 2 blocks. To reflect a more authentic clinical decision-making context, a status quo option was introduced in each choice task. An example of a DCE question is provided in Figure 1.



Factors	Scenario 1	Scenario 2	Status quo
Annual bleeding rate	0 times per year	6 times per year	12 times per year
Risk of developing inhibitors	2%	0%	4%
Dosing frequency	2 times per week	3 times per week	3 times per week
Dosing mode	Subcutaneous	Intravenous drip	Intravenous drip
Which one do you prefer?	☐	☐	☐

Figure 1. An example question in the discrete choice experiment (translated version).

The questionnaire encapsulated an introduction to the research background, attribute definitions, 9 DCE choice tasks, and sociodemographic inquiries. Preceding the official choice tasks, a practice task acclimated respondents to the forthcoming tasks. A question was repeated in each block to validate the internal consistency of the survey. The sociodemographic information gathered included sex, age, education level, employment status, and geographic location.

To ensure respondents comprehended the definition of the risk of developing inhibitors, they were posed a question regarding their understanding of risk percentages [36]. For instance, given a 4% risk of developing inhibitors, respondents were asked to determine how many patients out of 100 would potentially develop inhibitors. The successful answer to this question was a prerequisite for proceeding with the DCE choice tasks.

A pilot study was undertaken among adult patients with hemophilia A without inhibitors at the Shandong Province Hemophilia Treatment Center. The pilot sought to evaluate the understandability, acceptability, and validity of the questionnaire, resulting in revisions to the language and layout.

Sample Selection

This study's sample size was guided by a rule of thumb frequently used in DCE studies that the sample size should comprise no fewer than 75 respondents [37].

Participants were chiefly sourced from Shandong, Hebei, and Henan, which have the largest population of patients with hemophilia A registered with the Hemophilia Treatment Center Collaboration Network of China [38]. Additional patients were recruited from 4 other provinces: Jiangsu, Hubei, Hunan, and Chongqing. The inclusion criteria comprised a hemophilia A diagnosis, no inhibitors present at the time of recruitment, being aged 18 years or older, and receiving treatment for more than 50 exposure days. Exposure days refer to the cumulative number of days coagulation factor VIII was injected, which influences the likelihood of producing an inhibitor.

Data Collection

Formal data collection occurred between December 2021 and March 2022. To ensure data quality, we sent the electronic questionnaire to respondents first and then conducted the interview over the telephone in a one-on-one manner. The interviewers answered respondents’ questions. Through a warm-up section, the interviewers trained the respondents to familiarize themselves with the DCE choice tasks and guarantee they comprehended the whole questionnaire.

Model Specification

A mixed logit model was used to analyze the choice data in Stata (version 15.1; StataCorp), estimated through the simulated maximum likelihood approach [39,40]. The mixed logit model included an alternative-specific constant (ASC) indicative of the utility generated by the status quo option in comparison to non–status quo options. We hypothesized that the parameters of attribute levels would conform to a normal distribution. Parameter estimations were derived relative to the reference level within each attribute. The average preference value, termed *part-worth utility*, and the variability of the preference value among patients with hemophilia were represented by the mean and SD of a parameter, respectively. Model fit was determined by the Akaike information criterion (AIC), Bayesian information criterion (BIC), and log-likelihood ratio. To ensure the reliability of parameter estimates, we iteratively estimated the mixed logit model by incrementally increasing the number of random draws by 500, commencing with 50 draws. Estimation stability was achieved at 2500 draws, producing our final estimates [41].

We excluded patients who failed the consistency test or always chose the options on the left or right in all the choice tasks (ie, position bias) [15]. We also conducted a sensitivity check to examine whether the exclusion would significantly affect the results of the mixed logit model.

Dominant Preference Examination

Dominant preference refers to the phenomenon whereby a respondent’s choices are dictated by a single attribute, resulting in decisions that consistently favor the alternative with a superior level of 1 attribute in a choice task [42]. Such respondents avoid making trade-offs between attributes, impeding the analysis of relative importance between attributes [42]. We used nonparametric [42] and parametric [43] approaches to test for dominant preference. The nonparametric approach evaluated if respondents’ choices exhibited a pattern, that is, if the selected alternatives for the 7 tasks were invariably consistent with the alternatives with a higher level of a certain attribute in comparison to the other alternative in all 7 questions. The parametric approach compared the estimated coefficients of attribute levels between a full model encompassing all attributes and a reduced model containing only 1 attribute. Notable discrepancies between the coefficients indicated the presence of a dominant preference driven by that attribute. We iteratively inserted each attribute into the reduced model and compared the model estimates with the full model.

Attribute Relative Importance

The relative importance of each attribute was computed using the mixed logit model estimates through a widely used rescaling method [16,44]. The relative importance of each attribute was determined by dividing the range of coefficients within the attribute by the sum of all attribute ranges, which was subsequently rescaled to a 1-100 range. The highest value denoted the attribute perceived as most important by the respondents.

Interaction

A meticulous examination of all potential interactions between the characteristics of respondents and attribute levels was carried out using the multinomial logit model (MNL) [15]. Interaction terms were selected using a backward selection method based on the contribution of each term to model fit. The log-likelihood ratio test was used to compare the model specifications with a reduced model with 1 interaction term removed. If the removed term significantly influenced the model fit, the term was retained. Following the identification of interaction terms, we simulated a mixed logit model that incorporated the interactions to quantify the preference values assigned to the interaction terms by respondents.

Maximum Acceptable Risk

We quantified patients’ tolerance for the risk of developing inhibitors in exchange for improvements in other attributes. The outcome was termed the maximum acceptable risk (MAR) by patients. The MAR gauged the benefit-risk ratio that patients were willing to accept in terms of the trade-off between benefit and risk, given that the utility remained constant [45].

Subgroup Analysis

We conducted subgroup analyses by comparing the relative importance of attributes between different groups of respondents using individual-level preferences. We applied a mixed logit model to the variables used to categorize respondents, which encompassed education level, geographic location, and treatment type.

Ethics Approval

Ethical approval for this study was granted by the Center for Health Management and Policy Research, Shandong University (ECSHCMSDU20211102).

Results

Pilot Study

This pilot study incorporated a cohort of 15 patients, all of whom successfully completed the study. The derived model estimates were in alignment with our theoretical anticipations in terms of their coefficient signs and priority order, thereby affirming that the participants comprehended the choice tasks and that the quantity of questions was manageable. The mean time taken to conclude the study was approximately 15 minutes.

Patient Characteristics

We invited 140 patients who were eligible for inclusion, and 122 consented to participate (a response rate of 87%), of whom 113 completed the survey (a completion rate of 93%). On average, participants took 14.60 (SD 5.41) minutes to complete the questionnaire. Among those who completed the questionnaire, 10 participants did not pass the consistency test, while 1 participant exhibited position bias (ie, always choosing the left or right options); hence, we excluded them from further analysis. Thus, a total of 102 participants were included in the final analysis.

The demographic profile of the participants included in the analysis is presented in Table 2. The majority of patients were male (100/102, 98%), possessed an education level equivalent to high school or higher (54/102, 52.9%), were single (59/102, 57.8%), and resided in townships or rural areas (66/102, 64.7%). Most patients were diagnosed with severe hemophilia A (58/102, 56.9%) and received on-demand treatment (56/102, 54.9%).

Table 2. Sociodemographic characteristics of patients included in the analysis.

Characteristic	Patients included in the study (n=102)
Age (in years), mean (SD)	33.8 (7.5)
Sex, n (%)	
Male	100 (98)
Female	2 (1.9)
Education level, n (%)	
Middle school or below	48 (47.1)
High school or above	54 (52.9)
Marital status, n (%)	
Unmarried	59 (57.8)
Married	41 (40.2)
Divorced	2 (2)
Occupation status, n (%)	
Unemployed	42 (41.2)
Working full time	25 (24.5)
Working part time	11 (10.8)
Self-employed	9 (8.8)
Student	14 (13.7)
Retired	1 (1)
Geographic location, n (%)	
Urban	36 (35.3)
Rural	66 (64.7)
Severity of hemophilia A, n (%)	
Mild	3 (2.9)
Moderate	41 (40.2)
Severe	58 (56.9)
Treatment type, n (%)	
On-demand	56 (54.9)
Prophylaxis	41 (40.2)
Nonstandard prophylaxis	5 (4.9)

Patients' Preferences

Table 3 presents the mixed logit model results. The constant representing the status quo option was not statistically significant, indicating patients expressed no preference for the status quo compared with nonstatus quo alternatives.

Respondents expressed a higher likelihood of accepting either 0 or 6 instances of bleeding annually, as opposed to 12. Utility declined as the risk of developing inhibitors increased. In terms of dosing frequency, patients demonstrated a preference for 1 or 2 doses per week over 3. With respect to the mode of administration, intravenous pushes and subcutaneous injections were preferred over intravenous drips.

We did not identify the presence of dominant preferences through either parametric and nonparametric approaches. A sensitivity analysis was conducted by including the 11 patients who failed the internal validity test or exhibited position bias (Table S1 in Multimedia Appendix 1). We found no significant differences between the 2 models—one including and the other excluding these 11 patients—indicating that the exclusion did not affect the findings.

Table 3. Mixed logit model results.

	β	*P* value	SE	SD	*P* value	SE
Constant	0.72	.373	0.80	3.80	<.001	0.76
Annual bleeding times (reference level 12 per year)						
6 per year	1.80	<.001	0.25	0.00	.99	0.38
0 per year	3.64	<.001	0.39	1.49	<.001	0.31
Risk of developing inhibitors	−0.79	<.001	0.39	0.54	<.001	0.09
Dosing frequency (reference level 3 times per week)						
2 times per week	1.20	<.001	0.24	0.05	.88	0.32
1 time per week	1.58	<.001	0.25	0.01	.98	0.38
Dosing mode (reference level intravenous drip)						
Intravenous push	0.74	<.001	0.19	0.07	.84	0.33
Subcutaneous	1.35	<.001	0.29	1.95	<.001	0.34

Attribute Relative Importance

The frequency of annual bleeding events emerged as the most significant attribute from the perspective of the participants, with the attribute relative importance (ARI) score at 100. The risk of developing inhibitors ranked second in importance (ARI=87), while dosing frequency (ARI=43) and dosing mode (ARI=37) were considered comparatively less critical.

Interaction

The selection of interaction terms identified a significant interaction between the status-quo constant and the education level of participants (Table S2 in Multimedia Appendix 1). The positive preference value suggested that respondents with a higher level of education (ie, high school or above) were more likely to opt for the status quo alternative than those with a lower educational level (ie, middle school or below).

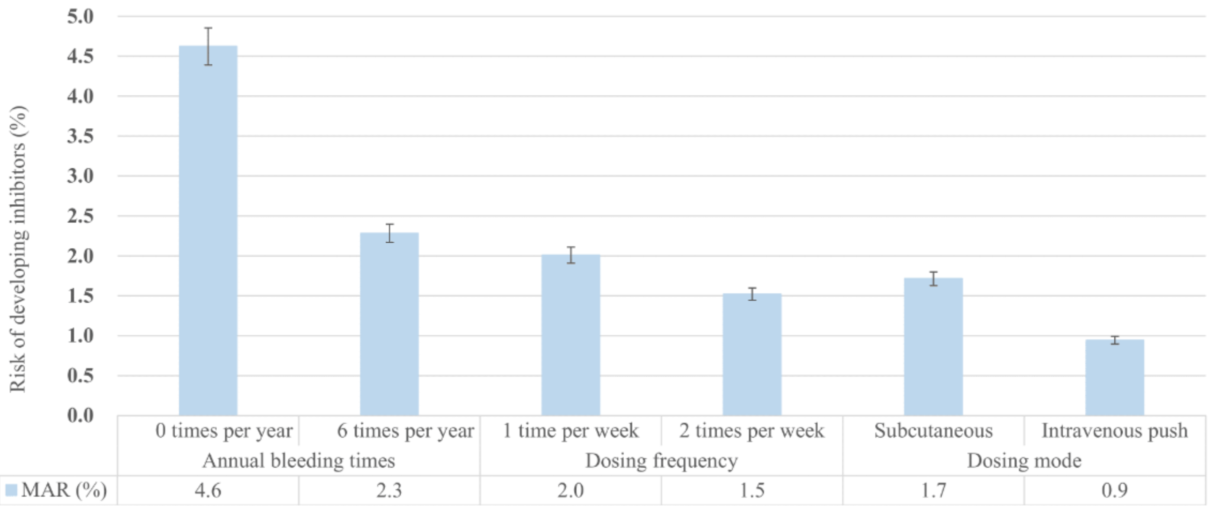
Subgroup Analysis

Subgroup analysis was performed based on variables such as education level, geographic location, and treatment type. Patients with lower education levels (middle school or below) considered the dosing mode more important than the dosing frequency. Conversely, patients with a higher education level (high school or above) placed greater importance on dosing frequency compared to dosing mode (Figure S1 in Multimedia Appendix 1). A similar contrast was observed between urban and rural respondents (Figure S2 in Multimedia Appendix 1). While urban respondents emphasized the dosing frequency over the dosing mode, rural respondents held the opposite view. The comparison of patients undergoing prophylaxis treatment versus those receiving on-demand treatment revealed a common preference pattern; both groups viewed dosing frequency as more important than dosing mode (Figure S3 in Multimedia Appendix 1).

Benefit-Risk Trade-Off

The results pertaining to MAR are depicted in Figure 2. For specified improvements in treatment attributes such as annual bleeding frequency, dosing frequency, and dosing mode, the MAR indicates the highest level of risk related to developing inhibitors that patients would tolerate, thereby hinting at patients’ willingness to accept a trade-off between potential benefits and risks.

Figure 2. Benefit-risk trade-off and maximum acceptable risk. MAR: maximum acceptable risk.



Patients were willing to accept an increase in the risk of developing inhibitors (MAR=4.6% for reducing annual bleeding instances from 12 to 0). They would also tolerate an increased risk of 2.3% for reducing the frequency of bleeding from 12 to 6 times per year. Furthermore, an increased risk of 2% would be acceptable to patients if the dosing frequency was decreased from 3 times a week to once a week, while an increased risk of 1.5% would be acceptable if the dosing frequency was reduced from 3 to 2 times a week. In terms of dosing mode, patients would tolerate a risk increase of 1.7% if the dosing model shifted from intravenous drip to subcutaneous injection and a risk increase of 0.9% if the dosing model was altered from intravenous drip to intravenous push.

Discussion

Overview

This is the first study investigating the preferences of patients with hemophilia A without inhibitors regarding prophylactic treatment by performing a DCE in China. We examined 4 attributes associated with prophylactic treatment, with results indicating patients placed higher value on clinical effectiveness (ie, reduction in annual bleeding times) and side effects (ie, risk of developing inhibitors) compared to aspects of the treatment process (ie, dosing frequency and mode). We also found that patients were willing to accept an increase of 4.6% in the risk of developing inhibitors for the reduction of bleeding from 12 times per year to 0 times per year.

This study showed that patients attach paramount importance to the reduction of annual bleeding times, an outcome consistent with previous investigations [21,25,27]. Our findings suggest that alterations in the mode and frequency of administration exert a relatively minimal influence on patients' preferences. In contrast, a previous study reported dissimilar results by using conjoint analysis to ascertain patient and parental preferences for prophylactic treatment [26]. Their study indicated that the frequency of prophylactic administration was deemed the most crucial attribute, followed by the annual bleeding times. This discrepancy could be attributed to differences in the standard of treatment across various countries. China primarily uses low-dose prophylaxis, which has comparatively less control over bleeding than standard-dose prophylaxis [46]. The aforementioned study, conducted in Australia, Britain, and the United States, demonstrated that reduced instances of breakthrough bleeds during prophylaxis (including 0, 1, 2, and 3 times per year) exerted a lesser influence on patient preferences. Given the current status of prophylactic treatment in China, it is plausible to propose that patients may favor a treatment regimen with enhanced bleeding control, which has implications for the development of personalized prophylactic treatment protocols [47].

Individual-Level Factors

Subgroup analysis revealed that patients with lower education levels prioritized the dosing mode. Patients residing in townships or rural areas also exhibited higher sensitivity toward the dosing mode compared to their urban counterparts. This could be attributed to the barriers they face in the self-administration of prophylactic infusions. Unlike typical oral or inhaled medications, coagulation factors require injection, necessitating specialized self-care skills or medical provider support. Self-injection therapy for patients with hemophilia remains challenging [48], particularly for patients with a lower level of education, who are less likely to master self-injection techniques. Patients in townships or rural areas often have a lower quality of life compared to those in urban areas [49]. Thus, it is essential to focus on self-management treatment services for patients with low education levels and those in rural areas. Such services could include intravenous injection training programs and consultation and guidance services [48].

Benefit-Risk Trade-Off

This study illustrated that patients demonstrated clear awareness of the benefit-risk assessment. The results suggested that patients were willing to accept a substantial risk of developing inhibitors for reducing the annual bleeding times, but were only willing to accept a minor risk alteration when changing drug administration from intravenous drip to intravenous push. The risk of developing inhibitors could be controlled by the treatment strategy [50,51]. Particularly, a heterogeneity analysis revealed that patients undergoing prophylactic treatment were more attuned to the risk of developing inhibitors. We propose that physicians must judiciously balance the trade-offs between bleeding and the risk of developing inhibitors when recommending prophylactic treatment for patients. This is of particular importance when optimal control of bleeding is achieved, as the risks of developing inhibitors may exceed the maximum acceptable range for the patient.

Limitations

This study fills a significant gap in our understanding of treatment preferences for people with hemophilia in mainland China. However, certain limitations persist. There could be potential sampling bias as we did not use random sampling. Nonetheless, to enhance the representativeness of our results, we examined the prophylactic preferences of adult patients with hemophilia A without inhibitors across 7 regions of China, accounting for geographical diversity and varied economic development status. Moreover, DCE, being a hypothetical choice scenario, cannot accurately track actual choice behavior. Therefore, to mitigate the impact of this potential discrepancy, we ensured the attribute levels were scientifically valid and realistic in the preliminary stage, thereby providing respondents with a credible profile for comparison and evaluation.

Conclusions

Our study's findings significantly contribute to understanding the preferences of adult patients with hemophilia A regarding prophylactic treatment. Acknowledging that patients will perceive trade-offs for the 4 attributes differently can enhance the dialogue between patients and clinicians on the risks and benefits of various prophylactic treatment modalities.

Acknowledgments

The authors would like to thank all participants for their contributions to this study. The authors would like to thank all the collaborators who cooperated to recruit patients with hemophilia A and the leaders of the organizations that supported this survey for patients with hemophilia. This work was supported by the National Natural Science Foundation of China (grant 72174110).

Authors' Contributions

SPL, LW, SML, CL, and YF designed the study. LW collected the data. LW, SML, SJ, and LL completed the data analyses and wrote the manuscript. SJ, SML, CL, LL, YF, and SPL edited the manuscript. All authors have read and agreed to the published version of the manuscript.

Abstract

Background: Breast cancer is the most common cancer and the most common cause of cancer death in women. Although survival rates have improved, unmet psychosocial needs remain challenging because the quality of life (QoL) and QoL-related factors change over time. In addition, traditional statistical models have limitations in identifying factors associated with QoL over time, particularly concerning the physical, psychological, economic, spiritual, and social dimensions.

Objective: This study aimed to identify patient-centered factors associated with QoL among patients with breast cancer using a machine learning (ML) algorithm to analyze data collected along different survivorship trajectories.

Methods: The study used 2 data sets. The first data set was the cross-sectional survey data from the Breast Cancer Information Grand Round for Survivorship (BIG-S) study, which recruited consecutive breast cancer survivors who visited the outpatient breast cancer clinic at the Samsung Medical Center in Seoul, Korea, between 2018 and 2019. The second data set was the longitudinal cohort data from the Beauty Education for Distressed Breast Cancer (BEST) cohort study, which was conducted at 2 university-based cancer hospitals in Seoul, Korea, between 2011 and 2016. QoL was measured using European Organization for Research and Treatment of Cancer QoL Questionnaire Core 30 questionnaire. Feature importance was interpreted using Shapley Additive Explanations (SHAP). The final model was selected based on the highest mean area under the receiver operating characteristic curve (AUC). The analyses were performed using the Python 3.7 programming environment (Python Software Foundation).

Results: The study included 6265 breast cancer survivors in the training data set and 432 patients in the validation set. The mean age was 50.6 (SD 8.66) years and 46.8% (n=2004) had stage 1 cancer. In the training data set, 48.3% (n=3026) of survivors had poor QoL. The study developed ML models for QoL prediction based on 6 algorithms. Performance was good for all survival trajectories: overall (AUC 0.823), baseline (AUC 0.835), within 1 year (AUC 0.860), between 2 and 3 years (AUC 0.808), between 3 and 4 years (AUC 0.820), and between 4 and 5 years (AUC 0.826). Emotional and physical functions were the most important features before surgery and within 1 year after surgery, respectively. Fatigue was the most important feature between 1 and 4 years. Despite the survival period, hopefulness was the most influential feature on QoL. External validation of the models showed good performance with AUCs between 0.770 and 0.862.

Conclusions: The study identified important factors associated with QoL among breast cancer survivors across different survival trajectories. Understanding the changing trends of these factors could help to intervene more precisely and timely, and potentially prevent or alleviate QoL-related issues for patients. The good performance of our ML models in both training and external validation sets suggests the potential use of this approach in identifying patient-centered factors and improving survivorship care.

Introduction

Breast cancer is the most common cancer and the most common cause of cancer death in women worldwide [1]. In the past years, breast cancer prognosis has significantly improved over time. Currently, the 5-year survival rates are in the range of 90%, and 10-year survival is about 80%. Given the increase in survival, a survivorship care plan is necessary over time, with particular attention to the quality of life (QoL) [2]. However, for many survivors, cancer survivorship is characterized by uncertainty regarding follow-up care and unmet psychosocial needs [3].

To develop tailored interventions and to provide appropriate survivorship care, it is necessary to find predictors for QoL during different phases of survivorship [4,5]. Although some predictors for QoL have been identified in several studies [6], almost all focused on 1 specific predictor. Fewer models have made individual predictions on QoL due to the complexity of clinical profiles and the inability to consider relevant interactions a priori. In addition, according to a recent cohort study, the QoL and the QoL-related factors change over time [7]. However, it is difficult to generate those models using traditional statistical methods.

To overcome the limitation of traditional models, a few machine learning (ML) models have been proposed in the literature that predict the QoL of breast cancer survivors. However, there were only a few ML models for QoL prediction with limitations [6,8-12]. First, most models did not fully include multidimensional factors. Although some studies included patient-centered factors such as functional impairment and psychological symptoms, they still missed key variables for the QoL of long-term survivors, such as spiritual well-being [13-16]. Second, only a few studies examined the predictors of QoL for long-term survivors. Third, QoL-related factors are known to change over time due to their multilayer and multidimensional characteristics [2], but previous models did not identify predictors as time varying. Fourth, the previous prediction models for QoL were difficult to interpret, and their overall prediction values were limited. Recently, it is possible to develop an ML algorithm that allows for interpretation [17]. Thus, this study aimed to identify patient-centered factors associated with QoL using an ML algorithm to analyze data from a cohort of Korean patients with breast cancer along different survivorship trajectories.

Methods

Study Population and Design

To produce a robust tool to identify factors associated with QoL during different survival phases, 2 different data sets were used. These included (1) the cross-sectional survey data from the Breast Cancer Information Grand Round for Survivorship (BIG-S) study to develop a model and (2) the longitudinal cohort data from the Beauty Education for Distressed Breast Cancer (BEST) cohort study to validate the model.

Development Set

The BIG-S study recruited consecutive breast cancer survivors (BCS) who visited the outpatient breast cancer clinic at the Samsung Medical Center in Seoul, Republic of Korea, between November 2018 and April 2019. The BIG-S study included survivors aged over 20 years and who did not have secondary cancer, metastasis, or recurrence. A total of 6265 survivors agreed to participate in the BIG-S study: before surgery (n=1980) and 1 year (n=653), 2 years (n=1265), 3 years (n=921), 4 years (n=682), and 5 years (n=764) after surgery.

External Validation Set

The BEST study (n=432) was conducted at 2 university-based cancer hospitals in Seoul, Republic of Korea, to evaluate the effect of cancer treatment-induced altered body image and QoL. Subjects were eligible to participate if they were between 18 and 65 years of age, had a diagnosis of breast cancer (ductal carcinoma in situ, stages I-III), had no sign of metastasis, were expected to have breast cancer surgery, and did not receive preoperative chemotherapy or radiation therapy [15]. There were 323 patients before surgery, and 297, 215, 214, and 232 patients who were followed prior to surgery and at 1, 2, 3, and 5 years following surgery, respectively.

Measures

In this study, the target variable was poor QoL, which was measured using a 7-point Likert scale with the European Organization for Research and Treatment of Cancer (EORTC) QoL Questionnaire Core 30 questionnaire. The single item has been validated to measure overall QoL [18].

To determine the factors associated with QoL, information about sociodemographics; diagnosis and treatment; and physical, psychological, social, and spiritual well-being was included based on a literature review (Table S1 in Multimedia Appendix

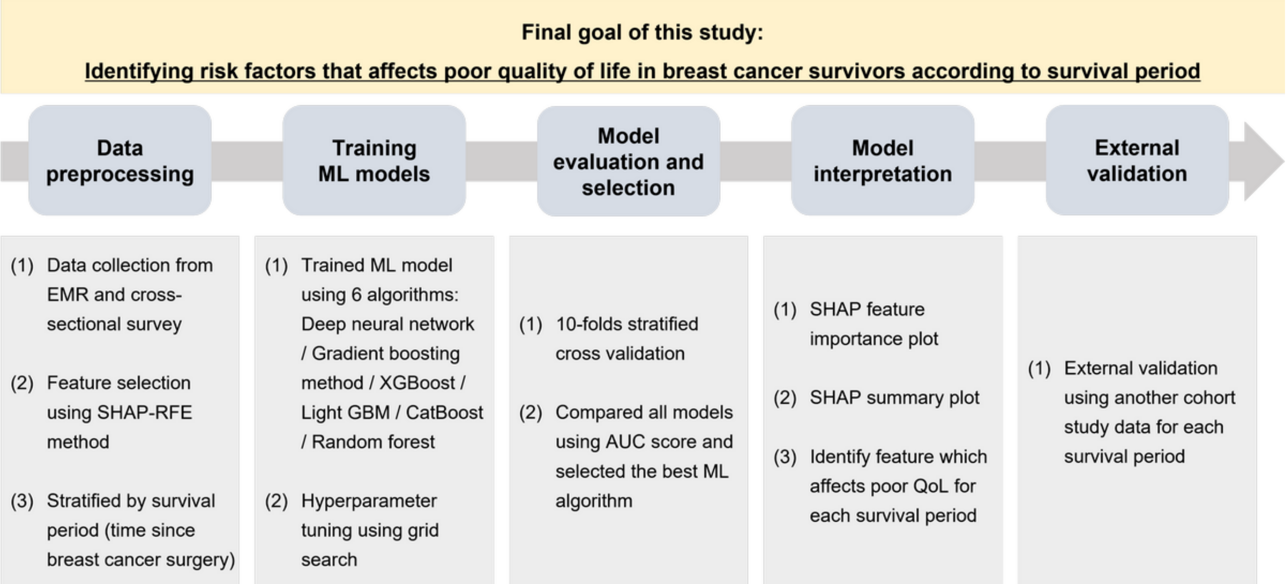
1) [5,15]. Sociodemographic factor data, including education level, marital status, monthly house income, working status during the survey, drinking status, and smoking status, were obtained using a standard questionnaire. Diagnosis and treatment data were obtained from electronic medical records. These data included types of operations, locations of tumors, comorbidities, laboratory test results, pathology stage, and type of treatment (chemotherapy, hormone therapy, target therapy, and radiotherapy).

In patient-reported outcomes, we followed the recommendation from International Consortium for Health Outcomes Measurement. To measure physical, psychological, and social well-being, the EORTC QoL Questionnaire Core 30 and Breast Cancer-Specific Module were used, and related symptoms and functions were evaluated. These included fatigue, pain, nausea and vomiting, emotional function, body image, social function, and role functioning. Spiritual well-being was evaluated using 3 questions from the Spiritual Well-being Domain of the Korean version of QoL of Cancer Survivors questionnaire [19]. In order to measure menopause symptoms, the Menopause Rating Scale (MRS) was used. The MRS included 11 items in 3 dimensions, including somatic-vegetative, psychological, and urogenital. The composite scores (score range 0-44) were based on adding the scores of the items from the respective dimensions.

Statistical Analysis

This study was conducted in five steps: (1) data preprocessing, (2) training ML models, (3) model evaluation and selection, (4) model interpretation, and (5) external validation (Figure 1). The target variable of "poor QoL" was defined as a score lower than 66 on the global health status scale (range 0-100). Factors associated with QoL were selected from the BIG-S data set. Since some of the treatment-related variables were not in the data collected prior to surgery, 37 and 45 features were selected for data preprocessing from variables collected before surgery and after surgery, respectively. In all algorithms, missing values were forward filled with the closest observation. If no past value was present, the training set mean was imputed by matching the participants' ages and pathology stages.

Figure 1. Workflow of machine learning. AUC: area under the curve; EMR: electronic media record; ML: machine learning; QoL: quality of life; SHAP: Shapley Additive Explanations; SHAP-RFE: shapley additive explanations-recursive feature elimination.



To train the ML models, the feature selection method and the recursive feature elimination method based on the Shapley Additive Explanation (SHAP) method were used to reduce the model complexity and to remove unnecessary features that generate noise in the prediction model. The SHAP method is one of the explainable artificial intelligence methods [20]. Through the Shapley values obtained using the SHAP method, how much a variable affects the outcome prediction and how the variable affects the outcome in each instance can be observed. For model evaluation and selection, we compared the performance of 6 different algorithms, including the deep neural network, gradient boosting machine, XGBoost, light gradient boosting machine, CatBoost, and random forest. For training the models, the grid search method was used for hyperparameter tuning. Hyperparameters are parameters that directly affect the learning process of the model and are determined by the user to improve model performance and avoid overfitting. After specifying the possible value range of hyperparameters for each model (Table S2 in Multimedia Appendix 1), models were trained using all possible combinations of hyperparameters, and then the optimal combinations were selected.

To validate and evaluate the model, 10-fold stratified cross-validation was used. The entire training data set was divided into 10-fold equal size subsamples by stratifying for the outcome variables. A single subsample was retained as the validation data for testing the model, and the remaining 9 subsamples were used as training data and the process was repeated 10 times. Using the 10 cross-validation results, the area under the receiver operating characteristic curve (AUC) scores were averaged for each model, and the final model with the highest mean AUC was selected. In this study, we also used SHAP values to interpret feature contributions and assess the clinical significance of predictive models. According to a previous study, the SHAP value is the measurement of the marginal contribution of each feature in different combinations.

The SHAP value of a feature can be interpreted as the difference between the model's predicted value when that feature is included versus when it is excluded, taking into account all possible combinations of other features. The base value, on the other hand, is the average predicted value of the model for all samples. When the SHAP value of a feature is positive, it means that including that feature has a positive effect on the predicted value, while a negative SHAP value indicates a negative effect. Overall, SHAP values help to explain how each feature contributes to the model's predictions, providing insight into the model's decision-making process [21,22].

Finally, external validation was confirmed using the BEST cohort data set, which was a completely different data set from that used for model training. The poor QoL group was predicted by inputting the external validation data set into the final model that trained the entire training data set using the ML algorithm selected by the survival period. It is notable that between the 3- and 4-year models, there was no validation data set because there was no participant follow-up within the BEST cohort for these time periods. The validation performances were also evaluated using AUC, accuracy, F1 score, sensitivity, and specificity, and were also compared with training performance.

All analyses were performed in the Python 3.7 programming environment (Python Software Foundation) and used the scikit-learn package and TensorFlow Keras framework.

Ethics Approval

The study was approved by the institutional review board of the Samsung Medical Center, Seoul, Republic of Korea, in the development set (SMC-2018-08-070) and external validation set (SMC-2011-07-019). Informed consent was obtained from all study participants.

Results

Characteristics of Participants

All 6265 participants were included in the full analysis data set. The mean age of the study participants was 50.6 (SD 8.66) years and 46.8% (n=2004) of participants were stage 1. In the training data set, 48.3% (n=3026) of the participants were classified into the poor QoL group (Table 1). The proportion of patients with breast cancer with poor QoL was 67.4% (n=1335) at diagnosis, and 41.8% (n=273), 39.3% (n=497), 40.1% (n=369), 36.1% (n=246), and 40.1% (n=306) patients had poor QoL at 1, 2, 3, 4, and 5 years after surgery, respectively (Table 1).

[a] Not available.

In the validation set, the mean age was 46.5 (SD 7.87) years, and 47.1% (n=428) of the participants were stage 1 (Table S3 in Multimedia Appendix 1). Compared to the training set, patients in the external validation set were relatively younger. Among these participants, 48.6% (n=573) were classified as having poor QoL. Patients with poor QoL prior to surgery and 1, 2, 3, and 5 years after surgery made up 70.4% (n=100), 53.2% (n=255), 49.4% (n=79), 48.5% (n=95), and 33.8% (n=72) of the groups, respectively (Table S4 in Multimedia Appendix 1).

Performances of Machine Learning Models for Each Survival Period

The available features in the training data set were used to build QoL prediction models based on 6 ML algorithms (Table S4 in Multimedia Appendix 1). From the whole data set, between 9 and 16 features were selected using the SHAP-RFE method. The AUC values of 6 ML algorithms were all over 0.75. Among 6 ML algorithms associated with the survival periods, all the final models were over 0.8 (Table S5 in Multimedia Appendix 1). The best predictive performances were observed using the CatBoost algorithm for all survival periods: overall (AUC 0.823), baseline (AUC 0.835), within 1 year (AUC 0.860), between 2 and 3 years (AUC 0.808), between 3 and 4 years (AUC 0.820), and between 4 and 5 years (AUC 0.826) (Table 2). All 5 model evaluation metric averages calculated through 10-fold stratified cross-validation for each survival period were higher than 0.7 and the AUC exceeded 0.8 (0.804-0.860), showing that the ML models performed well.

Table 2. Performance metrics by survival period.

Survival period	Overall[a]	Baseline[a]	Within 1 years[a]	Between 1 and 2 years[b]	Between 2 and 3 years[a]	Between 3 and 4 years[a]	Between 4 and 5 years[a]
AUC[c]	0.823	0.835	0.860	0.804	0.808	0.820	0.826
Accuracy	0.756	0.774	0.818	0.765	0.767	0.783	0.793
F1 score	0.707	0.817	0.782	0.705	0.709	0.723	0.752

Important Features for Each Survival Period

The most important prognostic features for each survival period were identified using the feature importance from the SHAP method (Figure 2).

Regardless of survival period, hopefulness (SHAP value 0.2005) was the most important feature, and fatigue, side effects, physical function, emotional function, and role function were also important features. By the survival period, menopause symptoms (SHAP value 0.2137) and emotional function (SHAP value 0.1715) were the most important features prior to breast cancer surgery (Table S6 in Multimedia Appendix 1). For the within 1-year period, physical function (SHAP value 0.3177) was the most important feature, followed by emotional function, side effects, hopefulness, and body image. For the periods between 1-2, 2-3, and 3-4 years, fatigue (SHAP values 0.2172, 0.1819, and 0.1503, respectively) was the most important feature, followed by menopause symptoms, social function, and emotional function. For the period between 4 and 5 years, hopefulness (SHAP value 0.2370) was the most important feature, followed by physical function, dyspnea, financial difficulties, monthly income, menopause symptoms, side effects, and emotional function (Figure 3).

External Validation

All 5 model evaluation metric averages calculated in the external validation set were higher than 0.7 (Table 3).

For external validation, the receiver operating characteristic curves for each survival period were used to calculate the AUC.

When the final trained models for each survival period were externally validated using the BEST data set, the validation AUC was between 0.770 and 0.862, and the differences from the results of the 10-fold stratified cross-validation for training were from 0.009 to 0.056 (Figure 4).

Table 3. Performance metrics for external validation for survival period.

Survival period	Overall[a]	Baseline[a]	Within 1 years[a]	Between 1 and 2 years[b]	Between 2 and 3 years[a]	Between 4 and 5 years[a]
AUC[c]	0.800	0.799	0.778	0.816	0.863	0.779

Discussion

Principal Findings

In this study, we developed and validated factors associated with QoL including physical, psychological, economic, spiritual, and social dimensions by survivorship trajectory using an ML algorithm. The developed model and external validation model performance were good for all survival trajectories. Before surgery, menopause symptoms and emotional function were important features. Within 1 year after the surgery period, physical function was the most important feature. Between 1 and 4 years, fatigue was the most important feature. Regardless of the survival period, hopefulness was the most influential feature of spiritual well-being.

In this study, the AUC for evaluating model performances surpassed 0.8 for all survival periods, and the results of external validation using data collected in other studies were also greater than 0.77. This performance is much better than that of previous studies that predicted QoL using ML modeling, which reported values ranging from 0.476 to 0.793 [6,9-12]. These ML-based breast cancer QoL prediction models were developed with not only clinical and sociodemographic factors but also with the integration of information from multiple factors, thus ensuring better model performance. Furthermore, this study stratified the model by time periods following surgery and found that there were different factors associated with QoL during each time period.

Prior to breast cancer surgery, menopause symptoms and emotional function were selected as important features that affect QoL in BCS. Among menopause symptoms, the most important factor was in the psychological domain, which included depressive mood, irritability, and anxiety. According to a previous study, depression and anxiety are the 2 most common psychiatric comorbidities encountered in patients with breast cancer [6,7]. Patients with breast cancer may experience depression or anxiety at any stage of their illness, from prediagnosis to the terminal phase of the illness. Studies in Western countries have shown that the prevalence of depression ranges from 1% to 56%, whereas the prevalence of depression found in Asian studies was between 12.5% and 31% [23]. Thus, timely psychosocial care should be needed for newly diagnosed distressed patients with cancer.

In this study, physical function was the most important feature that affected QoL in the group that was within 1 year after breast cancer surgery. This result was consistent with previous reports that BCS are susceptible to physical functioning–related problems and often experience treatment-related declines in their physical functioning capabilities within the 1-year period following their cancer diagnosis [24]. Treatment-related systemic side effects that occur after completion of treatment affect physical function, and poor physical function negatively affects the QoL of BCS [25]. Furthermore, physical functioning–related problems may persist even after treatment has been completed [26]. Persistent physical symptoms can increase fatigue and hinder patients' return to normal life, thereby reducing their QoL. Future research should focus on the development and testing of interventions for managing physical function in order to improve the QoL of patients with breast cancer.

Between 1 and 4 years after breast cancer surgery, fatigue is the most important feature that affects QoL in BCS. Cancer-related fatigue is one of the most distressing and common posttreatment sequelae among survivors of early-stage breast cancer [27]. More than 30% of patients with breast cancer experience persistent fatigue symptomatology up to 10 years after completion of treatment [28]. Cancer-related fatigue can result in substantial adverse physical, psychosocial, and socioeconomic consequences and has a negative impact on overall QoL. For BCS 1 year after diagnosis, reducing the burden of fatigue might be a preferable approach to improve their QoL and focusing on fatigue symptoms can help to enhance the long-term survivors' QoL [29]. Cancer-related fatigue is considered a complex symptom, with multidimensional and intricate aspects. The existence of physical, psychological, and emotional disturbance has been proven [30], and numerous evidence-based interventions for the management of fatigue have been recommended [31], most of them being complex nonpharmacological interventions. In order to address all dimensions of fatigue, nonpharmacological interventions should be tested and assessed.

Hopefulness was the most important feature in all survival period models, especially, between 4 and 5 years. Spiritual well-being was a predictor of improved QoL and is one of the important outcomes to measure in BCS [32]. Previous studies have indicated that survivors who had more hope in their lives were more likely to have better QoL [33]. Hope could help patients find a sense of health in the midst of disease to cope with various cancer symptoms and fear of recurrence and to find meaning and peace of mind [34]. These positive effects of hope might also improve QoL in BCS. Therefore, patient-centered interventions that help survivors find purpose in life by focusing on themes such as planning for life after cancer and value-based sources of meaning to have hope should be provided.

In this study, we performed an external validation to test the generalizability of our models, which is a strength compared to the previous study that did not perform external validation [6,9-12]. This aspect is important as it demonstrates the effectiveness of our models and their potential to be applied to other settings. Through external validation, we could assess our models' robustness and confirm their ability to provide accurate predictions in new and independent data sets. This enhances the reliability and use of our models, and highlights the potential of ML approaches in improving survivorship care for patients with breast cancer.

This study has several limitations. First, it is a cross-sectional study, and the directions of the associations between QoL; symptoms; and physical, psychosocial, and spiritual functions could be interchangeable. In fact, patients who had a poor QoL might report poorer function status. Second, QoL was measured using a single item from the EORTC-C30, and this might not be a reliable method to measure an individual's QoL. However, this single question has been validated to measure a person's overall QoL, and it has been widely used in different cultures and countries, including Korea. Lastly, the results of our study might not be generalizable to other cancer survivors in other settings. Further studies with various types of cancer survivors are necessary to confirm the study findings and its generalizability.

Despite these limitations, this study had several strengths. First, we included physical, psychological, economic, spiritual, and social dimensions and clinical factors. Second, we developed a prediction model to predict QoL from pretreatment to 5 years after surgery. Third, we developed different ML-based QoL surveillance models across survivorship. Fourth, we used SHAP methods, which allow for the interpretation of the model by the reader. Fifth, we performed external validation and the models showed good performance.

Conclusions

The results of this study may provide valuable information on developing a patient-centered survival care plan. Understanding the changing trends of influencing factors associated with QoL during different survival trajectories could help health care professionals intervene timely and appropriately in order to prevent or alleviate factors more precisely.

Abstract

Background: The recent pandemic had the potential to worsen the opioid crisis through multiple effects on patients' lives, such as the disruption of care. In particular, good levels of adherence with respect to medication for opioid use disorder (MOUD), recognized as being important for positive outcomes, may be disrupted.

Objective: This study aimed to investigate whether patients on MOUD experienced a drop in medication adherence during the recent COVID-19 pandemic.

Methods: This retrospective cohort study used Medicaid claims data from 6 US states from 2018 until the start of 2021. We compared medication adherence for people on MOUD before and after the beginning of the COVID-19 pandemic in March 2020. Our main measure was the proportion of days covered (PDC), a score that measures patients' adherence to their MOUD. We carried out a breakpoint analysis on PDC, followed by a patient-level beta regression analysis with PDC as the dependent variable while controlling for a set of covariates.

Results: A total of 79,991 PDC scores were calculated for 37,604 patients (age: mean 37.6, SD 9.8 years; sex: n=17,825, 47.4% female) between 2018 and 2021. The coefficient for the effect of COVID-19 on PDC score was –0.076 and was statistically significant (odds ratio 0.925, 95% CI 0.90-0.94).

Conclusions: The COVID-19 pandemic was negatively associated with patients' adherence to their medication, which had declined since the beginning of the pandemic.

Introduction

The opioid crisis is an ongoing problem in the United States. Recent reports and studies have shown an increase in the number of overdoses in 2020, suggesting an association between the COVID-19 pandemic and the worsening of the opioid crisis [1-3]. Disruptions in medical services and care due to lockdowns, stay-at-home orders [4], and the scarcity of health care services might be some of the factors involved in this association. Patient adherence to medications is an important factor in the success of medication for opioid use disorder (MOUD), and higher adherence is associated with a reduction in mortality rate [5]. Pharmacists, health care experts, and public and private health technology companies have expressed their concerns about medication adherence amid the pandemic, both in the United States [6,7] and internationally [8-11]. Increases in emergency medical services responses, including the administration of naloxone [12], suggest that these concerns are well founded.

A recent study [13] examined the changes in the prescribing of opioid analgesics and buprenorphine for opioid use disorder (OUD) throughout the COVID-19 pandemic. By looking at aggregate prescription levels, it found that existing patients who receive opioid analgesics and buprenorphine for OUD generally maintained access to these medications during the COVID-19 pandemic, whereas the initiation of buprenorphine remained at a low rate through August 2020. Another study investigating patients' access to chronic medications during the COVID-19 pandemic used a dichotomous measurement for patients' adherence; it found that since the beginning of the pandemic, patients were less likely to discontinue OUD therapy (buprenorphine or naloxone) [14]. However, both aggregate analyses and studies similar to Clement et al [14] that use dichotomous variables can conceal more fine-grained, individual-level changes.

In this study, we examined the trend of medication adherence for US Medicaid patients with an OUD diagnosis from 6 US states who were on opioid medications from January 2018 to March 2021. We calculated the proportion of days covered (PDC) as a method of measuring medication adherence for each patient in the 3 months following the first visit for an opioid-related disorder or opioid dependence indication, according to International Classification of Diseases, 10th revision (ICD-10) codes, and calculated the average monthly PDC score in each month. Then, we examined the adherence trend across time and investigated the association between the pandemic and PDC score, as well as the association between the pandemic and opioid overdose in a 3-month time window.

Methods

Overview

We analyzed US Medicaid claims data for 6 US states. The data set is provided by HMS (a Gainwell Technologies company) through the Digital Health Cooperative Research Centre and comprises Medicaid claims (inpatient, outpatient, dental, and pharmaceutical), a few demographic characteristics of the patients (age, sex, zip code, and Medicaid enrollment periods), and their unique identifiers. The data set links their claims across time, different settings of care, and multiple episodes of enrollment. Diagnosis codes associated with the patient, procedures codes, prescription date, dosage, duration, and other prescription details are among the information available in the data set. The data set covers claims from 2015 to 2021 and comprises over 1.16 billion claims for over 14.2 million unique individuals.

We used a continuous measurement of adherence called PDC as a proxy for medication adherence. We defined PDC as the ratio of the number of days a patient could have their opioid treatment medication to the number of days in the period of interest.

We created a subset of patients with at least one relevant F11 diagnosis ICD-10 code (codes F11.1 opioid abuse; F11.2 opioid dependence; and F11.9 opioid use, unspecified), who have filled their opioid treatment prescriptions in the 3-month window following the first visit with an F11 diagnosis code. We excluded the patients whose first F11 visit happened before 2018. For each patient with at least three months of opioid treatment medication, we calculated and assigned 3 monthly PDC scores for each month following their medical visit. To investigate the association between the COVID-19 pandemic and medication adherence, we took 2 separate approaches.

First, in an exploratory analysis, we plotted the average PDC score for all patients in each month to visualize any changes in the trend of the average PDC score since the beginning of the pandemic. To detect whether such changes exist and to avoid subjective judgements, we used an algorithm described by Bai and Perron [15] for simultaneous estimation of multiple breakpoints implemented in the *strucchange* R package [16]. To define how many breakpoints should be considered, we calculated the Bayesian information criterion (BIC) estimates for different numbers of breakpoints and chose the number that minimizes the BIC. The algorithm detects the time(s) where possible breakpoints occurred and the CIs for the detected times.

In the second approach, we applied a patient-level beta regression model to examine the effect of the COVID-19 pandemic (modelled as a binary variable with a value equal to 1 for months after March 2020) on the PDC score. We controlled for a set of other covariates, including the age, sex, state, and comorbidities of each patient. To reduce the dimensionality of comorbidities, we categorized diagnosis codes into Elixhauser general comorbidity categories [17] according to the Agency for Health Research Quality rules using the *icd* R package by Wasey and Lang [18]. The Elixhauser categories condense many dozens of ICD-10 (and other) administrative codes into 30 broader groupings (as termed by Elixhauser et al [17]), such as "Alcohol abuse" (ICD-10 codes F10, E52, etc) or "Drug abuse" (ICD-10 codes F11.x-F16.x, etc). In a separate model, we repeated the analysis with data inclusive of the patients with only 1 or 2 months of PDC scores to see the sensitivity of the model.

Ethical Considerations

The data were provided in deidentified form by HMS. On this basis, an ethical review by Macquarie University deemed it as having negligible risk, in line with Australia's National Statement on Ethical Conduct in Human Research 2007 (as updated in 2018).

Results

We calculated a total of 79,991 PDC scores for 37,604 patients in our subset OUD sample (age: mean 37.6, SD 9.8 years; sex: n=17,825, 47.4% female) between 2018 and 2021 from Medicaid claims data of 6 US states. Overall, 7816 patients who did not have a PDC score in the month following their F11 diagnosis or had a month without a PDC score between their first and second scores were excluded from the analysis. From the remaining patients, the most common treatment approach involved buprenorphine prescription (24,731/29,788, 83.02%), followed by prescriptions for naltrexone alone (3707/29,788, 12.44%); only small proportions were prescribed buprenorphine and naltrexone together (778/,29,788, 2.61%) or methadone (572/29,788, 1.92%). In terms of prescription filling patterns, only 24.9% (7417/29,788) filled their MOUD prescriptions in the month following their F11 diagnosis (mean PDC score 79.6), another 24.9% (7417/29,788) filled 2 months of MOUD prescriptions (mean PDC score 91.7), and 50.2% (14,954/29,788) filled 3 or more months of MOUD prescriptions (mean PDC score 96.1). To understand whether any drop in adherence as measured by PDC was related to patients discontinuing versus continuing OUD therapy, we separated out patients based on how many months were covered. As Figure 1 shows, the PDC score was lower for patients with fewer covered months. To focus on the change during the COVID-19 period for patients that were more adherent to their medication, for the main part of the analysis, we excluded the patients with less than 3 months of PDC scores.

Figure 2 shows the result of applying the breakpoint detection algorithm on the time series of the PDC scores for the selected patients. The shaded area denotes the time after the pandemic was announced (March 2020). The dash line represents the detected breakpoint by the algorithm in July 2020, and the red line represents the CI from April to August.

The results of the beta regression analysis with a logit link for features with statistically significant coefficients are reported in Table 1. The dependent variable is the calculated PDC score between 0 and 1 for each patient in each month. The independent variable of interest, named "COVID," is a binary variable that is 0 for PDC scores at months before March 2020 and 1 for PDC scores from March 2020 onward. The control variables in the model included age group, sex, the month from which the PDC is calculated (PDC first month, PDC second month, and PDC third month), state identifiers, and Elixhauser comorbidity groups calculated based on the clinical history of each patient. Although the independent variables in the model did not explain much of the variance of the PDC score (R^2 the model is 0.055), the coefficient for the effect of "COVID" was –0.76 and was statistically significant (odds ratio 0.925, 95% CI 0.90-0.94). This result is in line with findings of the exploratory analysis and breakpoint detection. The model inclusive of the patients with only 1 or 2 PDC scores showed similar results. The results showed that male patients had lower PDC scores (OR 0.97, 95% CI 0.96-0.99), whereas patients in all age groups older than the reference category (aged 17-29 years) had higher PDC scores. A history of obesity and alcohol use disorder were positively associated with the PDC score.

Figure 1. Average proportion of days covered (PDC) over time, a comparison of patients with 1, 2, and 3 months of PDC scores.

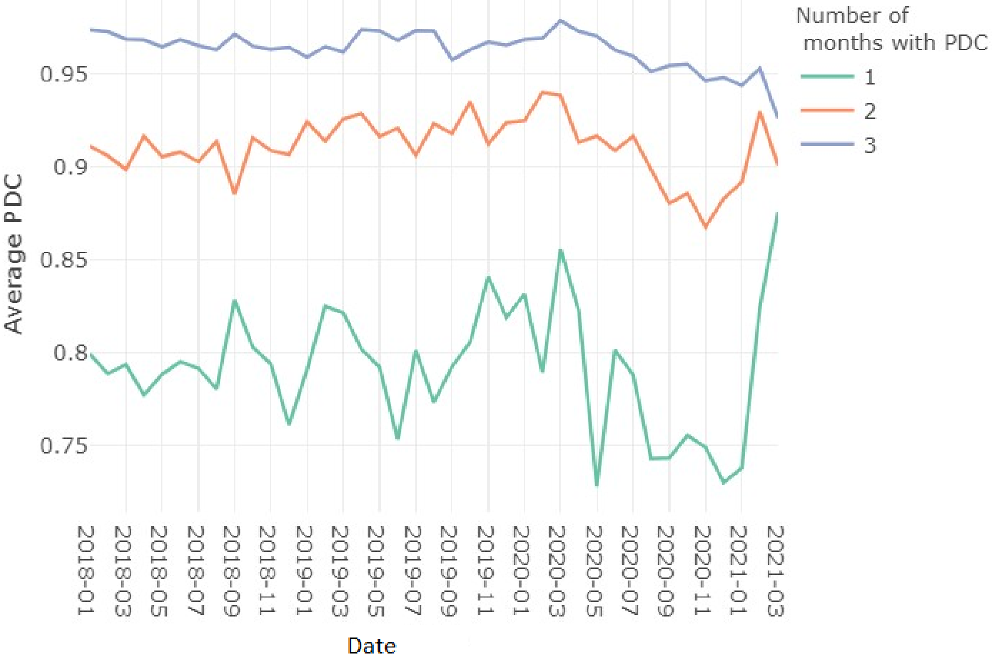

Figure 2. Detected breakpoints for patients with 3 months of proportion of days covered (PDC) scores.

Discussion

Our retrospective cohort study showed a change in adherence to MOUD during the COVID-19 pandemic; this change in adherence did not show up in previous aggregate and dichotomous-variable studies [13,14]. The results showed that patients' adherence to their medication dropped between April and August 2020 and remained low until the end of 2020. Our breakdown of patients by the number of covered months showed that this was true even for patients who had relatively good levels of adherence. (As a rule of thumb, a PDC score of 0.8

has been considered as being adherent, and Warren et al [19] supported this empirically.) This association of a drop in adherence and the COVID-19 period holds when taking into account other factors that also showed a strong association. In particular, state is a significant factor, which is likely to represent a range of factors (urban or rural distribution of population, education, etc). Although these data were not available at an individual level, a machine learning–based study of adherence to MOUD found that demographic proxy data did improve models [19]; that study nevertheless still found a state effect (across the 2 states studied) even after including these data. However, differences in response to COVID-19 could also be a factor. Other factors found to be significant here—sex, age group, etc—are also broadly in line with Warren et al [19].

These results that establish an association between a drop in adherence and the COVID-19 period do not tell us the cause of the drop in adherence, such as patients ceasing to go out to get or fill medication, patients tapering themselves, or some other cause. A small-scale study (429 patients) of opioid agonist treatment use during COVID-19 in Sydney, Australia [20], found that few patients disengaged from treatment, although the social restrictions there differed from the US cohort in this study, as did the distribution of medications (66% methadone in the Australian study). Given the importance of adherence to positive treatment outcomes for opioid addiction, interventions may be warranted. These could range from simple interventions, such as sending reminders and follow-up messages, to more complex ones, such as increased frequency of scheduled follow-up visits with treatment providers and, in some instances, case management. In the context of pandemic restrictions, telehealth offers some possibilities for interventions; the Sydney study [20] found it generally adequate for most clinical reviews, and a more recent study of telemedicine in a US OUD context [21] found that for a range of indicators, telemedicine constituted a comparable alternative to in-person OUD care.

Acknowledgments

We would like to thank the Digital Health Cooperative Research Centre (DHCRC) for access to the data set and Donna Price for support in making use of it. The content is solely the responsibility of the authors and does not necessarily represent the official views of the DHCRC. We would also like to thank the anonymous reviewers for very helpful suggestions.

Data Availability

Data cannot be shared publicly because the authors are not the owners of the data. Data are available from the Digital Health Cooperative Research Centre for researchers who meet the criteria for access to confidential data; access will be the same as that for the authors of this paper. Information about the process, along with a form to apply for data use and data usage agreements, are available on the web [22].

Abstract

Background: Carotid plaque can progress into stroke, myocardial infarction, etc, which are major global causes of death. Evidence shows a significant increase in carotid plaque incidence among patients with fatty liver disease. However, unlike the high detection rate of fatty liver disease, screening for carotid plaque in the asymptomatic population is not yet prevalent due to cost-effectiveness reasons, resulting in a large number of patients with undetected carotid plaques, especially among those with fatty liver disease.

Objective: This study aimed to combine the advantages of machine learning (ML) and logistic regression to develop a straightforward prediction model among the population with fatty liver disease to identify individuals at risk of carotid plaque.

Methods: Our study included 5,420,640 participants with fatty liver from Meinian Health Care Center. We used random forest, elastic net (EN), and extreme gradient boosting ML algorithms to select important features from potential predictors. Features acknowledged by all 3 models were enrolled in logistic regression analysis to develop a carotid plaque prediction model. Model performance was evaluated based on the area under the receiver operating characteristic curve, calibration curve, Brier score, and decision curve analysis both in a randomly split internal validation data set, and an external validation data set comprising 32,682 participants from MJ Health Check-up Center. Risk cutoff points for carotid plaque were determined based on the Youden index, predicted probability distribution, and prevalence rate of the internal validation data set to classify participants into high-, intermediate-, and low-risk groups. This risk classification was further validated in the external validation data set.

Results: Among the participants, 26.23% (1,421,970/5,420,640) were diagnosed with carotid plaque in the development data set, and 21.64% (7074/32,682) were diagnosed in the external validation data set. A total of 6 features, including age, systolic blood pressure, low-density lipoprotein cholesterol (LDL-C), total cholesterol, fasting blood glucose, and hepatic steatosis index (HSI) were collectively selected by all 3 ML models out of 27 predictors. After eliminating the issue of collinearity between features, the logistic regression model established with the 5 independent predictors reached an area under the curve of 0.831 in the internal validation data set and 0.801 in the external validation data set, and showed good calibration capability graphically. Its predictive performance was comprehensively competitive compared with the single use of either logistic regression or ML algorithms. Optimal predicted probability cutoff points of 25% and 65% were determined for classifying individuals into low-, intermediate-, and high-risk categories for carotid plaque.

Conclusions: The combination of ML and logistic regression yielded a practical carotid plaque prediction model, and was of great public health implications in the early identification and risk assessment of carotid plaque among individuals with fatty liver.

KEYWORDS

machine learning; carotid plaque; health check-up; prediction; fatty liver; risk assessment; risk stratification; cardiovascular; logistic regression

Introduction

Carotid plaque is an independent risk factor for cerebral stroke [1], myocardial infarction [2], and atherosclerotic cardiovascular disease [2], which are all leading causes of death and disability worldwide [3,4], presenting severe economic burden in both developed and developing countries [5]. Nearly 20% of stroke cases were caused by carotid atherosclerotic plaque [6]. The rupture or shedding of carotid plaque can lead to thrombosis and has become the major cause of cerebrovascular accidents [3,7]. It has been proposed that nearly one-third of Chinese adults were experiencing from carotid plaque [8]. With the growing aging population and the acceleration in urbanization, the incidence rates of cardiovascular disease in China would increase steadily in the next few decades [9]. Thus, early detection of carotid plaque can bring great benefits in the timely and active prevention of stroke and other cerebrovascular and cardiovascular diseases. It is necessary to develop effective tools to identify carotid plaque in the asymptomatic population and curb its progression at an early stage.

Recently, several studies have demonstrated significant associations exist between fatty liver disease and coronary artery disease, including carotid plaque and carotid stenosis [10-12]. Individuals with fatty liver disease were proved to have an elevated risk of developing carotid plaque. However, although liver ultrasound has been incorporated into the routine check-up program, carotid artery ultrasound examination is not prevalent due to cost-effectiveness reasons for the asymptomatic population [13]. As the most widely used method for evaluating carotid plaque [14], the low prevalence of carotid ultrasound may result in missed detection of such plaque populations, especially in individuals with fatty liver. Thus, identifying carotid plaque patients in the population with fatty liver is more cost-effective and is of great public health implications for the prevention of cardiovascular disease.

Wu et al [13] developed a carotid plaque risk prediction tool among asymptomatic population based on machine learning (ML) algorithms, including extreme gradient boosting (XGBoost), gradient boosting decision tree, random forest (RF), and support vector machine, and achieved good performance, but the substantial complexity of the model may limit its practical use, while the commonly used risk prediction tools in the cardiovascular field, including Framingham risk score [15] and its modified model [16], were mostly based on traditional statistical models, including logistic regression and cox proportional-hazards regression. Although numerous studies have demonstrated that ML algorithms outperformed traditional statistical models in predictive performance throughout medical fields [17-19] due to their capability to analyze and learn the complex interactions and nonlinear associations among variables [17,20,21], the latter still own irreplaceable strengths, including their natural transparency, interpretability, and robustness, which boost their practicality in clinical research [22]. Therefore, using ML algorithms alone or traditional regression methods alone to train prediction models usually results in either accurate but complicated black boxes or practical but unsatisfactory-performed scoring systems.

In this study, we combined ML, including RF, XGBoost, and elastic net (EN) with logistic regression together to develop a straightforward and practical risk prediction model to help better identify individuals at risk of carotid plaque in the population with fatty liver disease. We also provided robust cutoff points for carotid plaque risk stratification and verified the results on an external data set.

Methods

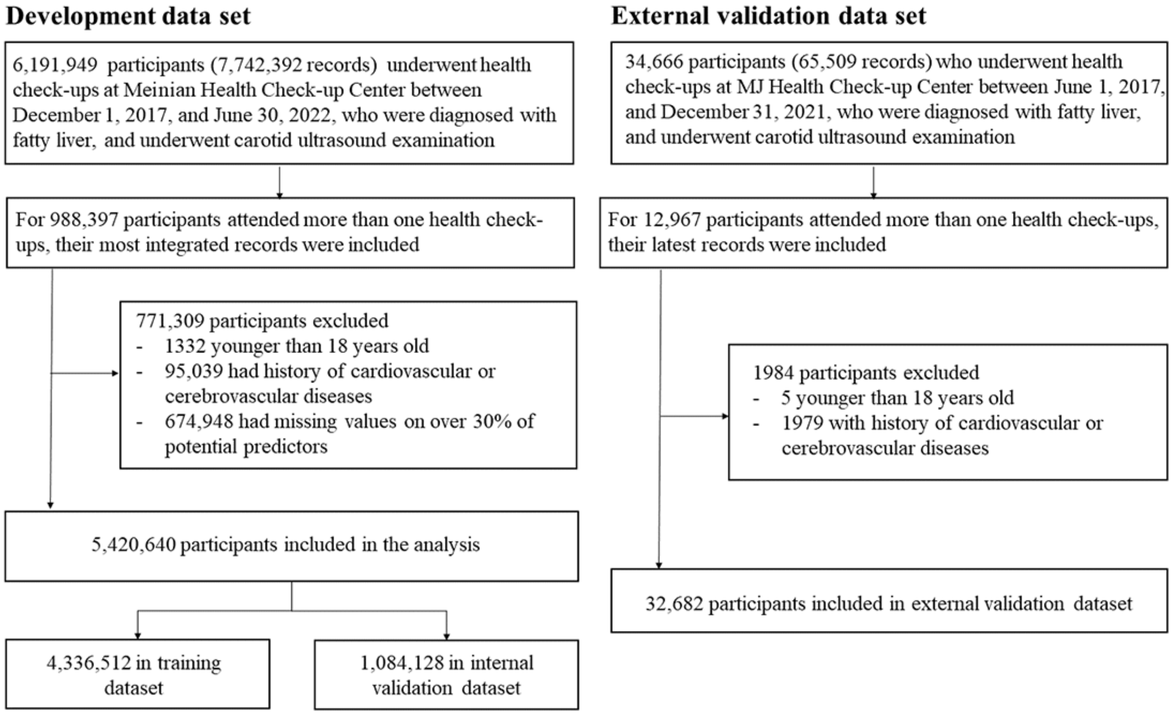
Data Source and Study Participants

Participants who attended health check-ups at Meinian Health Check-up Center and MJ Health Check-up Center were involved in this study for model development and external validation, respectively.

Development Data Set

Meinian Health Check-up Program is the largest check-up chain in China. It provides routine health check-up services for the whole population, with its check-up centers covering all 31 provinces in mainland China. Initially, participants diagnosed with fatty liver through hepatic ultrasonography and received carotid artery ultrasound examination between January 1, 2017, and June 30, 2022, were included. For those who attended 2 or more check-ups, the most integrated record was included in the analysis. Participants younger than 18 years, had missing values on over 30% of potential predictors, or had a history of cardiovascular or cerebrovascular diseases were excluded from the analysis. Finally, a total of 5,420,640 participants were included in the study for model development (Figure 1).

Figure 1. Flowchart of the study participants.



External Validation Data Set

MJ Health Check-up Center is a clinic in Beijing, China, it provides comprehensive health check-ups for the participants. Participants who underwent check-ups between June 1, 2017, and December 31, 2021, were diagnosed with fatty liver, and underwent carotid ultrasound examination were included. After excluding those younger than 18 years, or who had a history of cardiovascular or cerebrovascular diseases, 32,682 participants were included (Figure 1).

Ethical Considerations

The study was reviewed and approved by the institutional review board of Peking University Health Science Center (approval ID: IRB00001052-19077). The requirement for informed consent of participants was waived due to the use of deidentified data obtained as part of routine health check-ups.

Potential Predictors and Outcomes

All potential factors associated with carotid plaque reported by recent studies were considered. Considering the accessibility of the variables in the database, a total of 27 potential factors were extracted: (1) demographic characteristics: sex and age; (2) physical examination indicators: weight, height, BMI, systolic blood pressure (SBP), diastolic blood pressure, and heart rate; (3) laboratory examination indicators: total cholesterol (TC), triglyceride, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol (LDL-C), fasting blood glucose (FBG), alanine transaminase (ALT), aspartate aminotransferase (AST), ALT/AST, direct bilirubin, total bilirubin, alkaline phosphatase (ALP), uric acid, blood platelet count (PLT), white blood cell count, creatinine, and hepatic steatosis index (HSI, which was calculated as follows: HSI=8×(ALT/AST)+BMI+2 (if diabetes mellitus)+2 (if female) [12]); and (4) medical history: hypertension, diabetes, and hyperlipidemia.

The outcome was defined as whether the participant was diagnosed with carotid plaque by carotid artery ultrasound examination. Specifically, the common carotid arteries, the bifurcation, and the external and internal carotid arteries were examined on each side by experienced sonographers operating a Doppler ultrasound system (Sonoscape S50, China) with a linear 7.5 MHz probe under standardized protocols. The distance between the leading edge of the lumen-intima echo and the leading edge of the media-adventitia echo was defined as carotid intima-media thickness. Carotid plaque was accounted as a discrete, focal wall thickening ≥1.5 mm or focal thickening >50% greater than the surrounding carotid intima-media thickness in any of the arterial segments above [23].

Data Preprocessing and Statistical Analysis

The development data set was randomly divided into a training set (4,336,512/5,420,640, 80%) and an internal validation set (1,084,128/5,420,640, 20%). The training set was used for feature selection and model development, while the internal validation data set, together with the external validation data set, were used for model evaluation.

In the training set, missing data were imputed with the mean of each variable. And the imputed values derived from the training set were further used for missingness imputation in internal and external validation data sets. Outliers in the training set were defined as values distributed less than 1% or more than 99% quantile of the whole participants, and all the outliers were regarded as missing values.

Normally distributed continuous variables were presented as means with SDs and used the Student *t* test for statistical analysis. Non-normally distributed continuous variables were presented as a median and interquartile range and the Wilcoxon rank-sum test was used for comparison. Categorical variables were presented as counts and percentages and compared using the chi-square test.

Considering the limitations of *P* values in detecting group differences in large sample sizes, we used standardized mean difference (SMD) as an alternative method to compare the between-group differences. Unlike *P* values, SMD allows for standardized comparisons across groups despite differences in sample size, measurement scales, or variance [24]. An absolute value of SMD<0.20 can be considered as a small difference, and an absolute value of SMD<0.10 suggests a negligible difference.

Feature Selection and Model Development

Three ML algorithms were used for feature selection, including RF, EN, and XGBoost. To tune hyperparameters in the training set, 5-fold cross-validation was conducted. The top important features coselected by 3 algorithms were used for model development.

RF and XGBoost are 2 popular ensemble learning algorithms. Both of them use decision trees to construct their models. RF generates multiple decision trees in parallel by conducting random sampling and random feature selection, and the final prediction is made by aggregating the votes from all decision trees. Feature importance in RF can be measured by evaluating the mean Gini index of each feature across multiple trees.

In contrast, XGBoost builds decision trees sequentially, where each tree is trained to correct the errors of the previous ones, and eventually, the prediction is obtained by summing the results of all trees. Feature importance in XGBoost can be quantified by calculating the average gain that a feature brings when it is chosen as the splitting variable in any decision tree.

EN model extends logistic regression by adding L1 and L2 regularization terms to overcome multicollinearity and perform feature selection. The importance of each feature in EN model can be estimated by examining the magnitude of its coefficients.

Logistic regression was used to train the final prediction model by using the features selected. Collinearity was checked through clustering analysis and the most representative feature, that is owning the smallest value of $1\text{-}R^2$ in each cluster was further selected to train logistic regression.

Model performance was assessed using discrimination and calibration. Discrimination was evaluated by area under the receiving operating characteristic curve (AUROC), and calibration was investigated through the calibration curve and Brier score. The performance of the established model was compared with a model using backward selection logistic regression without ML based-feature selection, as well as the above 3 ML models. In addition, decision curve analysis was performed to see whether the net benefit would promote when using the prediction model.

Risk Stratification

Risk cutoff values were determined based on the Youden index, predicted risk probability distribution, and the prevalence rate of carotid plaque in the internal validation data set to divide participants into high-risk, intermediate-risk, and low-risk. Specifically, Youden index was used to identify the high-risk group, and then a cutoff value was selected for the remaining individuals based on the distribution of predicted probabilities determined by our prediction model and adjusted according to the prevalence rate of carotid plaque of the 2 groups below this cutoff point to achieve intermediate and low-risk stratification, and the effectiveness of these cutoff points was verified on an external validation data set.

All procedures were performed in SAS (version 9.4; SAS Institute) and Python (version 3.7; Python Software Foundation).

Results

Characteristics of Study Participants

Among the 5,420,640 participants in the development data set, 26.23% (1,421,970/5,420,640) were diagnosed with carotid plaque. The differences in all the potential predictors between participants with and without carotid plaque were statistically significant. Participants who developed carotid plaque were older, more likely to be female, and had higher SBP, diastolic blood pressure, TC, high-density lipoprotein cholesterol, LDL-C, FBG, direct bilirubin, total bilirubin, ALP, and lower height, weight, BMI, heart rate, triglyceride, ALT, AST, ALT/AST, uric acid, white blood cell count, creatinine, HSI when compared to their carotid plaque-free counterparts. The prevalence of hypertension, hyperlipidemia, and diabetes mellitus was also higher in the carotid plaque group compared to the carotid plaque-free group (Table 1). Among the 32,682 records in external validation, 21.64% (7074/32,682) were recorded for developing carotid plaque. The characteristics are presented in Table S1 of Multimedia Appendix 1. The differences between the development data set and external validation data set are presented in Table S2 of Multimedia Appendix 1.

Table 1. Characteristics of study participants in the development data set.

Characteristic	Total (N=5,420,640)	Carotid plaque			SMD[a]
		Yes (N=1,421,970)	No (N=3,998,670)	*P* value	
Sex, n (%)				<.001	–0.01
Male	3,667,424 (67.66)	955,704 (67.21)	2,711,720 (67.82)		
Female	1,753,216 (32.34)	466,266 (32.79)	1,286,950 (32.18)

[u] HSI: Hepatic Steatosis Index.

Feature Importance and Model Performance

Age, SBP, LDL-C, TC, FBG, and HSI were found to be the top important features through all 3 ML algorithms. These features ranked in the top 10 features of all 3 algorithms and were selected out of the 27 features to train the logistic regression model (Figure 2). Cluster analysis showed high collinearity existed between LDL-C and TC, thus the more informative one, LDL-C, was selected to develop the final model (Table 2). The formula for predicting the risk of carotid plaque, as determined by the final prediction model is given in the following equation:

Figure 2. Feature importance of the potential predictors on carotid plaque in population with fatty liver disease generated by (A) RF, (B) EN, and (C) XGBoost. The features highlighted in dark color represent those coselected by all 3 algorithms. ALP: alkaline phosphatase; ALT: alanine transaminase; AST: aspartate aminotransferase; Cr: creatinine; DB: diabetes; DBIL: direct bilirubin; DBP: diastolic blood pressure; EN: elastic net; FBG: fasting blood glucose; HDL-C: high-density lipoprotein cholesterol; HLP: Hyperlipidemia; HR: heart rate; HSI: hepatic steatosis index; HT: height; HTN: hypertension; LDL-C: low-density lipoprotein cholesterol; PLT: blood platelet count; RF: random forest; SBP: systolic blood pressure; TBIL: total bilirubin; TC: total cholesterol; TG: triglyceride; UA: uric acid; WBC: white blood cell count; WT: weight; XGBoost: extreme gradient boosting.

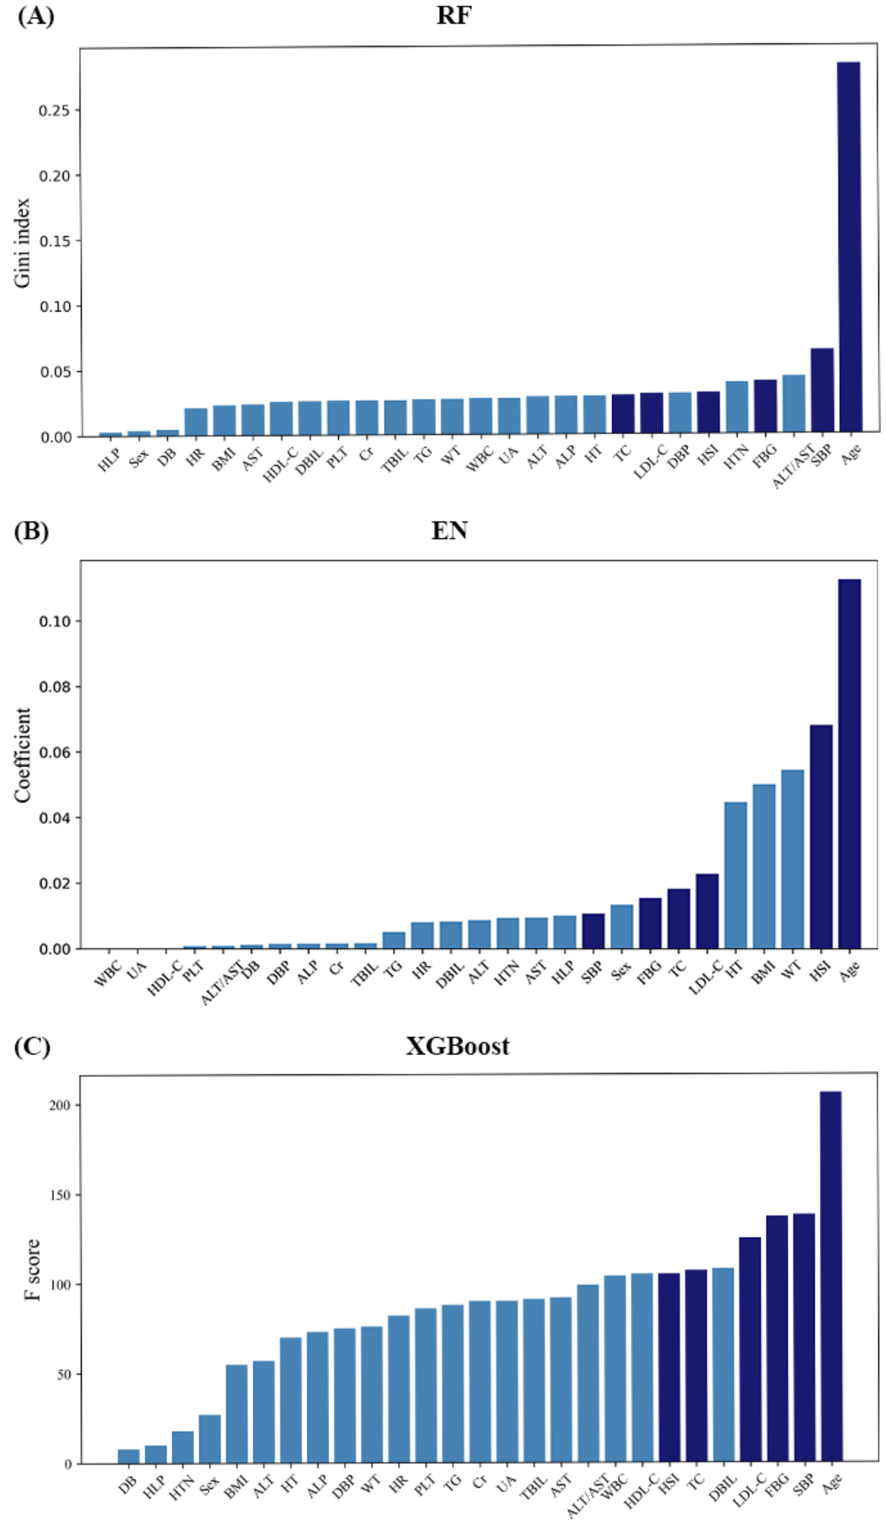

Table 2. Carotid plaque prediction model in population with fatty liver disease based on logistic regression.

Variable	β	SE	OR[a] (95% CI)
Intercept	–7.97380	0.015400	
Age	0.09230	0.000133	1.097 (1.096-1.097)
SBP[b]	0.01080	0.000070	1.011 (1.011-1.011)
FBG[c]	0.09840	0.000684	1.103 (1.102-1.105)
LDL-C[d]	0.16330	0.001480	1.177 (1.174-1.181)
HSI[e]	–0.00949	0.000289	0.991 (0.990-0.991)

[a] OR: odds ratio.

[b] SBP: systolic blood pressure.

[c] FBG: fasting blood glucose.

[d] LDL-C: low-density lipoprotein cholesterol.

[e] HSI: Hepatic Steatosis Index.

Model performance was evaluated in internal and external validation data sets, respectively, and the area under the curves achieved 0.831 and 0.801, respectively, both showing good discrimination capability (Figure 3A). The calibration curve in the internal validation data set lies tightly against the diagonal, while the external deviates a little, but still indicates good calibration capability (Figure 3B). When compared with the backward selection logistic regression model, which consisted of 15 features, or the 3 ML models involving 27 features, the prediction model we established with only 5 features was still competitive. The number of features and model performance in each model are shown in Table 3.

Figure 3. Model performance in discrimination and calibration for predicting the risk of carotid plaque in population with fatty liver disease evaluated by (A) ROC curves and (B) calibration curves. AUC: area under the curve; ROC: receiver operating characteristic.

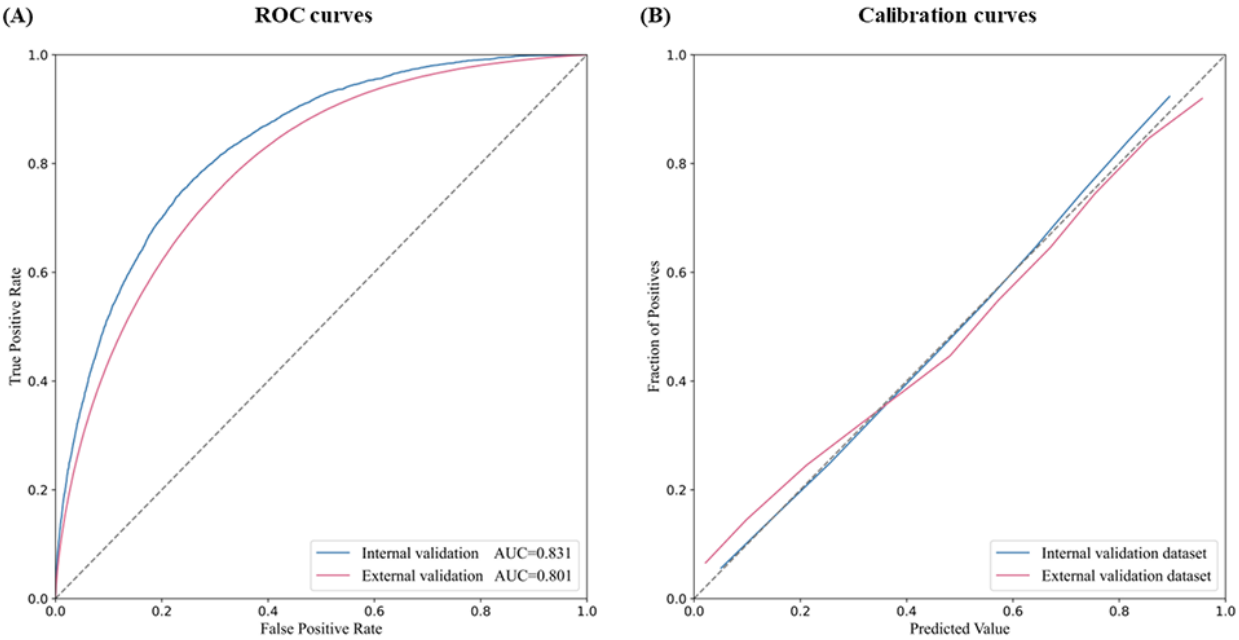

Table 3. The comparison of model performance for predicting the risk of carotid plaques in population with fatty liver disease in the internal validation data set.

Model	Features, n	AUC[a]	Brier score
LR-ML[b]	5	0.831	0.125
LR-BS[c]	13	0.822	0.139
RF[d]	27	0.832	0.151
EN[e]	27	0.834	0.178
XGBoost[f]	27	0.831	0.150

[a] AUC: area under the curve.

[b] LR-ML: ML-based feature selection logistic regression.

[c] LR-BC: backward selection logistic regression.

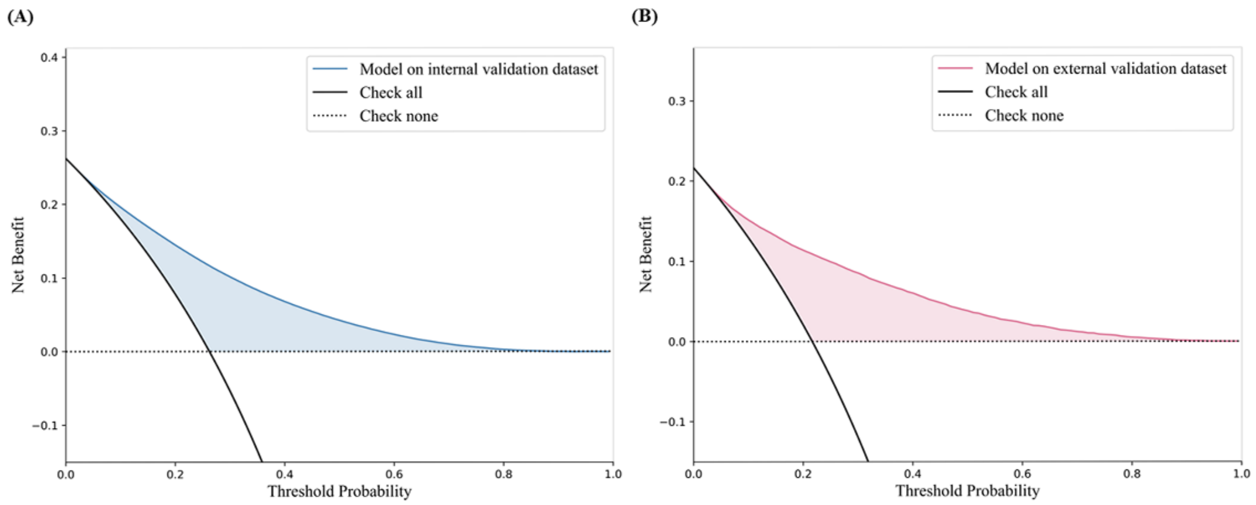
[d] RF: random forest.

[e] EN: elastic net.

[f] XGBoost: extreme gradient boosting.

The decision curve analysis showed that the application of the prediction model achieved promoted net benefits throughout all threshold probabilities both in internal and external validation data sets, indicating prospective utility in the real-world scenario (Figure 4).

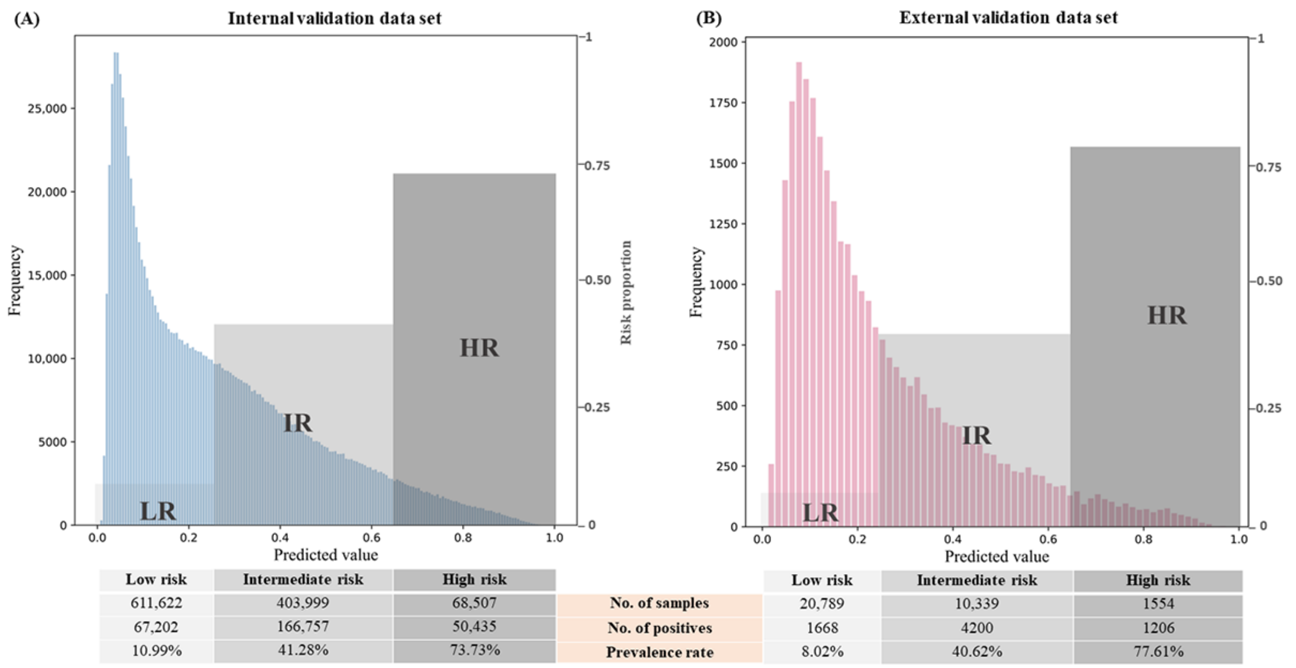
Figure 4. Decision curve analysis for predicting the risk of carotid plaque in population with fatty liver disease in (A) internal validation data set and (B) external validation data set.



Risk Stratification

The predicted risk probabilities of participants developing carotid plaque in 2 validation data sets were calculated and their histograms were presented in Figure 5. Using the Youden index, a threshold of 65% was used to categorize individuals as being at high risk, while a cutoff value of 25% was used to distinguish those at intermediate risk and low risk based on the distribution of predicted probabilities and the prevalence of carotid plaque in the remaining population. Our result revealed the prevalence of carotid plaque of 73.73%, 41.28%, and 10.99% for the high-risk, intermediate-risk, and low-risk groups, respectively. Upon application of these defined cutoff points to the external validation data set, we observed comparable prevalence rates of carotid plaque within each risk group when compared to the internal validation data set. Notably, the high-risk, intermediate-risk, and low-risk groups exhibited prevalence rates of carotid plaque amounting to 77.61%, 40.62%, and 8.02%, respectively. These findings indicate that the selected risk cutoff points can successfully stratify individuals with fatty liver disease into varying degrees of severity in terms of the risk of developing carotid plaque. The probability distribution, sample size, and prevalence rate in each level are also shown in Figure 5.

Figure 5. Probability distribution and risk classification plot generated by the carotid plaque prediction model in population with fatty liver disease in (A) internal validation data set and (B) external validation data set. The blue and pink colored columns represent the number of participants on different predicted probabilities, and the predicted probabilities are split into low risk, intermediate risk, and high risk by 0.25 and 0.65. Different levels of risks are presented by gray pillars of different opacities, the height of each pillar corresponds to risk proportion, which is calculated by the prevalence rate in each risk level. HR: high risk; IR: intermediate risk; LR: low risk.



Low risk	Intermediate risk	High risk		Low risk	Intermediate risk	High risk
611,622	403,999	68,507	**No. of samples**	20,789	10,339	1554
67,202	166,757	50,435	**No. of positives**	1668	4200	1206
10.99%	41.28%	73.73%	**Prevalence rate**	8.02%	40.62%	77.61%

Discussion

In this study, we established a practical and straightforward carotid plaque prediction model in population with fatty liver disease. By using only 5 features (Age, SBP, FBG, LDL-C, and HSI) coselected by 3 ML algorithms, the model achieved an AUROC of 0.831 and exhibited good calibration properties. Our study derived robust cutoff points of 25% and 65% for carotid plaque risk probability, enabling effective risk stratification and facilitating clinical decision-making regarding the need for carotid ultrasonography examination. These findings have practical implications for early detection and prevention of this condition, which can improve patient outcomes and reduce health care costs.

We identified specific features as strong predictors of the outcome. Age was selected as the top important feature by all 3 models, indicating its strong relationship with carotid plaque, prior studies have also drawn the same conclusion [8,25]. Previous research has demonstrated that increased SBP is a strong predictor of the development of carotid plaque, which was consistent with our findings [26-30]. Additionally, our study found evidence linking increased blood lipid levels, such as TC and LDL-C, and elevated glucose levels to a higher prevalence of carotid plaque. These findings are in line with prior research and support the notion that managing modifiable cardiovascular risk factors, such as dyslipidemia and hyperglycemia, is critical for reducing the likelihood of carotid plaque development [31-33]. HSI is a surrogate score for the noninvasive assessment of steatosis in patients with fatty liver [34] and is also a screening tool for nonalcoholic fatty liver disease [35]. In our study, we regarded this index as a continuous feature reflecting the severity of liver steatosis to predict carotid plaque. Although a cross-sectional study involving 768 patients with type 2 diabetes mellitus (T2DM) showed those with carotid plaque have significantly higher HSI (*P*<.001) compared with their healthy counterparts [36], our study came to the opposite conclusion. The following reason may explain the paradox. For all of the participants who have already been diagnosed with fatty liver disease, the severity may lead to behavior or lifestyle change and ulteriorly affect the development of carotid plaque. However, the lifestyle-related variables and diagnostic time of fatty liver were not included in our study, which may generate the opposite result with other studies.

Our findings revealed that the logistic regression model, comprising only 5 variables coselected by 3 ML algorithms, attained nearly equivalent area under the curve values as the ML models which included all 27 variables, but exhibited superior calibration capability. These results clearly indicated the superiority of adopting a combined approach. In regard to similar research, our predictive model remains competitive. For instance, in Wu's [13] investigations, the XGBoost model based on 34 variables acquired an AUROC of 0.8635, whereas our model, employing solely 5 variables, yielded a comparable AUROC value of 0.831 while preserving a more comprehensible and lucid modeling framework. In practical applications, our model accurately predicts outcomes using routine, easily measurable, and obtainable variables, indicating the potential for effective clinical implementation.

We aimed to identify high-risk individuals who may benefit from carotid ultrasonography screening for carotid plaque. Therefore, it is vital not only to estimate an individual's risk probability but also to determine optimal risk cutoff points for precise risk stratification and corresponding clinical guidance.

Although the Youden index is commonly used to determine the optimal cutoff predicted probability for risk stratification, it typically results in a binary classification of high-risk and low-risk groups [37-39]. However, our results have shown that the low-risk group often comprises a larger population with a wide range of risk probabilities from 0% to 65% when performing high-low risk stratification using the Youden index alone. Although this approach can effectively identify the high-risk group, providing identical guidance to individuals within the low-risk group with significantly different risk probabilities is not appropriate and unscientific. To achieve a more comprehensive risk stratification based on our large sample data, we further stratified the low-risk group generated by the Youden index into low and intermediate risk categories using risk probability distribution and prevalence rate of carotid plaque in each group. With our substantial sample size, selecting and adjusting cutoff points based on the distribution of risk probability and prevalence rate across different strata is achievable. This novel approach enables a more nuanced risk stratification beyond the binary classification of high and low-risk groups, potentially leading to the development of personalized health care plans.

We have developed customized health care recommendations for each risk group, providing precise guidance for carotid artery ultrasound examinations. Our results indicate that individuals in the high-risk group with a prevalence of carotid plaque of over 70% should strongly consider undergoing carotid artery ultrasound for definitive diagnosis. For those in the intermediate-risk group with a prevalence of over 40%, the examination is still advised, considering their individual financial circumstances. Furthermore, low-risk individuals with a prevalence of approximately 10% do not require a carotid artery ultrasound examination. By personalizing our approach based on an individual’s risk level and financial situation, we can effectively identify those who require further testing and optimize the cost-effectiveness of screening programs.

Currently, there are no established criteria for determining which populations require carotid ultrasound screening. Several guidelines and recommendations have been proposed to identify populations that may benefit from carotid ultrasound screening. For example, the guidelines for carotid artery ultrasound examination in Chinese health check-up populations specify that the evaluation standards for individuals undergoing carotid artery ultrasound include those at risk of hypertension, coronary atherosclerotic heart disease, stroke, and diabetes; high-risk populations such as smokers, overweight and obese individuals; individuals with moderate or higher cardiovascular risk assessment; and other suitable populations aged middle-aged or older. The American Heart Association recommends carotid ultrasound screening for asymptomatic patients who are over 65 years of age, men aged 55 to 75 years with a history of smoking or other risk factors, and women aged 55 to 75 years with a history of cardiovascular disease or other risk factors. However, the existing guidelines are primarily focused on risk stratification at the population level. Our objective, therefore, is to develop a prediction model for personalized risk stratification to enable better decision-making support in determining the need for carotid artery ultrasound monitoring on an individual basis. This approach would lead to more precise and personalized health care recommendations for the individuals under consideration.

Our prediction model and the cutoff points were verified on an independent external data set. The model was also able to accurately predict the risk of carotid plaque for each individual and the cutoff points remain robust in identifying different risk levels of groups, confirming the generalizability and applicability of our approach.

Several limitations need to be noted. First, due to the limitation of the database, some lifestyle variables, like smoking or drinking status [40,41], were not included in our model, which may affect the predictive performance to some extent. Second, because of the high calculation time cost caused by the huge sample size, bootstrap sampling was not used to generate a 95% CI of the performance metrics, a single measurement may not be forceful enough. Third, we opted to exclude individuals with cardiovascular and cerebrovascular diseases from our study sample, in recognition of their potential differences in baseline characteristics, health care–seeking behavior, and management strategies relative to the general population. These factors could introduce significant confounding effects and hinder the predictive performance of our model. Therefore, we excluded individuals with cardiovascular and cerebrovascular diseases at the beginning. However, this may have reduced the representativeness of our sample and introduced some selection bias. Fourth, although the check-up centers included in this study covered all provinces and all 3 economic zones (the eastern zone, central zone, and western zone) in mainland China, the check-up population may not be entirely representative of the general population, which may have biased our study towards a healthier group and thus limit the applicability and generalizability of our model to the broader population. Fifth, the cross-sectional design of our study means that the temporal relationship between the predictors and the outcome cannot be established, and there may be reverse causation or confounding effects that we have not accounted for.

In conclusion, we developed a prediction model that uses a set of routine and quantitative variables obtained from health checkup programs to estimate the risk of carotid plaque in individuals with fatty liver disease. The resulting model is cost-effective, easy to use, and demonstrated strong predictive performance. This approach provides a means for personalized risk assessment of carotid plaque and derives robust cutoff points for carotid plaque risk stratification, with potential implications for improving the cost-effectiveness of carotid ultrasound detection.

Abstract

Background: Chloride is the most abundant anion in the human extracellular fluid and plays a crucial role in maintaining homeostasis. Previous studies have demonstrated that hypochloremia can act as an independent risk factor for adverse outcomes in various clinical settings. However, the association of variances of serum chloride with long-term mortality risk in general populations has been rarely investigated.

Objective: This study aims to assess the association of serum chloride with all-cause and cause-specific mortality in the general American adult population.

Methods: Data were collected from 10 survey cycles (1999-2018) of the National Health and Nutrition Examination Survey. All-cause mortality, cardiovascular disease (CVD) mortality, cancer mortality, and respiratory disease mortality data were obtained by linkage to the National Death Index through December 31, 2019. After adjusting for demographic factors and relevant lifestyle, laboratory items, and comorbid factors, weighted Cox proportional risk models were constructed to estimate hazard ratios and 95% CIs for all-cause and cause-specific mortality.

Results: A total of 51,060 adult participants were included, and during a median follow-up of 111 months, 7582 deaths were documented, 2388 of CVD, 1639 of cancer, and 567 of respiratory disease. The weighted Kaplan-Meier survival analyses showed consistent highest mortality risk in individuals with the lowest quartiles of serum chloride. The multivariate-adjusted hazard ratios from lowest to highest quartiles of serum chloride (≤101.2, 101.3-103.2, 103.2-105.0, and ≥105.1 mmol/L) were 1.00 (95% CI reference), 0.77 (95% CI 0.67-0.89), 0.72 (95% CI 0.63-0.82), and 0.77 (95% CI 0.65-0.90), respectively, for all-cause mortality (*P* for linear trend<.001); 1.00 (95% CI reference), 0.63 (95% CI 0.51-0.79), 0.56 (95% CI 0.43-0.73), and 0.67 (95% CI 0.50-0.89) for CVD mortality (*P* for linear trend=.004); 1.00 (95% CI reference), 0.67 (95% CI 0.54-0.84), 0.65 (95% CI 0.50-0.85), and 0.65 (95% CI 0.48-0.87) for cancer mortality (*P* for linear trend=.004); and 1.00 (95% CI reference), 0.68 (95% CI 0.41-1.13), 0.59 (95% CI 0.40-0.88), and 0.51 (95% CI 0.31-0.84) for respiratory disease mortality (*P* for linear trend=.004). The restricted cubic spline analyses revealed the nonlinear and L-shaped associations of serum chloride with all-cause and cause-specific mortality (all *P* for nonlinearity<.05), in which lower serum chloride was prominently associated with higher mortality risk. The associations of serum chloride with mortality risk were robust, and no significant additional interaction effect was detected for all-cause mortality and CVD mortality (*P* for interaction>.05).

Conclusions: In American adults, decreased serum chloride concentrations were independently associated with increased all-cause mortality, CVD mortality, cancer mortality, and respiratory disease mortality. Our findings suggested that serum chloride may serve as a promising cost-effective health indicator in the general adult population. Further studies are warranted to explore the potential pathophysiological mechanisms underlying the association between serum chloride and mortality.

Introduction

Background

Chloride is the most abundant anion in human extracellular fluid, accounting for approximately one-third of plasma tonicity and two-thirds of all plasma negative charges [1], and is predominantly confined to the extracellular fluid compartment [2]. Serum chloride plays an important role in many physiological processes in the body, including the maintenance of osmotic pressure, electroneutrality of body fluids, muscular activity, and regulation of blood pressure [3,4]. Serum chloride levels are predominantly regulated by the gastrointestinal tract and kidney. Chloride is secreted in the gastric juice as hydrochloric acid and can be absorbed by the entire intestine during digestion. In the United States, the daily intake of chloride for adult men is 7.8 to 11.8 g, whereas that for adult women is 5.8 to 7.8 g [5]. The primary source of chloride in the body is table salt (sodium chloride) in the diet as well as salt-containing foods [6]. The kidney can filter 19,440 mmol of chloride every day, 99.1% of which is reabsorbed, and only 180 mmol of chloride is excreted into urine, maintaining serum chloride within a narrow range [7].

Many clinical situations are related to the dysregulation of serum chloride. Serum chloride can be reduced either by chloride depletion, such as vomiting, diarrhea, burns, diuretic use, renal diseases, adrenal insufficiency, and metabolic alkalosis, or by water retention, such as excessive water intake, congestive heart failure, liver cirrhosis, and nephrotic syndrome. In contrast, serum chloride can be elevated by the loss of hypotonic fluids (eg, fever), administration of hypertonic fluid, or metabolic acidosis [2]. Chloride is a crucial constituent in diagnostic tests across numerous clinical scenarios. However, unlike other serum electrolytes such as sodium, potassium, and calcium, the importance of serum chloride is often overlooked despite its extensive measurement in routine blood biochemical tests. In recent years, serum chloride has exhibited a robust independent prognostic value, which seems even better than serum sodium, in patients with heart failure [8-11], chronic kidney disease (CKD) [12], and pulmonary arterial hypertension [13] and in patients who are critically ill [14-16]. For instance, in patients diagnosed with congestive heart failure, both hypochloremia and hyperchloremia have been associated with higher rates of mortality and hospitalization [11,17]. Similarly, lower chloride levels have been associated with an increased risk of mortality and progression to end-stage renal disease in patients with CKD [12,14]. Lower chloride level at 6 months after pulmonary arterial hypertension could predict long-term mortality [13]. In addition, research conducted on patients who are critically ill has demonstrated that both low and high levels of chloride are associated with higher rates of mortality and dysfunction in organs [14-16]. However, most studies were conducted among specific patient populations (eg, patients who were hospitalized or participants with heart disease or kidney disease), and researchers mainly focused on patients with hypochloremia or hyperchloremia. Knowledge of the relationship between the generally distributed serum chloride and mortality from the community-based population remains limited and requires further clarification. Understanding the potential association between chloride levels and mortality in the general population is essential for identifying individuals at higher risk and providing preventive strategies.

Objective

To address this knowledge gap, we used a nationally representative cohort from the National Health and Nutrition Examination Survey (NHANES) 1999-2018 data set to investigate whether serum chloride was associated with all-cause and cause-specific mortality in the general American adult population.

Methods

Study Design and Participants Selection

The NHANES has been a continuous nationally representative survey investigating the health and nutritional status of the noninstitutionalized population of the United States since 1999 [18]. In this cohort study, we analyzed data in 10 cycles of NHANES from 1999-2018. Participants were restricted to those aged ≥18 years, not pregnant at the physical examination, and with eligible serum chloride measurement and mortality follow-up information.

Ethical Considerations

All participants in the study signed a written informed consent form, and the NHANES data collection was approved by the Research Ethics Review Board of the National Center for Health Statistics [19]. The NHANES has strict protocols and procedures in place to ensure confidentiality and protect against identification. As our study was a secondary data analysis, which lacked personal identifiers, and the data in NHANES are freely accessible to the public on the web [20], it did not require review by an institutional review board [19].

Measurement of Serum Chloride Concentration

Blood samples were collected and processed in the mobile examination center by certified laboratory professionals and then stored in biorepositories. Serum chloride was determined as part of the routine biochemistry profile with Beckman Synchron LX20 or Beckman Coulter UniCel DxC800 (Beckman

Coulter, Inc), both of which used indirect (or diluted) ion-selective electrode methodology for the determination of serum chloride concentrations. Details about the laboratory procedure have been described on the NHANES website [20].

Assessment of Covariates

The sociodemographic characteristics, namely, sex, age, race, education level, marital status, and family income-to-poverty ratio (PIR), were collected using standardized questionnaires during the household interview, as previously described [21].

Lifestyle factors were evaluated using a combination of data from physical examinations and questionnaires. BMI was calculated as weight (kg) divided by the square of height (m). Smoking status was classified as never (smoked <100 cigarettes/lifetime), former (≥100 cigarettes/lifetime but do not currently smoke), and current smokers. Alcohol users were classified as never (<12 drinks in a lifetime), former (≥12 drinks in a lifetime but did not drink in the last year), mild (≤1 drink/d for women or ≤2 drinks/d for men), moderate (≤2 drinks/d for women or ≤3 drinks/d for men), and heavy drinkers (>2 drinks/d for women or >3 drinks/d for men), where a drink referred to an alcoholic drink equivalent of 12 oz of beer, 4 oz of wine, or 1 oz of liquor (such as whiskey or gin) [22]. Diet quality was assessed by the Healthy Eating Index-2015 (HEI-2015), reflecting adherence to the 2015 to 2020 Dietary Guidelines for Americans [23]. Physical activity was quantified in metabolic equivalent tasks (METs) multiplied by exercise time (minutes) per week (METs min/wk) [24].

For laboratory variables, serum sodium, potassium, and bicarbonate levels were measured similarly to serum chloride levels, as described in the aforementioned method section. The estimated glomerular filtration rate (eGFR) was calculated using the CKD Epidemiology Collaboration equation (2009) [25].

Comorbid conditions were evaluated by combined information from NHANES data sets, as previously described [21]. Hypertension was determined by systolic blood pressure≥140 mm Hg, diastolic blood pressure ≥90 mm Hg, having been diagnosed by a physician, or current use of antihypertensive drugs. Diabetes was determined by fasting glucose level ≥7.0 mmol/L, random blood glucose level ≥11.1 mmol/L, Hemoglobin A1c level ≥6.5%, 2-hour glucose level ≥11.1 mmol/L after oral glucose tolerance tests, having been diagnosed by a physician or current use of the antidiabetic drug. Chronic obstructive pulmonary disease (COPD) was determined by first second of expiratory volume/forced vital capacity <0.7 after the use of bronchodilators in spirometry, having been diagnosed by a physician, or current use of drugs for COPD. Coronary heart disease (CHD), stroke, and cancer were assessed based on whether the participants had been diagnosed with these conditions by a doctor.

Ascertainment of All-Cause and Cause-Specific Mortality

Mortality status for people who took part in the NHANES study was ascertained through probabilistic matching with the National Death Index Public-Use Linked Mortality Files up to December 31, 2019 [26]. The primary outcome was all-cause and cause-specific mortality, classified according to the international classification of diseases-10 codes recorded as the leading cause of death, in which cardiovascular disease (CVD) mortality corresponded to I00-I09, I11, I13, I20-I51, and I60-I69; cancer mortality corresponded to C00-C97; and respiratory disease mortality corresponded to J09-J18 and J40-J47.

In this study, the survival time has been calculated as months from the date of examination to the date of death or the end of follow-up (December 31, 2019), whichever came first.

Statistical Analysis

Sample weights, clustering, and stratification were used in the data analyses to account for the stratified, multistage probability design of NHANES, in which the combined sample weight was calculated as 2/5×4-year sample weight for examinations in mobile examination centers for the period from 1999 to 2002 and 1/5×2-year sample weight for examinations in mobile examination centers for other survey cycles according to the NHANES analytic guidelines [27,28].

Data are presented as the survey-weighted mean (SE) for continuous variables or frequency (survey-weighted percentage) for categorical variables. Differences in baseline information were detected using survey-weighted ANOVA or chi-square test.

Survey-weighted Kaplan-Meier survival curves were plotted, and overall log-rank tests and pairwise comparisons between group levels with Benjamini and Hochberg corrections [29] were used to compare the cumulative survival in different serum chloride quartiles. Survey-weighted Cox proportional hazards models were used to estimate the hazard ratios (HRs) and 95% CIs for the association of serum chloride quartiles with all-cause and cause-specific mortality, with the first quartile as the reference, and the linear trend was evaluated by assigning a median value to each category as a continuous variable. The crude and multivariable models with different covariate adjustments were constructed to estimate mortality risk according to the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) reporting guideline [30], in which sex, age, and race were adjusted in model 1; education, marital status, PIR, BMI, smoking, alcohol use, HEI-2015, and physical activity were additionally adjusted in model 2; serum sodium, serum potassium, serum bicarbonate, eGFR, and use of diuretics as well as comorbidity of hypertension, diabetes, CHD, stroke, COPD, and cancer were additionally adjusted in model 3. Moreover, serum chloride was calculated as a continuous variable to estimate the mortality risk with each millimole per liter increase of serum chloride in different multivariate models. The proportion of missing data in the covariates was summarized, and in the primary analyses, the listwise deletion for missing variables was adopted for multivariate models.

To evaluate the potential nonlinear association of mortality with serum chloride, the restricted cubic spline analysis was performed in multivariable-adjusted models, in which the number of knots was determined based on the Akaike information criterion.

The subgroup analyses were performed according to the dichotomic stratified variables, namely, sex; age at recruitment;

race; education level; marital status; PIR; BMI; smoker; drinker; HEI-2015; physical activity (physically active [≥600 MET-min/wk] vs physically inactive [<600 MET-min/wk]); and comorbidity of hypertension, diabetes, stroke, COPD, cancer, and CKD, determined by eGFR ≤60 mL/min/1.73 m^2 or albuminuria ≥30 mg/g based on the Kidney Diseases Improving Global Outcomes guideline [31], using the fully adjusted model except for the specific stratification variable. The likelihood ratio test also inspected interactions of serum chloride with the stratification variables.

Robustness of the results was examined using several sensitivity analyses. First, participants who died within the first 2 years of follow-up were excluded to reduce potential reverse causation. Second, participants with extremely low or high serum chlorides (<1.5×IQR below the lower quartile or >1.5×IQR above the upper quartile) were excluded to test the effect of potential outliers. Third, participants with hypoalbuminemia (serum albumin level <35 g/L) were excluded to evaluate the impact of malnutrition on the relation between serum chloride and mortality. Fourth, hypochloremia has been confirmed to be associated with higher mortality in patients with heart failure; therefore, we additionally adjusted the history of congestive heart failure. Fifth, potassium-sparing diuretics and nonpotassium-sparing diuretics may have different effects on serum chloride concentration and outcomes [17], so we separately adjusted these 2 types of diuretics. Sixth, we used the multiple imputation method to impute all missing covariates to test the influence of these missing variables. Finally, to explore the potential influence of unmeasured confounders on our risk estimates, we performed an E-value analysis, which quantifies the required magnitude of an unmeasured confounder that would negate the observed association between serum chloride and mortality [32].

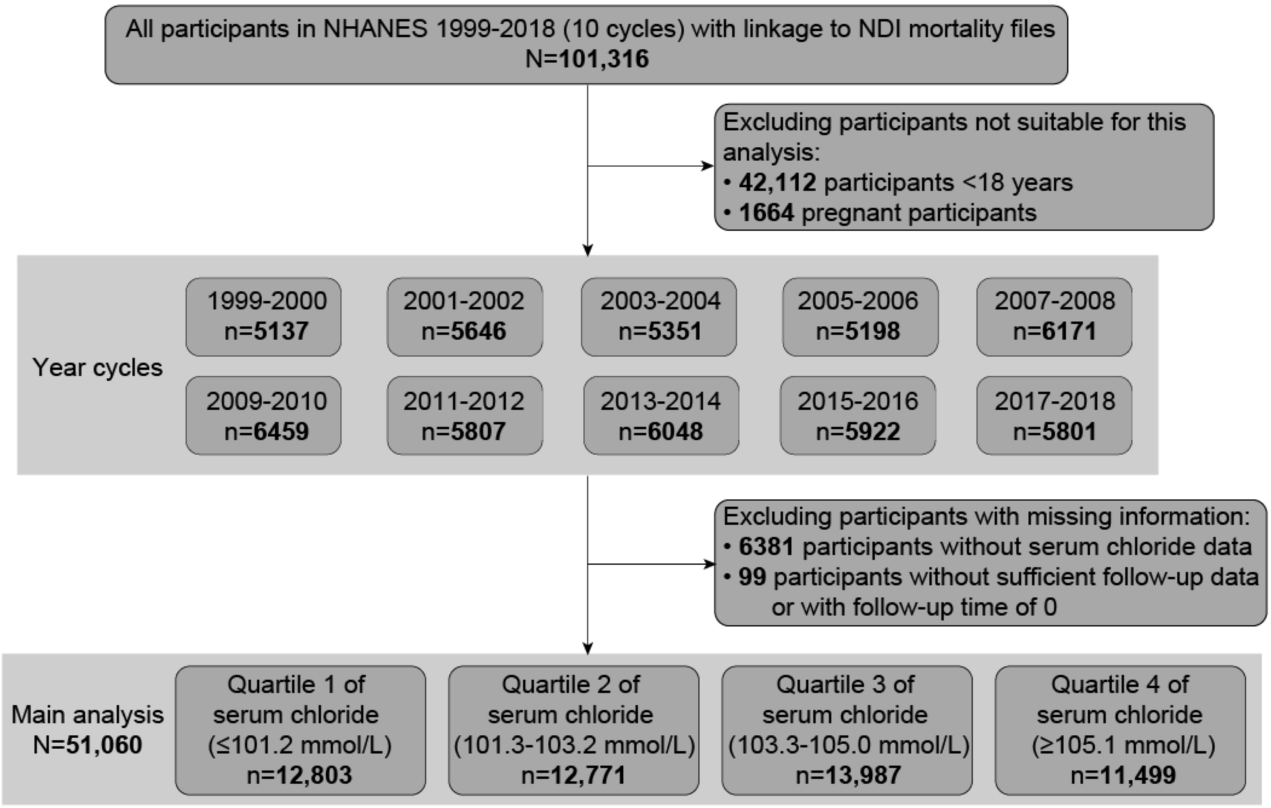
All statistical analyses were performed using the R program (version 4.2.1; R Foundation for Statistical Computing [33]) with package “survey” (version 4.1-1) for analysis of complex survey samples, package “survminer” (version 0.4.9) for survival curves plotting, package “rms” (version 6.6-0) for restricted cubic spline analysis, package “mice” (version 3.15.0) for multiple imputation, and package “Evalue” (version 4.1.3) for sensitivity analyses for unmeasured confounding and other biases. A 2-sided *P*<.05 was considered statistically significant.

Results

Selection of Participants

Of the total 101,316 participants in 10 cycles of NHANES (1999-2018), we excluded 42,112 participants aged <18 years, 1664 pregnant participants, 6381 participants without serum chloride data, and 99 participants without eligible follow-up data. The remaining 51,060 eligible participants were included in the final analysis (Figure 1).

Figure 1. Flowchart of participant selection from the US National Health and Nutrition Examination Survey (NHANES) 1999-2018. NDI: National Death Index.



Baseline Characteristics of Participants

Among the 51,060 participants, representing 209 million American adults, 25,632 (50.95%) were female; mean age was 46.4 (SD 16.6) years; and 22,199 (68.48%) were non-Hispanic White. The median serum chloride of the participants was 103.2 (IQR 101.2-105.0) mmol/L, and according to the quartiles, serum chloride values (mmol/L) were categorized into 4 groups: quartile 1 (Q1; ≤101.2), quartile 2 (Q2; 101.3-103.2), quartile 3 (Q3; 103.3-105.0), and quartile 4 (Q4; ≥105.1).

During a median follow-up time of 111 (IQR 59-169) months, overall 7582 deaths were documented, of which 1958 (24.76%) were attributed to diseases of the heart, 1639 (22.72%) were attributed to malignant neoplasms, 430 (5.02%) were attributed to cerebrovascular diseases, 409 (6.16%) were attributed to chronic lower respiratory diseases, and 158 (1.85%) were attributed to influenza and pneumonia, and the leading causes of death were reorganized into CVD, cancer, and respiratory disease in the following analyses (Multimedia Appendix 1).

The population baseline characteristic profiles were compared across the quartiles of serum chloride (Table 1). Briefly, individuals with lower serum chloride were more likely to be older, male, non-Hispanic White, and nonmarried; to have higher HEI-2015, lower serum sodium, higher serum bicarbonate, lower eGFR, more use of diuretics; and to have a higher prevalence of hypertension, diabetes, CHD, stroke, COPD, and cancer (Table 1).

Associations of Serum Chloride Quartiles With All-Cause and Cause-Specific Mortality

The unadjusted survey-weighted Kaplan-Meier survival analyses, followed by the log-rank test and pairwise comparisons between groups with corrections, showed that individuals with the lowest quartiles of serum chloride consistently bear the highest mortality risk (Figure 2).

After multivariable adjustment, the all-cause mortality risk was lower in the Q2-Q4 group of serum chloride than in the Q1 group. Briefly, compared with the reference group (Q1), the HRs for all-cause mortality were estimated to be 0.77 (95% CI 0.67-0.89) for the Q2 group, 0.72 (95% CI 0.63-0.82) for the Q3 group, and 0.77 (95% CI 0.65-0.90) for the Q4 group (*P* for linear trend<.001; Table 2). As a continuous linear variable, every millimole per liter increment in serum chloride was associated with a 4% reduced risk of all-cause mortality (HR 0.96, 95% CI 0.94-0.98; Multimedia Appendix 2).

Figure 2. Survey-weighted cumulative hazard curves and log-rank tests comparing mortality risks owing to all-cause (A), cardiovascular disease (CVD; B), cancer (C), and respiratory disease (D) for individuals in different serum chloride quartiles from the US National Health and Nutrition Examination Survey 1999-2018. Q1: quartile 1; Q2: quartile 2; Q3: quartile 3; Q4: quartile 4.

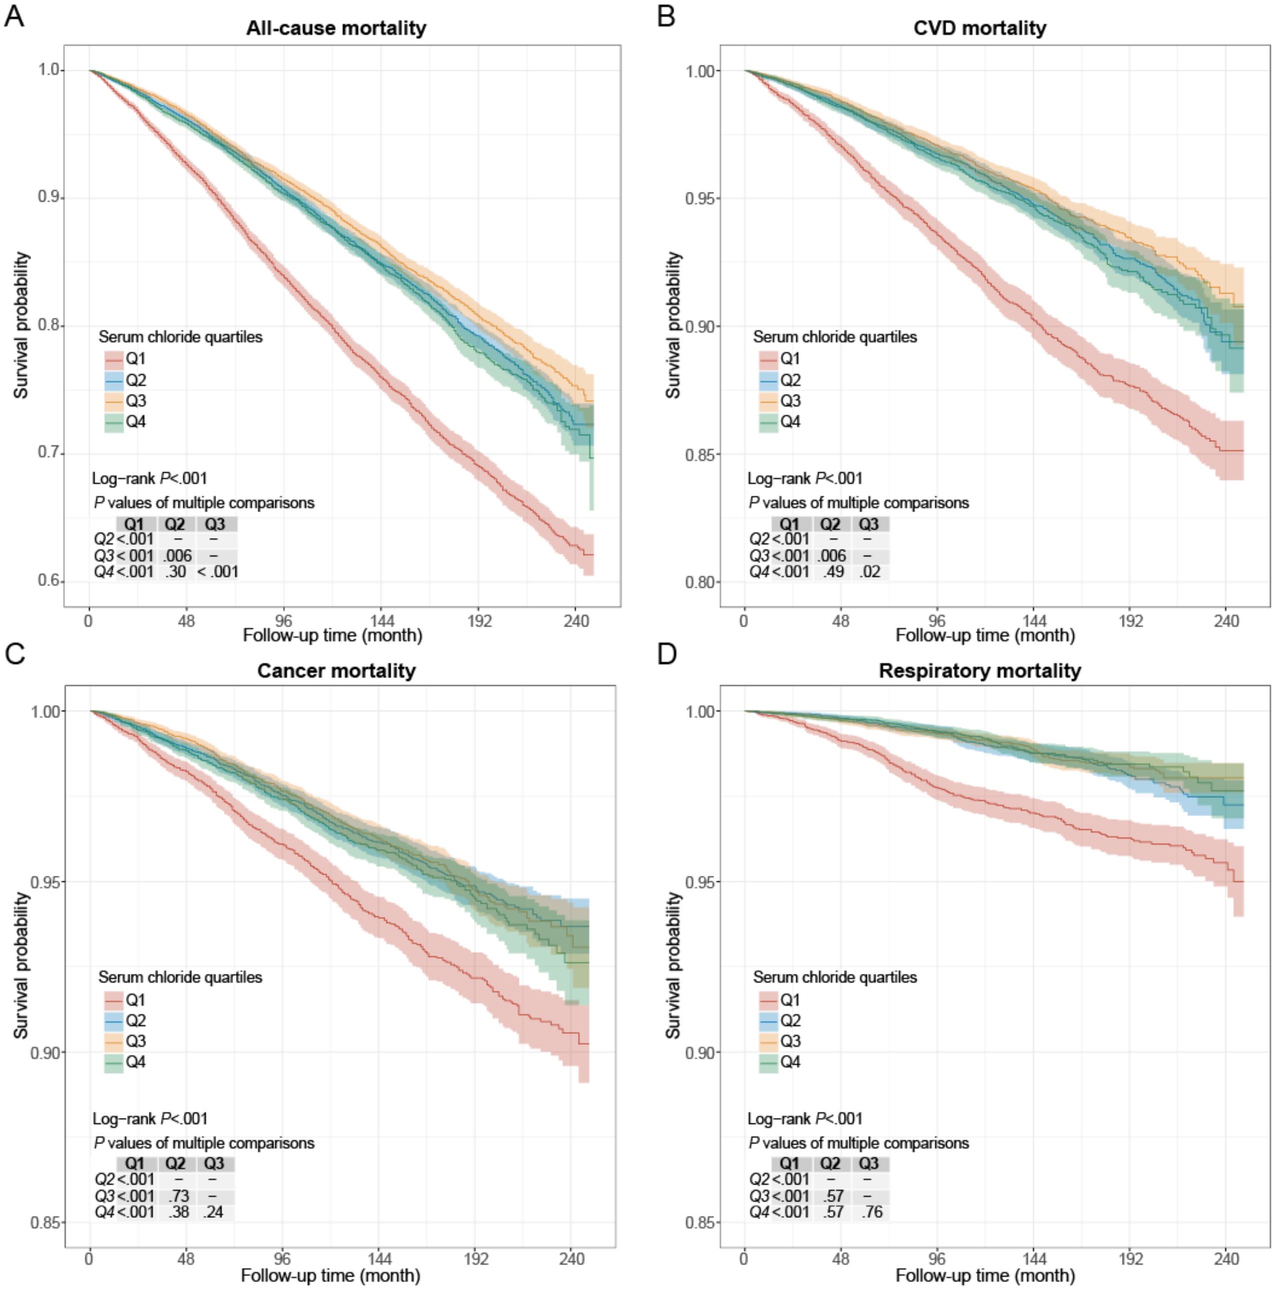

Table 2. Survey-weighted multivariate analyses of the associations of categorical serum chloride serum chloride with all-cause and cause-specific mortality for adults from the US National Health and Nutrition Examination Survey 1999-2018 (N=51,060)[a].

[a] Data were fitted to a multivariate Cox proportional hazards model for data from a complex survey design.

[b] Q1: quartile 1.

[c] Q2: quartile 2.

[d] Q3: quartile 3.

[e] Q4: quartile 4.

[f] The test for trend was based on the variable containing the median value for each quartile.

[g] HR: hazard ratio.

[h] Model 1: adjusted for sex, age, and race.

[i] Model 2: adjusted for sex, age, race, education, marital status, family income-to-poverty ratio, BMI, smoking, alcohol use, Healthy Eating Index-2015, and physical activity.

[j] Model 3: adjusted for sex; age; race; education; marital status; family income-to-poverty ratio; BMI; smoking; alcohol use; Healthy Eating Index-2015; physical activity; serum sodium; serum potassium; serum bicarbonate; estimated glomerular filtration rate; use of diuretics; and comorbidity or history of hypertension, diabetes, coronary heart disease, stroke, chronic obstructive pulmonary disease, and cancer.

Similarly, CVD mortality was consistently lower in the Q2-Q4 group of serum chloride than in the Q1 group in all models. After being fully adjusted, the HRs for CVD mortality were estimated to be 0.63 (95% CI 0.51-0.79) for the Q2 group, 0.56 (95% CI 0.43-0.73) for the Q3 group, and 0.67 (95% CI 0.50-0.89) for the Q4 group compared with the Q1 group (*P* for linear trend=.004; Table 2). As a continuous linear variable, every millimole per liter increment in serum chloride was associated with a 7% reduced risk of CVD mortality (HR 0.93, 95% CI 0.89-0.97; Multimedia Appendix 2).

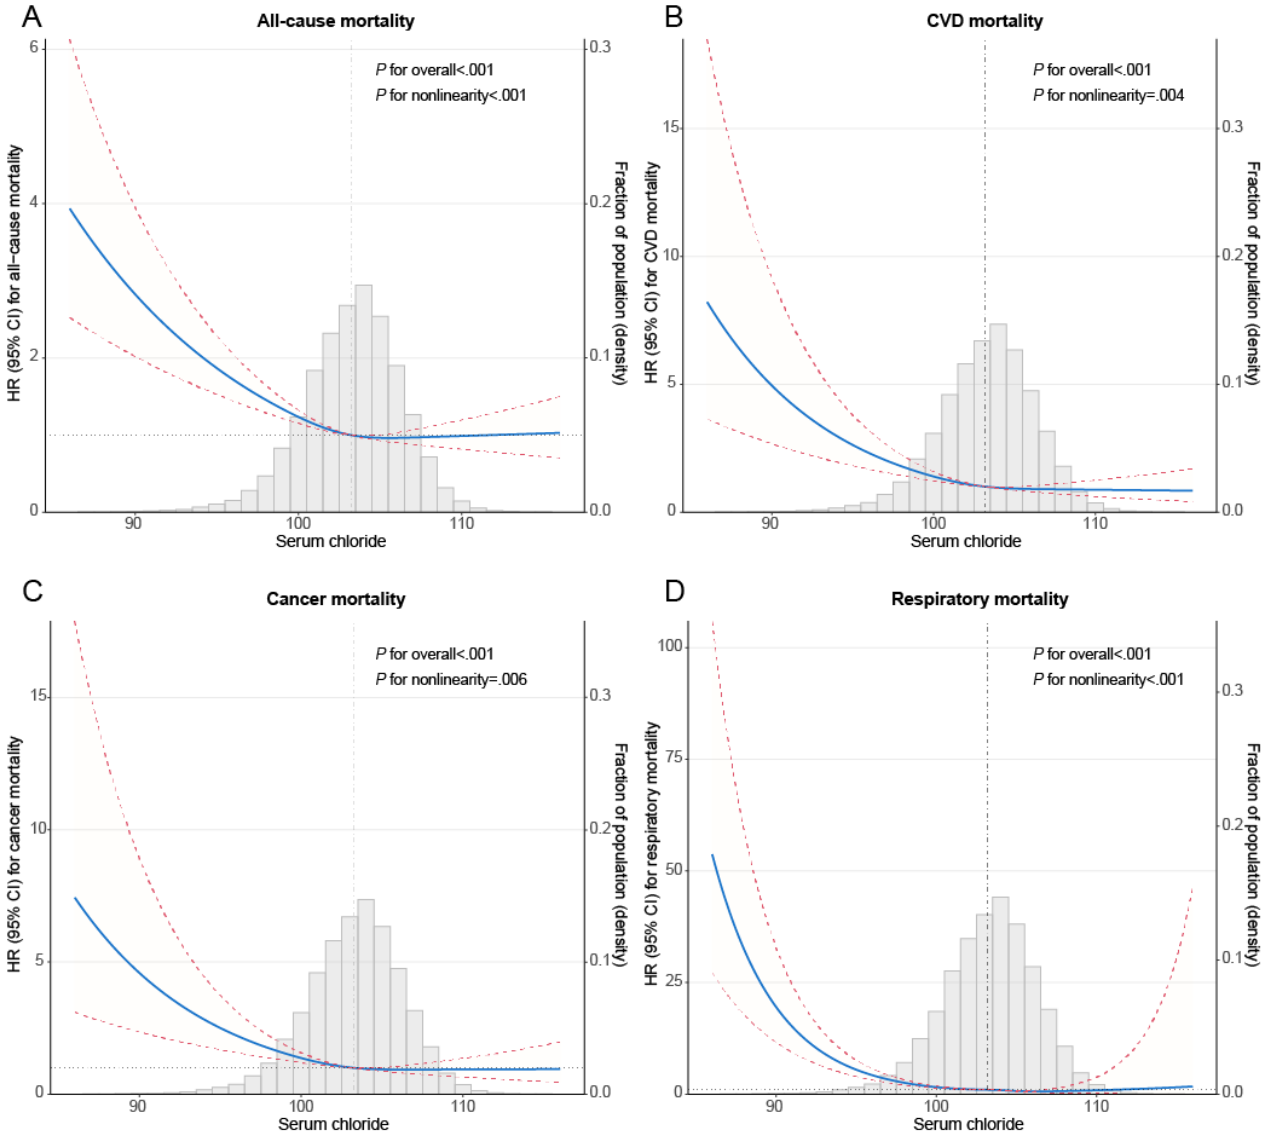
Moreover, cancer mortality was consistently lower in the Q2-Q4 group of serum chloride than in the Q1 group. With the total adjustment, the HRs for cancer mortality were estimated to be 0.67 (95% CI 0.54-0.84) for the Q2 group, 0.65 (95% CI 0.50-0.85) for the Q3 group, and 0.65 (95% CI 0.48-0.87) for the Q4 group compared with the Q1 group (*P* for linear trend=.004; Table 2). As a continuous linear variable, every millimole per liter increment in serum chloride was associated with a 6% reduced risk of cancer disease mortality (HR 0.94, 95% CI 0.89-0.98; Multimedia Appendix 2).

Similarly, consistently lower respiratory mortality was observed in Q3 and Q4 groups than in the Q1 group. With the full adjustment, the HRs for respiratory mortality were estimated to be 0.68 (95% CI 0.41-1.13) for the Q2 group, 0.59 (95% CI 0.40-0.88) for the Q3 group, and 0.51 (95% CI 0.31-0.84) for the Q4 group compared with the Q1 group (*P* for linear trend=.004; Table 2), and every millimole per liter increment in serum chloride was associated with a 15% reduced risk of respiratory mortality (HR 0.85, 95% CI 0.80-0.92; Multimedia Appendix 2).

The Nonlinear Analyses of the Association Between Continuous Serum Chloride and Mortality

Spline models with fully adjusted covariates were constructed to profile a more direct relationship between serum chloride and mortality. An L-shaped association was observed between serum chloride and all-cause mortality (nonlinear *P*<.001), in which all-cause mortality risk decreased steeply until around the median of serum chloride and then tended to be stable (Figure 3A). Similarly, L-shaped associations were observed between serum chloride and CVD mortality (nonlinear *P*=.004; Figure 3B), cancer mortality (nonlinear *P*=.006; Figure 3C), and respiratory mortality (nonlinear *P*<.001; Figure 3D).

Figure 3. Survey-weighted restricted cubic spline analyses of the associations of continuous serum chloride with all-cause mortality (A), cardiovascular disease (CVD) mortality (B), cancer mortality (C), and respiratory mortality (D), and the probability distribution histogram is represented in the background. All models were adjusted for sex; age; race; education; marital status; family income-to-poverty ratio; BMI; smoking status; alcohol use; Healthy Eating Index-2015; physical activity; serum sodium; serum potassium; serum bicarbonate; estimated glomerular filtration rate; use of diuretics; and comorbidity or history of hypertension, diabetes, coronary heart disease, stroke, chronic obstructive pulmonary disease, and cancer. Solid blue lines are multivariable-adjusted HR estimations, and the dashed red lines are the corresponding 95% CIs. The reference point was set at the median (103.2 mmol/L). HR: hazard ratio.



Subgroup Analyses of the Association of Serum Chloride With Mortality

Subgroup analyses were performed to depict the potential different associations of serum chloride quartiles and mortality in subpopulations. For the association with the primary outcome, all-cause mortality, no significant interactions were found between serum chloride and all these stratification variables (all *P* for interaction>.05), implying similar associations of serum chloride with all-cause mortality were detected in these subgroups (Table 3). Similarly, consistent associations of serum chloride with CVD mortality were detected across different subpopulations, and no significant interactions were detected (all *P* for interaction>.05; Multimedia Appendix 3). Regarding cancer mortality, more prominent associations of low chloride with mortality risk were detected in smokers and participants with hypertension, as shown by the interaction effect of serum chloride with smoking status (*P* for interaction=.04) and comorbid hypertension (*P* for interaction=.047; Multimedia Appendix 4). With regard to respiratory mortality, more prominent associations of low chloride with mortality risk were detected in adults with less physical activity, as indicated by its potential interaction effect with serum chloride (*P* for interaction=.02; Multimedia Appendix 5).

Table 3. Subgroup analyses of the associations of serum chloride quartiles with all-cause mortality for adults from the US National Health and Nutrition Examination Survey 1999-2018 (N=51,060)[a].

[a] Data were calculated using svycoxph to fit a multivariate Cox proportional hazards model to data from a complex survey design, with adjustment of dichotomic sex; age; race; education; marital status; family income-to-poverty ratio; BMI; smoking; alcohol use; Healthy Eating Index-2015; physical activity; serum sodium; serum potassium; serum bicarbonate; use of diuretics; and comorbidity or history of hypertension, diabetes, coronary heart disease, stroke, chronic obstructive pulmonary disease, cancer, and chronic kidney disease, except for the specific stratification variable. The test for trend was based on the variable containing the median value for each quartile. The interaction effect was evaluated using the likelihood ratio test.

[d] Q3: quartile 3.

[e] Q4: quartile 4.

[f] HR: hazard ratio.

Sensitivity Analyses of the Association of Serum Chloride With Mortality

All sensitivity analyses showed a robust association of serum chloride with all-cause mortality and cause-specific mortality. Briefly, after excluding participants who died in the first 2 years (992/51,060, 1.94%), the association of categorical serum chloride with all-cause and cause-specific mortality remained stable (Multimedia Appendix 6). The association of categorical serum chloride with mortality was slightly attenuated in the fully adjusted model, especially with cancer mortality, when excluding participants with potential serum chloride outliers (936/51,060, 1.83%; Multimedia Appendix 7). In addition, excluding participants with possible hypoalbuminemia (714/51,060, 1.4%) did not cause substantial shifts in the results (Multimedia Appendix 8). Additional adjustment of history of congestive heart failure or separate adjustment of potassium-sparing diuretics and nonpotassium-sparing diuretics did not cause substantial shifts in the results (Multimedia Appendix 9). Furthermore, there were some missing data on covariates (Multimedia Appendix 10), and multiple imputation of them strengthened the associations of serum chloride with all-cause and cause-specific mortality, probably owing to the increased power (Multimedia Appendix 11).

Finally, we calculated E-values to assess the sensitivity to unmeasured confounding. Briefly, the all-cause mortality risk of low serum chloride (Q1) could be influenced only when the unmeasured covariates had risk ratios >1.92 for both serum chloride and all-cause mortality, and similarly, to account for the association we observed between serum chloride and cause-specific mortality and to address any unmeasured confounding, the strength of the relationship would need to be >2.34, 2.35, and 2.78 (Multimedia Appendix 12).

Discussion

Principal Findings

In this study, we used a prospective cohort with a relatively large sample size to explore the link between serum chloride level and all-cause and cause-specific mortality in American adults. After adjusting for demographic factors, relevant lifestyle, and comorbid factors, low serum chloride levels were significantly associated with higher risks of all-cause mortality, CVD mortality, cancer mortality, and respiratory disease mortality within a certain range. Further analysis revealed an L-shaped relationship between serum chloride levels and all-cause and specific-cause mortality in the general population. The associations of serum chloride and mortality risk were consistent across different subgroup populations and were rather robust in different settings. These findings suggested that serum chloride may serve as a promising cost-effective health indicator in the general adult population.

The widely acknowledged normal range of serum chloride for an adult is 96 to 106 mmol/L [2], and in our study population, the serum chloride was 103.2 (101.2-105.0) mmol/L, which subtly fluctuated according to sex, age, or race as well as lifestyle factors and clinical situations. We found that participants with lower serum chloride tended to be older and have a lower BMI. Considering that low chloride levels may be a symptom of malnutrition [34], lower BMI and older age might reflect a nutritional deficiency in the population. In addition, lower chloride levels are also observed in people with comorbidities such as hypertension, kidney disease, and diabetes mellitus.

The association of remarkable abnormality of serum chloride, hypochloremia, and hyperchloremia with mortality risk has been investigated in various hospital settings. Thus, serum chloride level (<100 mmol/L) in patients with hypertension was independently associated with a 20% higher mortality rate, as shown by a cohort of 12,968 patients with hypertension [35]. Similarly, serum chloride levels were found to be inversely associated with all-cause mortality in patients with CKD [14] and with intensive care unit mortality in patients with cirrhosis who were critically ill [36]. However, in the community-based population, the association between serum chloride distribution and mortality has been scarcely discussed and seems contradictory. Consistent with our study, a cohort study in the general population in Belgium that was followed up for 10 years showed that serum chloride levels <100 mmol/L were associated with increased all-cause, CVD, and non-CVD mortality [37]. Although we drew a conclusion similar to their study, we studied a different target population with a larger sample size and included different covariates. Another cohort study including 16,483 participants in NHANES III (1988-1994) followed up to 2011 found that low serum sodium level was associated with increased cardiovascular mortality, whereas lower serum chloride level was not, which was inconsistent with this study [38]. In our study, we included 51,060 participants (1999-2018) and followed them up to 2019. We included more covariates and conducted a more comprehensive analysis to confirm the results. Thus, the differences in the sample size, follow-up time, and statistical method might explain this discrepancy.

In our study, we found that low chloride level was not only associated with all-cause mortality but also with cause-specific mortality, including CVD mortality, cancer mortality, and respiratory mortality. Consistent with our findings, various studies have shown that lower chloride levels are associated with CVD mortality and play a prognostic role in CVD [11,37,39,40]. Several hypotheses have been proposed regarding the mechanism behind this. First, lower chloride levels or hypochloremia could increase the activity of a family of with no lysine kinases, which leads to diuretic resistance [41]. Second, as chloride, not sodium, is the principal regulator of renin release from the juxtaglomerular apparatus, hypochloremia can decrease chloride delivery to the macula densa and hence increase the renin release, which has long-term deleterious effects in patients with heart issues, such as venous congestion and pathologic myocardial remodeling [42]. Third, hypochloremia may impair the activity of the cardiac chloride channel, which may result in impaired cardiac contractility and arrhythmia and lead to sudden death [43,44]. Furthermore, electrolyte imbalance including hypochloremia can result in the dysregulation of myocyte intracellular pH, which also contributes to arrhythmia [45].

Studies on the association between serum chloride and cancer mortality are rare. A retrospective study in China demonstrated that low chloride levels were associated with increased mortality in patients with colorectal cancer after surgery [46]. Another prospective study in a hospital in Saudi Arabia reported that lower chloride level was a unique prognostic marker for high-risk polyps, which was associated with colorectal cancer [47]. Several hypotheses may elucidate the underlying mechanism. A cancer diagnosis may induce chronic stress in patients [48], which causes relative disruption of adrenal hormones and results in a decrease of chloride level [49]. Tumor-associated abnormal expression of some ion channel proteins can also lead to electrolyte disorders including hypochloremia and thus lead to adverse outcomes [50]. In addition, our subgroup analysis showed that smokers and adults with hypertension might be more susceptible to cancer mortality related to low serum chloride levels; however, further studies are needed to clarify the potential mechanisms.

Literature on the association between serum chloride and respiratory mortality is also limited. Consistent with our study, a retrospective cohort study in Glasgow showed that mortality in patients with COPD increased linearly as serum chloride levels <105 mmol/L [51]. Lower chloride level is a metabolic indicator of chronic respiratory acidosis [52]. Patients with COPD usually have an increase in partial pressure of carbon dioxide and bicarbonate; thus, chloride decrease may be a renal response to the increasing partial pressure of carbon dioxide to assure the electroneutrality. Moreover, our subgroup analysis indicated that participants with less physical activity may bear a higher respiratory mortality risk with low chloride compared with the counterparts with active physical activity, and further studies are needed to fully elucidate the mechanism.

Compared with Q1 and Q4 groups, participants in the Q2 and Q3 groups of serum chloride tend to have relative lower hazards, probably because their serum chloride levels (101.3-105.0 mmol/L) represents an ideal homeostasis which may, in some degree, avoid the risk of adverse events related to hypochloremia or hyperchloremia. Surprisingly, our study demonstrated that all-cause and specific-cause mortality did not increase when the serum chloride level was >105.1 mmol/L, which is in accordance with a recent community-based study conducted in

Israel [53] and studies involving people with high blood pressure [35] or those with chronic heart problems [9]. However, some inconsistent results are also noteworthy, in which a retrospective cohort in South Korea showed that the 90-day mortality was increased in patients after noncardiac surgery when serum chloride level was >110 mmol/L [54], and early hyperchloremia was associated with higher odds of death or disability at 90-day, in patients with acute ischemic stroke [55], and high serum chloride level at admission was associated with higher in-hospital mortality in patients in medical intensive care units [56]. The significant difference in the clinical characteristics, demographics, and laboratory variables in the different population settings may partially explain this discrepancy. Moreover, previous literature suggests that hyperchloremia is often hospital acquired, whereas hypochloremia is community acquired [57], in which people with unfavorably high serum chloride levels or hyperchloremia are more likely to be patients in the hospital but not individuals from the community, as in our study.

Fluctuation of serum chloride usually occurs with concomitant changes in serum sodium, potassium, and bicarbonate; therefore, we adjusted them in the final models and confirmed the chloride-specific risk independent of hyponatremia or acid-base disturbances. Serum chloride is largely influenced by renal function and the use of diuretics; therefore, we adjusted eGFR and diuretic use in the final model and performed stratified analysis according to the renal function and diuretic use, validating the consistent association of low serum chloride with mortality risk. In our study, the cutoff point for low serum chloride was set as the first quartile of chloride distribution in the population (101.2 mmol/L), whereas hypochloremia was commonly defined as ≤96 mmol/L [10,58], and some researchers selected 100 mmol/L as the cutoff point [13,35]; therefore, the differences in definition criteria should be taken into account when explaining the effect size of low serum chloride on mortality risk.

This study had several strengths, including the relatively large sample size (>50,000) and the nationally representative sample design, which facilitates the generalization of our findings. Moreover, we took into account a multitude of potential confounding factors, including sociodemographic factors, lifestyle factors, laboratory tests, drug use, and comorbidities with extensive statistical methods, which guaranteed the robustness of our findings.

Limitations

However, some limitations of this study must be acknowledged. First, causality cannot be determined owing to the observational study design, which requires randomized controlled studies for confirmation. Second, the serum chloride concentration was investigated only once at baseline, which may be influenced by temporary factors; therefore, repeated measurements are advisable in future studies. Third, the study participants were US adult civilians; thus, the associations and size effect need to be confirmed when trying to generalize the results to other populations. Finally, the possibility of residual and unknown confounding cannot be entirely excluded.

Conclusions

In conclusion, we found that decreased serum chloride concentrations were independently associated with increased all-cause mortality, CVD mortality, cancer mortality, and respiratory disease mortality in the American adult population, and these findings emphasized the importance of monitoring serum chloride in health evaluation. However, further studies are still warranted to verify the predictive role of serum chloride and to explore the potential pathophysiological mechanisms underlying the differences in mortality.

Abstract

Background: It is believed that smoking is not the cause of approximately 53% of lung cancers diagnosed in women globally.

Objective: The study aimed to develop and validate a simple and noninvasive model that could assess and stratify lung cancer risk in nonsmoking Chinese women.

Methods: Based on the population-based Cancer Screening Program in Urban China, this retrospective, cross-sectional cohort study was carried out with a vast population base and an immense number of participants. The training set and the validation set were both constructed using a random distribution of the data. Following the identification of associated risk factors by multivariable Cox regression analysis, a predictive nomogram was developed. Discrimination (area under the curve) and calibration were further performed to assess the validation of risk prediction nomogram in the training set, which was then validated in the validation set.

Results: In sum, 151,834 individuals signed up to take part in the survey. Both the training set (n=75,917) and the validation set (n=75,917) were comprised of randomly selected participants. Potential predictors for lung cancer included age, history of chronic respiratory disease, first-degree family history of lung cancer, menopause, and history of benign breast disease. We displayed 1-year, 3-year, and 5-year lung cancer risk–predicting nomograms using these 5 factors. In the training set, the 1-year, 3-year, and 5-year lung cancer risk areas under the curve were 0.762, 0.718, and 0.703, respectively. In the validation set, the model showed a moderate predictive discrimination.

Conclusions: We designed and validated a simple and noninvasive lung cancer risk model for nonsmoking women. This model can be applied to identify and triage people at high risk for developing lung cancers among nonsmoking women.

Introduction

China has the most lung cancer death cases around the world in 2020. In 2020, according to estimates provided by the International Agency for Research on Cancer, there were approximately 1.80 million cases of deadly lung cancer globally. China accounted for 39.8% of these cases [1]. In China, the continuous rise in lung cancer deaths during the past 2 decades was attributed to the rising prevalence of lung cancer in women [2]. Additionally, 50% or more of lung cancers in women in Southeast Asia were diagnosed in nonsmokers [3-5]. Most of the Chinese lung cancer cases were reported to be clinically progressed in 2012-2014, with 64.6% of them being stage III-IV lung cancers [6]. The lung cancer survival rate in China, which was defined as 5 years as standard, grew up to 20% between 2003 and 2015 [7]. The prognosis of lung cancer is strongly associated with the stage in which it was detected; the 5-year survival rate ranges from 0% in cases detected in patients with stage IV cancer to >80% in cases detected in stage I and whose patients underwent surgery [8].

Started in 2002, the National Lung Screening Trial indicated that low-dose computed tomography screening may decrease lung cancer deaths by 20% [9]. However, this project only screened people (41% women) at high risk for lung cancer based on age and smoking history (aged 55-74 years, smoked no fewer than 30 pack-years, and had no more than 15 years of having quit smoking). Women in China have their own characteristics of lung cancer risk factor exposure and incidence patterns, the most critical of which is that although the smoking rate among women is much lower than that of high-income countries such as the United States (2.4% in China and 23.6% in the United States), the lung cancer frequencies are relatively similar (22.8/100,000 in China and 30.8/100,000 in the United States, based on the standardized lung cancer incidence rate of the world population) [10,11]. This finding shows that the existing worldwide guidelines for lung cancer screening focused on smoking as the primary predictor for high-risk individuals, which would be inappropriate for Chinese women, particularly for nonsmoking women. Therefore, determining a way that accurately forecasts the risk of lung cancer in nonsmoking women and directing them toward the more cost-effective low-dose computed tomography screening is a feasible method for achieving efficient early diagnosis and treatment of lung cancer.

Earlier research has developed numerous lung cancer risk predictive models related to specific population demographics [12-41]; however, few of the predictive methods focused on nonsmoking women in mainland China [42]. Consequently, the development of lung cancer risk predicting tools for nonsmoking Chinese women according to consistently established risk factors in earlier studies has become a top goal [43]. Nevertheless, this goal is demanding and difficult. In contrast to the findings of lung cancer caused by tobacco, there are no identified risk variables for the progression of lung cancer in nonsmoking women. Although other risk factors were suggested, their relative importance varies greatly between geographical locations [3,4,44,45]. It was observed that the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial (PLCO) models, which included nearly 2000 Asian nonsmokers and only 7 cases of lung cancer, could be inapplicable to Asian nonsmokers [46]. Among the nonsmokers who participated in the PLCO study (n=65,711), none of them had a 6-year risk that was greater than 0.0151.

On the basis of the Cancer Screening Program in Urban China (CanSPUC), we created such a model [47]. In this paper, we aimed to create and internally validate a lung cancer risk predicting model for nonsmoking Chinese women, with the focus on established risk factors for lung cancer routinely available in general cancer-screening settings.

Methods

Data Source and Subjects

This retrospective, cross-sectional cohort study was carried out inside the scope of CanSPUC, a continuing statewide cancer-screening program for China’s urban population. CanSPUC is designed to detect the 5 most common malignancies, including lung cancer, colorectal cancer, upper gastrointestinal cancer, liver cancer, and female breast cancer. The CanSPUC approach was detailed in previous studies [47,48]. All of the qualified subjects were questioned by highly skilled staff to gather information about their exposure to risk variables and to assess their cancer risk using a specific cancer risk score system. The household registration system was used in local communities to identify eligible permanent residents who were aged 40-74 years and asymptomatic for lung cancer with no history of cancer diagnosis. Individuals who were unable to give informed consent, had a medical disability and were unlikely to complete curative lung cancer surgery, had a history of lung cancer, had received treatment for or had evidence of any cancer within the past 5 years (with the exception of nonmelanoma skin cancer and most in situ carcinomas), or had symptoms suggestive of lung cancer (including unexplained weight loss of >7.5 kg within the past 12 months or unexplained hemoptysis) were not eligible to participate. In October 2013, CanSPUC was implemented in Henan province, which encompassed 8 cities with complete cancer registration data (Zhengzhou, Zhumadian, Anyang, Luoyang, Nanyang, Jiaozuo, Puyang, and Xinxiang). We examined the data collected over the first 6 years (from October 2013 to October 2019) in the Henan province for our research. Only nonsmoking women were included in this investigation.

Ethics Approval

The Ethics Committee of the Affiliated Cancer Hospital of Zhengzhou University and Henan Cancer Hospital evaluated and authorized the research (no.2021-KY-0028-001). Our sample was drawn from retrospective encounters documented in the electronic health record; these data were deidentified for both sets of analyses and did not require informed consent.

Outcome, Variables, and Measurements

All new cases of lung cancer were identified by matching with the cancer registry database in Henan province, China (by unique ID number), and histologically confirmed between October 1, 2013, and March 10, 2020. In Henan province, records of lung cancer are first submitted to local cancer registries by the hospitals and medical institutions and then submitted to the Henan Provincial Central Cancer Registry of China by the local cancer registries. The International Classification of Diseases, Tenth Revision was used to classify newly diagnosed lung malignancies by site. Lung cancers were identified by the International Classification of Diseases, Tenth Revision code of C33-C34. To find possible lung cancer risk variables, self-reported information was collected (Textbox 1).

Textbox 1. Self-reported information collected.

1. **Demographic factors, such as age, ethnicity, educational status, marital status, height, and body weight**
    - A low-educational level was defined as elementary school or less, a medium educational level as junior or senior high school, and a high-educational level as college or above
    - According to the "Guidelines for the Prevention and Control of Overweight and Obesity in Chinese Adults," BMI was dependent on the individual's height as well as weight and segmented to "<18.5 kg/m^2," "18.5-23.9 kg/m^2," "24.0-27.9 kg/m^2," and "≥28.0 kg/m^2" categories [49]
2. **Dietary habit**
    - Dietary intake of the following food in the past 2 years: vegetables (green-leafy plants and fungi except potatoes, sweet potatoes, and starches) <2.5 kg/week or ≥2.5 kg/week; roughage (all other grains except for white flour and rice) <0.5 kg/week or ≥0.5 kg/week; and fruit <1.25 kg/week or ≥1.25 kg/week. The weight of the food was measured prior to cooking
3. **Living environment, behavior, and habits**
    - Cooking oil fume exposure: exposure is considered as "none or a little" if chimneys, fume extractors, or smokeless pots were used during cooking; otherwise, it was considered as "a lot"
    - Passive smoking: regular living or employment in an enclosed area where people routinely smoke was regarded as "yes"; otherwise, it was regarded as "no"
    - Alcohol consumption: "current" referred to those who had consumed alcohol at least once weekly on average for more than 6 months; "former" referred to those who had ceased drinking; "never" referred to those who had never consumed alcohol
    - Physical activity: swimming; taijiquan, qigong, or walking; long range running; aerobics; sporting events (such as basketball, table tennis, badminton, etc); Yangko dancing or fast walking; and other physical activities (such as mountains climbing, rope jumping, and shuttlecock kicking). Subjects who engage in at least three sessions of practice weekly for a total of ≥90 minutes weekly were classified as engaging in "heavy physical activity"; otherwise, they were classified as engaging in "moderate or no physical activity"
4. **Psychology and emotions, such as a history of serious trauma and more than 6 months of mental depression**
    - Serious trauma was described as a major illness or death of a family member, family conflict and separation, significant loss of property, unexpected job loss, severe unexpected physical injury, violent danger, etc
5. **Comorbidities, such as chronic respiratory disease, tuberculosis, chronic bronchitis, emphysema, asthma bronchiectasis, hypertension, hyperlipidemia, and diabetes**
    - Every self-reported case of comorbidity required an evaluation from a professional medical facility
6. **Family history of lung cancer**
    - Whether first-degree relatives, second-degree relatives, or third-degree relatives had lung cancer or not
7. **Physiology and fertility**
    - Including age of menarche (<12 years or ≥12 years), menopause (yes or no), fertility status (yes or no), lactation status (yes or no), history of benign breast illness (yes or no), and a history of reproductive system surgery (yes or no)

Statistical Analysis

To contrast the profiles of those who have lung cancer and those without cancer, descriptive statistics, presented as percentages for categorical data, were used. Chi-square tests were used to examine the univariate correlation between baseline characteristics and lung cancer progression. For continuous variables, mean (SD) or median (IQR) were used.

In this investigation, the integrated model was applied to generate a nomogram to measure the 1-year, 3-year, and 5-year estimations of the lung cancer risk in the training set, according to the independently prognostic variables using the stepwise multivariable Cox regression (P_{entry}=.15 and P_{stay}=.10). The calibration curve was used to determine the nomogram's validity. By applying 50% and 84% quantiles, the risk predictions were grouped into the low-risk group, medium-risk group, and high-risk group, as suggested previously [50]. As per the risk prediction model, Kaplan-Meier curves were displayed for the low-risk group, medium-risk group, and high-risk group for lung cancer. The log-rank analyses were performed to compare the 3 curves. Receiver operating characteristic curves and the area under the curve (AUC) were used to quantify the prediction performance of 1-year, 3-year, and 5-year lung cancer risk estimations in the training set and validation set. By comparing observed and predicted probabilities, the bootstrap sampling method was used to evaluate the calibration of the current model.

All statistical analysis was carried out via R (version 4.0.3; R Foundation for Statistical Computing) and SAS (version 9.4; SAS Institute) software. The nomogram was drawn using the *rms* package. The receiver operating characteristic curves were drawn by using the *survivalROC* package. Using the *ggplot2* package, a calibration curve was created. All of the tests were done using 2-tailed hypotheses, and *P*<.05 was determined to be statistically significant.

Results

Characteristics of the Study Population

This research consisted of a total of 151,834 qualified participants with an average age of 55.34 (SD 8.65) years. The subjects were randomly separated into a training set of 75,917 and a validation set of 75,917 (Figure 1). By March 2020, 204 lung cancer cases occurred within 151,834 subjects, resulting in an incident density of 42.24 per 100,000 person-years. Lung cancer cases were more frequent in those who were older (*P*<.001), had a history of respiratory illness (*P*=.001), had a first-degree family history of lung cancer (*P*=.02), and had menopause (*P*<.001). Extra features are shown in Table 1 and Table S1 in Multimedia Appendix 1.

Figure 1. Flow chart of participants included in this analysis.

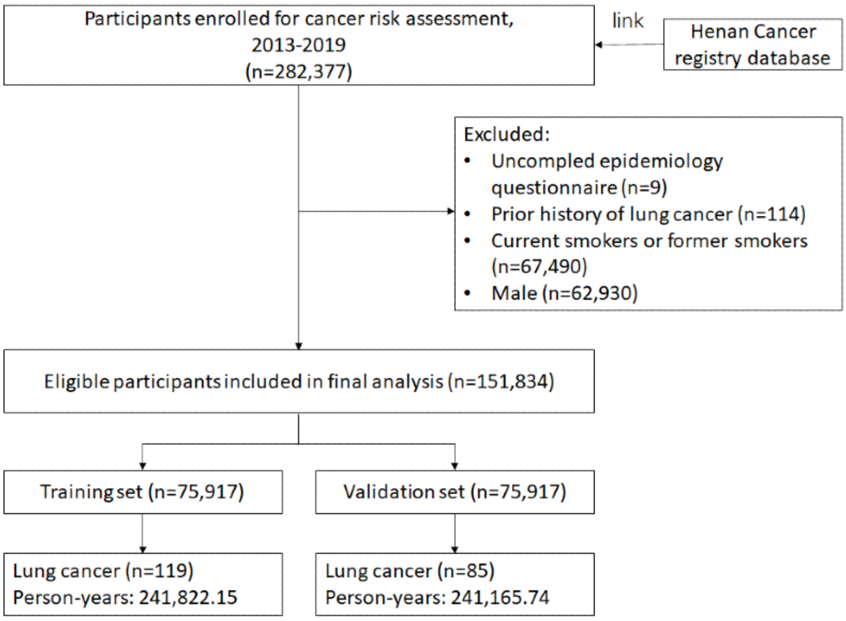

Table 1. Comparison of baseline characteristics between the non–lung cancer and lung cancer groups using chi-square test in the training set.

Variables	Total (N=75,917)[a]	Non–lung cancer[b]	Lung cancer[b]	χ^2 (*df*)	*P* value

Development of the Lung Cancer Risk Assessment Model

Table 2 displays the hazard ratios (HRs) with its 95% CI for every indicator. In the training set, age (≥55 years: HR 1.34, 95% CI 0.38-4.80; ≥60 years: HR 2.33, 95% CI 0.67-8.11; ≥65 years: HR 2.41, 95% CI 0.69-8.49; ≥70 years: HR 1.79, 95% CI 0.43-7.40), history of chronic respiratory disease (HR 1.94, 95% CI 1.24-3.04), first-degree family history of lung cancer (HR 1.60, 95% CI 0.91-2.83), menopause (HR 2.16, 95% CI 0.90-5.19), and history of benign breast disease (HR 0.58, 95% CI 0.36-0.94) were independent risk factors for lung cancer. Consequently, we applied these parameters to construct the model. We drew 1-year, 3-year, and 5-year risk–predicting nomograms for lung cancer (Figure 2A).

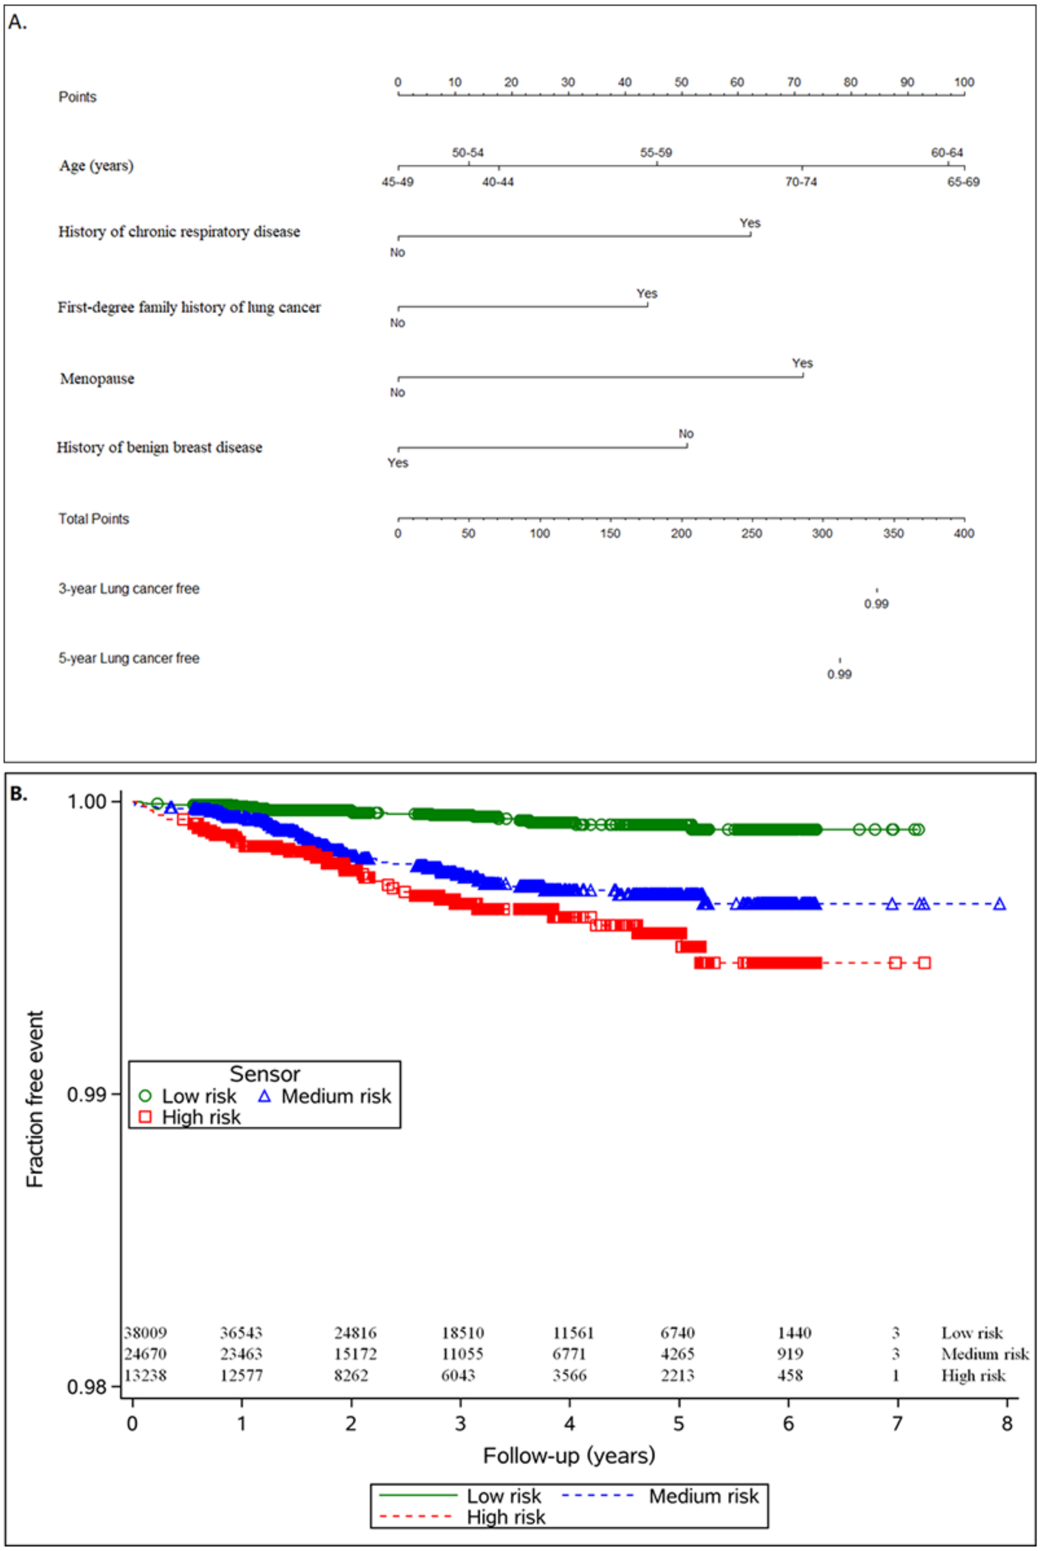
[c] Italicized values indicate statistical significance.

Figure 2. (A) Nomogram to calculate the personal 1-year, 3-year, and 5-year risk of lung cancer, and (B) the lung cancer incidence across different cancer risk categories.



Predictive Performance of the Model

The risk predictions were categorized into low-risk, medium-risk, and high-risk categories, and a log-rank test revealed significant differences across the 3 groups (Figure 2B; *P*<.001).

By using this model, the AUC for 1-year, 3-year, and 5-year lung cancer risk in the training set was 0.762, 0.718, and 0.703, respectively. The model yielded a greater AUC for passive smokers (1-year: 0.787, 3-year: 0.715, and 5-year: 0.745) than for nonpassive smokers (1-year: 0.741, 3-year: 0.721, and 5-year: 0.689; Figure 3). Calibration was acceptable, with very similar observed and predicted hazards (Figure 4).

Figure 3. The receiver operating characteristic curves of prediction models in the training set. (A) Whole population; (B) Nonpassive smokers; (C) Passive smokers. AUC: area under the curve.

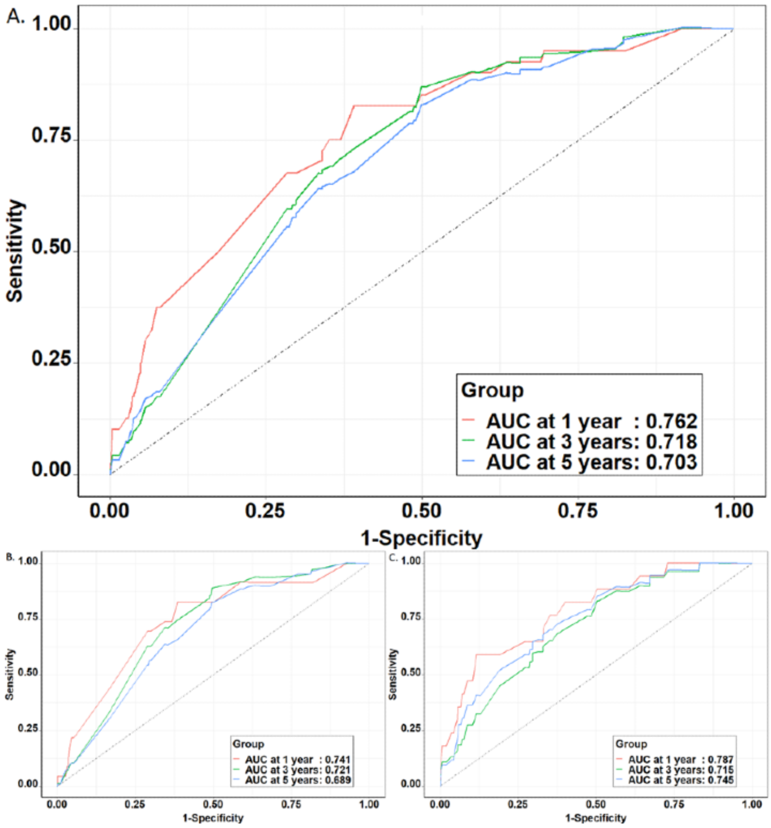


Figure 4. Calibration curves of the nomogram for (A) 1-year, (B) 3-year and (C) 5-year lung cancer–free rates in the training set.

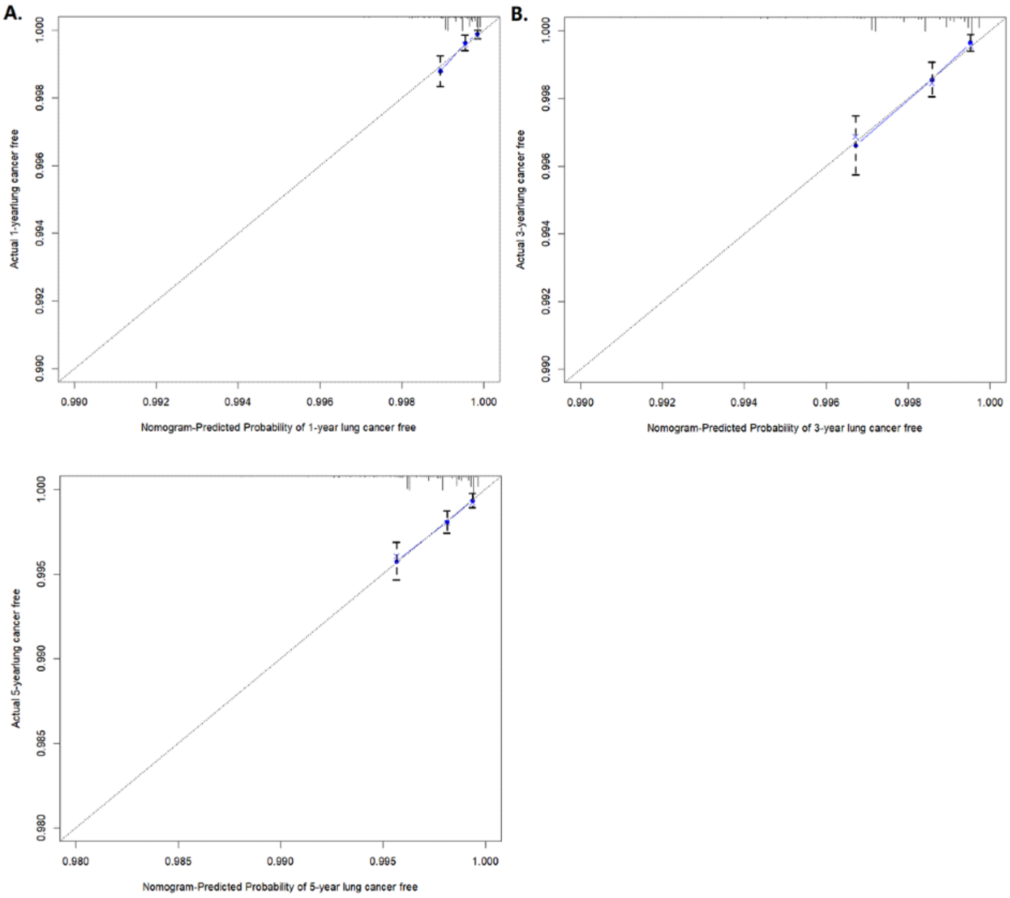

Validation of the Lung Cancer Risk Model

The model demonstrated a moderate predictive discrimination in the validation set, with AUCs of 0.646, 0.658, and 0.650 for 1-year, 3-year, and 5-year lung cancer risks, respectively (Figure S1 in Multimedia Appendix 1), and satisfactory calibration of relative risk (Figure S2 in Multimedia Appendix 1).

Discussion

We constructed and validated a simple risk predictive model internally for lung cancer in nonsmoking women relying on 5 commonly accessible factors such as demographics (age), comorbidities (chronic respiratory disease), first-degree family history of lung cancer, and fertility (menopause and history of benign breast disease). Our results showed that the model has moderate discriminatory accuracy and goodness of fit for both nonpassive smokers and passive smokers.

Multiple lung cancer risk variables were discovered for nonsmoking women, such as passive smoking [51,52], prior lung diseases (tuberculosis, chronic bronchitis, emphysema, and prior lung disorders [chronic obstructive pulmonary disease]) [53], indoor radon [54], cooking oil fume [55], and a family history of lung cancer [56]. The established risk variables for lung cancer, such as age, a family history of lung cancer, and a history of chronic respiratory disease, are similar to the findings. Age is the most important risk variable for lung cancer in nonsmoking women according to our survey, which found that the risk was more than 2.4 times higher in the age group of 65-69 years than 40-44 years.

Menopause was associated with an increased risk of developing lung cancer, with an overall odds ratio of 1.33 (95% CI 0.90-1.96), according to a pooled analysis of nested case-control data [57], which is consistent with our findings. Interestingly, we found that women with a history of benign breast disease were less likely to develop lung cancer, possibly because these women may be more careful about their lifestyle and diet after developing breast disease than those who did not. This finding will need to be validated in future studies.

Besides the accurate indicators, risk predicting models should achieve performance standards for discrimination (the differentiation capacity to distinguish lung cancer cases from control ones) and calibration (defined as the consistency between observed and predicted risk for lung cancer). Since 2010, the substantial growth in the numbers of investigations on lung cancer risk predicting models shows the necessity of using predictive models to drive population triage. Initially, models, such as the Bach model [12], Spitz model [13], Liverpool Lung Project model [14], and PLCO$_{M2012}$ model [58], emphasized the importance of applying the classic epidemiological risk variables, including age, smoking history, personal history of disease, and family history of cancer. To the best of our knowledge, this study is one of the few studies to model the prediction of lung cancer risk among nonsmoking Chinese women. Due to the fact that each model was created in a distinct population with different baseline risks and lengths of follow-up, it is challenging to compare the discriminating performance of risk predictive models. The discriminating ability of every model was quite equal, with C-statistics ranging between 0.72 and 0.86. Compared to prior research, our models showed comparable predictive performance.

In understanding our findings, certain strengths and limitations should be carefully considered. Our research is conducted on a large population-based cancer-screening program in mainland China, which is a strong point. In addition, the variables included in this model could be easily collected and updated without any imaging, sophisticated testing, or calculation. Furthermore, the model will be used as a convenient method to triage high-risk people among nonsmoking women, and it will be involving in public health initiatives, such as recommendations regarding the control of lung cancer in nonsmokers. Nonetheless, the statistics based on self-report may be susceptible to social acceptability bias as well as recall bias. Since data collection and quality control were carried out to a high standard, the vast volume of information can be relied upon. Second, the performance of our risk-predicting model was not validated against an external data set before it was used. The findings of the internal calibration, on the other hand, suggest that this model will function satisfactorily when applied to a variety of populations.

In conclusion, a large-scale lung cancer–screening project in China served as the foundation for the creation and internal calibration of a straightforward risk predictive model for lung cancer in nonsmoking women. The model has moderate discrimination and could be used as a tool for triaging high-risk people to prevent lung cancer in nonsmoking women. To validate the concept in external populations, additional prospective studies are needed.

Acknowledgments

This study was supported by the Natural Science Foundation of Henan Province (No. 212300410261) and the training project for young and middle-aged excellent talents in health science and technology innovation of Henan province (YXKC2022045). We sincerely thank all the members of the Cancer Screening Program in Urban China from the National Cancer Center of China and Henan province. We are also grateful to the participants for be involved in this study.

Data Availability

The data sets for this manuscript are not publicly available because all our data are under regulation of both the National Cancer Center of China and The Affiliated Cancer Hospital of Zhengzhou University and Henan Cancer Hospital. Requests to access the data sets should be directed to SZ.

Abstract

Background: As of January 2022, the number of people infected with COVID-19 worldwide has exceeded 350 million. As the COVID-19 pandemic continues, people are affected in a wide range of areas of life, which in turn causes numerous psychological problems. Depression is a serious problem for people who have suffered from COVID-19. Depression can worsen COVID-19 precautionary behavior compliance or the health behavior itself. In addition, these depressive symptoms may have different characteristics depending on the individual's gender.

Objective: The aim of this study was to determine whether depression is a factor that may affect COVID-19 fear, precautionary behavior compliance, and health behavior, and how these characteristic trends differ by gender.

Methods: This was a secondary analysis of data from the 2020 Korea Community Health Survey (KCHS), a national cross-sectional survey conducted with complex sampling analysis. In 2020, the KCHS included COVID-19–related questions. For this study, we used the KCHS data from both the COVID-19–related questions and the Patient Health Questionnaire-9 scale. After weighting the data according to the KCHS guidelines, we calculated the distribution of men and women according to depression level. The data were collected using multiple-choice questions related to precautionary behavior compliance, COVID-19–related fears, and health behavior changes.

Results: Of the 204,787 participants, those who were clinically depressed had a greater tendency to not comply with precautionary behaviors. Regarding COVID-19, "fear" showed a decreasing trend in both men (adjusted odds ratio [AOR] 0.72, 95% CI 0.61-0.83) and women (AOR 0.74, 95% CI 0.63-0.86) with clinically relevant depression. Moreover, for both men and women, health behaviors deteriorated as depression intensified; the AOR for sleep duration changes was 2.28 (95% CI 2.00-2.59) in men and was 2.15 (95% CI 1.96-2.36) in women. Notably, the responses of clinically depressed women revealed a doubled increase in both their drinking (AOR 2.25, 95% CI 1.88-2.70) and smoking (AOR 2.71, 95% CI 1.95-3.77) habits compared with those of nondepressed women.

Conclusions: Both men and women with more severe depression were more likely to violate precautionary health behaviors as their depression worsened. Health behaviors also deteriorated for both genders, but women tended to show a greater change. Therefore, additional studies and interventions for vulnerable groups such as severely depressed people are needed. More research is also necessary to develop interventions based on statistical comparisons of men and women.

KEYWORDS

COVID-19; precautionary behaviors; COVID-19 fear; health behavior deterioration; gender differences

Introduction

As of January 25, 2022, 349,641,119 people worldwide had been infected with COVID-19 and the death toll had reached 5,592,266 [1]. Since the World Health Organization's March 11, 2020, declaration that the world was facing a pandemic, various restrictions have been implemented to prevent the global spread of the virus. These restrictions have included lockdowns for all or some educational facilities and nonessential businesses, travel limitations, quarantine measures, social isolation, and mandatory mask-wearing [2-4]. However, COVID-19 has had a profound impact on all countries, racial groups, and socioeconomic classes [5]. Secondary problems arise from these restrictions.

Among all the problems that have occurred, mental health issues related to COVID-19 are among the most important health concerns and have received considerable attention. Direct stress caused by illness and concerns about medical service interruption, employment, financial stability, and social contact restrictions may cause psychological problems [6-9]. Additionally, COVID-19 fear is associated with several mental health problems such as anxiety, depression, psychological distress, and sleep issues [10-12]. In particular, depression is one of the most representative mental health problems during COVID-19, which is associated with deterioration in health behaviors, including decreased physical activity and sleep and increased smoking [13-15].

Moreover, various empirical studies have reported gender differences in depression associated with the COVID-19 pandemic [16-18]. Depression is known to have some gender-specific characteristics, and depression rates are generally higher in women regardless of COVID-19 [19,20]. For example, among Australian adults, women were found to be more likely to have clinically significant depression and anxiety [17]. In the case of COVID-19, these differences still apply, as indicated by a study of adults aged 25-69 years showing that women reported more depression, anxiety, stress, loneliness, and a higher rate of increased cannabis use compared to pre-COVID-19 levels [16].

Mental health is not only a concern in and of itself, but may also impede health behaviors or COVID-19 precautionary actions [15,21,22]. Olapegba et al [23] reported that psychological distress caused by COVID-19 fear hinders precautionary behavior compliance. Moreover, depression can lead to even more significant health problems by reducing COVID-19 precautionary behavior compliance and general healthy behavior. In addition, given that severe degrees of fear can negatively impact an individual's ability to respond appropriately during the COVID-19 pandemic [24], the impact of depression may vary in severity, and, at the same time, gender differences may also exist. To date, studies have been conducted on the gender gap in depression related to COVID-19 or the following problems: medical service interruption, employment, financial stability, social contact restrictions [25-27], and the impact of depression on COVID-19 precautionary behavior compliance [22,28]. However, studies that have analyzed the severity of depression according to gender are scarce. Therefore, the purpose of this study was to determine whether depression is a factor that worsens COVID-19 fears, precautionary behavior compliance, and health behavior, and whether these characteristic trends differ by gender.

Methods

Study Design

This was a secondary analysis of data from a national cross-sectional survey: the 2020 Korea Community Health Survey (KCHS) conducted by the Korea Centers for Disease Control and Prevention [29]. The Community Health Survey, initiated in 2008, is an annual, anonymous, computer-assisted personal interview survey that evaluates the health status and behaviors of South Korean adults. A trained surveyor visits the households selected as samples and conducts a one-on-one interview using a laptop computer equipped with a survey program. The 2020 Community Health Survey covered 18 geographical areas and comprised 142 survey questions, including those pertaining to health behaviors such as exercise, smoking, and drinking. Given the global health context in 2020, the survey for that year was revised to include questions related to the COVID-19 pandemic.

The data were collected from August 16, 2020, to October 31, 2020 [29]. The target population of 2020 KCHS was adults aged 19 years or older, and a sample group was extracted through a composite sample design to minimize sample bias [30]. Next, in the first official extraction, probability proportional to size sampling was performed to ensure that the extraction probability was proportional to the number and size of households by housing type in Tong, Ban, and Ri (the smallest administrative district units). The second extraction was a systematic extraction based on the number of households in Tong, Ban, and Ri. In total, 229,269 people were surveyed; after excluding incomplete responses, the data from 204,787 respondents were available for analysis. To request the KCHS data for use in the present study, we signed a written pledge to confirm our intentions and submitted a usage plan describing the purpose for which we intended to use the data if, after the Korea Centers for Disease Control and Prevention reviewed the plan, the data request was approved. Only those who have received approval can download and use the raw data of KCHS.

Ethical Approval

This study was conducted after review from the Institutional Review Board (IRB) of Chung-ang University. Because this was a secondary analysis of data from a national cross-sectional survey, the study received an exemption by the IRB (approval number 1041078-202201-HR-002).

Measures

General Participant Characteristics

To determine the participants' general characteristics, we included data about their sociodemographic characteristics and individual health. Sociodemographic characteristics were assessed according to age, gender, educational level, monthly household income, profession, and region. Age was divided into four generational groups based on the criteria used in the

Korean Longitudinal Study of Aging and previous studies [31-33]: 20 to 44 years (youth), 45 to 64 years (middle age), and 65 years or older (older adults). According to a previous study, education levels were categorized as follows: (1) elementary or less, (2) middle school, (3) high school, and (4) college or higher. Monthly household income was classified into quartiles as Q1 (<25%), Q2 (25%-49%), Q3 (50%-74%), and Q4 (≥75%), and professions were organized according to the Korean version of the Standard Classification of Occupations and previous studies [34,35]. After referring to previous research, we reclassified occupations into four categories: white (white collar), pink (sales and service), blue (agricultural, forestry, fishing, and military), and unemployed. Region was divided into urban and rural areas.

Questions related to individual health conditions included drinking at least once a month, current smoking status, stress awareness, and subjective health status. Possible answers for drinking at least once per month, current smoking status, and stress awareness were either “yes” or “no.” Subjective health status was defined by the self-evaluation of one’s health as “very good” or “good,” and possible answers were “poor” and “fair.”

Depression Assessment

The Patient Health Questionnaire-9 (PHQ-9) was used to measure self-reported depression, with possible scores ranging from 0 to 27 [35]. PHQ-9 consists of nine items used to evaluate the diagnostic criteria for major depressive disorder in accordance with the Diagnostic and Statistical Manual of Mental Disorders, fifth edition. A high PHQ-9 score indicates a higher level of depressive symptoms, with 0-4 representing no depression, 5-9 indicating mild depression, 10-14 representing moderate depression, 15-19 indicating moderately severe depression, and 20-27 representing severe depression. In general, a PHQ-9 score ≥10 indicates major or clinically relevant depression [36]. To ensure greater clarity in the explanation of the results, we divided the PHQ-9 scores into three categories: 0-4 (none), 5-9 (mild), and ≥10 (clinically relevant).

Precautionary Behavior Compliance

Precautionary behavior compliance was defined as whether personal quarantine rules (eg, wearing a mask indoors, wearing a mask outdoors) and social distancing rules (eg, maintaining a healthy distance) were observed for the past week with the intention of helping to prevent the spread of COVID-19. According to a previous study [37], eight factors were used to evaluate precautionary behavior compliance as follows: in the last 7 days, had the individual (1) covered his or her mouth and nose while sneezing or coughing, (2) experienced daily ventilation at least twice a day, (3) had everyday spaces disinfected once per day, (4) wore a mask in facilities used by unspecified people, (5) worn a mask when it was impossible to keep an adequate distance, (6) maintained a 2-meter distance between themselves and others, (7) limited visiting sick people, and (8) limited going out or attending gatherings and events? Based on the KCHS’s indicator definition, for each of the eight items, only those who answered “very much” or “yes” were considered to have complied with each precautionary behavior. For example, only the respondents who answered “very much” or “yes” to the question “covered his or her mouth and nose while sneezing or coughing” were considered to have performed precautionary behavior.

COVID-19 Fear

COVID-19 fear is defined as a psychological concern due to the spread of COVID-19 and is assessed by five factors: fear of infection, dying from infection, public criticism, a family member getting infected, and economic loss due to infection. Based on the KCHS’s indicator definition, only those who answered “strongly agree” or “agree” for any of the above five factors were evaluated as having COVID-19 fear of each factor.

Health Behavior Deterioration

Criteria pertaining to physical activity, sleep duration, fast food or energy drink consumption, food consumption, alcohol consumption, and smoking were included to investigate health behavior deterioration during the COVID-19 pandemic. Possible responses were “increased,” “same,” “decreased,” or “not applicable.” With reference to a previous study [37], health behavior deterioration was measured as follows: decreased physical activity, changes in sleep duration (either increased or decreased), increased consumption of instant meals/soda, increased consumption of delivery food, increased alcohol consumption, and an increase in the number of cigarettes smoked per day.

Data Analysis

The distribution of men and women according to depression level was calculated after weighting based on the KCHS guidelines. The weighted values of the distribution of men and women according to depression level are shown as descriptive statistics such as frequency, percentage, and standard error. The participants’ general characteristics according to depression level and gender were also analyzed using descriptive statistics such as frequency, percentage, and standard error. We performed a χ^2 test to confirm the general distribution of the characteristics according to the depression level of the participants.

Depression levels, gender-specific precautionary behavior noncompliance, COVID-19 fear, and health behavior deterioration were analyzed using logistic regression. After controlling for general characteristics (age, educational level, monthly household income, profession, region, heavy drinking, current smoking status, stress awareness, and subjective health status), logistic regression analysis was used to identify differences in depression level and gender-specific precautionary behavior noncompliance, COVID-19 fear, and health behavior deterioration. The adjusted odds ratios (AORs) and 95% CIs for failure to comply with precautionary behaviors, COVID-19–related fear, and health behavior deterioration were calculated. All results are presented as weighted values. The results were statistically analyzed using SPSS version 26.0 (IBM Corp, Armonk, NY, USA).

Results

Table 1 shows the weighted and unweighted distributions of depression in the population according to gender. This study included 204,787 participants (92,739 men and 112,048 women).

Approximately 2% and 3.5% of men and women were classified as having clinically relevant depression, respectively.

Table 2 shows the participants' general characteristics, and Table 3 and Table 4 further summarize these data by depression levels for men and women, respectively. To better represent the general population of South Korea, the percentages and standard errors are presented as weighted values. The largest group of men with clinically relevant depression (48.8%) were aged 20-44 years, and 44.6% of men with clinically relevant depression had a college degree or higher. Approximately 41.6% belonged to the income level Q1, and the rate of unemployment reached 45.5%. Although there was no significant difference in the level of mental health by region, 45.6% of the men with clinically relevant depression reported heavy drinking and 44.5% were current smokers. Among the men with clinically relevant depression, only 21.3% answered that they had stress, but 79.3% evaluated their subjective health condition as poor. Among the women with clinically relevant depression, 60.3% were unemployed. Notably, self-reported heavy drinking increased to 19.4% and current smoking increased to 11.7%, which was five times higher than that of women without depression symptoms

Table 1. Overall and weighted distribution of depression in the sample population (N=204,787).

Depression level[a]	Unweighted, n (%)	Weighted[b]	
		Participants, n (%)	SE
Men (n=92,739)			
None (0-4)	83,026 (89.5)	16,832,027 (88.4)	0.1
Mild (5-9)	7889 (8.5)	1,799,468 (9.5)	0.1
Clinically relevant (≥10)	1824 (2.0)	399,490 (2.1)	0.1
Women (n=112,048)			
None (0-4)	93,305 (83.3)	15,943,821 (82.3)	0.2

[e] Classified into white (white collar), pink (sales and service), blue (agricultural, forestry, fishing, and military), and none (unemployed).

Table 5 illustrates how compliance with precautionary behaviors, COVID-19 fear, and health behavior deterioration differed according to gender and mental health determined using logistic regression analysis after adjusting for general characteristics. The crude odds ratios from the unadjusted model are shown in Multimedia Appendix 1. The precautionary behavior noncompliance rate was found to increase as the depression worsened; this was the case for most items compared to the group without depressive symptoms. The AOR of the noncompliance rate regarding wearing a mask indoors was lower in participants with mild depressive symptoms compared to that for participants with clinically relevant depression, which was the case for both men and women (Table 5). However, in the case of noncompliance with precautionary behaviors related to social distancing, the trend was different between men and women. Among men who had mild depressive symptoms, nonobservance of maintaining physical distance increased by more than that among men with clinically relevant depression. By contrast, the AOR of not maintaining physical distance in women was higher for those with clinically relevant depression than for those with mild depression, showing a tendency to worsen as mental health deteriorated.

The data also showed different characteristics of COVID-19 fear between men and women. The AOR of the fear of infection was similar for women and men with clinically relevant depression. However, the fear of death due to infection was significant only in women for those with mild depressive symptoms. In the case of public criticism, a significant association appeared only among women with clinically relevant depression.

As depression increased in severity in both men and women, health behaviors likewise deteriorated. Changes in sleep duration, an increase in drinking amount, and smoking frequency more than doubled for both men and women with clinically relevant depression. Regarding delivery food consumption, the AOR was the highest for men with mild depressive symptoms, which was similar to that for women with clinically relevant depression.

Table 5. Adjusted odds ratios (95% CIs) for failure to comply with precautionary behaviors, health behavior deterioration during the COVID-19 outbreak, and COVID-19–related fear according to depression levels.[a,b,c]

COVID-19–related questions	Men (n=92,739)			Women (n=112,048)		
	No depression[d] (0-4)	Mild depression (5-9)	Clinically relevant depression (≥10)	No depression[d] (0–4)	Mild depression (5–9)	Clinically relevant depression (≥10)
Failure to comply with precautionary behaviors						
Not covering mouth while coughing	1	*1.29 (1.13-1.46)* [e]	*1.56 (1.26-1.93)*	1	*1.38 (1.24-1.55)*	*1.65 (1.40-1.95)*

[a] Depression level was classified according to scores on the nine-item Patient Health Questionnaire.

[b] Logistic regression model adjusted for age, educational level, monthly household income, profession, region, heavy drinking, current smoking status, stress awareness, and subjective health status.

[c] Data were weighted to yield nationally representative estimates (total N=38,395,036).

[d] Reference category.

[e] Values in italics indicate a statistically significant association.

Discussion

Principal Findings

The purpose of this study was to determine the effect of an individual's depression level on noncompliance precautionary behavior, COVID-19 fear, and health behavior deterioration, and to compare the different trends according to gender. Overall, there was a significant difference in noncompliance with precautionary behavior and health behavior deterioration according to the degree of mental health. Additionally, some components pertaining to COVID-19 fear were different according to depression status. Men and women with clinically relevant depression were more likely to not comply with precautionary behaviors. Furthermore, as mental health deteriorated, health behaviors declined, which tended to be worse in women.

In the case of men with clinically relevant depression, not performing regular ventilation and not wearing a mask indoors significantly increased. Similarly, women with clinically relevant depression were more than twice as likely to not ventilate regularly or not wear a mask indoors than were women who were not depressed. These results are similar to those of several previous studies [23,38,39]; however, in some important ways, they conflict with the results of other studies. For example, one study indicated that poor mental health increased preventive activities, while another suggested that there was no association between precautionary behaviors and mental distress in those with severe mental illness [40,41]. This dichotomy may also exist in relation to COVID-19 fear. Generally, feelings of distress such as anxiety and fear are known to increase precautionary behavior [23,42,43]. However, in our study, the participants tended to have decreased levels of fear as their mental health deteriorated. This association between fear and precautionary behaviors suggests that reduced fear may increase precautionary behavior noncompliance.

Generally, health behaviors decrease as mental health worsens. Notably, women with clinically relevant depression showed a dramatic increase in heavy alcohol consumption and smoking frequency. Previous studies have also reported that women's drinking behaviors increased during the COVID-19 pandemic [44] and that depressive symptoms were also associated with an increase in heavy drinking [45].

However, an increase in social responsibility and a decrease in social support could worsen the mental health of women. In the context of the COVID-19 pandemic, women have been facing a variety of high-demand roles, including childcare and elder care, which most countries have traditionally imposed on them [17,46-48]. In addition, it is generally well known that social support has more of an effect on mental health for women than for men [49-51]. Restrictions on social gatherings, such as social distancing and guidelines that formed part of various quarantine measures, might have weakened the vital social support for women. In fact, various studies have provided empirical evidence that social distancing can affect mental health [52-54]. Moreover, research suggests that reduced physical activity due to social distancing may impair mental health [55]. Given that mental health is associated with smoking and drinking [56], changes in increased social responsibility and reduced social support can also worsen women's mental health and lead to dramatic increases in drinking and smoking.

Overall, the trend of noncompliance with precautionary behaviors and a decrease in health behaviors according to worsening depression showed a greater change in women than in men. Although precautionary behavior compliance is the most important factor in responding to pandemic-related situations [57], health behaviors constitute the basic foundation for maintaining one's physical and mental health, not only in the present but also in the future. Therefore, interventions that consider the degree of depression are necessary to alleviate depression, which could affect the implementation of precautionary behavior and health behavior. Additionally, further studies should examine different ways of implementing such interventions depending on gender.

Study Limitations

This study had several limitations. First, the study did not consider time changes; it was difficult to ascertain causal relationships between the effects of depression and precautionary and health behaviors. In particular, since the KCHS data did not confirm the antecedent relationship between depression and COVID-19, it could not be confirmed whether the depression was due to COVID-19 or other factors. Second, in this study, the trends of precautionary behavior compliance, COVID-19 fear, and health behaviors according to the degree of depression were identified by gender, but it was not shown how vulnerable women were compared to men and their statistical significance. Third, because the data used in this research were collected in the early stages of the COVID-19 pandemic, the precautionary behavior compliance rate created a fairly high temporary bias. In other words, if the data were collected at the end of the pandemic, the results of precautionary or health behaviors may have changed. Finally, in light of the fact that a self-reporting survey was conducted, there is a possibility that measurement errors may have occurred because of the inherent difficulty in checking whether COVID-19 precautionary behaviors were actually being followed and whether health behavior had actually changed. However, this study was cross-sectional and used a representative sample from the entire Republic of Korea. Additionally, this study is valuable in that it examined how depressive symptoms and gender affect precautionary behaviors, even when social aspirations and interest in precautionary behaviors are high.

Conclusion

In this study, we were able to identify how precautionary behavior compliance, COVID-19 fear, and health behaviors change according to the degree of depression and trends according to gender. We found that regardless of gender, people suffering from clinically relevant depression were highly likely to infringe on precautionary behaviors and deteriorate health behaviors. Additionally, this trend was more noticeable in women. These results can be useful for developing related interventions and for future studies that consider both mental status and gender.

Abstract

Background: The United Nations Sustainable Development Goals for 2030 include reducing premature mortality from noncommunicable diseases by one-third. Although previous modeling studies have predicted premature mortality from noncommunicable diseases, the predictions for cancer and its subcategories are less well understood in China.

Objective: The aim of this study was to project premature cancer mortality of 10 leading cancers in Hunan Province, China, based on various scenarios of risk factor control so as to establish the priority for future interventions.

Methods: We used data collected between 2009 and 2017 from the Hunan cancer registry annual report as empirical data for projections. The population-attributable fraction was used to disaggregate cancer deaths into parts attributable and unattributable to 10 risk factors: smoking, alcohol use, high BMI, diabetes, physical inactivity, low vegetable and fruit intake, high red meat intake, high salt intake, and high ambient fine particulate matter (PM2.5) levels. The unattributable deaths and the risk factors in the baseline scenario were projected using the proportional change model, assuming constant annual change rates through 2030. The comparative risk assessment theory was used in simulated scenarios to reflect how premature mortality would be affected if the targets for risk factor control were achieved by 2030.

Results: The cancer burden in Hunan significantly increased during 2009-2017. If current trends for each risk factor continued to 2030, the total premature deaths from cancers in 2030 would increase to 97,787 in Hunan Province, and the premature mortality (9.74%) would be 44.47% higher than that in 2013 (6.74%). In the combined scenario where all risk factor control targets were achieved, 14.41% of premature cancer mortality among those aged 30-70 years would be avoided compared with the business-as-usual scenario in 2030. Reductions in the prevalence of diabetes, high BMI, ambient PM2.5 levels, and insufficient fruit intake played relatively important roles in decreasing cancer premature mortality. However, the one-third reduction goal would not be achieved for most cancers except gastric cancer.

Conclusions: Existing targets on cancer-related risk factors may have important roles in cancer prevention and control. However, they are not sufficient to achieve the one-third reduction goal in premature cancer mortality in Hunan Province. More aggressive risk control targets should be adopted based on local conditions.

Introduction

Cancer is a leading cause of death worldwide, accounting for nearly 10 million deaths in 2020 or nearly one in six deaths [1]. In China, cancer affected more than 4.56 million people and caused 3 million deaths in 2020, accounting for 30.2% of all deaths in the world [2]. Furthermore, cancer is a leading cause of disability-adjusted life years (DALYs), accounting for 17.64% of all DALYs in China in 2019, which was nearly double the global value of 9.88% [3]. The high mortality and disability related to cancer pose a major disease burden worldwide. Cancer not only directly affects the lives of those diagnosed but also has its sequelae impact the family, society, and economy. The socioeconomic burden of cancer has been reported to be substantial, which includes both the direct health care costs and the lost productivity through premature mortality of the working population [4,5].

Cancer is a disease commonly believed to be preventable. In a nationwide study on the risk factors of cancer across 31 provinces of mainland China, Chen et al [6] found that nearly half (45.2%) of all cancer deaths could be attributed to 23 potentially controllable risk factors, which were classified into five categories: behavior, diet, metabolism, environment, and infection. This suggests that millions of deaths could be prevented or delayed each year if appropriate strategies were developed to control these modifiable risk factors, which would undoubtedly greatly reduce the cancer burden in China.

In 2016, the United Nations (UN) set a target to achieve a relative one-third reduction from the 2015 level in premature mortality from noncommunicable diseases (NCDs), including cancer, by 2030 in its Sustainable Development Goal (SDG) target 3.4 [7]. In response to UN SDG target 3.4, the Chinese government issued the Healthy China 2030 Plan with disease prevention and longevity improvement as two of its primary goals [8,9]. A series of policies targeting cancer prevention and treatment was introduced by the government to reduce the burden of premature cancer death in an effort to accomplish SDG target 3.4 of a one-third reduction in premature mortality of NCDs overall. However, considering the vast territory in China and substantial regional differences in socioeconomic and hygienic conditions, the ability to meet SDG target 3.4 will vary greatly across the provinces. Therefore, there is an urgent need for China to implement tailored, region-specific cancer control measures based on reliable data and valid evidence from studies focusing on the local populations.

Hunan Province, located in the central-south of China, is one of the most populous provinces with over 73 million residents. The gross domestic product of Hunan Province was 4.18 trillion yuan (approximately US $606.03 billion) in 2020, ranking 9th among 32 provincial administrative divisions in mainland China. Cancer incidence and mortality rates in Hunan Province in 2018 were 248.24/100,000 and 154.50/100,000, respectively, representing a medium level across the nation [10]. The burdens of years of life lost and DALYs of cancer in Hunan Province were reported to be significantly higher than the national averages [11]. Of note, due to the special local lifestyle habits, Hunan Province has a much higher burden of certain cancer types than other regions, such as oral cavity cancer and nasopharynx cancer, with obviously higher incidences and mortality than national average levels [12,13].

Since publication of the World Health Organization (WHO) Global Monitoring Framework in 2013 [14], several modeling analyses have been conducted to examine the effects of selected risk factor control on reducing NCD mortality under different scenarios worldwide. Kontis et al [15] set six risk factor scenarios based on the Global Monitoring Framework, and estimated their impact on global and regional NCD mortality between 2010 and 2025 using a time-based, population impact fraction formula. They found that achieving all of these targets could efficiently reduce premature mortality from the four main NCDs, including cancers, by nearly 25% globally and in some specific regions [15]. Su et al [16] used an age-period-cohort model for prediction, which suggested that targets of reducing tobacco use could be more ambitious in Taiwan to meet the goal of a 25% reduction in premature cardiovascular disease mortality. Other studies indicated that the risk factor targets recommended by the WHO would be sufficient to help achieve the goal of a one-third reduction in premature mortality for all NCDs combined, but not for certain major subdivisions such as cancers [17,18].

In general, most previous modeling studies focused on overall NCDs at a national level, and there is limited evidence on cancer and its subcategories at a local provincial level. Moreover, the WHO's voluntary global targets did not include dietary and environmental factors, which are known to be important risk factors for cancer, and it remains unknown whether and how control of these factors may help with cancer prevention.

In light of such research gaps, we performed this study to project premature mortality from cancer in Hunan Province through 2030 under different risk factor control scenarios. Specifically, we projected whether SDG target 3.4 can be met for cancer prevention in Hunan Province and how many deaths from cancers can be prevented if all selected risk factors were controlled. The risk factors were selected based on the Global Monitoring Framework [14] while adding dietary and environmental factors. Projecting future premature mortality under various risk factor control scenarios is crucial for informing decision-making on cancer control and allocating the limited clinical and public health resources to curb the increasing deaths caused by cancer. Our results will help policy makers better formulate priorities for interventions that focus on these risk factors for cancer prevention and control.

Methods

Ethics Approval

This analysis centered on publicly available data with no identifiable information on the subjects studied. Therefore, research ethics board approval was not required for this study.

Selection of Cancer Sites and Related Risk Factors

Cancer sites were selected based on the rank of cancer deaths in the Hunan cancer registry annual report series over the past 10 years, while also taking into account endemic cancer types associated with special local lifestyle habits in Hunan, such as oral cavity cancer and nasopharynx cancer. Finally, 10 leading subcategories were selected, including cancers of the lung, esophagus, liver, stomach, pancreas, prostate, breast, colorectum, oral cavity, and nasopharynx.

Correspondingly, risk factors were selected based on the following criteria: (1) causally associated with cancers as evidenced by the latest Global Burden of Disease (GBD) study [3] or the Continuous Update Project (CUP) Expert Report (low vegetable and fruit intake were included due to consistent evidence showing their causal associations with cancers [19]); (2) available data of exposure levels from officially representative surveys or epidemiological studies; (3) potentially modifiable by available interventions; and (4) recognized as one of the leading global or national causes of disease burden. Ultimately, 10 risk factors were selected, including smoking, alcohol use, physical inactivity, high BMI, low vegetable intake, low fruit intake, high red meat intake, high salt intake, diabetes, and fine particulate matter (PM2.5). Details of cancer sites and related risk factors are shown in Multimedia Appendix 1.

Data Sources

The National Program of Cancer Registries (NPCR), launched in 2008, is responsible for the collection, evaluation, and publication of cancer data in China. In Hunan Province, 70.4% of cancer patients have registered in the NPCR to date [20], and all cancer cases are coded according to the International Classification of Diseases, 10th Revision. The details of data collection, management, and analysis for cancer registration in China have been described elsewhere [21]. In this study, we extracted the cause-specific cancer death rates, along with annual population data, between 2009 and 2017 from Hunan Statistical Yearbook 2020 to estimate the number of cancer deaths throughout the province. Information on risk factors was mainly obtained from the Chinese Chronic Disease and Risk Factor Surveillance (CCDRFS) survey, which is an ongoing, nationally representative survey involving a set of standard questionnaire interviews, physical examinations, and biological sampling [22]. In this analysis, we used exposure data in the years 2010 and 2018 to represent 2009 and 2017, respectively, due to a lack of investigations. Regarding PM2.5, since systematic monitoring in China did not start until 2013, we extracted data for Hunan from China Regional Estimates (V4.CH.03) of the Saint Louis University Atmospheric Composition Analysis Group, which applied a geographically weighted regression to calibrate regional PM2.5 concentrations through ground-based observations. Overall, population exposures to these risk factors were measured using metrics related to their variable types. For instance, smoking status and alcohol use were measured as the prevalence of people exposed, while dietary factors were measured as continuous variables. The specific details of risk factor measurements are shown in Multimedia Appendix 1.

To ensure data quality, the relative risk (RR) estimates for risk-cancer pairs were preferentially derived from summary results published by the GBD series and the CUP Expert Report. If these were not available, priority was given to meta-analyses or systematic reviews conducted in China or Asia. Studies that provided RRs on our predefined metrics were preferred and estimates for both genders were assumed to be equal if no separate values were available.

Constructing Risk Factor Scenarios

Based on the Global Monitoring Framework and Healthy China 2030, we constructed 12 separate scenarios of risk factor exposure for the year 2030. Among them, the baseline scenario projected cancer mortality to 2030 assuming that all risk factors continue to follow current trends (see Multimedia Appendix 2 for details on the risk factor exposure estimation). The baseline scenario was simulated using a proportional change model based on the historical trends of risk factors. The other 11 scenarios projected cancer mortality assuming that each of the 10 risk factors achieved the target of domestic or foreign control standards, both separately and in combination. Specifically, the first 10 scenarios were modeled when each risk factor achieved its target, respectively, and the last scenario was modeled when all 10 risk factors achieved their targets. Targets for red meat, vegetable, and fruit intake were set according to the currently available literature. Given that the current annual average PM2.5 concentration in Hunan Province has reached grade II of China’s air quality standards, we used grade I of 15 μg/m^3 as the target for PM2.5, which was also consistent with phase III of the WHO’s air quality guidelines [23]. Targets for other risk factors were set according to the WHO’s voluntary global targets [14]. Among the 10 risk factors, categorical exposures were lowered directly to the target levels in 2030, whereas targets for continuous exposures were established by shifting the population distributions left or right, assuming a constant distribution for each age-sex stratum. Exceptionally, metrics for exposures such as BMI and diabetes were held constant. Table 1 provides the details of the risk factors for each of the 12 scenarios.

Table 1. Scenario specifications in risk factor exposure projection according to the World Health Organization Global Monitoring Framework.

Scenario	Scenario specification
Natural trend	Age- and sex-specific risk factor exposures were projected assuming the annual change rate remained similar to that between 2009 and 2017.
Harmful alcohol use	Age- and sex-specific prevalence of harmful alcohol use is reduced relatively by 10% from the 2013 level. All other risk factors follow the natural trends.
Smoking	Age- and sex-specific prevalence of smoking in 2030 is reduced relatively by 30% from the 2013 level. All other risk factors follow the natural trends.
Physical inactivity	Age- and sex-specific prevalence of physical inactivity in 2030 is 10% relatively lower than that in 2013. All other risk factors follow the natural trends.
Diabetes	Age- and sex-specific prevalence of diabetes in 2030 is the same as in 2013. All other risk factors follow the natural trends.
High BMI	Age- and sex-specific distributions of BMI in 2030 are the same as in 2013. All other risk factors follow the natural trends.
Low vegetable intake	Age- and sex-specific prevalence of low vegetable intake in 2030 is reduced relatively by 30% from the 2013 level. All other risk factors follow the natural trends.
Low fruit intake	Age- and sex-specific prevalence of low fruit intake in 2030 is reduced relatively by 30% from the 2013 level. All other risk factors follow the natural trends.
High red meat intake	Age- and sex-specific prevalence of high red meat intake in 2030 is reduced relatively by 30% from the 2013 level. All other risk factors follow the natural trends.
High salt intake	Age- and sex-specific mean population salt intake in 2030 is reduced relatively by 30% from the 2013 level. All other risk factors follow the natural trends.
PM2.5[a]	The annually averaged PM2.5 concentration in 2030 is reduced to 15 μg/m^3, according to grade I of air quality standard GB3095-2012. All other risk factors follow the natural trends.
All targets are achieved in 2030	All targets described above are achieved in 2030.

[a] PM2.5: fine particulate matter.

Projection of Cancer Mortality

Our analysis was focused on examining premature mortality under 12 different scenarios. Consistent with the global documents, we defined premature cancer mortality as the probability of dying from cancers between the ages of 30 and 70 years [24]. To predict mortality for 2030, we considered the annual total deaths to be a function of two separate projections: a trend of deaths potentially driven by the selected risk factors and a business-as-usual (BAU) trend unattributable to these risk factors. Based on these trends, several steps were involved. First, according to the comparative risk assessment [25], we used the population-attributable fraction (PAF) to divide annual deaths into two parts that were attributable or unattributable to the specified risk factors. The PAF estimates the fraction of health outcomes that would be eliminated if the exposures were altered to ideally counterfactual distributions, and different formulas were applied for discrete and continuous variables in the calculations [25]. Second, we projected the unattributable deaths using the proportional change model, assuming that changes in this part would continue to follow the trends observed between 2009 and 2017. Risk factors in the baseline scenario were projected in the same manner. For the other 11 scenarios, the targeted change of each factor was distributed evenly between 2017 and 2030 to obtain an annual PAF value. Third, the total deaths for different scenarios in 2030 could be estimated using the unattributable deaths and PAFs, and the premature mortality could be calculated using age-specific death rates (in 5-year age groups) with a life table method. The levels in 2013 were considered as the baseline for calculations of relative reductions in this study. Analyses for PAF were performed using MATLAB 7.0, while other data were analyzed in SAS 9.4. Details of the analysis methods are shown in Multimedia Appendix 3.

Results

Premature Mortality From Cancers 2009-2017

Table 2 shows the estimated number of cancer deaths and mortality by gender in Hunan Province, China, from 2009 to 2017. The number of cancer deaths increased each year for both genders. The age-standardized mortality rates showed an increasing trend, with an annual percentage change of 1.60% for the total population, 2.19% for men, and 1.65% for women.

The premature mortality rates from selected cancers are shown in Table 3 and the trend analysis results are shown in Table 4. The average annual percentage change (AAPC) showed a significant increasing trend for all cancers combined (2.61%), with the largest AAPC occurring in oral cavity cancer (17.26%), followed by esophageal cancer (7.60%), colorectal cancer (7.13%), pancreatic cancer (7.10%), and lung cancer (4.06%). For the other cancers, the premature mortality remained stable with nonsignificant AAPC values, although a decreasing trend was observed in stomach cancer (–1.16%) and liver cancer (–1.92%), while an increasing trend was observed in nasopharynx cancer (2.00%), prostate cancer (11.91%), and breast cancer (4.82%).

Table 2. Estimated cancer deaths and mortality rates in Hunan Province, China, 2009-2017.

Year	Total			Men			Women		
	Deaths, n	Mortality rate (1/100,000)	Standardized mortality rate (1/100,000)	Deaths, n	Mortality rate (1/100,000)	Standardized mortality rate (1/100,000)	Deaths, n	Mortality rate (1/100,000)	Standardized mortality rate (1/100,000)
2009	81,159	117.56	89.53	50,480	140.88	108.62	30,679	92.49	69.51

[a] Premature mortality is the probability of dying between the ages of 30 and 70 years from a specific cause that was calculated using the life table method.

Table 4. Annual percentage change (APC) in premature mortality from selected cancers in Hunan Province, China, 2009-2017.

Cancer type	APC (95% CI)	*P* value
Lung	4.06 (2.50 to 5.60)	<.001
Gastric	–1.16 (–4.00 to 1.80)	.38
Liver	–1.92 (–5.40 to 1.70)	.24
Colorectal	7.13 (3.00 to 11.50)	.005
Esophageal		
2009-2012	21.59 (2.20 to 44.60)	.04
2012-2017	0.03 (–7.50 to 8.00)	.99
Average	7.60 (1.60 to 13.90)	<.001
Pancreatic	7.10 (2.90 to 11.40)	.005
Nasopharynx		
2009-2012	13.91 (3.20 to 25.70)	.02
2012-2017	–4.59 (–8.70 to –0.30)	.04
Average	2.00 (–1.30 to 5.30)	.20
Oral cavity	17.26 (3.60 to 32.80)	.02
Prostate	11.91 (–1.30 to 26.80)	.07
Breast	4.82 (–2.40 to 12.60)	.17
All cancers	2.61 (1.40 to 3.80)	.001

Premature Mortality in the Baseline Scenario by 2030

Table 5 shows a comparison of premature deaths and mortality between 2013 and projected for 2030 in the baseline scenario where all risk factors continue their current trends. In 2030, an estimated 97,787 people would die prematurely from all cancers, with a premature mortality rate of 9.74%, which was 44.47% higher than that in 2013 (Table 5). For the number of premature deaths, lung cancer was expected to account for the largest proportion of total cancer deaths (29,337 deaths), followed by liver cancer (15,545 deaths), colorectal cancer (12,342 deaths), oral cavity cancer (7470 deaths), and esophageal cancer (5977 deaths). All cancers showed increases in the number of premature deaths except for gastric cancer, which was expected to decrease from 4104 in 2013 to 3053 in 2030. The mortality rate of all cancers was estimated to increase by 81.55% from 143.54 to 260.59 per 100,000 people. All cancers exhibited increasing trends in mortality rate except for gastric cancer, which was expected to decrease by 24.62% from 2013 to 2030.

The premature mortality rates for all cancers and each subcategory were consistently higher in men than in women, with differences of more than 5-fold (Table 5). For all cancers, relative increments of 61.47% and 13.46% were observed among men and women, respectively. For men, all cancers showed substantial increases in premature mortality, ranging from 38.25% for lung cancer to 1194.33% for oral cavity cancer, except for gastric cancer, which showed a decreasing trend (–32.51%). For women, most cancers showed increases in premature mortality, ranging from 14.04% for lung cancer to 158.84% for colorectal cancer, except for esophageal cancer (–64.61%), gastric cancer (–52.16%), pancreatic cancer (–45.08%), and nasopharynx cancer (–21.86%). Despite significant gender discrepancies, premature mortality for the whole population generally showed an increasing trend, with the greatest increase occurring in oral cavity cancer (971.53%).

Table 5. Deaths and premature mortality of main cancers for people aged 30-70 years in 2013 and projections for 2030 if risk factor trends continue in Hunan Province, China.

Premature Deaths Avoided and Premature Mortality in Multiple Scenarios

Table 6 shows the projected premature deaths and mortality in 2030 with all risk factors under control, which was further compared with the rates for 2013 and the baseline scenario. Compared with the baseline scenario where all risk factors continue their current trends, 14.90% of premature deaths from cancers would be avoided if all risk factor targets were achieved. Lung cancer had the largest decrease in the number of cancer deaths compared to the baseline scenario (–27.30%), followed by colorectal cancer (–19.88%), esophageal cancer (–17.73%), and breast cancer (–14.08%). A further comparison of avoided cancer deaths by gender showed that men (–15.53%) benefited much more through these combined risk factor control targets than women (–13.16%).

The modeling scenarios seek to avert one-third of premature mortality by 2030. However, this goal is hard to accomplish. For all cancers combined, premature mortality among the total population was expected to increase by 23.65% compared to the baseline year of 2013, even if all risk factor control targets were reached by 2030 (Table 6, Figure 1).

For subcategories, all cancers showed increases in premature mortality compared with that in 2013 in the combined risk factor control target-achieved scenarios, except for gastric cancer with a decrease of 41.63% in the total population (34.45% for men and 53.40% for women). However, it should be noted that the premature deaths and mortality of gastric cancer would still decrease substantially even if all risk factors continue their current trends, as shown in the baseline scenario. A decrease in premature mortality was also found for women in esophageal cancer (72.63%), pancreatic cancer (48.71%), and nasopharynx cancer (29.44%) under combined target–achieved scenarios. Although the combined risk factor control targets failed to achieve the one-third reduction of the cancer mortality rate set by the UN, they could still lead to notable decreases in premature mortality compared with the baseline scenario in 2030.

Moreover, the impact on cancer premature mortality varied substantially across different risk factors. For all cancers combined, diabetes and low fruit intake were the top two leading risk factors of cancer premature mortality for both genders. For instance, halting the rise in the prevalence of diabetes may contribute to nearly half of the reductions in cancer premature mortality for both genders (Figure 1). The impact of other risk factors on cancer premature mortality depended on gender. A halt in the rise of BMI had the third-largest impact for men, whereas for women (Figure 2), it was the reduction in ambient PM2.5 levels (Figure 3). For risk factors such as smoking, high red meat intake, and physical inactivity, the predefined risk factor control targets seemed to be insufficient to have pronounced benefits on cancer premature mortality. For risk factors such as harmful alcohol use and high salt intake, the predefined control targets set by the WHO showed much smaller reductions in mortality than the baseline BAU scenario, indicating the need for setting more ambitious targets. In all simulated scenarios, men were projected to have greater gains than women for all cancers after risk factor controls. Scenario projections by gender are shown in Multimedia Appendix 4.

Discussion

Principal Findings

In this study, we projected premature mortality from 10 leading cancers in Hunan Province under 12 different risk factor control scenarios in 2030 and evaluated whether SDG target 3.4 can be met for cancer prevention. The results suggest that the one-third reduction goal in premature cancer mortality would not be achieved in Hunan, even if all related risk factor control targets were reached by 2030. This finding is similar to that of a previous study conducted by Li et al [17], showing that achieving all related risk targets would lead to a one-third reduction for all NCDs combined, but not for cancers, in China. These findings suggest that meeting SDG target 3.4 for cancers would require extra efforts from both national and local governments. Notably, Li et al [17] only included six risk factors, in which merely three (ie, smoking, BMI, and physical inactivity) were modeled in the projection of cancer burdens. It seems difficult to achieve dramatic reductions in premature cancer mortality by only controlling for a limited number of risk factors; thus, further inclusion of more risk factors is needed for simulation in the whole country. Although our study contained a wider range of risk factors, the predicted premature cancer mortality in Hunan Province failed to reduce by one-third in 2030, which may be due to the combined effect of several factors such as the conservativeness of some risk factor targets and population aging. According to Chen et al [26], the proportion of people aged over 55 years is expected to increase to more than 30% in Hunan in 2030 [26]. In addition, epidemiological studies have shown that cancer mortality is significantly higher in people over 55 years old than in other age groups, and approximately 27% of cancer deaths were attributed to population aging in China in 2019 [10,21,26], which makes it more difficult to reverse the status quo. Hence, more stringent targets on key risk factors may be required in Hunan.

As for various cancer subcategories, it is interesting that risk factor control targets appeared to generate relatively minor additional benefits for cancers that had already experienced dramatic reductions under the BAU scenario. For other cancers that had not experienced reductions under the BAU scenario, the joint control of all related risk factors may generate larger additional benefits. For instance, the control of all five modifiable risk factors of lung cancer would reduce premature mortality by 28.2% for men and by 23.6% for women compared to the BAU scenario in 2030. These findings suggest that it is more cost-effective to control risk factors for cancers with tendencies toward worse conditions.

Through modeling, our estimates also illustrated significant discrepancies in premature mortality reduction across various risk factor control targets. In parallel with the previous study conducted by Li et al [17], improving physical inactivity resulted in minimal reduction in premature cancer mortality, which might be largely because physical inactivity was only causally related to two cancer sites (ie, colorectal cancer and breast cancer). Another explanation may be that the mild reduction of 10% in physical inactivity was not sufficient to produce a significant reduction in premature cancer mortality in 2030. A similar result was also seen for high red meat intake, which was only causally associated with breast and colorectal cancers. In comparison, smoking is causally associated with a wide range of cancers and showed the largest effect in reducing premature cancer mortality by smoking control. As the largest tobacco producer and consumer globally, China has enacted a set of antismoking policies and regulations after signing the WHO's Framework Convention on Tobacco Control in 2003 [27], which include public smoking bans, a rise in tobacco taxes, and warnings on the cigarette pack. The serial national surveys on smoking showed that the smoking prevalence in China had been declining steadily in recent years, although remaining at a high plateau among men [28]. Hunan Province has a consistently higher smoking prevalence than the national average level [29], possibly due to a later implementation of smoking restrictions. Recently, Hunan Province launched a series of feasible and effective smoking restriction policies, which have greatly reduced the smoking rate. Several rounds of CCDRFS surveys have also indicated a favorably moderate decrease of the smoking prevalence in Hunan, which may partly account for the relatively lower benefit in mortality reduction through the control of smoking than the control of high BMI and diabetes that have been rising steadily in Hunan. In addition, due to the especially low smoking prevalence among women in Hunan, the WHO target of a 30% reduction may produce much less benefit for women than that among men.

The past decade has also seen significant decreases in the mean population salt intake and prevalence of harmful alcohol use in Hunan, both of which led to more favorable trends than those of the WHO targets. Of note, the prevalence of current alcohol use was still maintained at a high level and was much higher in men than women, especially for hazardous and harmful alcohol use. The high alcohol use prevalence among men in China may be explained by the traditional Chinese culture that encourages drinking as a socially acceptable way to show their dominant positions in society. Disturbingly, there was a substantial increase in alcohol use following the rapid economic transition in China [30]; yet, the current legislation on alcohol use only focuses on problematic alcohol use such as drunk driving, rather than on alcohol use per se. Evidence has shown that alcohol use is the fourth-leading modifiable risk factor that contributes to cancer mortality among Chinese men [6], and abstinence from alcohol would increase life expectancy by 0.77 years [31]. These findings suggest that more effective measures are warranted to reduce alcohol use. The WHO has recommended some cost-effective alcohol prevention measures named "best buys," which included increasing taxes, enforcing bans on alcohol advertising, and restricting the availability of alcohol [32]. With respect to high salt intake, studies have shown that the daily salt intake in China had been decreasing slowly, which was largely attributed to the government's multicomponent strategies, including labeling, media campaigns, and voluntary reformulation of the salt industry, among others [33,34]. However, the mean salt intake in 2019 was approximately 9.3 grams per day [35], which was still much higher than the WHO's recommended level of 6.0 grams per day. Hence, there is still room for improvement in reducing the salt intake among Chinese residents.

Apart from the above risk factors, whether SDG target 3.4 can be realized in 2030 largely depends on the high-impact factors, including diabetes, high BMI, and insufficient intake of fruits and vegetables. China has the largest population of individuals with diabetes in the world, and the prevalence of diabetes has been sharply increasing in recent decades in China, including in Hunan Province [36]. Without proper measures to control blood glucose, China will continue to have the largest population of diabetes in 2030 with a predicted number of 140 million [37]. Previous studies discovered that high concentrations of glucose could provide steady energy for the growth of tumor cells [38,39], and thus diabetes was identified as an independent risk factor for several cancer types [40]. It was estimated that achieving the risk control target for diabetes in 2030 would avoid 57,400 deaths from NCDs in China [17], and our study also predicted notable benefits in premature cancer mortality reduction from the control of diabetes. In China, a range of programs such as primary diabetic health care have been promoted to curb the rapid rise in diabetes [41]. However, due to the imbalanced regional economic development, the capacity of primary medical services is relatively backward in the central and western regions of China, resulting in a lack of standardized diabetic management and low screening rates of diabetes-related complications [42]. Thus, there is still a long way to go to meet the commitments of the UN agenda.

Overweight and obesity prevalence among adolescents and adults has been increasing steadily in China, including Hunan Province, for the past two decades [35]. This is largely attributable to high-calorie dietary habits and reduced physical activity. Researchers have projected that the prevalence of overweight and obesity, if not controlled effectively, might reach 65.3% in adults and 31.8% in adolescents by 2030, with more than 800 million people reaching the overweight and obese categories in China [43]. The government has made great efforts to prevent overweight and obesity, including several school-based programs (such as the Healthy Children Action Plan and National Nutrition Campus Program) and community-based programs (such as the National Healthy Lifestyle Action) to promote healthy diet and exercise among the population [43]. However, existing policies on overweight and obesity are still fragmented in China; thus, coordinated and multisectoral strategies are needed to reach the target of halting the rise in overweight and obesity by 2030.

Fruit and vegetable intake is an indispensable part of a healthy diet. Studies have shown that the average daily intake of fruit in Hunan Province has been increasing steadily in recent years, while the intake of vegetables has been declining [44,45], which reflects a remarkable transition in dietary structure. Despite these trends, the proportions of adults who reached the recommended levels of Chinese dietary guidelines for both fruit and vegetable intake remained at low levels. Globally, inadequate consumption of fruits and vegetables has been validated to contribute to a large portion of the cancer burden in many countries such as the United Kingdom, Japan, and China [3,6,46]. In China, an unhealthy diet including low fruit and vegetable intake has accounted for more than 10% of DALYs [3]. Dietary guidelines with different recommendations have been developed worldwide to tackle the problem. The WHO recommends a total consumption of at least 400 grams per day of fruits and vegetables for adults, while in China the recommended level is 500 grams per day. Although the Global NCD Action Plan has included the prevalence of inadequate intake of fruits and vegetables as a monitoring indicator, no specific target has been set by the WHO to date. In our study, a 30% reduction for inadequate fruit and vegetable intake displayed relatively high benefits in cancer mortality reduction, further supporting the beneficial role of dietary risk control in achieving SDG target 3.4. Currently, health education with a focus on children is the major approach for promoting a healthy diet in China, which indeed has increased people's awareness [47]. Nevertheless, given that other factors such as availability and prices may also influence eating behavior, there is still much work to be done.

We also validated our projection with other methods or assumptions. In the baseline scenario, where all risk factors continue their current trends, the number of premature deaths from cancers increased from 65,443 in 2017 to 97,787 in 2030.

Given that approximately 4 million deaths are expected to occur in 2030 in China [48], an increase of only 32,344 premature deaths in such a populous province may be underestimated. Nevertheless, we further estimated the total number of cancer deaths for all ages and found that the value increased from 111,719 in 2017 to 235,578 in 2030 (see Multimedia Appendix 5), which indicated that people older than 70 years represented the major group of cancer deaths. In addition, assuming that cancer mortality trends continued to 2030 with constant change, we validated the predicted deaths in the BAU scenario using the proportional change model, which showed similar results with only a 3.6% difference in total cancer deaths and a 1.6% difference in overall premature mortality (see Multimedia Appendix 6). Therefore, we believe our projections to be credible.

Limitations

Some limitations of our work s*f*hould be considered. First, Hunan launched its cancer registry program in 2009, and the work at the early stages might be imperfect with low population coverage. Even by the end of 2020, the cancer registration in Hunan had only covered approximately 70% of the population, without achieving full coverage, which may to some extent cause a certain bias in the estimation of actual cancer deaths. Nevertheless, with the efforts of local governments, the coverage of cancer registration has rapidly expanded and the data quality has steadily improved in recent years. Some of the data were even cited in monographs of the International Agency for Research on Cancer. In addition, our data for risk factors were drawn from the CCDRFS survey; therefore, all limitations in estimates of levels in the CCDRFS study apply to this analysis.

Second, we used RR estimates primarily from the GBD series and the CUP Expert Report due to the lack of high-quality meta-analyses and prospective cohort studies in China, which may make our results statistically unstable. However, with more and more large cohort studies being carried out in China, more reliable RRs for China could be available in future studies. Third, due to a lack of dynamic monitoring data, some region-specific risk factors such as betel quid, which is classified as a class 1 carcinogen and has a high prevalence in Hunan, has not been included in this analysis. Considering that the Chinese government has made great efforts on sales restriction and increasing the public awareness of its harm in recent years, the prevalence of betel quid chewing in Hunan may decline steadily; thus, modeling without consideration of betel quid may lead to overestimation of future cancer mortality. Furthermore, there are potential interactions among the selected risk factors; however, due to the absence of information on most interactions, we simply calculated their combined effects on cancers based on the assumption of independence, which may lead to some uncertainties in our results. Hence, solid evidence–based joint RRs on cancers are warranted for future studies.

Fourth, we did not investigate the impact of population aging on premature cancer mortality due to insufficient technological conditions and time. In further studies, we will try to examine the fractions and trends attributable to population aging and its interactions with various risk factors on premature cancer mortality. Fifth, since the current health outcome reflects the cumulative effect of past exposures, risk factors such as smoking and alcohol were subdivided by duration and amount whenever possible. However, no lag effect was considered when data on specific information were unavailable. Nevertheless, calculations of PAFs in our study referred to the comparative risk assessment model from the latest GBD series, and the results were similar to those of previously published literature [6].

Conclusions

In summary, this modeling study illustrates that the absolute burden of premature deaths due to cancers will continue to increase over the next dozen years in the Hunan province of China. Notable health gains could be achieved by addressing unhealthy risk factors for cancers. However, existing targets on related risk factors are not sufficient, particularly in men, to achieve the one-third reduction goal in premature cancer mortality. More aggressive risk targets based on local conditions are urgently needed.

Acknowledgments

We thank all those who provided data for our analyses. This research was supported by the Science and Technology Innovation Program of Hunan Province (grant number 2022SK2050); Hunan Cancer Hospital Climb Plan (grant number YF2021007); and the Natural Science Foundation of Hunan Province, China (grant number 2021JJ40326).

Abstract

Background: Low-dose computed tomography (LDCT) screening is effective in reducing lung cancer mortality in smokers; however, the evidence in nonsmokers is scarce.

Objective: This study aimed to evaluate the participant rate and effectiveness of one-off LDCT screening for lung cancer among smokers and nonsmokers.

Methods: A population-based prospective cohort study was performed to enroll participants aged between 40 and 74 years from 2013 to 2019 from 4 cities in Zhejiang Province, China. Participants who were evaluated as having a high risk of lung cancer from an established risk score model were recommended to undergo LDCT screening. Follow-up outcomes were retrieved on June 30, 2020. The uptake rate of LDCT screening for evaluated high-risk participants and the detection rate of early-stage lung cancer (stage 0-I) were calculated. The lung cancer incidence, lung cancer mortality, and all-cause mortality were compared between the screened and nonscreened groups.

Results: At baseline, 62.56% (18,818/30,079) of smokers and 6% (5483/91,455) of nonsmokers were identified as high risk (*P*<.001), of whom 41.9% (7885/18,818) and 66.31% (3636/5483) underwent LDCT screening (*P*<.001), respectively. After a median follow-up of 5.1 years, 1100 lung cancer cases and 456 all-cause death cases (116 lung cancer death cases) were traced. The proportion of early-stage lung cancer among smokers was 60.3% (173/287), which was lower than the proportion of 80.3% (476/593) among nonsmokers (*P*<.001). Among smokers, a higher proportion was found in the screened group (72/106, 67.9%) than the nonscreened group (56/114, 49.1%; *P*=.005), whereas no significance was found (42/44, 96% vs 10/12, 83%; *P*=.20) among nonsmokers. Compared with participants who were not screened, LDCT screening in smokers significantly increased lung cancer incidence (hazard ratio [HR] 1.39, 95% CI 1.09-1.76; *P*=.007) but reduced lung cancer mortality (HR 0.52, 95% CI 0.28-0.96; *P*=.04) and all-cause mortality (HR 0.47, 95% CI 0.32-0.69; *P*<.001). Among nonsmokers, no significant results were found for lung cancer incidence (*P*=.06), all-cause mortality (*P*=.89), and lung cancer mortality (*P*=.17).

Conclusions: LDCT screening effectively reduces lung cancer and all-cause mortality among high-risk smokers. Further efforts to define high-risk populations and explore adequate lung cancer screening modalities for nonsmokers are needed.

KEYWORDS

lung cancer; screening; smoker; nonsmoker

Introduction

Background

Lung cancer is the second most commonly diagnosed cancer and the leading cause of cancer-related death worldwide; in 2020, there were an estimated 2.2 million new cases and 1.8 million deaths [1]. In 2019, more than one-third of all newly diagnosed lung cancers and approximately 40% of global cancer-related deaths occurred in China [1], where lung cancer was the leading cause of disability-adjusted life years and years of life lost [2], resulting in a high disease and socioeconomic burden. These trends underscore the need for continued efforts to improve lung cancer outcomes.

Screening with low-dose computed tomography (LDCT) is effective in reducing lung cancer mortality in rigorously randomized controlled trials such as the National Lung Screening Trial (NLST) and the Dutch-Belgian lung cancer screening trial (Nederlands Leuvens Screening Onderzoek [NELSON]); however, such trials have high LDCT uptake rates exceeding 90% [3,4]. These high uptake rates are not attainable in real-world settings; thus, evidence from real-world screening settings with imperfect uptake rates is crucial to inform appropriate and effective screening policies. Moreover, current findings are only applicable to smokers, who are considered as a high-risk lung cancer subgroup. The prevalence of nonsmoking-related lung cancer in East Asian countries is higher than that in Europe and the United States [5]. In China, tobacco smoking is responsible for 75% of lung cancer cases in men and 18% in women [6]. Therefore, the effectiveness of LDCT screening among nonsmokers at high risk of lung cancer still needs to be evaluated.

Objectives

The Cancer Screening Program in Urban China (a large public health service project) conducted in 2012 included both smokers and nonsmokers and targeted 5 types of cancer (lung cancer, female breast cancer, esophageal and gastric cancer, colorectal cancer, and liver cancer) [7]. In Zhejiang, the smoking rate of people aged ≥15 years was over 20%, which is relatively low among all provinces in China [8]. Nevertheless, Zhejiang Province has a higher lung cancer incidence than the national average [9,10]. These phenomena make Zhejiang an appropriate setting to study the effectiveness of lung cancer screening among smokers and nonsmokers. Using lung cancer screening data from the Cancer Screening Program in Urban China conducted in the first 7 years between October 2013 and September 2019 in Zhejiang, we evaluated the effectiveness of one-off LDCT screening in the early detection and reduction of lung cancer mortality and all-cause mortality among smokers and nonsmokers, respectively.

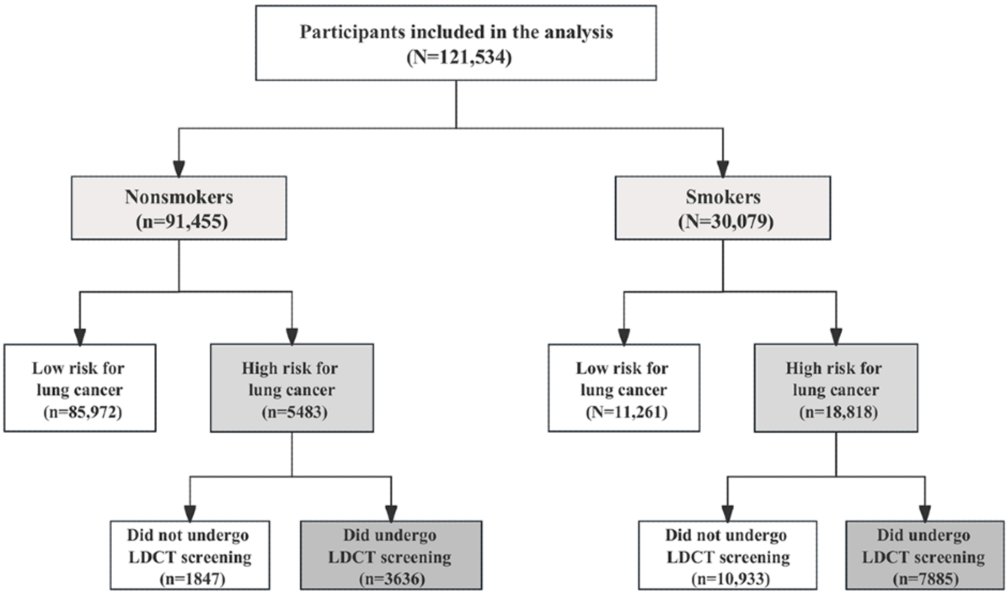
Methods

Study Design and Participants

We performed a population-based prospective study using the framework of the Cancer Screening Program in Urban China [11]. Trained staff called or visited residents aged 40-74 years living in selected communities of the participating cities. Patients with a history of cancer and those undergoing treatment for other serious medical and surgical diseases were excluded. For this screening program, only participants at high risk of lung cancer (refer to Risk Assessment Procedure) were recommended to undergo LDCT free of charge at a tertiary-level hospital designated by the program. All participants provided written informed consent.

We used data from lung cancer screening conducted between October 2013 and September 2019 in Zhejiang Province, which covered 4 cities (Hangzhou, Ningbo, Quzhou, and Jinhua). Overall, 121,534 eligible individuals participated in the lung cancer screening program (Figure 1). For this study, smokers were defined as those who had previously smoked or were currently smoking tobacco more than once per day for at least 6 months. The smokers and nonsmokers enrolled in this study were classified into 3 groups: the screened group (high-risk participants who underwent LDCT screening), the nonscreened group (high-risk participants who did not undergo LDCT screening), and the low-risk group.

Figure 1. Flow diagram of the study population. LDCT: low-dose computed tomography.



Ethics Approval

The study was approved by the ethics committee of the Chinese Academy of Medical Sciences's Cancer Hospital (approval number 15-070/997) and Zhejiang Cancer Hospital (approval number IRB-2022-271).

Risk Assessment Procedure

Eligible participants completed a cancer-related risk assessment questionnaire designed by the Cancer Screening Program in Urban China before LDCT that included questions regarding cigarette smoking history, occupational exposure to hazardous substances, frequent exercise, chronic respiratory diseases, family history of lung cancer, dietary intake of fresh vegetables in the previous year, and passive smoking. We adopted the sex-specific risk score systems derived from the Harvard Cancer Risk Index to evaluate the risk of lung cancer [12,13]. Each risk factor was assigned a score by an expert panel based on the magnitude of its association with lung cancer. Cumulative risk scores were calculated and divided by the average risk score in the general population, yielding final individual relative risks. Individuals with a relative risk >2.0 or aged ≥50 years with a smoking index of ≥400 (number of cigarettes smoked per day multiplied by years of smoking) were defined as being at high risk for lung cancer [12,13].

Individuals labeled as being at high risk for lung cancer were recommended to undergo a free LDCT scan with ≥16 slices at a tertiary-level hospital designated by the program. These participants then underwent a process of shared decision-making that included information about the potential benefits and harms of screening with LDCT to ensure that their decisions on LDCT scans were based on their free will.

Follow-up Data

To account for potential immortal time bias, where individuals in the screened group had to survive (be alive and event free) until the LDCT scan was conducted, the cohort entry date was defined as the date of screening in the screened group. For individuals in the nonscreened group, the cohort entry date was estimated based on the screening date of the individual in the screened group whose risk assessment date was closest to that of the nonscreened group. Time to lung cancer occurrence was calculated from the cohort entry date until the earliest occurrence of lung cancer, death, or administrative censoring (June 30, 2020). Accordingly, time to lung cancer death or all-cause death was calculated from the cohort entry date until death or administrative censoring, whichever occurred first.

Outcome Assessment and Quality Control

The primary outcomes of interest were incidence of lung cancer, lung cancer mortality, and all-cause mortality. The secondary outcomes were the proportion of early-stage lung cancer (stage 0-I) and the participation rate of LDCT. Lung cancer was defined according to the International Classification of Diseases (10th revision) and was coded as C34. Outcome data were retrieved from national linkages, including the cancer registry system and death surveillance system, every 6 months.

Paper-based standardized documentation forms (epidemiological questionnaire and LDCT report) were collected from trained staff and physicians. Form validity was checked and entered into the data management system by trained study staff. A consistency check was performed, and if inconsistencies were identified, errors were corrected by retrieving the original records. Each participant had a unique identification number that was used to track all individual-related documentation forms. All data were transmitted to the Central Data Management Team of the National Cancer Center of China, where databases were constructed and analyzed.

Definitions of Covariates

Covariates from the baseline survey included demographic characteristics (age: 40-54 years and 55-74 years; sex; education level: low [primary school or below], medium [primary school to high school], and high [high school or above]; and BMI), lifestyle factors (smoking status, passive smoking, occupational exposure to hazardous substances, and frequent exercise), family history of lung cancer, and baseline comorbidities (chronic respiratory diseases, digestive diseases, hepatobiliary diseases, hypertension, diabetes, and hyperlipidemia). Passive smoking referred to involuntary inhalation of tobacco smoke. Occupational exposure to hazardous substances included occupational exposure to asbestos, rubber, dust, pesticides, radiation, beryllium, uranium, and radon for at least 1 year. Frequent exercises were defined as exercises conducted at least 3 times per week for ≥30 minutes each. Respiratory diseases included pulmonary tuberculosis, chronic bronchitis, emphysema, asthmatic bronchiectasis, silicosis, and pneumoconiosis.

Statistical Analysis

Baseline study population characteristics were summarized using frequencies and percentages for categorical variables and arithmetic means and SDs for continuous variables. Baseline factors were compared between the nonsmoker and smoker groups using a 2-tailed Student *t* test or chi-square test. Group-specific participation rates of LDCT screening for high-risk populations by common factors were also calculated. Multivariable logistic regression was used to explore the potential determinants of the participant rate of LDCT screening. For lung cancer outcomes, cumulative incidence was estimated using the cumulative incidence function, accounting for the competing risk of mortality. Lung cancer mortality was estimated using the cumulative mortality function, accounting for the competing risk of death from other causes. Gray tests were used to assess differences between the groups for cumulative lung cancer incidence and lung cancer mortality. All-cause mortality was calculated using Kaplan-Meier analysis with a log-rank test to assess differences between groups. Owing to the small number of deaths among nonsmokers, we only used a Cox proportional hazards model among smokers to calculate the hazard ratios (HRs) and 95% CI of LDCT screening with lung cancer incidence, mortality, and all-cause mortality. All hypothesis tests were 2 sided. Statistical analyses were performed using R (version 3.5.1; R Foundation for Statistical Computing) and SAS (version 9.4; SAS Institute Inc), and *P*<.05 was considered statistically significant.

Results

Baseline Characteristics

In total, 121,534 participants aged 40-74 years who were enrolled in the program were included in this study; of them, 75.3% (n=91,453) were nonsmokers and 24.7% (n=30,079) were smokers. Compared with nonsmokers, smokers were older; were more likely to be male; were more likely to have medium and high educational levels; were more overweight and obese; and had more occupational exposure to hazardous substances, passive smoking, family history of lung cancer, chronic respiratory diseases, digestive diseases, hepatobiliary diseases, hypertension, hyperlipidemia, and diabetes but were less likely to exercise frequently (*P*<.001; Table 1). Comparisons of baseline characteristics by risk assessment and screening status for smokers and nonsmokers are, respectively, presented in Multimedia Appendices 1 and 2.

[a] Overall: 200 participants without information on BMI, 289 participants without information on passive smoking, 10,625 participants without information on family history of lung cancer, 10,904 participants without information on hypertension, 10,913 participants without information on hyperlipidemia, and 10,909 participants without information on diabetes.

[b] Nonsmokers: 152 participants without information on BMI, 129 participants without information on passive smoking, 8445 participants without information on family history of lung cancer, 8579 participants without information on hypertension, 8587 participants without information on hyperlipidemia, and 8583 participants without information on diabetes.

[c] Smokers: 48 participants without information on BMI, 160 participants without information on passive smoking, 2180 participants without information on family history of lung cancer, 2325 participants without information on hypertension, 2326 participants without information on hyperlipidemia, and 2326 participants without information on diabetes.

[d] *P* values were generated by using the chi-square or *t* test (2-tailed) by smoking status.

Participation Rates for LDCT Screening for High-risk Participants

Among smokers, 62.56% (18,818/30,079) were identified as being at high risk for lung cancer, which was significantly higher than 5.8% (5483/94,455) among nonsmokers (*P*<.001). Among the high-risk participants, 41.9% (7885/18,818) underwent LDCT screening among smokers, which was significantly lower than 66.31% (3636/5483) among nonsmokers (*P*<.001; Figure 1). The data on LDCT participation by subgroup are shown in Table 2. Results from multivariable logistic regression models showed that female participants (odds ratio [OR] 1.33, 95% CI 1.11-1.58; *P*<.001), older participants (OR 1.24, 95% CI 1.16-1.33; *P*<.001), participants with occupational exposure to hazardous substances (OR 1.50, 95% CI 1.38-1.62; *P*<.001), participants with a family history of lung cancer (OR 1.74, 95% CI 1.60-1.90; *P*<.001), participants with chronic respiratory diseases (OR 1.40, 95% CI 1.29-1.51; *P*<.001), participants with digestive diseases (OR 1.24, 95% CI 1.16-1.33; *P*<.001), participants with hepatobiliary diseases (OR 1.35, 95% CI 1.25-1.45; *P*<.001), participants with hyperlipidemia (OR 1.19, 95% CI 1.10-1.30; *P*<.001), and participants with diabetes (OR 1.16, 95% CI 1.04-1.29; *P*<.001) had higher LDCT participation rates among smokers. Among nonsmokers, participants with occupational exposure to hazardous substances (OR 1.37, 95% CI 1.19-1.58; *P*<.001), participants with a history of passive smoking (OR 1.22, 95% CI 1.04-1.44; *P*<.001), participants with a family history of lung cancer (OR 1.83, 95% CI 1.62-2.08; *P*<.001), and participants with hepatobiliary diseases (OR 1.37, 95% CI 1.21-1.56; *P*<.001) had higher LDCT participation rates.

[a] Nonsmokers: 11 participants without information on BMI, 71 participants without information on passive smoking, 185 participants without information on family history of lung cancer, 723 participants without information on hypertension, 726 participants without information on hyperlipidemia, and 725 participants without information on diabetes.

[b] Smokers: 32 participants without information on BMI, 148 participants without information on passive smoking, 1471 participants without information on family history of lung cancer, 1763 participants without information on hypertension, 1764 participants without information on hyperlipidemia, and 1764 participants without information on diabetes.

[c] *P* values were generated by using the chi-square and Cochran-Armitage test statistics for differences where appropriate; missing values are not included.

[d] OR: odds ratio. ORs are presented for variables with significance in the multivariate logistic regression.

[e] The variable is excluded from the final model and OR is not available.

[f] All nonsmokers were female .

Overall Lung Cancer Incidence and Mortality

After a median follow-up time of 5.1 years (IQR 3.1-5.9 years), 377 lung cancer cases, 202 all-cause death cases, and 67 lung cancer death cases were observed among smokers, and 733 lung cancer cases, 254 all-cause death cases, and 49 lung cancer death cases were observed among nonsmokers (Table 3). The crude lung cancer incidence density was 277.57 (95% CI 250.92-307.05) per 100,000 person-years in smokers and 178.51 (95% CI 166.05-191.92) per 100,000 person-years in nonsmokers (Table 4), resulting in a crude rate ratio of 1.555 (95% CI 1.547-1.563). The crude all-cause mortality rate and lung cancer mortality rate in smokers was 147.89 (95% CI 128.83-169.76) per 100,000 person-years and 49.05 (95% CI 38.61-62.33) per 100,000 person-years, respectively, which were higher than 61.63 (95% CI 54.50-69.69) per 100,000 person-years and 11.89 (95% CI 8.99-15.73) per 100,000 person-years in nonsmokers, yielding a crude rate ratio of 2.4 (95% CI 2.382-2.417) and 4.126 (95% CI 4.057-4.195), respectively. Among lung cancer patients with available data on stage and histological information, the proportion of stage 0-I was 60.3% (173/287) among smokers and lower than the proportion of 80.3% (476/593) among nonsmokers (*P*<.001), and the proportion of adenocarcinoma was 61.2% (194/317) among smokers and lower than the proportion of 90.2% (607/673) among nonsmokers (*P*<.001; Table 3). Subgroup analyses showed that the proportion of stage 0-I was 67.9% (72/106) in the screened group, which was significantly higher than 49.1% (56/114) in the nonscreened group (*P*=.005) among smokers, and no significance was found of the proportion of stage 0-Ibetween the screened group (42/44, 96%) and the nonscreened group (10/12, 83%) among nonsmokers (*P*=.20).

[a] Rate is the number of cases per 100,000 person-year.

[b] Rate is adjusted by age group and gender.

[c] *P* value is generated by comparing the 3 groups (low-risk group, nonscreened group, and screened group).

[d] N/A: not applicable.

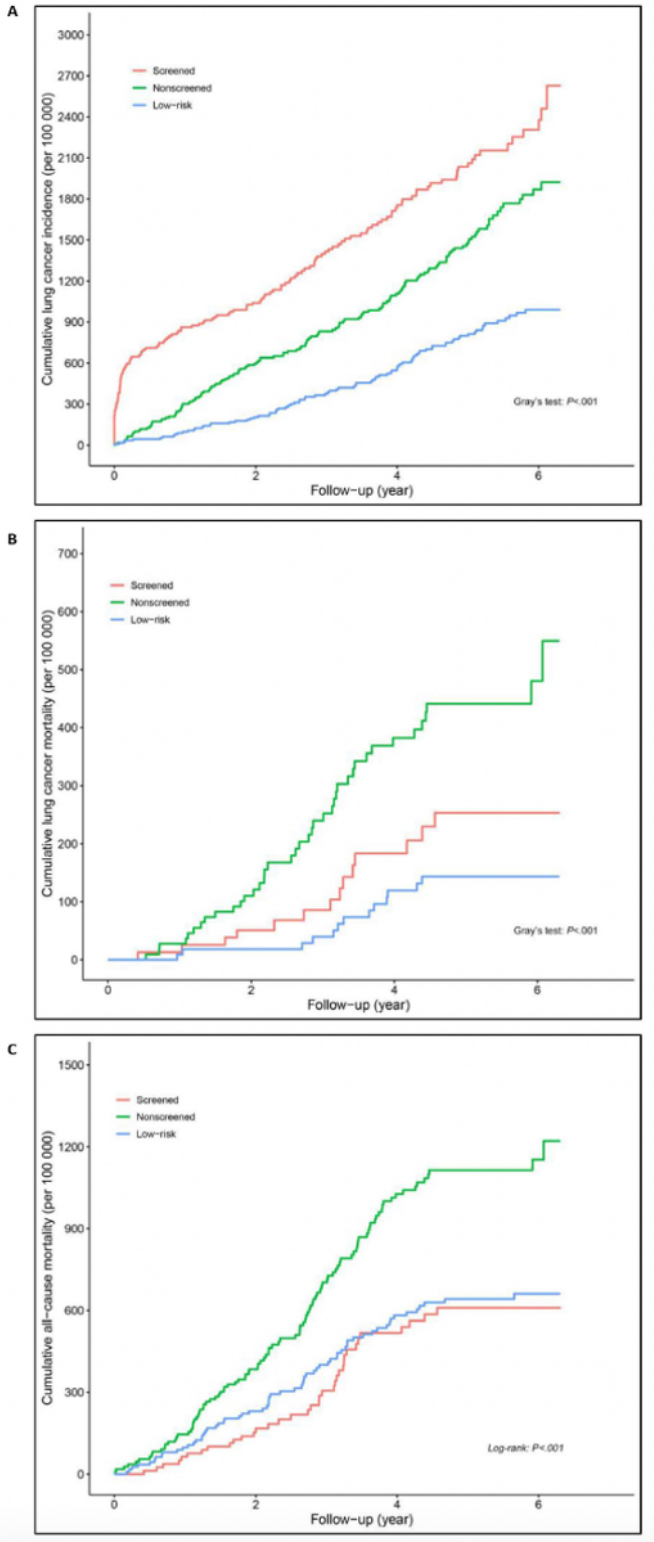
[e] *P* value is generated by comparing the 2 groups (nonscreened group and screened group).

[f] No lung cancer death cases were reported for the group.

Lung Cancer Incidence and Mortality in Smokers

For smokers, the crude lung cancer incidence densities in the low-risk, nonscreened, and screened groups were 157.80 (95% CI 127.74-194.94) per 100,000 person-year, 306.10 (95% CI 260.55-359.61) per 100,000 person-year, and 433.71 (95% CI 368.14-510.96) per 100,000 person-year, respectively (*P*<.001; Figure 2A-C; Table 4). After adjusting for potential confounders, participants at high risk had significantly higher lung cancer incidence intensity (HR 2.20, 95% CI 1.72-2.82; *P*<.001), lung cancer mortality (HR 2.93, 95% CI 1.60-5.37; *P*<.001), and all-cause mortality rate (HR 1.42, 95% CI 1.06-1.91; *P*=.02) than participants at low risk, and participants in the screened group had significantly higher lung cancer incidence (HR 1.39, 95% CI 1.09-1.76; *P*=.007) but lower lung cancer mortality (HR 0.52, 95% CI 0.28-0.96; *P*=.04) and all-cause mortality (HR 0.47, 95% CI 0.32-0.69; *P*<.001) than the nonscreened group (Multimedia Appendix 3).

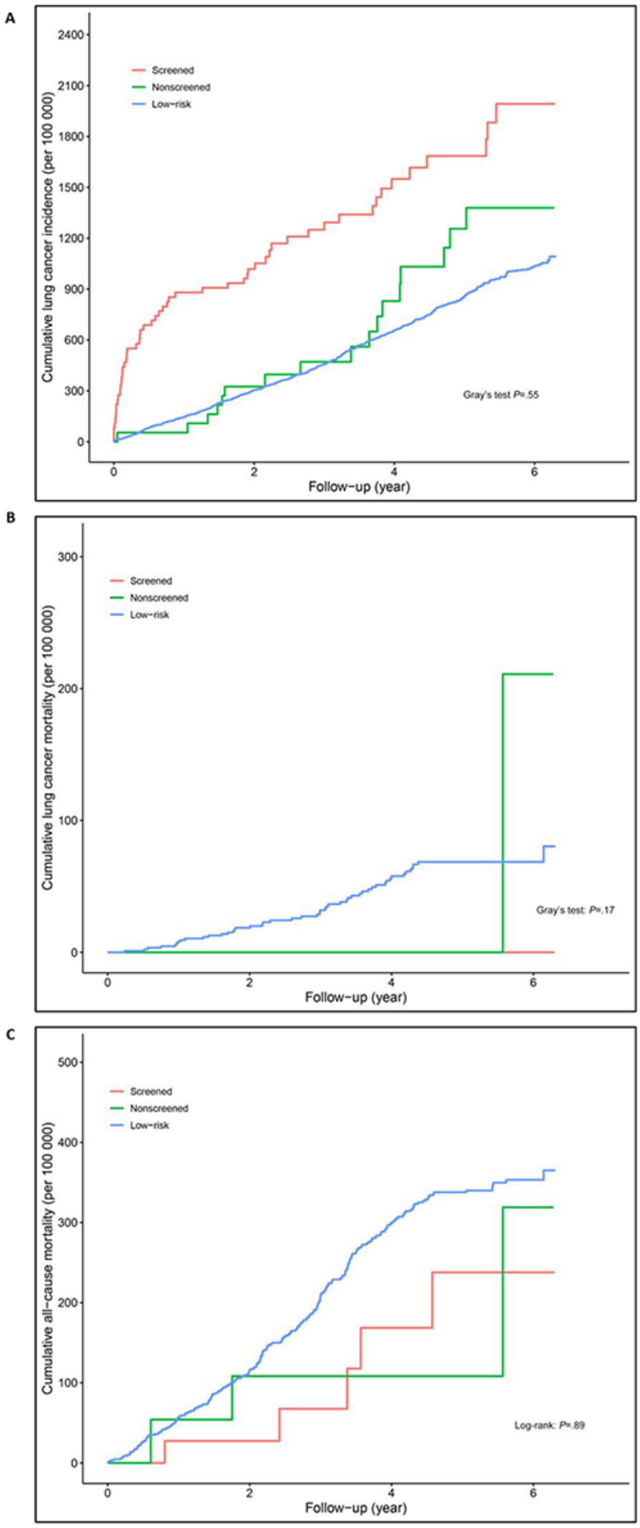
Figure 2. (A) Cumulative intensity of lung cancer incidence, (B) cumulative lung cancer mortality, and (C) cumulative all-cause mortality in smokers.



Lung Cancer Incidence and Mortality in Nonsmokers

For nonsmokers, lung cancer incidence densities in the low-risk, nonscreened, and screened groups were 170.23 (95% CI 157.74-183.70) per 100,000 person-year, 223.72 (95% CI 139.08-359.88) per 100,000 person-year, and 382.33 (95% CI 292.82-499.21) per 100,000 person-year, respectively. No significant differences were detected in lung cancer intensity (*P*=.06), all-cause mortality (*P*=.89), and lung cancer mortality (*P*=.17) between the screened and nonscreened groups (Table 4; Figure 3).

Figure 3. (A) Cumulative intensity of lung cancer incidence, (B) cumulative lung cancer mortality, and (C) cumulative all-cause mortality in nonsmokers.



Discussion

Principal Findings

In this multicenter-based prospective cohort study involving ≥120,000 participants, we found a higher participation rate of LDCT screening among nonsmokers than among smokers (3636/5483, 66.31% vs 7885/18,818, 41.9%). Statistically significant reduced lung cancer mortality and all-cause mortality were observed among smokers in the screened group compared with those in the nonscreened group, with a higher proportion of early-stage lung cancer (72/106, 67.9% in the screened group and 56/114, 49.1% in the nonscreened group). However, we failed to find a significant mortality reduction among screened nonsmokers, relative to nonscreened nonsmokers.

Comparison With Prior Work

The LDCT screening participation rate for nonsmokers was higher than that for smokers, as reported in other studies [13,14]. Studies have consistently shown that smokers have lower recognition of tobacco harm, lower health awareness, or preferred not to be notified of their status of lung cancer [14-18]. Women accounted for the majority of nonsmokers, and women had better awareness of cancer prevention than men [19]. This called for a multipronged approach to enhance engagement and extensively scale up lung cancer screening among smokers in China. As expected, nonsmokers and smokers with lung cancer risk factors (such as occupational exposure to hazardous substances, family history of lung cancer, and history of hepatobiliary diseases) had better LDCT screening compliance, as these disease-related factors may raise people's awareness of lung cancer. For individuals with high lung cancer risk but low screening compliance, promotion of and training on the benefits and need for lung cancer screening are urgently required. Therefore, health education should target these residents to develop good living habits and improve cancer awareness.

As expected, a higher lung cancer incidence density was detected in the high-risk and screened groups, and most lung cancers among the nonsmoker participants were detected in the early stages (476/593, 80.3% were in stage 0-I), in contrast to those among smokers (173/287, 60.3% were in stage 0-I). Moreover, our study showed that the proportion of early-stage lung cancer was also high in the nonscreened group (10/12, 83% vs 56/114, 49.1%). A multicenter hospital-based study in China reported that the proportion of patients with stage I lung cancer was only 19% [20]. This disparity implies that screening programs involving health education, even without the provision of free LDCT examination, might increase the detection rate of early-stage lung cancer when it is still curable.

In our study, the most frequent histological type was adenocarcinoma, with a proportion of 90.2% (607/673) among nonsmokers and 61.2% (194/317) among smokers. East Asian female never-smokers tend to develop adenocarcinoma, with the majority developing from oncogenic mutations [21]. Significantly higher proportions of adenocarcinoma among nonsmokers can be explained by the higher proportion of women among nonsmokers. In addition, in the screened group, the proportion of stage 0-I disease among nonsmokers was higher than that among smokers (42/44, 96% vs 72/106, 67.9%). Similar results were found in a population screened in Korea (92.7% vs 63.6%) [22]. These findings strongly suggest that LDCT screening may be an effective strategy to detect early-stage lung cancer in nonsmokers and smokers in Asia, even though the incidence density of lung cancer is lower in nonsmokers. Despite the poor prognosis of lung cancer, patients with stage I disease have a 5-year survival rate of >75% [23,24]. Therefore, our results establish the potential value of lung cancer screening programs for smokers and nonsmokers.

Over a median follow-up time of 5.1 years, among smokers who were evaluated as high risk, we found a remarkable 48% lung cancer mortality reduction by screening with LDCT. LDCT screening has high potential benefit in decreasing lung cancer mortality worldwide, as shown in the NLST, NELSON, and the German Lung Cancer Screening Intervention Trial studies, which demonstrated that LDCT screening reduced lung cancer mortality by 20%, 24%, and 26%, respectively [3,4,25]. The reduction in our study was greater because we focused on the smoker subgroup. In the Multicentric Italian Lung Detection trial, a similar reduction (39%) was observed in lung cancer–related mortality following LDCT screening among smoking high-risk participants with ≥20 pack-years [26]. As tobacco smoking is a major risk factor for lung cancer [27], we conclude that participants with a history of smoking are likely to derive the greatest benefit from screening. Unlike in trials, the participants were randomly allocated into the LDCT screening group and control group, whereas in our study, the nonscreened group was determined from high-risk participants who declined to participate in further LDCT examination. This indicates that individuals in the nonscreened group (who are at high risk of lung cancer but did not undergo an LDCT scan) were more likely to have poor health awareness and less likely to seek medical assistance. This could be explained by the lowest proportion of early-stage lung cancer, highest all-cause mortality rate, and highest lung cancer mortality rate among the nonscreened group, followed by the low-risk and screened groups. Therefore, we strongly recommend LDCT screening for lung cancer in regions with high smoking rates [28].

The promising effects of the LDCT screening program observed in this study may be because of sufficient medical resources and health care infrastructure in Zhejiang. Zhejiang is a coastal province with a relatively high economy level in China, of which the gross domestic product per capita was US $14,600 in 2020, which was 1.40 times that of the national average and 1.45 times that of the global average. Due to its rapidly growing economy and a well-developed medical system, cancer screening has been well received and undertaken since the 1970s [28,29]. With screening practices in place for decades, Zhejiang has successfully established relatively mature screening networks in local or primary care and has developed multidisciplinary teams of professionals, resulting in a successful and effective LDCT screening program.

We observed a significant 53% reduction in all-cause mortality following LDCT screening among smokers, which was higher than that reported by the NLST (6.7%); however, several European randomized controlled trials, such as the detection and screening of early lung cancer with novel imaging technology and NELSON trials [4,30], found no significant reduction. Much larger sample sizes are needed to detect a significant reduction in all-cause mortality [31]; the sample size in our study was adequate. The consistent reduction in lung cancer mortality and all-cause mortality that we observed in our study is reassuring and supports the accuracy of cause of death assignment and suggests no important harms of screening [32]. In addition to early detection of lung cancer, LDCT screening provides an opportunity to detect cardiovascular disease, pulmonary disease, and extrapulmonary neoplasms [33-35], as a beneficial reduction in all-cause mortality may result from clinically significant incidental findings.

We did not observe a significant reduction in either lung cancer mortality or all-cause mortality by screening for nonsmokers.

This may be because (1) a high proportion of early-stage lung cancers might lead to a favorable prognosis and a limited number of deaths; (2) considering the inadequate sample size as well as the limited follow-up time, no lung cancer deaths were traced in the follow-up period of this study among nonsmokers; or (3) we lacked accurate risk stratification strategies of nonsmokers for lung cancer screening. In East Asia, approximately one-third of lung cancers are unrelated to smoking [36,37]. Between 60% and 80% of women with lung cancer in Asia are nonsmokers compared with between 15% and 20% in the United States and Europe [5]. The current recommendation in the United States is that nonsmokers should not be screened; however, this recommendation is based on modeling in a predominantly White population, making the conclusion likely not applicable to Asian countries with a higher proportion of lung cancers in nonsmokers [38,39]. Moreover, in a population-based ecological cohort study among young women in Taiwan of China who rarely smoke, a significant upward trend in lung cancer incidence after LDCT screening but a stable trend in mortality was observed [40], which is suggestive of screening-related lung cancer overdiagnosis. Nevertheless, LDCT screening decreased the lung cancer mortality rate (HR 0.41) among nonsmokers in Hitachi City, Japan [41], suggesting that LDCT screening is effective in preventing lung cancer death among nonsmokers. In this study, the high adherence to LDCT screening and the high proportion of early-stage lung cancer may reflect a high level of conscientiousness among nonsmokers, indicating that the screening program involving health education has been advantageous for nonsmokers. However, it remains unclear whether LDCT screening can help nonsmokers in reducing mortality. Hence, longer follow-up data are urgently required to evaluate the effects of LDCT screening among nonsmokers. A risk prediction model that is applicable to Asian populations to identify nonsmokers with a high risk of lung cancer for LDCT screening must be established.

Limitations

Our study had some limitations. First, this study may not be representative of the entire general population of China, but it can provide a scientific basis for other regions with similar socioeconomic status. Second, this was a real-world study rather than a randomized controlled trial, which might have led to residual confounders. We admit that a health volunteer effect existed in our study. Our program increased the health awareness of all participants involved in the program, including those in the screened, nonscreened, and low-risk groups. This can explain why the early-stage distributions were higher among all groups than in the general population. These findings suggest that screening programs involving health education may also increase the early detection of lung cancer and potentially decrease disease-specific mortality. Third, the median follow-up of 5.1 years in this study might be insufficient to trace cases and achieve consistent findings. Therefore, additional studies with extended follow-up times should be conducted to further evaluate the screening effects. Fourth, the smoker group was not categorized into heavy and light smokers because of the limited number of cases, and male participants without available information on smoking history were excluded. Passive smoking was only considered for women, which potentially induced gender disparity in smokers and nonsmokers. Finally, the outcome data presented here were obtained from the cancer registry and death surveillance systems, which might have resulted in a misclassification bias. Nevertheless, the cancer registry data in Zhejiang definitively met the requirements of the International Agency for Research on Cancer and the International Association of Cancer Registries, and the data were included in *Cancer Incidence in Five Continents* (*Volume VIII-XI*) consecutively [42-44]. Thus, the data quality obtained from Zhejiang Province was reliable.

Conclusions

In conclusion, our findings suggest effective reduction of all-cause and lung cancer mortality among smokers following LDCT screening, whereas evidence of LDCT screening effectiveness for nonsmokers is still insufficient. It is important to not only target smokers but also identify nonsmokers at high risk of developing lung cancer to implement lung cancer screening programs and maximize screening benefits in China. Our study has significant health service implications, thus providing promising evidence to support the implementation of a national lung cancer screening program and to define optimal guidelines for lung cancer screening in China.

Abstract

Background: People who smoke and who face challenges trying to quit or wish to continue to smoke may benefit by switching from traditional cigarettes to noncombustible nicotine delivery alternatives, such as heated tobacco products (HTPs) and electronic cigarettes (ECs). HTPs and ECs are being increasingly used to quit smoking, but there are limited data about their effectiveness.

Objective: We conducted the first randomized controlled trial comparing quit rates between HTPs and ECs among people who smoke and do not intend to quit.

Methods: We conducted a 12-week randomized noninferiority switching trial to compare effectiveness, tolerability, and product satisfaction between HTPs (IQOS 2.4 Plus) and refillable ECs (JustFog Q16) among people who do not intend to quit. The cessation intervention included motivational counseling. The primary endpoint of the study was the carbon monoxide–confirmed continuous abstinence rate from week 4 to week 12 (CAR weeks 4-12). The secondary endpoints included the continuous self-reported ≥50% reduction in cigarette consumption rate (continuous reduction rate) from week 4 to week 12 (CRR weeks 4-12) and 7-day point prevalence of smoking abstinence.

Results: A total of 211 participants completed the study. High quit rates (CAR weeks 4-12) of 39.1% (43/110) and 30.8% (33/107) were observed for IQOS-HTP and JustFog-EC, respectively. The between-group difference for the CAR weeks 4-12 was not significant (*P*=.20). The CRR weeks 4-12 values for IQOS-HTP and JustFog-EC were 46.4% (51/110) and 39.3% (42/107), respectively, and the between-group difference was not significant (*P*=.24). At week 12, the 7-day point prevalence of smoking abstinence values for IQOS-HTP and JustFog-EC were 54.5% (60/110) and 41.1% (44/107), respectively. The most frequent adverse events were cough and reduced physical fitness. Both study products elicited a moderately pleasant user experience, and the between-group difference was not significant. A clinically relevant improvement in exercise tolerance was observed after switching to the combustion-free products under investigation. Risk perception for conventional cigarettes was consistently higher than that for the combustion-free study products under investigation.

Conclusions: Switching to HTPs elicited a marked reduction in cigarette consumption among people who smoke and do not intend to quit, which was comparable to refillable ECs. User experience and risk perception were similar between the HTPs and ECs under investigation. HTPs may be a useful addition to the arsenal of reduced-risk alternatives for tobacco cigarettes and may contribute to smoking cessation. However, longer follow-up studies are required to confirm significant and prolonged abstinence from smoking and to determine whether our results can be generalized outside smoking cessation services offering high levels of support.

Trial Registration: ClinicalTrials.gov NCT03569748; https://clinicaltrials.gov/ct2/show/NCT03569748

KEYWORDS

harm reduction; heat not burn; electronic cigarettes; smoking cessation; smoking reduction; e-cigarette; public health; psychological well-being

Introduction

According to the World Health Organization, smoking is endemic, with more than 1.1 billion smokers worldwide, resulting in approximately 7 million premature deaths every year [1]. Deaths are primarily due to lung cancer and fatal complications of ischemic heart disease and chronic obstructive pulmonary disease (COPD) [1-3]. The risk of developing diseases has been shown to significantly reduce when stopping smoking [4,5].

Achieving cessation is challenging, because quit rates are low, relapse rates are high, and many smokers wish to continue to smoke [6,7]. The compulsion to smoke is difficult to break, and even for those who do quit smoking, relapse is the norm. For unsupported quit attempts, 80% of people relapse in the first month [7,8], and among people who smoke and use treatments, 75% fail within 6 months, with the large majority resuming smoking within 2 weeks [9]. Even among those who quit smoking during hospitalization and intended to stay quit, 25% relapsed on the first day after discharge [10].

Substitution of combustible tobacco cigarettes with less harmful combustion-free nicotine delivery alternatives (NDAs), such as electronic cigarettes (ECs) and heated tobacco products (HTPs), is now a relatively new option available to smokers [6,11-13].

ECs operate by heating an element that vaporizes a solution. HTPs consist of a holder that electronically transfers controlled heat to tobacco sticks that generate a nicotine-containing aerosol. Since the emission aerosols of combustion-free NDAs are produced at a much lower vaporizing/heating temperature compared to that of combustion (which generally starts above 400 °C), they contain less harmful and potentially harmful chemicals than tobacco smoke [14-19].

Although not completely risk free, EC and HTP use may help respiratory patients to achieve sustained abstinence from cigarette smoking, with clinically relevant health gains [20,21]. The most recent Cochrane review concluded that ECs with nicotine increased quit rates, and compared to nicotine replacement therapy, a risk ratio (RR) of 1.53 was reported, indicating, in absolute terms, an additional 3 quitters for every 100 using ECs [22]. However, formal demonstration of the efficacy of HTPs for smoking cessation is not yet available [23].

HTPs often mimic a hand-to-mouth experience that is very similar to that of conventional tobacco cigarettes. By mimicking the experience of tobacco smoking and its associated rituals, the use of HTPs can provide adequate compensatory physical and behavioral effects [24,25], likely serving as an effective method of relapse prevention [21].

It is not clear if HTPs provide a more gratifying smoking experience compared to ECs, and a direct comparison between the 2 types of products has never been investigated. With this in mind, we conducted a prospective randomized noninferiority switching trial to compare effectiveness, tolerability, and product satisfaction/adoption between HTPs and refillable ECs among people who smoke and do not intend to quit.

Methods

Study Participants

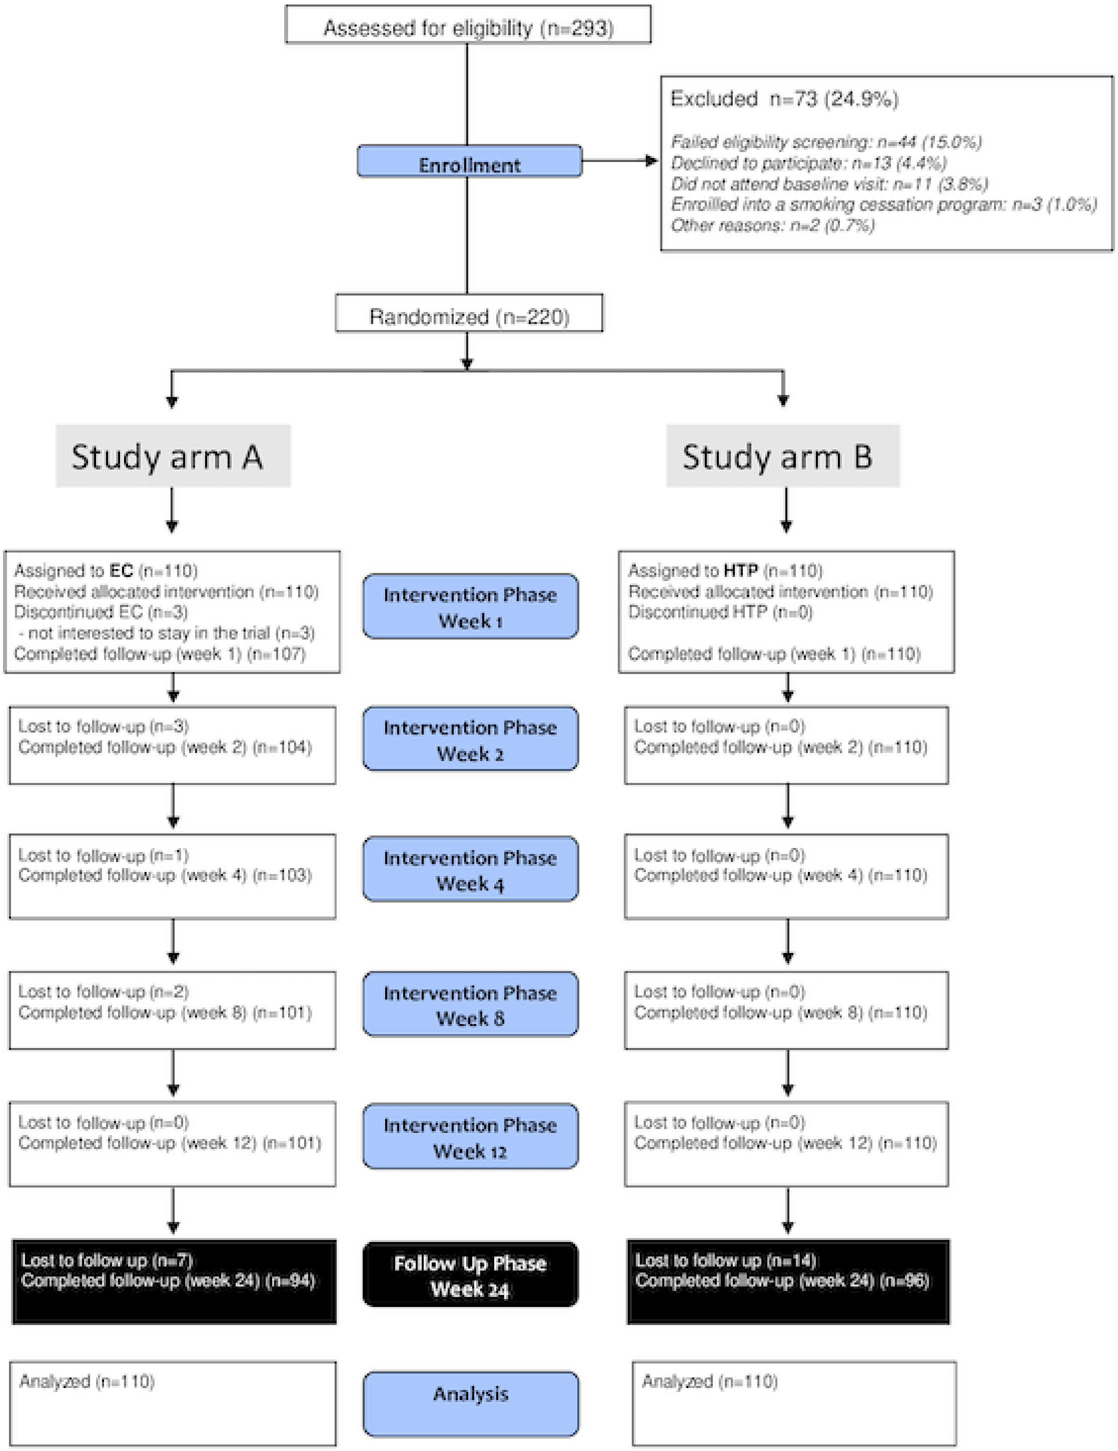
Eligibility criteria have been described previously in detail [26]. In brief, adult people smoking ≥10 cigarettes per day for the past year, having an exhaled carbon monoxide (eCO) level of ≥7 ppm, not intending to quit in the next 30 days, and interested in switching to combustion-free NDAs were recruited among hospital/university staff, via social media, or through word of mouth. Unwillingness to quit was confirmed by the answer "No" to the following questions: "Do you plan to quit smoking within the next 30 days?" and "Do you wish to participate in a smoking cessation program?" The exclusion criteria were as follows: (1) history of depression, panic disorder, psychosis, or bipolar disorder; (2) significant history of alcoholism or drug/chemical abuse within 12 months prior to screening; (3) known clinically significant diseases that, in the opinion of the investigator, would jeopardize the safety of the participant or impact the validity of the study results; (4) use of any tobacco/nicotine delivery device (except for own brands of cigarettes) within the last 3 months; and (5) use of nicotine replacement therapy or other smoking cessation therapies within the last 3 months.

Trial Design and Study Visits

Details of the study design and protocol have been previously published [26]. In brief, this was a 12-week, randomized, 2 parallel arm, open-label, noninferiority trial conducted to compare effectiveness, tolerability, adoption rates, and acceptability between HTPs and ECs in regular smokers (Multimedia Appendix 1). The trial consisted of a total of 8 study visits (see Multimedia Appendix 1). Participants could choose 1 out of 3 different flavors for each class of products and were provided with their preferred flavor for the whole duration of the study. Motivational counseling [27,28] was offered throughout the study to maximize study product adherence, to favor transition away from combustible tobacco cigarettes, and to prevent relapse back to smoking. Activities carried out during study visits are detailed in Multimedia Appendix 2.

The study was conducted in accordance with the Guideline for Good Clinical Practice and followed the Consolidated Standards of Reporting Trials (CONSORT) reporting guidelines for randomized studies (Figure 1).

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram. EC: electronic cigarette; HTP: heated tobacco product.



Study Products

HTPs and ECs were provided for the whole duration of the intervention phase (12 weeks).

HTPs

Participants randomized to the HTP arm of the study received IQOS 2.4 Plus consisting of a pen-like holder into which a tobacco stick is inserted and heated, and a battery case to recharge the holder after each use. IQOS 2.4 Plus was the only HTP available on the Italian market when this trial was designed. The device is to be used with tobacco sticks specifically processed and manufactured for IQOS (named *HEETS*). Participants could choose from 3 varieties of tobacco sticks (*HEETS* Amber, rich tobacco; *HEETS* Yellow, smooth tobacco; and *HEETS* Turquoise, menthol-flavored tobacco), which were available for sale on the Italian market at the time of the study.

ECs

Participants randomized to the EC arm of the study received JustFog Q16 Starter Kit consisting of a battery and a 1.9-mL refillable tank fitted with a 1.6-Ohm nichrome coil. Participants could choose from 3 varieties of e-liquid flavors (Puff Riserva Country 16 mg, sweet tobacco flavor; Puff Riserva Toscana 16 mg, full tobacco flavor; and Puff Artic 16 mg, menthol flavor;

all 3 are formulated in 50% propylene glycol/40% vegetable glycerin/10% H_2O), which were chosen for the trial by an expert panel to match the sensory experiences of the 3 IQOS tobacco sticks selected for the study.

Study Endpoints

The primary efficacy endpoint of the study was the continuous abstinence rate (CAR) from week 4 to week 12 (CAR weeks 4-12). Abstinence from smoking was defined as eCO-verified (<10 ppm) self-reported abstinence from cigarette smoking. CAR weeks 4-12 was used to compare quit rates between IQOS-HTP and JustFog-EC.

The secondary efficacy endpoints were the 7-day point prevalence of abstinence at week 12 and the continuous reduction rate (CRR) from week 4 to week 12 (CRR weeks 4-12). Smoking reduction was self-reported. A reduction in the number of cigarettes smoked per day of 50% from baseline was considered of importance and excluded those labeled as CAR weeks 4-12. The CRR weeks 4-12 was used to compare reduction rates between IQOS-HTP and JustFog-EC. Participants who could not be classified as CAR weeks 4-12 or CRR weeks 4-12 were considered to have failed. Safety reporting details have been previously published [26].

Product satisfaction was investigated by using the following questionnaires adapted and validated for EC and HTP use: modified Cigarette Evaluation Questionnaire (mCEQ) and modified Smoking Cue Appeal Survey (mSCAS). Risk perception was assessed by using the Perceived Risk Instrument for conventional cigarettes (PRI-P CC) and the Perceived Risk Instrument for reduced risk products (PRI-P RRP). The effect on quality of life was investigated by questionnaires (ie, EQ-5D-5L and EQ VAS) and by measuring changes in body weight and exercise tolerance (ie, $\dot{V}O_2$ max by the Chester step test). Self-reported EC or HTP use at each study visit was verified against the product use check and reported in the electronic case report form (e-CRF). The product use check was used to calculate daily consumption.

Study Assessments

The assessments carried out during study visits are listed in Multimedia Appendix 2 and included the following: (1) number of cigarettes smoked per day; (2) adverse events; (3) eCO levels evaluated with a calibrated handheld device (MicroCO); (4) resting blood pressure and heart rate taken with a semiautomated oscillometric sphygmomanometer (Smart Pressure, CA-MI); (5) body weight, height, body fat, visceral fat, fat-free mass, body muscle mass, bone body mass, metabolic age, and water content taken with a body composition analyzer (Tanita SC-240, Tanita); (6) BMI calculated by dividing weight by height square (kg/m^2); and (7) Chester step test to determine maximal aerobic capacity (ie, $\dot{V}O_2$ max).

Other measurements included the following questionnaires: (1) Fagerstrom Test for Cigarette Dependence [29]; (2) mCEQ [30]; (3) mSCAS [31]; (4) PRI-P CC and PRI-P RRP [32]; and (5) EQ-5D-5L and EQ VAS, a standardized measure of health-related quality of life [33].

Secondary analyses of blood pressure, heart rate, BMI, and Chester step test results by smoking phenotype classification will be reported in separate papers.

Ethical Considerations

The Ethical Review Board of Azienda Ospedaliero Universitaria "Policlinico-V. Emanuele," Universita` di Catania, Italy, reviewed and approved the study (approval reference number: 215/2017/PO). All participants provided written informed consent prior to participation in the study. The study has been registered at ClinicalTrial.gov (trial registration ID: NCT03569748). Study data are deidentified, and participants did not receive compensation.

Statistical Methods

A detailed description of the sample size calculation can be found in the published research protocol [26].

All the analyses were performed using SAS Version 9.4 (SAS Institute Inc). The primary efficacy endpoint of the study in the experimental study group was calculated with a noninferiority threshold of 15%. An α level of .05 was considered. Quit rates were evaluated on an intention-to-treat basis. CAR weeks 4-12 percentages and odds ratios (ORs) were calculated and used to compare quit rates between the IQOS-HTP and JustFog-EC study groups with the chi-square test. Moreover, CRR weeks 4-12 percentages and ORs were calculated and used to compare reduction rates between the IQOS-HTP and JustFog-EC study groups with the chi-square test. For the 7-day point prevalence of smoking abstinence and reduction, percentages were calculated at each study visit to illustrate trends.

Safety data were presented as descriptive statistics separately by study group. Any events documented in the period from the point of product randomization (V1) until the end of the intervention phase at 12 weeks when study products were withdrawn (V6) were considered as relevant for safety analysis.

Descriptive statistics of product acceptability measures (ie, mCEQ and mSCAS) were presented as summary tables by study group and study visit. Changes in mCEQ and mSCAS scores within and between study groups were analyzed using the Wilcoxon signed rank test and Wilcoxon rank sum test, respectively.

For risk perception, descriptive statistics of PRI-P CC and PRI-P RRP values were presented as summary tables by study group and study visit. Changes in PRI-P scores within and between study groups were analyzed using the Wilcoxon signed rank test and Wilcoxon rank sum test, respectively.

EQ-5D-5L, EQ VAS, body weight, and exercise tolerance were presented as descriptive statistics, and within- and between-group comparisons were carried out using the Wilcoxon signed rank test and Wilcoxon rank sum test, respectively.

A multiple logistic regression model was prepared to identify variables able to influence the primary outcome CAR weeks 4-12. We performed an a priori selection of variables able to act as determinants, effect modifiers, or confounders of quitting success. The continuous variables were categorized according to cutoffs based clinically. The univariate analysis was performed considering the subgroups CAR and no CAR as the outcome. The following factors, for which a statistical difference was detected, were included in the model: gender, daily cigarette consumption, and 4 psychological aspects included as domains in the questionnaires (ie, product satisfaction, psychological reward, enjoyment, and craving).

Results

Baseline Characteristics

The CONSORT flow diagram of the study subjects is shown in Figure 1. A total of 220 smokers were enrolled in the study, with 211 (95.9%) participants completing the intervention phase. Baseline characteristics of the participants are shown by study product assignment in Table 1 and were comparable between the study groups. On average, participants were Caucasian adults (approximately 41 years old), were mostly men (approximately 57.3%), had smoked about a pack daily for approximately 24 years, had a moderate Fagerstrom Test for Cigarette Dependence score of about 5, and had an average of 2 quit attempts in the past.

Table 1. Baseline characteristics of the participants.

Characteristic	HTP[a] group (N=110)	EC[b] group (N=110)	*P* value
Sex, n			.06
Female	56 (50.9)	70 (63.6)	
Male	54 (49.1)	40 (36.4)	
Age (years), mean (SD)	41.3 (16.1)	41.3 (16.9)	.97
Education level, n (%)			.84
Primary school	2 (1.8)	1 (0.9)	
Secondary school	20 (18.2)	24 (21.8)	
High school	64 (58.2)	61 (55.5)	
University	24 (21.8)	24 (21.8)	
Cigarettes per day, mean (SD)	22.6 (10.1)	22.8 (10.9)	.91
Exhaled carbon monoxide (ppm), mean (SD)	26.2 (13.6)	26.9 (15.4)	.71
Fagerstrom Test for Cigarette Dependence score	5.8 (2.1)	6.0 (2.2)	.47
Years of smoking, mean (SD)	24.5 (15.6)	22.9 (16.0)	.44
Number of quit attempts, mean (SD)	1.9 (2.7)	1.9 (2.5)	.96

[a] HTP: heated tobacco product.

[b] EC: electronic cigarette.

Smoking Abstinence and Reduction Rates

Smoking abstinence rates (CAR weeks 4-12), reduction rates (CRR weeks 4-12), and 7-day point prevalence of smoking abstinence and reduction are shown in Figure 2, and Figures 3A and 3B.

Figure 2. Smoking abstinence rates and smoking reduction rates. CAR: continuous abstinence rate; CRR: continuous reduction rate; EC: electronic cigarette; HTP: heated tobacco product.

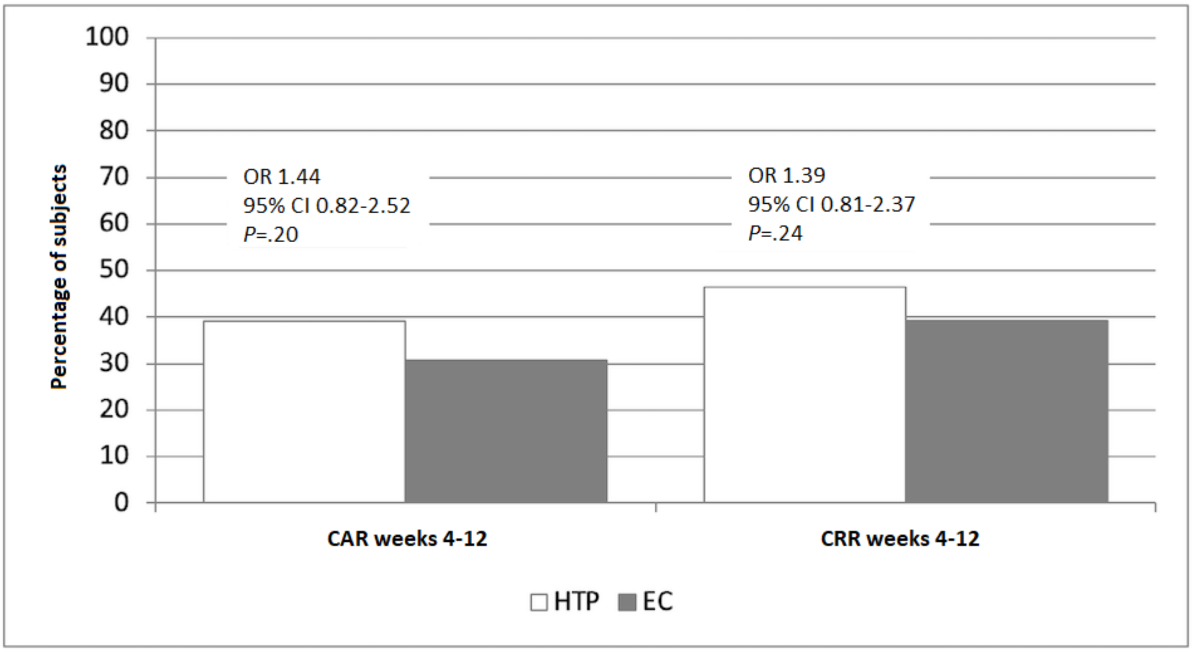


Figure 3. Seven-day prevalence of smoking abstinence and reduction in the electronic cigarette (A) and heated tobacco product (B) study groups.

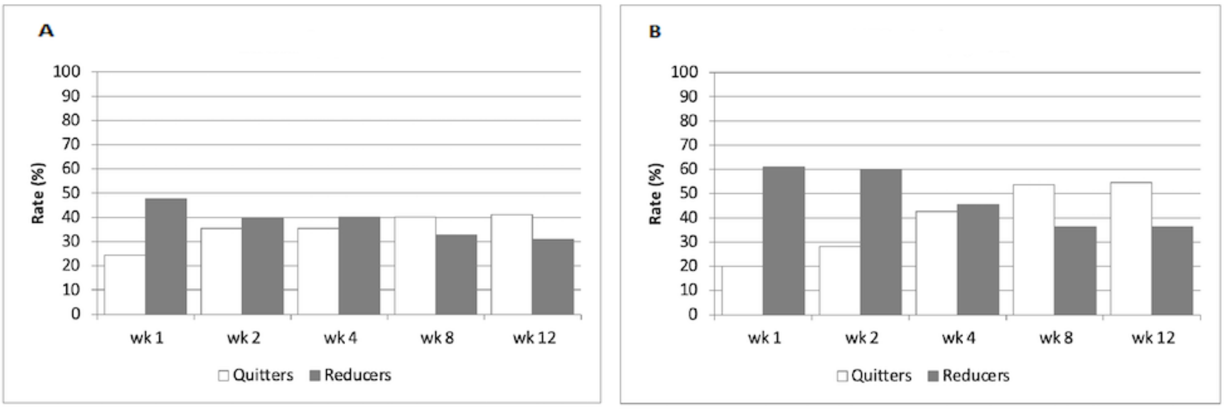


High quit rates, evaluated on an intention-to-treat basis, were observed for both study groups; the CAR weeks 4-12 values for IQOS-HTP and JustFog-EC were 39.1% (43/110) and 30.8% (33/107), respectively (Figure 2). The between-group difference for the CAR weeks 4-12 was not significant (*P*=.20; chi-square test) and satisfied the noninferiority criteria of the study that differences in quit rates between products did not exceed 15% (OR 1.44, 95% CI 0.82-2.52).

High reduction rates, assessed among participants who were still smoking, were also reported, and the CRR weeks 4-12 values for IQOS-HTP and JustFog-EC were 46.4% (51/110) and 39.3% (42/107), respectively (Figure 2). The between-group difference for the CRR weeks 4-12 was not significant (*P*=.24; chi-square test; OR 1.39, 95% CI 0.81-2.37).

The 7-day point prevalence of smoking abstinence was >20% throughout the intervention phase, with values peaking at week 8 (V5) and week 12 (V6) (Figures 3A and 3B). The 7-day point prevalence of smoking abstinence values for IQOS-HTP and JustFog-EC were 53.6% (59/110) and 40.2% (43/107) at week 8, and 54.5% (60/110) and 41.1% (44/107) at week 12, respectively.

The 7-day point prevalence of smoking reduction (ie, dual use) was higher during the first 2 weeks of the intervention phase (Figures 3A and 3B). The 7-day point prevalence of smoking reduction values for IQOS-HTP and JustFog-EC were 60.9% (67/110) and 47.7% (51/107) at week 1, and 60.0% (66/110) and 39.3% (42/107) at week 2, respectively.

For both study products, Figures 3A and 3B also show progressive reduction in the proportion of dual use in the study, which was paralleled by rising prevalence of exclusive single use by the end of the intervention phase.

Product Preference, Acceptability, and Risk Perception

Among participants in the EC study arm, 50.9% (56/110) chose Puff Riserva Country, 30.9% (34/110) chose Puff Riserva Tuscan, and 18.2% (20/110) chose Puff Artic e-liquid. Among participants in the HTP study arm, 56.4% (62/110) chose *HEETS* Amber, 33.6% (37/110) chose *HEETS* Yellow, and 10.0% (11/110) chose *HEETS* Turquoise tobacco sticks. Technical issues (eg, device malfunctions) were relatively uncommon (Multimedia Appendix 3).

Appeal of the study products was analyzed using the mCEQ and mSCAS. No significant within-group changes in the mCEQ and mSCAS scores were observed (Wilcoxon signed rank test; Multimedia Appendix 4). Between-group changes were also not significantly different (Wilcoxon rank sum test; Multimedia Appendix 4). Moderate liking of the study products, mild psychological reward, moderate enjoyment of the respiratory tract sensation, and craving reduction with minimal aversion were noted (Multimedia Appendix 4). The mSCAS showed that the study products elicited a moderately pleasant user experience (Multimedia Appendix 4).

As expected, risk perception for conventional cigarettes was consistently higher than for the combustion-free study products (Multimedia Appendices 4 and 5). Within-group changes in PRI-P CC scores were small but significantly higher for both study groups (IQOS-HTP, *P*<.001; JustFog-EC, *P*=.003; Wilcoxon signed rank test). Between-group comparisons were not statistically significant (Wilcoxon rank sum test). No significant within- or between-group changes were observed for PRI-P RRP.

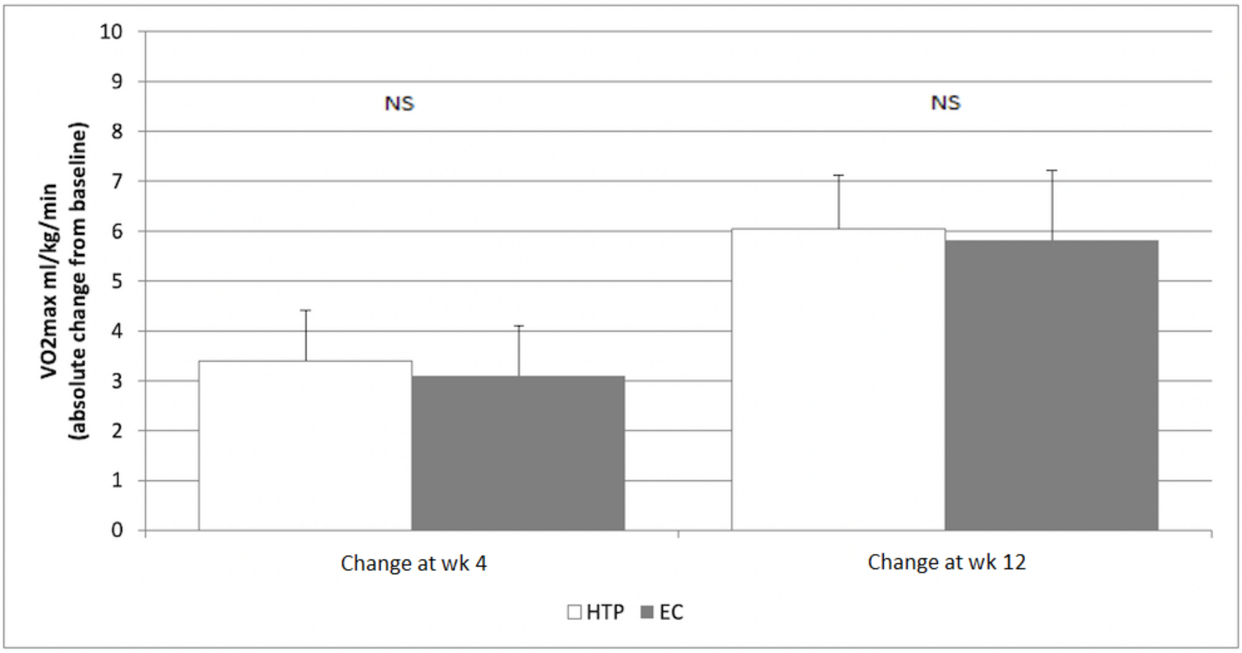
Consumption patterns of conventional tobacco cigarettes, vaping products, and HTPs throughout the study are illustrated in Multimedia Appendices 6 and 7.

Evaluation of Participant Well-being

EQ-5D-5L and EQ VAS results are summarized in Multimedia Appendix 8. No significant changes were observed between the 2 study groups. Within-group analyses for both IQOS-HTP and JustFog-EC showed small but significant changes in all EQ-5D-5L domains, with the exception of domain 2. Regarding EQ VAS, within-group analyses for both IQOS-HTP and JustFog-EC showed small but significant changes from baseline (IQOS-HTP and JustFog-EC; *P*<.001 for all comparisons).

Changes in exercise tolerance between study products were not significant (Figure 4; Multimedia Appendix 8). However, a significant improvement from baseline was observed after switching to the combustion-free products under investigation. For JustFog-EC, reported changes of 2.6 and 7.0 mL/kg/min were noted at week 4 and week 12, respectively (*P*<.001), while for IQOS-HTP, reported changes of 3.4 and 6.4 mL/kg/min were noted at week 4 and week 12, respectively (*P*=.007) (Figure 4; Multimedia Appendix 8). These $\dot{V}O_2$ max improvements were consistently greater than the minimum clinically important difference (MCID) defined as an improvement in the anaerobic threshold of at least 2 mL O_2/kg/min.

Figure 4. Chester step test results. EC: electronic cigarette; HTP: heated tobacco product; NS: not significant.



Predictors of Smoking Abstinence

The results of the abovementioned logistic regression model showed the following evidence: males were less likely to achieve CAR weeks 4-12 compared to females (OR 0.457, 95% CI 0.249-0.840), subjects who had a high consumption of the product were likely to achieve CAR weeks 4-12 compared to those who had a low consumption of the product (OR 0.450, 95% CI 0.212-0.956), and subjects who had a high craving reduction were likely to achieve CAR weeks 4-12 compared to those who had a low craving reduction (OR 0.391, 95% CI 0.186-0.825).

Adverse Events

The reported numbers of adverse events are listed in Multimedia Appendix 9. Most adverse events were rated as mild or moderate and did not led to discontinuation of product use in either study group. In general, the most commonly reported adverse events were cough and reduced physical fitness. Oropharyngeal irritation and dyspnea were more frequent in the EC group than in the HTP group. No serious adverse events were reported during the study. No significant changes in the mean resting heart rate, blood pressure, and BMI during product use were observed between and within study groups.

Discussion

HTP use elicited a marked reduction in cigarette consumption, resulting in almost 40% abstinence from smoking by the end of the study. When present, adverse events were mild and transitory. This is the first study to directly compare ECs to HTPs, showing comparable effectiveness and tolerability between the JustFog-EC and IQOS-HTP study groups.

RCT findings for IQOS-HTP are in agreement with the findings of an American Cancer Society analysis that found a substantial decline in cigarette sales after the introduction of IQOS in Japan [34] and an observational study of COPD patients that reported substantially attenuated or ceased cigarette consumption in the long term after switching to IQOS [21], but are different from the findings of a recent online survey of Korean adults showing a low probability of quitting among IQOS users [35].

Multiple factors contributed to the high quit rate observed among IQOS-HTP and JustFog-EC users: (1) participants were keen to switch to combustion-free NDAs; (2) personalized motivational counseling was administered by psychologists proficient in both smoking cessation and harm reduction at each study visit; (3) top selling products in their respective category (ie, JustFog for ECs and IQOS for HTPs) were given for free in the study and most participants found these products appealing; (4) study products had a pharmacokinetic profile of nicotine uptake mimicking that of conventional cigarettes [36,37]; (5) participants perceived the study products as less harmful than their own cigarettes; and (6) regular use of study products relieved cigarette-induced symptoms and improved exercise tolerance.

The same factors might have contributed to the comparable effectiveness between ECs and HTPs and to the progressive transition from dual use to solo use by the end of the intervention phase. Dual use is known for being a common transitory state, with transitions to solo use taking variable time to occur [38,39]. In our switching trial, IQOS users reported increased dual use in the first 2 weeks compared to JustFog users, but this quickly stabilized by week 4. This could indicate different learning curves for the 2 products.

For this study, we selected the top selling products in their respective category (ie, ECs and HTPs). Both IQOS-HTP and JustFog-EC performed well in the study, as technical issues (eg, malfunctions) were relatively uncommon. Participants enjoyed using both study products, with mCEQ scores showing mild to moderate positive responses in terms of product acceptability, cigarette craving reduction, and physical and psychological reward; mSCAS scores indicating a moderately pleasant user experience; and consumption data revealing regular constant product use throughout the study. This is consistent with the notion that a positive sensorial experience and product enjoyment can contribute to the effectiveness of combustion-free products in terms of cessation outcomes [40-42]. Analyses of PRI-P scoring showed that the study products were perceived to be much less harmful than combustible cigarettes, confirming findings from previous studies [43,44]. IQOS-HTP was perceived to be slightly riskier than JustFog-EC, and in the authors' opinion, this is probably because IQOS shows marked similarities with conventional cigarettes. Moreover, regular use of the study products provided adequate control of cravings (thereby serving as an effective method of relapse prevention), reduced symptoms, and had an overall positive impact on physical fitness, with similar improvements for IQOS-HTP and JustFog-EC. This may also explain why the trend in quit rates increased over time in this switching study; this is discordant to what is generally observed in standard smoking cessation studies in which success rates decline over time.

Adverse events were mild and did not led to discontinuation of product use in either study group. None of the participants abused the products under investigation in terms of excessive daily consumption. In some participants, HTP use was associated with mild cough and reduced physical fitness in line with previous observations [23]. However, the frequency of these symptoms was much lower by the end of the study compared to baseline. Previous smoking history is a key confounder when evaluating the health effects of combustion-free nicotine alternatives in switching studies, as shown by the progressive reduction in the frequency of symptoms by the end of this study. Oropharyngeal irritation was more frequent in the EC group than in the HTP group, probably because of the relatively high level of propylene glycol (a respiratory irritant) in the vaping products under investigation (formulated in 50% propylene glycol/40% vegetable glycerin/10% H_2O). This common irritative response has been shown to be transient and is of uncertain prognostic value [45].

A clinically relevant improvement in exercise tolerance was observed after switching to the combustion-free products under investigation as early as 4 weeks. Greater improvement was observed at 12 weeks as there was a much higher prevalence of quitters by the end of the intervention phase compared to 4 weeks. This is in agreement with the improvement in the level of exercise tolerance shown in prospective studies of COPD patients who switched to ECs [20] and HTPs [21]. The time-dependent improvement in exercise tolerance that occurs after switching may be explained by the marked decline in carbon monoxide exposure and in carboxyhemoglobin levels following cigarette substitution with combustion-free alternatives [46,47].

The trial had strengths and limitations. First, among the innovative features of this randomized controlled switching study, adherence to the study products was enhanced by offering a selection of different products to choose from according to preference/liking. Three aromas of tobacco sticks and three e-liquid flavors were provided to best match participants' sensorial experiences. Nonetheless, these choices remain limited (ie, only 3 different flavors for each class of products) and product specific, thus reducing the generalizability of the study findings. In addition, multiple flavor use is common among e-cigarette users, and switching between flavors is frequently reported even during daily use [48,49]. Du et al also reported that only 1.8% of regular e-cigarette users were using only 1 flavor on a regular basis [50]. Thus, the effectiveness of vaping products for smoking substitution may be further improved.

Second, after close scrutiny, we chose to offer the best vaping devices and HTPs available on the Italian market at the time of the study. More details about the selection process have been published previously [26]. Obviously, product assignment could not be blinded, and strong product preference (IQOS-HTP vs JustFog-EC) could have introduced an allocation bias. Only 3 subjects dropped out soon after randomization when they learned that their product allocation (ie, JustFog-EC) was not their preferred one (ie, IQOS-HTP). However, we cannot exclude that if JustFog-EC was seen as an inferior option, participants in this study group might have put less effort into their switching attempt than those allocated to IQOS-HTP. Nonetheless, the CARs in the JustFog-EC group were at least as high as previously reported [22].

Third, study products were provided in combination with personalized motivational counseling administered by psychologists proficient in both smoking cessation and harm reduction. Provision of expert guidance in the context of a switching trial conducted at specialized smoking cessation services may limit the generalizability of the study findings. Changes in tobacco/nicotine use behavior and product use will be investigated in a separate follow-up study under real-life conditions.

In conclusion, this study confirmed the effectiveness of ECs for cigarette substitution and smoking cessation [22,51], and revealed for the first time that HTP use can promote abstinence from cigarette smoking in combination with motivational counseling. HTPs provided a comparable experience to ECs. Moreover, these results were paralleled by a marked reduction in reported symptoms. Based on the findings of this study, HTPs may represent a valuable addition to the arsenal of reduced-risk products in terms of their smoking substitution potential, but longer follow-up studies are required to confirm significant and prolonged abstinence from smoking and to determine whether our results can be generalized outside smoking cessation services offering high levels of support.

Acknowledgments

The authors would like to thank the staff at Centro Prevenzione Cura Tabagismo (CPCT) for their invaluable assistance with subject recruitment. We are also grateful to Fabio Cibella for the fruitful scientific advice about the statistical analysis plan and Adrian Shalivari for the refinement of the electronic data capture system. The authors' thoughts and prayers go out to all the victims of the Russia-Ukraine conflict. This research was supported by an investigator-initiated study award by Philip Morris Products SA (PMI.IIS.2016.006). Philip Morris Products SA had no role in the design of the study and will not have any role during its execution, data analysis, or data interpretation, or during writing of the manuscript.

Data Availability

We may share deidentified individual participant-level data that underlie the results reported in this article. Data will be available on receipt of a request detailing the study hypothesis and statistical analysis plan. All requests should be sent to the corresponding author. Based on the scientific rigor of the proposal, the study authors will discuss all requests and decide whether data sharing is appropriate. All applicants will be asked to sign a data access agreement.

Abstract

Background: Systemic lupus erythematosus (SLE) is a systemic autoimmune disease involving multiple organs throughout the body. The health care–seeking behaviors, disease progression of SLE, and patients' knowledge of and attitudes toward SLE have not been characterized in China.

Objective: The aim of this study was to depict the health care–seeking behaviors, disease progression, and medications in patients with SLE and to examine the factors associated with their disease flares, knowledge, and attitudes toward SLE in China.

Methods: We conducted a cross-sectional survey in 27 provinces in China. Descriptive statistical methods were used to depict the demographic characteristics, health care–seeking behaviors, medications, and health status. Multivariable logistic regression models were used to identify the factors associated with disease flares, medication changes, and attitudes toward SLE. An ordinal regression model was used to examine the factors associated with the knowledge of the treatment guidelines.

Results: We recruited 1509 patients with SLE, and 715 had lupus nephritis (LN). Approximately 39.96% (603/1509) of the patients with SLE were primarily diagnosed with LN, and 12.4% (112/906) developed LN (mean time 5.2 years) from non-LN. Patients whose registered permanent residences or workplaces in other cities from the same province and adjacent provinces seeking health care accounted for 66.9% (569/850) and 48.8% (479/981) of the patients with SLE in the provincial capital cities, respectively. Mycophenolate mofetil was the most commonly used immunosuppressive drug in patients without LN (185/794, 23.3%) and patients with LN (307/715, 42.9%). Femoral head necrosis (71/228, 31.1%) and hypertension (99/229, 43.2%) were the most common adverse event (AE) and chronic disease during treatment, respectively. Change of hospitals for medical consultation (odds ratio [OR] 1.90, 95% CI 1.24-2.90) and development of 1 chronic disease (OR 3.60, 95% CI 2.04-6.24) and AE (OR 2.06, 95% CI 1.46-2.92) and more were associated with disease flares. A pregnancy plan (OR 1.58, 95% CI 1.18-2.13) was associated with changes in medication. Only 242 (16.03%) patients with SLE were familiar with the treatment guidelines, and patients with LN tended to be more familiar with the disease (OR 2.20, 95% CI 1.81-2.68). After receiving treatment, 891 (59.04%) patients changed their attitudes toward SLE from fear to acceptance, and patients with college education or higher (OR 2.09, 95% CI 1.10-4.04) were associated with a positive attitude toward SLE.

Conclusions: A large proportion of patients seeking health care in the provincial capital cities of China migrated from other cities. Persistent monitoring of potential AEs and chronic diseases during SLE treatment and managing patients who changed hospitals for medical consultation are essential for controlling disease flares. Patients had insufficient knowledge about SLE treatment guidelines and would benefit from health education to maintain a positive attitude toward SLE.

KEYWORDS

systemic lupus erythematosus; health care–seeking behaviors; disease progression; medications; knowledge; attitudes

Introduction

Systemic lupus erythematosus (SLE) is a systemic autoimmune disease involving multiple organs throughout the body [1]. With continuous improvements in diagnosis and treatment, the 5-year survival rate of patients with SLE has increased significantly to more than 90% in the past 2 decades [2]. In China, different regions have different levels of medical resources, and the provincial capital cities have better medical resources, which attract patients with SLE from other cities in the province or surrounding provinces [3,4]. Patients may also switch hospitals during treatment to seek better health care in China. However, the variation in medical insurance reimbursements and the pursuit of health care in different cities will result in a higher economic burden to patients, including the costs of transportation and time [5,6]. Therefore, it is crucial to study patients’ health care–seeking behaviors to provide a basis and guidance for the allocation of medical resources in China in the future.

Disease flare is a state of increased disease activity and has been reported to occur in more than 20% of the patients within 2 years after remission [7-10]. Disease progression, including disease flares, has become the most common cause of hospitalization for patients with SLE, and the risk of damage accrual has doubled [11,12]. In addition to 30%-60% of patients diagnosed with lupus nephritis (LN), a common SLE complication at the onset, some patients may develop LN during treatment [13-15]. However, only few studies have examined the disease progression of LN in patients with no LN in China. After the diagnosis of SLE, patients are given medications, including hydroxychloroquine, glucocorticoids, and immunosuppressive and biological agents. Later, the accompanying increase of adverse events (AEs) or chronic diseases may potentially impact the change in these medications [16]. Further, medications may become potentially changed if patients with SLE plan to become pregnant [17-19]. A retrospective study in Japan revealed that 9.8% of the patients with SLE had changed their medications, but the factors associated with the medication change were not assessed [20]. Understanding reasons for the change in the medications may improve the clinical management of patients with SLE in China [21].

The updated 2020 Chinese guidelines for the diagnosis and treatment of SLE and the 2019 Chinese guidelines for the diagnosis and treatment of LN (hereafter referred to as the treatment guidelines) are further divided to standardize the diagnosis and treatment standards, which not only provide a basis for the diagnosis and treatment of SLE but also provide a transparent guide for patients with SLE [21,22]. Knowledge about SLE can increase a patient’s adaptation to SLE and its treatment [23]. Insufficient general medical knowledge of the disease would result in doubts about medications, thereby increasing the risk of poor treatment adherence [24]. Nevertheless, there is a dearth of studies focusing on patients' familiarity with the treatment guidelines, which reflects the patient's knowledge of the disease to some extent. Socioeconomic and psychosocial factors impact the prognosis of SLE [25]. Negative attitudes, including fear and depression, reduce treatment compliance [26]. A study conducted in Germany showed that negative emotion was associated with 11% reduction in treatment adherence in patients with SLE [27]. A study in China reported that patients with SLE who had anxiety and depression were more likely to have a lower quality of life [28]. Hence, it is essential to explore patients' attitudes toward SLE from the time of their diagnosis to treatment in China. To sum up, the purposes of our study were to examine the disease progression and health care–seeking behaviors of patients with SLE, depict their medication use, analyze the factors associated with disease flares, and assess the predictors of familiarity with the treatment guidelines and their attitudes toward SLE.

Methods

Study Design

The data set in our study was based on an electronic-based questionnaire designed by rheumatologists, epidemiologists, statisticians, and clinicians from multiple centers. The survey was primarily answered by 20 patients and adjusted according to their feedback, and the final version consisted of 4 parts and 51 questions. The first part of the survey was the basic introduction to the study, which required the patient to read the relevant operations carefully and be familiar with the purpose of the study. The second part was about the baseline characteristics of the patients; the third part was about the time of diagnosis, health status, and medications; and the last part was about the knowledge of the treatment guidelines and attitudes toward SLE. The set of questions included fill-in-the-blank, multiple-choice questions with only 1 answer, and multiple-choice questions with several possible answers. To compare the regularity of disease occurrence, we designed the survey by using a large number of time indicators (eg, when were you first diagnosed with SLE and when were you first diagnosed with LN). The detailed contents of the survey are shown in Multimedia Appendix 1.

Ethics Approval

Ethics approval for this study was obtained from the ethics committee of the Third Affiliated Hospital of Sun Yat-sen University (reference [2021] 02-312-01) on October 19, 2021. All patients signed the informed consent before participating and answering the questions in this study. Information such as the objectives, methods, and expected outcomes from this study was presented in the consent form. The privacy and confidentiality protection description for the participants was provided in the consent form.

Tool and Data Collection

This survey was designed using a web-based questionnaire tool (WJX), and a quick response code was generated for distribution in hospitals in China. The survey was filled out by patients with SLE who scanned the quick response code under the guidance of the doctors at each visit. The study period was from June 2021 to December 2021, and data were collected from 105 hospitals and 27 provinces. The inclusion criteria were inpatients or outpatients who were diagnosed with SLE and who signed informed consent. Detailed information on the settings is shown in Table S1 of Multimedia Appendix 2.

To ensure the completeness and credibility of the survey, we made each question mandatory to answer. The key questions were asked in a way (eg, from the diagnosis of the disease to treatment, how many chronic diseases have you developed) such that they were verified by the questions in the subsequent sections (eg, the chronic disease(s) you have developed is/are). The survey had to be filled out in the presence of at least one research doctor. If a patient was not familiar with the way of using the tool or did not understand the way of answering in the relevant columns, the doctor would fill it out.

Definitions

Health care–seeking behavior refers to the seeking of health care in the provincial capital cities and changing of hospitals during treatment (ie, patients sought health care in a hospital different from where they were primarily diagnosed and treated). Disease progression refers to disease flares and the development of AEs and chronic diseases. Disease flares refer to developing LN from non-LN and relapse in all patients with SLE. The Systemic Lupus Erythematosus Disease Activity Index was used to measure relapse in patients without LN if the score increased by at least 4. The reoccurrence of proteinuria or rapid increase of serum creatinine levels was considered as relapse for patients diagnosed with LN [29,30]. Changes in medication meant switching therapy among immunosuppressive drugs and biological agents after the initial treatment. Development of AEs or chronic diseases during treatment referred to the number of AEs or chronic diseases that increased during treatment compared to that in the patients before they were diagnosed with SLE. Patients having a pregnancy plan refers to those with a desire and plan to have children.

Knowledge of the disease was measured by familiarity with the treatment guidelines, which consisted of 3 categories: unfamiliar, less familiar, and familiar. Patients who had not heard of the treatment guidelines were considered unfamiliar. Patients who did not read the treatment guidelines but obtained limited diagnostic and treatment information from other sources were considered less familiar. Patients who read the treatment guidelines in detail and judged their own conditions and guided their medication based on the treatment guidelines were regarded to be familiar with the treatment guidelines. Attitudes toward the disease varied from diagnosis to treatment and were categorized into 4 types: fear throughout treatment (fear →fear), from fear to acceptance (fear →acceptance), from acceptance to fear (acceptance→fear), and acceptance throughout treatment (acceptance→acceptance).

Statistical Analyses

Descriptive statistical methods were used to depict the demographic and clinical characteristics of patients with no LN and patients with LN. Proportions were calculated and presented in a graphical and tabular form. Progression of SLE, patients' health behaviors that included self-discontinuation of patients who stopped the treatment prematurely, irregular treatment of patients who had irregular follow-up and medications, knowledge of the treatment guidelines, and attitudes toward the disease were depicted in a Sankey diagram. Multivariable-adjusted logistic regression models were used to explore the factors associated with the development of LN from non-LN, relapse, and changes in medication. An ordinal regression model was adopted to examine the factors associated with the knowledge of the treatment guidelines. One of the key assumptions of the ordinal regression model is the parallel regression assumption, which requires the coefficients in the cumulative binary logistic regression models to be consistent. The Brant test compares the separate fits to binary logistic regression models and hence was suitably used for assessing the parallel regression assumption for ordinal regression [31]. A logistic regression model was used to investigate the factors associated with attitudes toward the disease.

Results

Characteristics of the Patients

The data of 1509 patients were collected: 794 (52.62%) patients without LN and 715 (47.38%) patients with LN, with a mean age of 34.9 years and 34.6 years, respectively (Table 1). The mean age of the patients with a primary diagnosis of SLE with non-LN and LN was 29 years and 28.4 years, respectively; 1412 (93.57%) patients with SLE were females, and 616 (40.82%) had a college or higher education. The monthly income of the patients with LN was lower than that of the patients without LN (*P*=.01). Relapse (*P*<.001), changes in medication (*P*<.001), and development of AEs (*P*=.003) and chronic diseases (*P*<.001) in patients with LN were higher than those in patients without LN. Only 242 (16.03%) patients with SLE were familiar with the treatment guidelines, and patients with LN were more familiar with the treatment guidelines than those without LN (*P*<.001); 891 (59.04%) patients with SLE changed their attitudes toward the disease from fear at primary diagnosis to acceptance during the treatment, whereas the proportion of patients' attitude changing from acceptance to fear was higher in patients with LN (47/715, 6.6%) than in patients without LN (27/794, 3.4%). Of the 1509 patients with SLE, 489 (32.41%) sought health care in a hospital different from the hospital where they were primarily diagnosed and treated, and 719 (47.64%) had a pregnancy plan. The detailed information of the patients is presented in Table 1.

Figure 1 shows the progression of SLE, health behaviors, and the proportion of patients regarding their familiarity with the disease and attitudes. The mean time for the treatment for patients was 6.4 years. Approximately 39.96% (603/1509) of the patients with SLE were primarily diagnosed with LN, and 12.4% (112/906) of the patients without LN developed LN in the later stage, with a mean time of 5.2 years. Self-discontinuation, irregular treatment, and drug resistance in patients who developed LN from non-LN versus those in patients who experienced relapse were 49.1% (55/112) versus 44.4% (242/545), 36.6% (41/112) versus 2.8% (15/545), and 9.8% (11/112) versus 5.3% (29/545), respectively. Approximately 90.58% (1367/1509) of the patients with SLE developed a positive attitude after treatment.

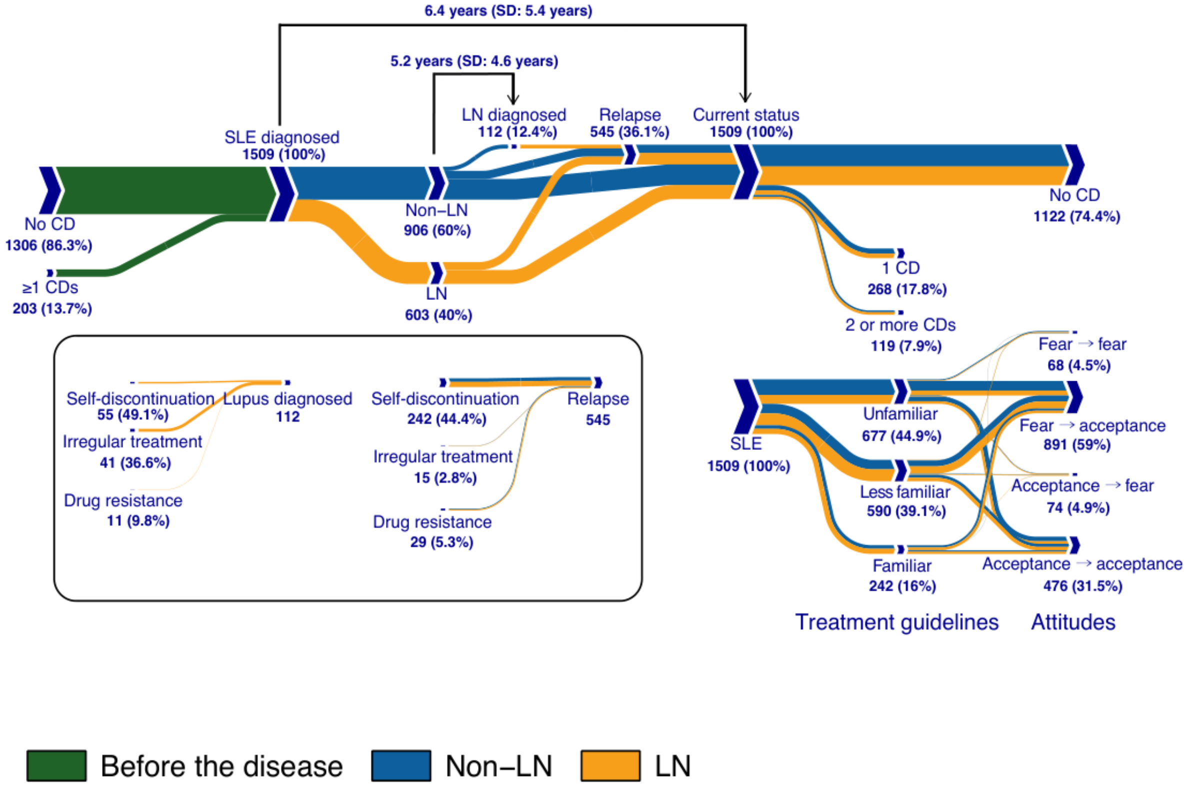
[f] The development of adverse events or chronic diseases during the treatment compared to that before patients were diagnosed with systemic lupus erythematosus.

[g] The attitude of patients from diagnosis to treatment: fear throughout treatment (fear→fear), from fear to acceptance (fear→acceptance), from acceptance to fear (acceptance→fear), and acceptance throughout treatment (acceptance→acceptance).

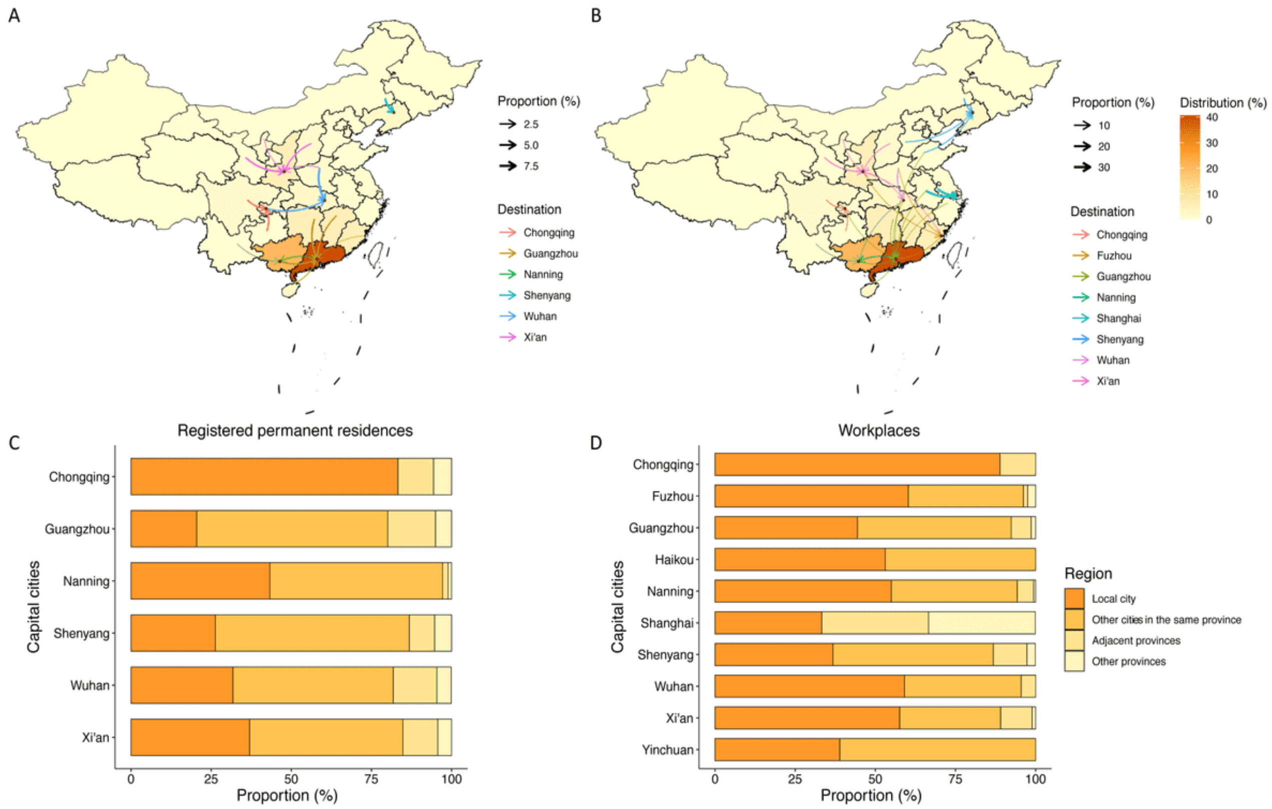
Figure 1. Progression of systemic lupus erythematosus, health behaviors, patients' knowledge of, and attitudes toward the disease. CD: chronic disease; LN: lupus nephritis; SLE: systemic lupus erythematosus.



Health Care–Seeking Behaviors

The distribution of the responses of patients with SLE and the proportions of patients seeking health care in hospitals in provincial capital cities determined by their registered permanent residence or workplaces are presented in Figure 2. Four provincial capital cities (Wuhan, Nanning, Guangzhou, and Shenyang) attracted over half of the total patients whose registered permanent residences were located in other cities from the same province and the adjacent provinces, ranging from 55.6% (99/178) in Nanning to 74.5% (374/502) in Guangzhou. The proportion reached 66.9% (569/850) in the 6 provincial capital cities. Ten provincial capital cities attracted 48.8% (479/981) of the patients whose workplaces were located in other cities in the same province and from the adjacent provinces, among which Guangzhou and Nanning attracted 54.2% (272/502) and 43.8% (78/178) of the patients, respectively.

Figure 2. Distribution of the responses of patients with systemic lupus erythematosus in provinces and the health-seeking behaviors in patients from adjacent provinces when considering the registered permanent residences (A) or the workplaces (B), and the proportion of patients from different cities in provincial capital cities when considering the registered permanent residences (C) or the workplaces (D).

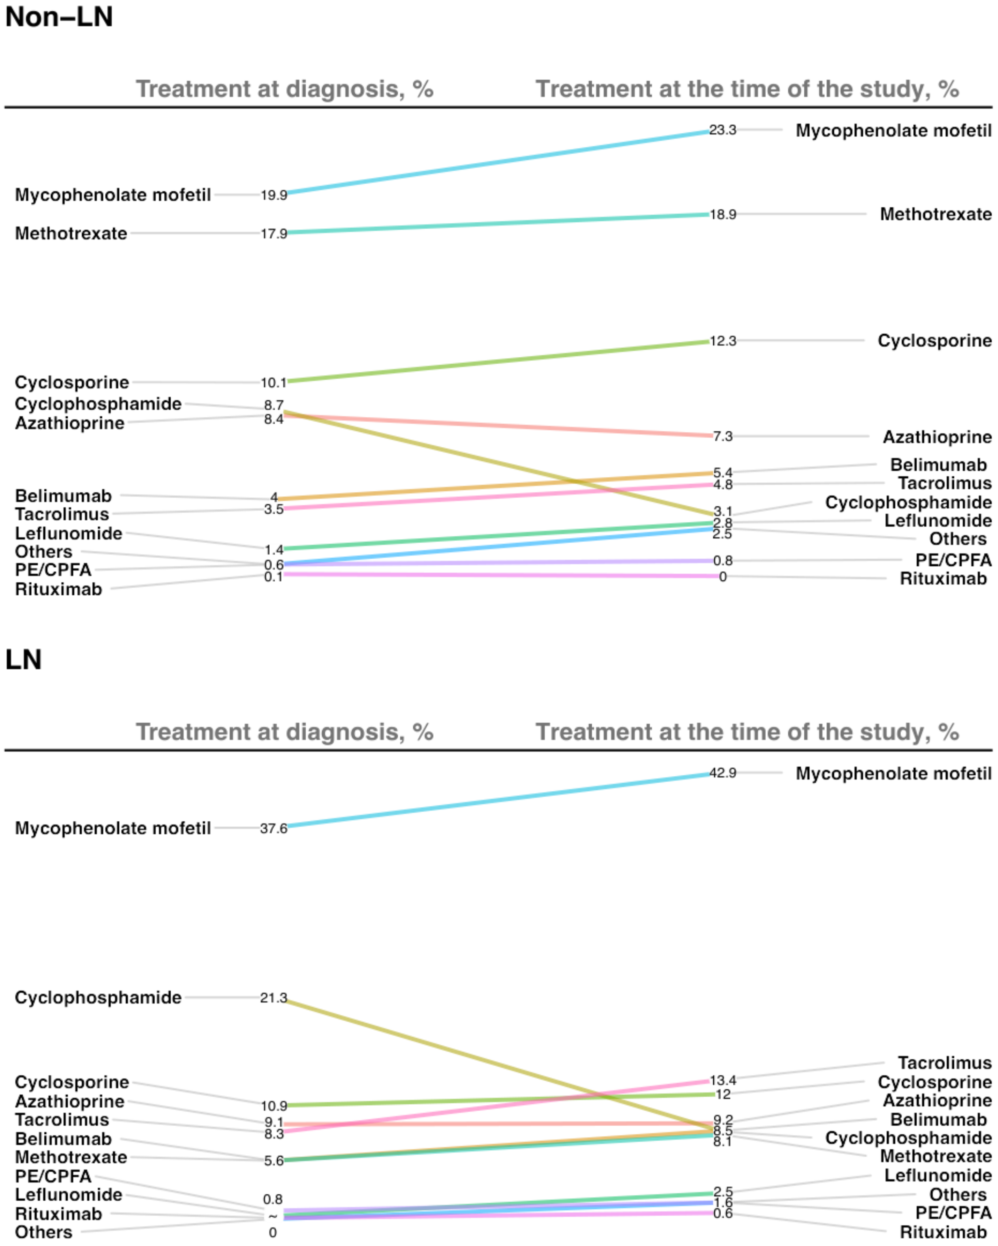


Medications and the Development of AEs and Chronic Diseases

The most common medication used by patients without LN at the time of the study was mycophenolate mofetil (185/794, 23.3%), followed by methotrexate (150/794, 18.9%) and cyclosporine (98/794, 12.3%). These 3 types of immunosuppressive drugs were also the most commonly used in patients without LN at the time of diagnosis, with 19.9% (158/794) on mycophenolate mofetil, 17.9% (142/794) on methotrexate, and 10.1% (80/794) on cyclosporine, respectively (Figure 3). For patients with LN, the most common medication used at the time of the study was mycophenolate mofetil (307/715, 42.9%), followed by tacrolimus (96/715, 13.4%) and cyclosporine (86/715, 12%). Cyclophosphamide (CYC) (152/715, 21.3%) was the second most commonly used immunosuppressive drug at the time of diagnosis, and only 8.4% (60/715) of the patients used it at the time of the study. Belimumab, one of the biological agents, was used less frequently at the time of the study in patients without LN (43/794, 5.4%) and in patients with LN (61/715, 8.5%).

Concerning the development of AEs and chronic diseases, femoral head necrosis (71/228, 31.1%), cataracts (63/228, 27.6%), and retinal macular degeneration (29/228, 12.7%) were the most common serious AEs that occurred during the treatment, while hypertension (99/229, 43.2%), dyslipidemia (45/229, 19.7%), and chronic gastritis (32/229, 14%) were the 3 common chronic diseases developed during the treatment (Table S2 and Table S3 of Multimedia Appendix 2). The highest educational level (college or higher), change of hospitals, development of AEs and chronic diseases, pregnancy plan, and LN were associated with changes in medication.

Figure 3. Medication use in patients with systemic lupus erythematosus at diagnosis and treatment during the time of this study. CPFA: continuous plasma filtration absorption; LN: lupus nephritis; PE: plasma exchange.



Factors Associated With Disease Flares, Knowledge of, and Attitudes Toward SLE

Change of hospitals (odds ratio [OR] 1.90, 95% CI 1.24-2.90) and development of 1 chronic disease (OR 3.60, 95% CI 2.04-6.24) or 2 or more chronic diseases (OR 4.67, 95% CI 2.13-9.95) were associated with LN development (Table 2). In addition, the development of 1 AE and 2 or more AEs during treatment compared with no AE development and LN status compared with non-LN status was associated with a higher risk of relapse. More factors, namely, age and college or higher education, were significantly associated with medication changes.

Only patients with LN (OR 2.20, 95% CI 1.81-2.68) were associated with familiarity with the knowledge of the treatment guidelines (Table 3). The parallel regression assumption was satisfied by the Brant test (Table S4 of Multimedia Appendix 2). Higher education, including senior high school and college or higher, was associated with a positive attitude to the disease, whereas patients with LN were associated with the risk of a negative attitude, together with the development of 1 AE (table 3).

Discussion

Principal Results

A noteworthy finding in our study is that 55.6% (473/850) of the patients with SLE who sought health care in the provincial capital cities migrated from other cities in the same province when considering their registered permanent residences. When considering the workplace, hospitals in provincial capital cities also lured 42.9% (421/981) of the patients with SLE from the same provinces to seek health care even if the workplaces of these patients were not located in the capital city. In addition, compared with general provincial capitals, high-income provincial capitals also attracted patients from adjacent provinces such as Guangzhou and Xi'an. This can be partly explained by the push-pull theory, as the provincial capital city has more resources in the province, including more hospital options, more medical experts, and better medical technology, which could be considered as the social factors for patients to achieve better quality of life [32]. However, out-of-town visits will increase patients' economic burdens such as transportation and accommodation costs. Therefore, targeted measures should be adopted by various departments for these patients. Hospitals in provincial capital cities can establish a unique medical channel that can provide personal support for people who migrate from other cities to seek medical care through effective identification. The medical insurance departments of each province should simplify the medical reimbursement process for patients from other cities in the same province and the adjacent provinces to reduce the economic burden of patients.

Factors associated with relapse in patients with SLE have been reported in many studies, including the increased anti-double-stranded deoxyribonucleic acid, B lymphocyte stimulator, renal organ involvement, deficiency of hydroxychloroquine, premature discontinuation, and poor compliance [22,33-35]. Consistent with the factors above, we found that patients with LN had a higher risk associated with relapse, among which 49.1% (55/112) of the patients self-discontinued the treatment. In addition, our results showed that the development of 1 or more AEs and chronic diseases during treatment increased the risk of disease flares, including the development of LN from non-LN and relapse in all patients with SLE. The mean time of disease progression in Chinese cohorts was 5.2 years, corresponding to an international inception cohort study with a mean time of 4.6 years [14]. The outcomes in our study may extend the previous finding [14].

A novel finding in our study is that switching from the first hospital where patients were primarily diagnosed and treated was associated with their risk of development of LN and relapse and was significantly associated with changes in their medications. This finding implies that the hospital that the patient first visited may have provided improper treatment. Requesting more meticulous care and treatment for patients with a record of switching hospitals from other cities, especially in the provincial capital cities, is imperative because the major public hospitals have a large number of patients from other cities, with outpatient visits and hospitalizations increasing. A study in 1 hospital in Kunming city, a provincial city in the Yunnan province, showed that outpatient visits and hospitalizations increased from 188,530 and 6620 in 2001 to 369,510 and 12,380 in 2010, respectively [36]. Another hospital in Shanghai showed that outpatient visits increased from 734,923 in 2013 to 881,376 in 2017 [37]. Although medical resources are more concentrated in provincial capital cities, individualized management of patients in those cities, including consideration of the patient's diagnosis and treatment history, at the initial hospital and the patient's home city is indispensable [3,4].

Apart from factors such as older age, higher education, development of at least 1 AE and chronic disease, change of hospitals, and LN development that were associated with changes in medication, nearly half of the patients with SLE had a pregnancy plan, which was also a significant factor (OR 1.58, 95% CI 1.18-2.13). It has been confirmed that using CYC leads to ovarian failure [38]. Our study shows that the use of CYC decreased by 60.5% (92/152) in the current treatment (at the time of the study) compared with that during the primary treatment, and the proportion of patients using CYC among those with a pregnancy plan was significantly lower than that among those without a pregnancy plan (Table S5 of Multimedia Appendix 2). This finding shows that in addition to considering clinical symptoms, the plans and the needs of the patients are also worth considering by doctors in the treatment process.

The familiarity with treatment guidelines reflects a patient's knowledge of the disease to a certain extent [39]. Our results indicated that only 12.5% (99/794) of the patients without LN and 20% (143/715) of the patients with LN were familiar with the treatment guidelines. Moreover, only patients with LN were more familiar with the treatment guidelines than patients without LN. The limited proportion of patients with knowledge of the treatment guidelines in China can be worrisome, as these results revealed 2 issues. First, the knowledge of the disease was inadequate; therefore, the treatment decision was more passive or physician-led. Furthermore, the lack of education and knowledge of SLE would increase the risk of disease flares [24]. Second, patients were more familiar with the disease in a severer state than when the disease was in a mild stage, indicating that patients focused less on their disease in the early stage. A study has shown that patients' knowledge of the disease could be improved by reading the treatment guide [39]. Therefore, the potential solution is to condense and simplify the relevant content of diagnosis and treatment in the treatment guidelines and to distribute the guidelines to doctors and patients in electronic or paper versions in a simple booklet for their study and reference. In addition, patients should be rendered a comprehensive understanding of the disease when the disease status is mild rather than after the disease has worsened.

Patients' attitudes toward SLE, on the whole, reflected acceptance, with approximately 90.58% (1367/1509) of the patients expressing a positive attitude during the treatment period, although nearly half of the patients felt fear at the time of diagnosis. An important factor was patients with LN who had a higher risk of developing a fearful attitude at diagnosis than patients without LN. One way to improve the patient's attitude is by providing health education. Studies have indicated that good education is associated with higher knowledge of diseases and increased self-awareness of one's health and assessment of health care [40-42]. Further, the interaction between doctors and patients can be strengthened, including using the evaluation function of the survey (WJX) to test patients' understanding of the latest research progress on the disease and monitoring patients' attitude changes to the disease at different stages, which can be achieved through a series of scoring and incentive measures [43].

Limitations In This Study

Our findings have some limitations and must be interpreted with caution. First, although we set the time points for collecting variables, the chronological order of the factors and the outcomes might not be explicit. For example, we dynamically described a change in the development of chronic diseases before and after the diagnosis of SLE. However, whether its increase occurs before or after the development of LN or relapse has not been elucidated. This limitation is because, on the one hand, the study design was cross-sectional. On the other hand, even in the existing medical database, the corresponding time point is relatively vague; therefore, reverse causality or simultaneity may appear. Second, a more detailed measurement of health emotions may improve health decision-making [44-46]. Our study lacked such measurement of attitudes toward SLE, and a further study evaluating patients' emotions on a numerical scale may improve the findings' accuracy. Third, our study might have responder bias. Since Guangdong is the most populous province in China, more samples were collected from Guangdong, while samples from other regions were more evenly distributed. Furthermore, recall bias might arise in the data collection process, especially for those who had received long-term treatment for more than 10 years. It was challenging for patients to recall their physical condition and medication regimen before the diagnosis. In order to reduce this limitation, we set the number of entries and specific names in the survey to achieve consistency and to ensure that recall bias was minimized.

Conclusions

In our study, a large proportion of patients seeking health care in provincial capital cities migrated from other cities in the same province and the adjacent provinces. Mycophenolate mofetil was the most commonly used immunosuppressive drug in the treatment of patients without LN and patients with LN at the time of this study. Femoral head necrosis was the most common AE, followed by cataract and retinal macular degeneration, while hypertension, dyslipidemia, and chronic gastritis were the 3 common chronic diseases developed during the treatment. Change of the hospital where patients were primarily diagnosed and treated and the development of AEs and chronic diseases were associated with disease flares and changes in medication. A pregnancy plan was also associated with changes in medication. Patients had insufficient knowledge about the treatment guidelines, and patients without LN tended to be less familiar with the treatment guidelines compared to patients with LN. Patients with SLE who had college education or higher were associated with a positive attitude rather than those who had only a junior high school education or lower. Our findings suggest that disease flares should be controlled by monitoring potential AEs and chronic diseases during treatment and by effectively managing patients who switched hospitals for their medical consultation. In addition, patients would benefit from health education to maintain a positive attitude toward SLE.

Acknowledgments

We thank all the doctors and patients who participated in our study. This work was supported by the Ten and Five Project of the Third Affiliated Hospital of Sun Yat-sen University (grant SW201901) and the Distinguished Young Scholar Candidates Program of the Third Affiliated Hospital of Sun Yat-sen University (grant A2675).

Data Availability

The data are not publicly available due to the potential violation that may compromise the privacy of the research participants. However, data may be available upon proper request from the corresponding author.

Authors' Contributions

ZD contributed to the study design, data analysis, and manuscript drafting. EHYL contributed to the study design, data interpretation, manuscript revision, revision, and approval. ZL contributed to study design, manuscript revision, and approval. The other authors were responsible for data collection and interpretation. All authors critically approved the final manuscript.

Conflicts of Interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest. The surveys of 7 older patients (age range 67-86 years) among the 1509 participants were filled out by their doctors because these patients could not operate the digital survey or understand the questions. The surveys were answered by doctors in the presence of these patients who also confirmed the responses. There was no conflict of interest for the doctors who assisted the 7 older patients.

Abstract

Background: The recently published "Life's Essential 8" (LE8) by the American Heart Association has overcome some limitations in evaluating cardiovascular health (CVH) in the previous "Life's Simple 7."

Objective: We aimed to examine the secular trends in CVH, as assessed by the LE8, in US adults from 2005 to 2018.

Methods: Using cross-sectional data from the National Health and Nutrition Examination Survey between 2005-2006 and 2017-2018, we calculated the age-standardized mean scores of overall CVH and each of the LE8 components, where a higher score (range 0-100 points) means a better health status. A total of 21,667 adults aged 20-79 years were included in this analysis.

Results: The overall CVH did not significantly change between 2005-2006 and 2017-2018 (65.5, 95% CI 63.9-67.1 to 65.0, 95% CI 62.8-67.1; *P*=.82). The individual metrics did not significantly change for diet (41.0, 95% CI 38.0-43.9 to 41.5, 95% CI 36.5-46.6; *P*=.94), physical activity (57.5, 95% CI 53.0-61.9 to 53.0, 95% CI 48.7-57.3; *P*=.26), and blood pressure (68.4, 95% CI 65.2-71.5 to 68.6, 95% CI 65.3-71.9, *P*=.35), improved for nicotine exposure (64.7, 95% CI 61.1-68.4 to 71.9, 95% CI 67.7-76.2; *P*<.001), sleep health (83.7, 95% CI 81.6-85.7 to 84.1, 95% CI 81.2-87.1; *P*=.006), and blood lipids (61.6, 95% CI 59.1-64.0 to 67.0, 95% CI 63.5-70.4; *P*<.001), and worsened for BMI (63.4, 95% CI 59.7-67.1 to 56.2, 95% CI 52.5-59.9; *P*<.001) and blood glucose (83.9, 95% CI 82.4-85.4 to 77.4, 95% CI 74.5-80.3; *P*<.001).

Conclusions: According to the LE8, the overall CVH did not change among US adults from 2005 to 2018, as well as 3 components (diet, physical activity, and blood pressure). Other metrics such as nicotine exposure, blood lipids, and sleep health improved, while BMI and blood glucose deteriorated over time.

Introduction

Cardiovascular disease (CVD) is a major public health issue worldwide [1]. In the United States, nearly one in 10 adults (aged ≥20 years) are suffering from CVD (mainly coronary heart disease and stroke) [2], and the annual direct and indirect costs due to CVD in the United States are estimated to amount to US $378 billion [2]. Although the age-standardized mortality rate attributable to CVD has largely declined over the past decades in the United States, the total health and economic burdens due to CVD remain huge, partly due to population growth and aging [3,4].

Given that a large part of the CVD burden is attributable to a limited number of health and behavioral factors, the American Heart Association (AHA) promoted 7 cardiovascular health (CVH) metrics (also known as the Life's Simple 7 [LS7]) in 2010 [5], including 4 behavioral factors (no smoking, sufficient physical activity [PA], healthy diet, and having a normal BMI), and 3 health factors (normal levels of blood lipids, blood pressure [BP], and blood glucose). Each of these 7 metrics was categorized by scores of 0, 1, and 2 points to represent a poor, intermediate, and ideal health status, respectively. The overall CVH score in the LS7 was calculated as the sum of the scores of these 7 metrics, which can range from 0 (worst health) to 14 points (optimal health). Unfortunately, the prevalence of people with ideal CVH (ie, with high LS7 score) has been consistently extremely low (eg, <1% have an optimal score of 14 points) [2].

The LS7 was widely used in the past decade and had played an important role in promoting CVH in the United States and around the world. However, there are some limitations to the LS7 [6]. First, the categorization (poor, intermediate, and ideal) of the LS7 components inherently reduces a precise assessment of the risk factors that all actually have a graded relation with CVD outcomes. Second, the definitions of poor, intermediate, and ideal categories for each component are arbitrary (eg, PA duration from 1 minute to 149 minutes per week are all categorized in the same intermediate category). Third, several social or behavioral CVD risk factors such as psychological factors and sleep are not included in the LS7. Fourth, some of the LS7 metrics are not assessed comprehensively. For example, the LS7 diet metric was assessed by the sole intake of 4 foods and nutrients (ie, fruits and vegetables, fish, whole grains, sweetened beverages, and sodium).

The newly released Life's Essential 8 (LE8) metrics proposed by the AHA [6] addressed several of the limitations of LS7 (Table S1 in Multimedia Appendix 1). For example, some score categories have been further defined—sleep health has been added as an eighth metric, the definition of a healthy diet has been expanded, the use of inhaled nicotine-delivery system and secondhand smoke exposure have been considered in addition to combustible cigarette use, hemoglobin A_{1c} level has been added in addition to fasting glucose, and non–high-density lipoprotein cholesterol is used rather than total cholesterol to assess blood lipids [6]. One recent study reported that 47.3% of young individuals who were evaluated as having ideal CVH by the LS7 were reclassified into the low CVH category by the LE8 [7], suggesting that the new LE8 can reduce the misclassification of CVH status. However, although the AHA acknowledged the importance of psychological health and well-being and strongly encouraged more routine assessment and intervention in clinical settings [6], these factors are also not considered in the LE8 as obligatory indicators.

The new CVH score defined by the LE8 has recently been shown to be inversely associated with the risk of all-cause and CVD mortality [8-10]. One study based on 23,110 adults in the United States indicated that every 10-score increase in overall CVH score could decrease the risk of all-cause mortality by 14% and CVD mortality by 19% [8]. Understanding the secular trends of overall CVH and its components is useful to inform and guide targeted health care and public health policies by the US government and other relevant organizations [11]. Therefore, based on the newly published CVH concept of the LE8, we examined the secular trends in overall CVH and its each component among the US adult population based on 7 serial nationally representative cross-sectional surveys conducted between 2005-2006 (which we refer to as "2005" hereafter) and 2017-2018 (which we refer to as "2018").

Methods

Study Population

Data were obtained from the National Health and Nutrition Examination Survey (NHANES), which consists of serial cross-sectional surveys conducted by the National Center for Health Statistic of the US Centers for Disease Control and Prevention to evaluate the health and nutritional status in US adults and children. Participants were selected using a multistage cluster probability sampling method, and all eligible participants were invited to complete a household interview and a physical examination. The questionnaire includes information on demographic, socioeconomic, lifestyle, and other health-related variables, and the physical examination consists of anthropometric and biological measurements. Data from the NHANES are publicly available [12]. The NHANES began in 1999-2000, and subsequent surveys were carried out every 2 years. In this study, we used the data from the 7 survey waves that were conducted from 2005 to 2018 since information on sleep health (1 component of the LE8) was initially collected since 2005. A total of 39,749 adults aged ≥20 years were initially included. We excluded individuals aged >79 years (n=2776), those with missing values on CVH metrics (total of 10,355, including 7996 due to missing data on diet [missing values on all two 24-hour dietary recalls: n=3876; missing on a 24-hour dietary recall: n=4120]) or demographic variables (n=2037), pregnant women (n=481), women who were breastfeeding (n=198), or individuals with self-reported CVD history (n=2235; Figure S1 in Multimedia Appendix 1). A total of 21,667 adults aged 20-79 years were included in this analysis.

We performed analyses in consideration of several demographic characteristics: age, sex, race or ethnicity, educational level, marital status, and household income. We classified participants into three age groups: 20-39, 40-64, and 65-79 years [13]. Self-reported race or ethnicity was classified as Hispanic, non-Hispanic White, non-Hispanic Black, and "Other" (including mainly Asian participants). To characterize an individual's socioeconomic status, we used the ratio of family income to poverty by dividing family income by the federal poverty threshold for the survey year, adjusting for household size, categorized as <1.30 (low income), 1.30-2.99 (middle income), and ≥3.00 (high income) [14]. Educational level was divided into 4 groups: <high school graduate, high school graduate, some college or associate degree, and college graduate or above. Marital status was categorized as married, divorced/separated/widowed, and unmarried/cohabitation status.

Ethics Approval

The NHANES was approved by the National Center for Health Statistics Research Ethics Review Board. Written informed consent was obtained from all participants. This study was exempted from ethical approval by the institutional review board of Shandong University given the use of deidentified and open access data.

Quantification of CVH

The LE8 score is based on 4 "behavioral factors" (diet, PA, smoking, and sleep health) and 4 "health factors" (BMI, blood lipids, blood glucose, and BP). Diet quality was assessed using the Healthy Eating Index 2015 (HEI-2015) based on data from 2 interviewer-administered 24-hour dietary recalls. Diet was assessed using the "Food Patterns Equivalents Database 14" from the US Department of Agriculture [15]. PA was assessed through self-reported frequency and duration of moderate (resulting in light sweating or a small increase in breathing or heart rate) and vigorous activity (resulting in heavy sweating or a large increase in breathing or heart rate) over the past 30 days. The PA duration was calculated by the frequency of PA in a week multiplied by the duration of PA each time. Nicotine exposure was assessed based on self-reported consumption of combustible cigarettes and use of e-cigarettes and other tobacco products in the previous 30 days, as well as self-reported secondhand smoke exposure in a participant's household. Sleep health was assessed from the question on usual sleep duration per day. Height and weight were objectively measured using a stadiometer and digital weight scale, respectively, and BMI was calculated as weight (kg)/height squared (m^2). BP was measured for three consecutive times after 5 minutes of seated rest, and the average of the second and third readings was used (or the average of the first and second measurements for participants who only had 2 readings or using the first measurement for participants who only had 1 reading). Information on the use of antihypertensive drugs was obtained from the interviewed questionnaire at home. Blood samples were collected at a mobile examination center and sent to a central laboratory for the assessment of blood lipids, fasting glucose, and hemoglobin A_{1c}. Data on the use of lipid-lowering medications, insulin, or oral hypoglycemic agents were obtained from the interviewed questionnaire at home. Changes for some biochemical indexes in measurement methods and used instruments over time were adjusted according to the official recommendation to make them comparable across different survey years [16]. The 8 behavioral and health factors and the thresholds used to allocate scores for each component in detail are shown in Table S2 in Multimedia Appendix 1. Scores for each component ranged from 0 to 100 points according to the AHA scoring algorithm [6], with a higher score meaning a better health status. The overall CVH score was calculated as the mean of the sum of all 8 metrics and similarly ranged from 0 (if the mean score of all components was 0) to 100 (optimal CVH). In this study, scores for the overall CVH and individual components were categorized into poor (0-50 points), intermediate (50-79 points), and high (80-100 points) status according to the AHA recommendation [6].

Statistical Analysis

Differences in percentages of demographic characteristics across the 7 survey waves were assessed with the chi-square test. We calculated the age-standardized mean scores and their 95% CI for the overall CVH score and for each of the 8 CVH components. We performed stratified analysis by sex, age group, educational level, marital status, race or ethnicity, and family income category. We used linear regression model to estimate the linear trends between 2005 and 2018 with adjustments for sex, age group, educational level, marital status, and family income category if appropriate. Data were standardized for age using a direct standardization method based on the age distribution of the 2018 US population (20-39 years: 38.6%; 40-64 years: 44.6%; 65-79 years: 16.8%) [17]. Since oversampling was done in some particular subgroups of the total population in the NHANES to increase the reliability and precision of health indicators in the specific population, the appropriate sample weights, as well as strata and primary sampling units provided by the NHANES were used to make the data national representative of the US population. All statistical analyses were performed using Stata software (version 16.0, Stata Corp), and 2-sided *P* values of <.05 were considered statistically significant.

Results

A total of 21,667 participants aged 20-79 years were included in this study. The distributions of sex, age group, race or ethnicity, marital status, and family income did not differ across the survey waves. Participants with an educational level lower than high school decreased from 13.9% in 2005 to 8.6% in 2018 (*P*=.01; Table 1).

The age-standardized mean overall CVH score changed from 65.5 (95% CI 63.9-67.1) in 2005 to 65.0 (95% CI 62.8-67.1) in 2018 (Figure 1), but the result was not statistically significant (*P* for trend=.82), as well as in almost all subgroups (Table 2). Trends in crude overall CVH score over time showed a similar pattern (Table S3 in Multimedia Appendix 1). Adults with age-standardized high (≥80 points), intermediate (50-79 points), and low (<50 points) overall CVH scores accounted for about 20%, 65%, and 15% in the US population, respectively, in each survey wave (Figure 2). The results were similar when based on the crude proportion (Figure S2 in Multimedia Appendix 1). The overall CVH score significantly worsened between 2005 and 2018 in older, Hispanic, and non-Hispanic White individuals, but no difference was found in other covariate categories.

The age-standardized mean scores of diets, PA, and BP did not significantly change from 2005 to 2018 (Figure 1), as well as in almost all subgroups (Table S4 in Multimedia Appendix 1). The age-standardized mean score of PA fluctuated over time. The age-standardized mean scores improved for nicotine exposure (64.7, 95% CI 61.1-68.4 to 71.9, 95% CI 67.7-76.2), sleep health (83.7, 95% CI 81.6-85.7 to 84.1, 95% CI 81.2-87.1), and blood lipids (61.6, 95% CI 59.1-64.0 to 67.0, 95% CI 63.5-70.4) from 2005 to 2018. However, the age-standardized mean scores significantly decreased for BMI (63.4, 95% CI 59.7-67.1 to 56.2, 95% CI 52.5-59.9) and blood glucose (83.9, 95% CI 82.4-85.4 to 77.4, 95% CI 74.5-80.3; Figure 1, Table S4 in Multimedia Appendix 1). The results were similar within subgroups of sex, age, race or ethnicity, marital status, and family income (Table S4 in Multimedia Appendix 1). Similar trends were found based on the crude scores of the 8 metrics (Table S5 in Multimedia Appendix 1). Among all 8 metrics, blood glucose, sleep health, and nicotine exposure had the largest proportion (>50%) of high score (≥80 points); PA and diets had the largest proportion (40%-50%) of the low score (<50 points) over time (Figure 2). The results were similar when based on crude proportions (Figure S2 in Multimedia Appendix 1). Distributions of scores categories for 8 individual CVH metrics according to the specific scoring algorithm in detail are shown in Figure S3 in Multimedia Appendix 1 (aged-standardized proportion) and Figure S4 in Multimedia Appendix 1 (crude proportion).

By 2018, Americans who were female (66.9, 95% CI 63.9-70.0), young adults aged 20-34 years (69.8, 95% CI 67.2-72.4), non-Hispanic White (65.9, 95% CI 63.1-68.6), or in the “Other” category (including mainly Asian individuals: 66.4, 95% CI 62.9-70.0) had (or tended to had) higher (better) age-standardized mean LE8 scores of overall CVH than those who were male (63.0, 95% CI 60.8-65.2, older adults aged 65-79 years (61.1, 95% CI 59.4-62.9) and non-Hispanic Black (60.1, 95% CI 57.8-62.5), and the age-standardized mean LE8 scores of overall CVH were also much higher in Americans with higher educational level (73.1, 95% CI 70.0-76.1) versus lower educational level (57.1, 95% CI 53.5-60.6), in those who were married (66.3, 95% CI 64.2-68.5) versus those who were unmarried (60.4, 95% CI 56.6-64.2), and in those with higher family income (68.3, 95% CI 65.7-71.0) versus those with lower family income (59.0, 95% CI 55.4-62.6; Table 2).

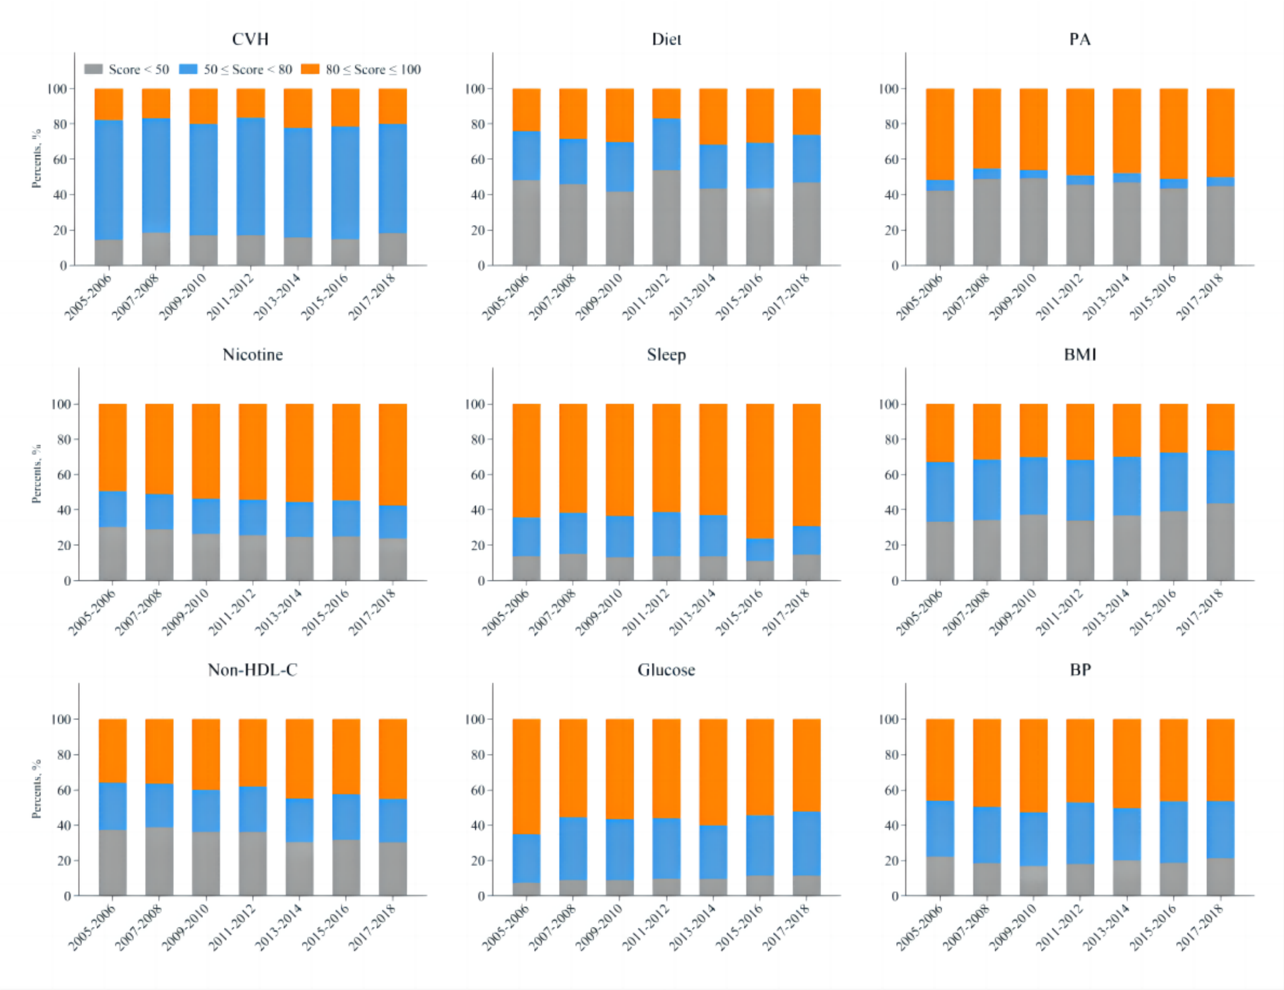
[a] Higher score denotes better cardiovascular health.

[b] Linear trends were examined using linear regression model, with adjustment for sex, age, race or ethnicity, educational level, marital status, and the

ratio of family income to poverty.

Figure 2. Trends in distributions of age-standardized scores categories of low (<50 points), median (50-79 points), and high (80-100 points) status of overall cardiovascular health and its 8 components based on the Life's Essential 8 in US adults from 2005-2006 to 2017-2018 (higher score denotes better CVH). BP: blood pressure; CVH: cardiovascular health; non–HDL-C: non–high-density lipoprotein cholesterol; PA: physical activity.



Discussion

Principal Findings

To our knowledge, this study is the first to examine the secular trends in CVH among US adults based on the new LE8 scoring algorithm proposed by the AHA. Using the 7 cross-sectional surveys between 2005 and 2018, the overall CVH score did not significantly change over time. However, the overall CVH status significantly worsened between 2005 and 2018 in older adults, Hispanic participants, and non-Hispanic White participants. There was no significant change over time for 3 CVH components (diet, PA, and BP) but 3 components (nicotine exposure, sleep health, and blood lipids) significantly improved, whereas 2 components (BMI and blood glucose) significantly, and markedly, worsened over time.

Although a number of public health and health care policies and programs have been implemented to prevent CVD since 2010 [18-20], the decline in age-standardized CVD mortality rate has slowed down or even stagnated considerably in recent years among US adults [2,21]. For example, the age-standardized mortality rate for heart disease declined between 1999 and 2010 by 8.3%, but only by 1.7% between 2010 and 2017 [21]. One important reason for this deceleration of the CVD decline may be that some CVD risk factors have not significantly improved or even deteriorated. This is consistent with other studies, which showed that the mean number of ideal CVH metrics based on the LS7 had not significantly changed in the past years [22,23]. For example, the Behavioral Risk Factor Surveillance System data showed a nonsignificant change in the mean number of ideal CVH metrics from 3.89 in 2011 to 3.96 in 2017 [22]. Another NHANES study among US adults showed that the mean number of ideal CVH components did not significantly change from 2007 to 2018 in both female participants (4.40 to 4.48) and male participants (3.97 to 3.93) [23]. In addition, previous studies among adults based on the LS7 also showed that there was no significant improvement in CVH among US adults [24,25]. Results of our study, which are based on the new LE8 scoring algorithm, are consistent with no change in CVH reported by the abovementioned studies based on the LS7, highlighting that there is still a long way to go to improve CVH among US adults.

The stable trends in the overall CVH score may mask disparities in trends in CVH components. We found that the mean scores of 4 CVH metrics including nicotine exposure (increase), BMI (decrease), non–high-density lipoprotein cholesterol (increase), and blood glucose (decrease) changed over time but not all in the same direction, and some (diet) did not change over time. Unhealthy diet is a major risk factor for CVD [26], but unfortunately, the dietary component gathered the lowest mean score [24]. Despite some improvement in some dietary components, the overall dietary quality did not significantly improve [27]. This emphasizes the need for interventions on those dietary components that tend to decline or do not improve over time. Actually, a number of interventions have already been implemented during the past years in the United States [28]. The smoking rate decreased from 24.8% in 1999-2000 to 18.1% in 2017-2018 [29], and this translated into improved mean LS7 scores of smoking from 1.53 in 2007-2010 to 1.60 in 2015-2018 [24], as well as in our study. Data from the NHANES showed that mean BMI increased from 28.0 kg/m^2 in 1999-2000 to 29.8 kg/m^2 in 2017-2018 [29], with the corresponding obesity prevalence dramatically increasing from 27.5% to 43.0% [30]. He et al [29] reported that the mean total cholesterol decreased from 203.3 mg/dL in 1999-2000 to 188.5 mg/dL in 2017-2018, which is consistent with our finding that the LE8 blood lipid component improved over time. Previous studies showed that the estimated prevalence of diabetes increased from 9.8% in 1999-2000 to 14.3% in 2017-2018 [31], consistent with the decreasing LS7 mean score of blood glucose from 1.42 in 2007-2010 to 1.29 in 2015-2018 [24], as well as the decreasing LE8 mean score observed in our study.

However, there were also several inconsistent findings in our study compared with previous studies regarding the secular trends in 2 CVH components (PA and BP) [24,32,33]. It is reported that the estimated prevalence of meeting the PA guideline target increased from 26.0% in 1998 to 37.4% in 2018 [32]. However, the overall mean score of PA in our study still remained unchanged and at a low level. As for hypertension, the prevalence as defined by the 2017 American College of Cardiology/AHA decreased (suggesting an improvement) from 48.1% in 1999-2000 to 44.1% in 2015-2016 [33]. However, another study reported that the mean BP score based on the LS7 slightly decreased (suggesting a deterioration) from 1.28 in 2007-2010 to 1.24 in 2015-2018 [24]. Inconsistent with the above 2 studies, we did not observe a significant change in the mean LE8 component score of BP between 2005 and 2018. In addition, the national data showed that more than half of the US population did not reach the sufficient sleep duration (20-64 years: 7-9 hours per day, 65-79 years: 7-8 hours per day) recommended by the National Sleep Foundation [34]. Inappropriate sleep duration (<6 hours or ≥9 hours) has been associated with an increased risk of CVD and related mortality [35]. Although previous studies reported a persistent deterioration of sleep quality in the US population from 2005 to 2018 [36,37], we observed an opposite trend with a significant increase (improvement) in the mean LE8 component score of sleep health from 2005 to 2018. These disparities might be partly due to methodological issues in assessing sleep quality across studies.

Consistent with previous studies [13,14], the overall LE8 score of CVH and its components differed markedly across the subgroups of sex, age, race or ethnicity, and socioeconomic status, with individuals who were female, younger, non-Hispanic White, and those with better socioeconomic status being more likely to have a better CVH. Although trends in the CVH metrics over time in these subgroups were mostly consistent with those in the overall population, there are some interesting findings. First, non-Hispanic White participants and the "Other" group (including mainly Asian participants) had a higher overall CVH score than non-Hispanic Black participants, but the difference decreased over time, partly due to deterioration in CVH over time among non-Hispanic White participants. The deterioration of 2 CVH components (diet and PA) among non-Hispanic White participants may be the reason for the worsening trend in overall CVH score in this subgroup. This highlights the need to consider LE8 trends according to racial or ethnic groups when designing CVD prevention and control policy and programs. Second, none of the CVH metrics significantly improved among older participants (65-79 years) over time. CVH usually markedly decreases with age [38], largely driven by the strong relation among hypertension, dyslipidemia, and type 2 diabetes with age. The CVH in older adults is a main challenge, as most hard CVD outcomes develop at an older age. In general, the less ideal CVH at all ages found in this study stresses the need for life course approaches to CVH and the need for high-risk individual-level approaches (clinical care) at middle and older ages. Third, the mean LE8 component of BMI (obesity) markedly deteriorated in all subgroups. This trend is particularly worrying, given the major role of adiposity on glucose metabolism, including insulin resistance, hypertension, and more generally poor CVH [39,40]. This highlights the need to strengthen preventive and medical approaches to weight gain prevention and control, including a broader use of novel effective clinical approaches [41]. Fourth, socioeconomic status such as educational level and family income are important social determinants of CVD [42]. Consistent with abundant literature on this topic, our results show that participants with higher socioeconomic status had much better CVH and the CVH gap (as assessed with the LE8 metrics) between individuals with low versus high socioeconomic status did not decrease over time, highlighting the need to further address social disparities in CVD prevention and control.

Strengths and Limitations

Our study is the first to examine the secular trends in CVH from 2005 to 2018 among US adults based on the nationally representative NHANES data using the new AHA LE8 metrics. However, several limitations should be mentioned. First, our study was based on data from 7 surveys over a rather short time period (<15 years). Second, data on diet, PA, nicotine exposure, and sleep health were obtained by self-report, which may be inaccurate due to recall and social desirability biases. Third, the 8 behavioral and health components are given equal weight (implying the same predictive performance) in calculating the LE8 overall CVH score. Fourth, although the 8 components constitute major or important risk/preventive factors for CVH, a number of other factors (eg, familial history/genetics, other conditions, or comorbidities) can largely alter CVD risk, particularly at the individual level. Fifth, missing values on relevant variables, especially for dietary variables, might have affected the representativeness of the study population.

However, the inclusion of data on one 24-hour dietary recall showed similar results (age-standardized score did not significantly change from 40.46 in 2005-2006 to 40.47 in 2017-2018, *P* for trend=.77) with the primary ones.

Conclusions

In summary, based on the LE8 metrics, the overall CVH score did not significantly change from 2005 to 2018 among US adults. Very few individuals had CVH scores in good or optimal ranges, implying a large scope for improvement for most adults. Three CVH components remained unchanged over time (diet, PA, and BP), 3 improved (nicotine exposure, sleep health, and blood lipids), and 2 worsened (BMI and blood glucose), suggesting avenues for improving CVH status among US adults.

Acknowledgments

The authors thank the National Center for Health Statistics of the Centers for Disease Control and Prevention for sharing the NHANES data. This work was supported by the Innovation Team of “Climbing” Program of Shandong University, and Youth Team of Humanistic and Social Science of Shandong University (20820IFYT1902) and National Key Research and Development Plan: Real-Time Intelligent Active Intervention on Integration of Ten Important Chronic Diseases (2020YFC2003504-2).

Data Availability

The data sets generated and analyzed during this study are publicly available on the US Centers for Disease Control and Prevention website [12].

Authors' Contributions

BX conceptualized the study. CL drafted the first draft of the manuscript. YL analyzed the data. BX, MZ, CZ, and PB critically revised the manuscript for key intellectual content. Abstract

Background: Internalizing and externalizing personality traits are robust risk factors for substance use and mental health, and personality-targeted interventions are effective in preventing substance use and mental health problems in youth. However, there is limited evidence for how personality relates to other lifestyle risk factors, such as energy balance–related behaviors, and how this might inform prevention efforts.

Objective: This study aimed to examine concurrent cross-sectional associations between personality traits (ie, hopelessness, anxiety sensitivity, impulsivity, and sensation seeking) and sleep, diet, physical activity (PA), and sedentary behaviors (SB), 4 of the leading risk factors for chronic disease, among emerging adults.

Methods: Data were drawn from a cohort of young Australians who completed a web-based, self-report survey in 2019 during early adulthood. A series of Poisson and logistic regressions were conducted to examine the concurrent associations between the risk behaviors (sleep, diet, PA, and sitting and screen time) and personality traits (hopelessness, anxiety sensitivity, impulsivity, and sensation seeking) among emerging adults in Australia.

Results: A total of 978 participants (mean age 20.4, SD 0.5 years) completed the web-based survey. The results indicated that higher scores on hopelessness were associated with a greater daily screen (risk ratio [RR] 1.12, 95% CI 1.10-1.15) and sitting time (RR 1.05, 95% CI 1.0-1.08). Similarly, higher scores on anxiety sensitivity were associated with a greater screen (RR 1.04, 95% CI 1.02-1.07) and sitting time (RR 1.04, 95% CI 1.02-1.07). Higher impulsivity was associated with greater PA (RR 1.14, 95% CI 1.08-1.21) and screen time (RR 1.06, 95% CI 1.03-1.08). Finally, higher scores on sensation seeking were associated with greater PA (RR 1.08, 95% CI 1.02-1.14) and lower screen time (RR 0.96, 95% CI 0.94-0.99).

Conclusions: The results suggest that personality should be considered when designing preventive interventions for lifestyle risk behaviors, particularly in relation to SB, such as sitting and screen time.

KEYWORDS

personality; emerging adulthood; screen time; sedentary; sleep; diet; physical activity; prevention; mental health; risk factor; sedentary behavior; chronic disease

Introduction

Chronic diseases, such as cancer, cardiovascular disease, and mental disorders, are the leading causes of disability and death across the globe [1]. It is estimated that almost one-third of chronic diseases could be prevented by reducing exposure to modifiable lifestyle risk behaviors [2], such as physical inactivity, poor diet, alcohol use and smoking, poor sleep, and sedentary behaviors (SB; sitting and screen time) [3,4]. These risk behaviors are highly prevalent among adolescents in Australia [5] and worldwide [6] and are associated with significant health consequences, including increased risk of obesity [7] and emotional and behavioral problems [8,9]. They typically have their onset early in life, and once established, they track into adulthood, increasing the risk for chronic disease over the life course [4,10-12]. Identifying and implementing innovative strategies to prevent or modify these lifestyle risk behaviors during adolescence is critical for promoting lifelong health.

One plausible target for preventing lifestyle risk behaviors and associated harms is personality traits. Numerous studies have demonstrated robust associations between personality traits and substance use [13], particularly with respect to the internalizing personality profiles of *anxiety sensitivity* (fear of anxiety-related physical sensations) and *hopelessness* (tendency toward low mood; worthlessness; and negative beliefs about oneself, the world, and the future), and the externalizing profiles of *sensation seeking* (elevated need for stimulation and intolerance to boredom) and *impulsivity* (rapid decision-making and poor response inhibition) [14]. Each personality trait has been shown to be associated with specific patterns of substance misuse, motivations for use, and comorbid psychopathology. For example, hopelessness has been associated with the early onset of alcohol use and depressive symptoms, while impulsivity has been associated with drinking problems, tobacco use, other drug use, and conduct problems [15]. These personality profiles have been shown to be reliable predictors of future substance use and mental health problems and are therefore important targets for screening and prevention [13,15-17].

Improved understanding of the way in which personality traits are associated with other highly prevalent, yet modifiable risk behaviors among youth has considerable implications for tailoring prevention programs to account for particular personality styles. To date, much of the research examining associations between personality and energy balance–related behaviors (ie, health behaviors related to energy intake and energy expenditure) such as dietary intake, SBs (sitting and screen time), physical activity (PA), and sleep has focused on children and early adolescents [18,19]. For example, a 2019 cross-sectional study among 8-11 year olds in the United States found that adequate sleep duration and reduced screen time were associated with less impulsive behavior among children [18]. On the contrary, there is little research on the associations between personality and lifestyle risk behaviors during emerging adulthood (18-25 years), a critical, yet poorly understood period characterized by numerous personal and social role changes, increased autonomy over lifestyle choices, declines in health behaviors [20,21], and increased risk of anxiety, depression, and substance use disorders [22]. The limited existing literature on this population has found relationships between sleepiness and impulsivity [23] and extraversion and SB [24]. However, further research among larger samples of emerging adults and addressing a broader range of energy balance–related risk behaviors is required. Therefore, this study aimed to examine cross-sectional associations between 4 personality traits (hopelessness, anxiety sensitivity, impulsivity, and sensation seeking) and 5 energy balance–related behaviors (screen time, sitting time, fruit and vegetable intake, sleep duration, and moderate-to-vigorous physical activity [MVPA]) among a sample of emerging Australian adults.

Methods

Study Design

The sample was derived from the long-term follow-up of an existing cohort of young Australians who participated in a cluster randomized controlled trial (RCT). A total of 2190 grade 8 students (54% male; mean age 13.3, range 11.9-15.4 years) from 26 Australian secondary schools in New South Wales and Victoria (17 private or independent and 9 public) were originally recruited to the RCT in 2012. This 4-arm cluster RCT evaluated the impact of universal and selective interventions (separately and together) for the prevention of alcohol and other drug use delivered in grade 8. Intervention content did not focus on the behaviors measured for this study. All participants had received health education as usual (either as part of the control arm of the study in grade 8) or over the period of follow-up in grades 9 and 10 at school. This trial is registered with the Australian New Zealand Clinical Trials Registry (ACTRN12612000026820), and full details of the RCT, including detailed descriptions of the interventions, adherence, and attrition are published elsewhere [25-27]. Despite the longitudinal nature of the cohort, given data on healthy lifestyle behaviors were only obtained during the final follow-up period, this study uses cross-sectional data collected from 978 participants (mean age 20.4, SD 0.5 years) who completed the 7-year follow-up assessment in 2019.

Procedure

Using multiple sources of locator information provided during previous assessments (including email, phone number, postal address, Facebook handle, and parents' email address), participants were contacted and invited to complete a web-based, self-report survey at a time and location of their choice.

Ethics Approval

All procedures were approved by the Human Research Ethics Committees of the University of New South Wales (HC16881) and The University of Sydney (HREC 2018/845). All participants were required to provide digital informed consent prior to participation, which allows secondary analyses, such as this study, without additional consent. To ensure privacy and confidentiality, all data were deidentified. Respondents were compensated AUD $30 (USD $19.80) (or an equivalent voucher) for their time.

Measures

Overview

All measures were self-report and were completed digitally.

Demographics

The following demographic variables were assessed: sex (male, female, and other), employment status (full-time, part-time, unemployed, and other), and tertiary education in progress or completed (none, trade/technical, and university/college).

Personality

Personality was measured using the Substance Use Risk Profile Scale (SURPS), a 23-item tool developed to assess 4 personality traits relevant to substance use: impulsivity, hopelessness, anxiety sensitivity, and sensation seeking [13,16]. The tool measures 4 dimensions of personality: impulsivity (eg, I often don't think things through before I speak), sensation seeking (eg, I enjoy new and exciting experiences even if they are unconventional), hopelessness (eg, I feel that I am a failure), and anxiety sensitivity (eg, I get scared when I experience unusual bodily sensations). The SURPS is scored on a 4-point Likert scale (strongly agree—strongly disagree) and has demonstrated acceptable to good internal consistency and reliability (α=.62-.86) as well as good concurrent and predictive validity among a comparable sample of Australian youth [15]. The total scores for each of the 4 subscales were calculated and converted into *z*-scores based on the total sample mean and SD.

Fruit and Vegetable Consumption

Fruit and vegetable intake were assessed using 2 validated items commonly used in health research [28,29]: "About how many serves of fruit/vegetables do you usually have each day?" Possible response options were "don't eat fruit/vegetables," "1 serve or less," "2-3 serves," "4-5 serves," and "6 serves or more." Participants were provided with written information about what constitutes one serving of fruit and vegetables. In line with the Australian dietary guidelines [30], responses were dichotomized so that poor fruit intake was defined as less than 2 servings per day, and insufficient vegetable intake was classified as less than 4-5 servings per day. A new variable was constructed to represent both fruit and vegetable intake with two categories: (1) adequate fruit or vegetable intake and (2) inadequate fruit and vegetable intake.

Physical Activity

Self-reported MVPA was assessed using items from the International Physical Activity Questionnaire-Short Form (IPAQ-SF), which has demonstrated good psychometric properties in a diverse range of samples [31]. Respondents were asked to indicate how many days during the past 7 days and for how long each day (in hours and minutes) they had performed vigorous PAs (eg, heavy lifting, digging, aerobics, or fast bicycling). Participants were also asked to report the number of days they did moderate PAs (eg, carrying light loads, bicycling at a regular pace, or doubles tennis, excluding walking) in the past 7 days and how much time they usually spent doing these activities on one of those days (in hours and minutes). The number of hours spent performing both vigorous and moderate PA in the past 7 days was summed and divided by 7 to calculate the average number of hours per day engaged in MVPA.

Sedentary Behaviors

Self-reported daily sitting time (in hours) was assessed using a single item from the IPAQ-SF [31]:

> *How many hours do you spend sitting in a typical 24-hour day (eg, travelling to/from school, university or work; at school, university or work; watching television, using a computer at home and leisure time).*

To assess screen time, respondents were asked to report the amount of time (hours and minutes) in the past week they typically spent (1) watching television or videos during their free time and (2) using a computer during their free time (including computers, laptops, Xbox, PlayStation, iPads or other tablets, smartphones, YouTube, Facebook or other social media, and the internet). Separate items were used to assess average screen time on weekdays and weekend days. The total number of hours per week spent on both TV and computer during their free time was calculated by multiplying the sum of weekday TV and computer time by 5, multiplying the sum of weekend day TV and computer time by 2, and dividing by 7 to generate an average screen time per day over a typical week.

Sleep Duration

To assess sleep duration (in hours), respondents were asked "How many hours in each 24-hour day do you usually spend sleeping (including at night and naps)?" The total number of hours was used as a continuous indicator of sleep.

Statistical Analyses

Given prior work has demonstrated sex differences in the prevalence of lifestyle risk behaviors [32,33], descriptive statistics (means and frequencies) were determined for each of the risk behaviors by sex. Inspection of the outcomes in terms of the underlying distribution were used to inform the selection of appropriate regression models. A series of Poisson (for MVPA, sleep, screen time, sitting time) with a log link, and logistic regressions (for fruit or vegetable intake) with a logit link were estimated to examine the associations between risk behaviors and personality type. Rate ratios (RRs) derived by exponentiating the coefficients from Poisson regressions were presented for semicontinuous count data (MVPA, sleep, screen time, and sitting time), whereas odds ratios (ORs) derived by exponentiating the coefficients from logistic regressions were presented for binary data (fruit or vegetable intake). Initial data inspection indicated that the semicontinuous count variables (MVPA, sleep, screen time, and sitting time) demonstrated a significant negative skew, indicative of count data and suitable for Poisson models in comparison to linear models. Separate models were estimated to examine the association of each personality type with the multiple health behavior outcomes with sex, education status, and employment included in each model as covariates. Additional sensitivity analyses were conducted by reestimating the Poisson and logistic regression models for each outcome but included all personality scores in a single model as well as the additional covariates of sex, education status, and employment to determine independent effects of personality scores on each risk behavior. All analyses were conducted in SAS (version 9.4; SAS Institute).

Results

Sample Characteristics

A total of 978 participants (n=478, 49% male; mean age 20.4, SD 0.4 years) completed the web-based survey. Table 1 summarizes the sample characteristics, and Table 2 reports descriptive statistics for the lifestyle risk behaviors by sex among those who provided adequate data for the risk behaviors. Overall, the means and SDs of the raw personality scores are 13.6 (4.1) for negative thinking, 12.0 (2.9) for anxiety sensitivity, 10.0 (2.7) for impulsivity, and 15.7 (3.8) for sensation seeking.

Table 1. Sociodemographic characteristics of the sample at the 2019 assessment wave.

Characteristic	Values
Age (years)	
Mean (SD)	20.4 (0.4)
Range	18.2-22.0
Sex, n (%)	
Male	478 (48.9)
Female	499 (51.1)
Tertiary education (completed or in progress), n (%)	
None	36 (4)
Trade or technical	88 (9)
University or college	854 (87.3)
Employment status, n (%)	
Full-time	100 (10.2)
Part-time	707 (72.3)
Unemployed	157 (16.1)
Other	14 (1)

Table 2. Prevalence of lifestyle risk behaviors by sex at the 2019 assessment wave.

	MVPA[a] (n=829; h/day), mean (SD)	Sleep duration, (n=977; h/day), mean (SD)	Screen time (n=880; h/day), mean (SD)	Sitting time (n=974; h/day), mean (SD)	Fruit or vegetable (n=977), % inadequate intake/day[b]
Total sample	1.6 (2.7)	7.9 (2.4)	7.7 (6.1)	7.4 (3.4)	84.4
Male	2.0 (2.6)	7.8 (2.2)	8.1 (6.7)	7.3 (3.4)	89.3

Associations Between Personality and Lifestyle Risk Behaviors

Table 3 presents the RR, OR, and 95% CI from the regression models. Results indicated that a 1 SD higher score on hopelessness was associated with a 12% higher rate of screen time (RR 1.12, 95% CI 1.10-1.15) and a 5% higher rate of sitting time (RR 1.05, 95% CI 1.03-1.08). Similarly, a 1 SD higher score on anxiety sensitivity was associated with a 4% higher rate of both screen time and sitting time (RR 1.04, 95% CI 1.02-1.07; RR 1.04, 95% CI 1.02-1.07). A 1 SD higher score on impulsivity was associated with a 14% higher rate of MVPA (RR 1.14, 95% CI 1.08-1.21) and a 6% higher rate of screen time (RR 1.06, 95% CI 1.03-1.08). Finally, a 1 SD higher score on sensation seeking was associated with an 8% higher rate of MVPA (RR 1.08, 95% CI 1.02-1.14) and a 4% lower rate of screen time (RR 0.96, 95% CI 0.94-0.99). Personality was not associated with inadequate fruit and vegetable intake in any of the models (RRs 0.88-1.18; all CIs included 1.0). Sensitivity analyses adjusted for all other personality scores in the models are provided in Multimedia Appendix 1 and demonstrate the robustness of the key findings.

Table 3. Rate ratios, odds ratios, and 95% CI from the regression models examining associations between personality type and lifestyle risk behaviors at the 2019 assessment wave.

Personality type	MVPA[a] (n=829), RR[b] (95% CI)	Sleep duration (n=977), RR (95% CI)	RR (95% CI)	Sitting time (n=974), RR (95% CI)	Inadequate fruit or vegetable[c] (n=977), OR[d] (95% CI)
Hopelessness	0.95 (0.90-1.01)	1.00 (0.98-1.02)	*1.12 (1.10-1.15)*[e]	*1.05 (1.03-1.08)*	1.18 (0.99-1.41)
Anxiety sensitivity	1.02 (0.97-1.08)	1.01 (0.99-1.03)	*1.04 (1.02-1.07)*	*1.04 (1.02-1.07)*	0.91 (0.76-1.09)
Impulsivity	*1.14 (1.08-1.21)*	0.99 (0.97-1.01)	*1.06 (1.03-1.08)*	0.99 (0.96-1.01)	1.05 (0.87-1.25)
Sensation seeking	*1.08 (1.02-1.14)*	0.99 (0.97-1.02)	*0.96 (0.94-0.99)*	0.98 (0.96-1.00)	0.88 (0.74-1.06)

[a] MVPA: moderate-to-vigorous physical activity.

[b] RR: risk ratio.

[c] Odds ratios derived from logistic regression with reference category as adequate fruit and vegetable intake. All models controlled for sex, employment status, and education.

[d] OR: odds ratio.

[e] Italics indicates significance at the *P*<.05 level.

Discussion

Principal Results

This study examined the cross-sectional associations between personality traits (hopelessness, anxiety sensitivity, sensation seeking, and impulsivity) and sleep duration, diet, PA, and SB, 4 of the leading risk factors for chronic disease among a sample of emerging Australian adults. We found that hopelessness was associated with greater screen and sitting time, and anxiety sensitivity was associated with higher screen and sitting time. In terms of the externalizing personality traits, impulsivity was associated with greater screen time and MVPA, while sensation seeking was associated with greater MVPA but less screen time. There were no significant associations between any of the personality traits and sleep or diet.

Comparison With Prior Work

This study adds to the limited literature on personality traits and energy balance–related behaviors during emerging adulthood. The finding that participants high on hopelessness engaged in greater daily screen and sitting time among our sample of Australian 20 year olds is consistent with prior research among young people. For example, a longitudinal study conducted among a community-based sample of Canadian youth (spanning ages 10-21 years) similarly found that higher levels of depression were associated with greater screen time [34]. Although the personality trait of hopelessness measured in our study is not a direct measure of depressive symptomology, previous research has shown that the 2 constructs are moderately to strongly correlated [15,35]. The finding is also consistent with coping styles associated with hopelessness (and depressive symptomatology) such as withdrawal from others, avoidance of in-person social interaction, and distraction [13]. Relatedly, the present findings support previous work that has found the symptoms of depression to be associated with reduced PA among both adolescents and young adults [34,36], likely reflective of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) Diagnostic Criteria for depression of reduced physical movement and loss of energy. Our findings that impulsivity was associated with greater screen time, and sensation seeking with less screen time, is largely consistent with prior work [18]. For example, a small study among young Australian adults found that extraversion, which is correlated with the SURPS sensation-seeking scale [16], was negatively associated with both sitting time and leisure screen time [24], and a study among Spanish adolescents showed that extraversion was linked to a reduced risk of excessive use of social network sites [19]. Taken together, it seems that although young people exhibiting high levels of sensation seeking may have an increased risk of substance use and mental health problems [15], they are less likely to engage in risky levels of screen time and physical inactivity. Those exhibiting hopelessness and anxiety sensitivity, on the other hand, are more likely to engage in risky levels of screen time and sitting time as well as being at risk of substance use and mental health problems [15].

Interestingly, we did not find evidence of an association between the 4 personality traits and inadequate diet or less sleep. The lack of an association between personality and dietary intake is likely due to the fact that only fruit and vegetable consumption was measured, and we did not assess other dietary behaviors such as intake of sugar-sweetened beverages or junk food. Indeed, prior research suggests that individuals high on impulsivity are more likely to find it difficult to resist impulses related to unhealthy food choices [37], and impulsivity is associated with excessive overeating of high-calorie food or food addiction [38]. Similarly, our results in terms of sleep and personality somewhat contradict prior work that has found associations between sleep problems and impulsivity among young adults in the United States; however, the US-based study assessed daytime sleepiness, rather than total sleep duration [23]. It is also worth highlighting that self-reported sleep duration in the present sample was relatively high, with a mean of 7.9 (SD 2.4) hours of sleep reported per day. Although this is comparable to a recent Australian cohort where young adults (aged 18-24 years) reported sleeping 7.2 hours on average per night [39], it falls within the Australian health guidelines for sleep (7-9 hours per night) among young adults, so this may have limited our ability to examine associations between personality and sleep duration among those at the lower end of the sleep spectrum. Finally, our study did not assess sleep quality, which recent studies have suggested could be a better measure than sleep quantity as an index for assessing sleep, and further that in people with an average sleep duration of 7 hours, average sleep *quality* may be better related to health and other factors [40]. Future studies that include more nuanced sleep measures may shed more light on the relationship between personality traits and sleep. Similarly, levels of MVPA were also high among our sample. While a recent Australian study using self-reported data from the National Health Survey, estimated over half (55% or 1.2 million) of all 18-24 year olds were sufficiently active for their age [41], future studies with samples reporting MVPA levels at the lower end of the spectrum would be useful.

Implications for Prevention

The findings from this study have important implications for the prevention of chronic disease risk factors, especially excessive screen time, a highly prevalent behavior that has increased among children and adults in the wake of the COVID-19 pandemic [42,43]. Indeed, in 2019, before the global pandemic, this sample of young adults reported very high rates of daily recreational screen time, with an average of 7.7 (SD 6.1) hours of screen time per day (including watching TV or videos, using a computer, or playing videogames). Excessive sitting time was also prevalent, with participants reporting sitting a mean of 7.4 (SD 3.4) hours per day. High levels of SB have been associated with a range of negative health consequences [44]. Among adolescents, for example, excessive screen time is linked to markers of adiposity and cardiometabolic disease risk [45], poor mental health [46] and quality of life [47], and increased risk of all-cause, cardiovascular disease, and cancer-related mortality, and incidence of these diseases, in adults [48,49]. Therefore, public health approaches to modify SB are critical. Prior research has suggested that understanding the ways in which personality and risk behaviors are related may be important for designing more effective and appealing public health campaigns [36]. For example, a campaign that links reductions in SB to changes in mood may be more appealing to young adults than a campaign that simply focuses on moving more.

In addition, our results suggest that identifying young people with high levels of hopelessness, anxiety sensitivity, and impulsivity could be a means of intervening to reduce SB, such as sitting and screen time, and increasing MVPA. For example, a program targeting young people with high hopelessness could also teach young people strategies to improve both their mood and physical health, such as reducing screen time, spending time with others outdoors, and engaging in PA. Designed to target young people based on personality risk factors for substance misuse and other emotional and behavioral problems, the *Preventure* intervention is a selective, personality-targeted program that has been shown to reduce alcohol use, alcohol-related harms, illicit substance use, depressive symptoms, delinquency, truancy, bullying, and conduct problems in RCTs in North America and Australia up to 7 years post intervention [26,50-53]. It is a brief, manual-based intervention that includes character profiles and case studies to teach young people about their target personality style, help them to explore ways of coping with unhelpful thoughts and emotions related to their personality, and to identify and challenge personality-specific cognitions that lead to problematic behaviors [13,54]. Adaptations to programs such as Preventure could include specific personality-tailored content aimed at lifestyle risk behaviors such as screen time and sleep, as well as concurrent targeting of several related lifestyle risk behaviors, potentially offering synergistic effects on multiple risk behaviors [55].

Limitations

There are several limitations that should be considered. First, our measures of lifestyle risk behaviors were self-reported and were limited to simple indicators of each behavior. Future research should aim to assess a broader range of outcomes, including sugary foods and drinks, sleep quality, and specific types of screen time, including device and content viewed, and different types of PA (eg, active transport). Future research could also consider the inclusion of objective measures of lifestyle risk behaviors, noting that the benefits need to be weighed against the higher costs and practicalities of assessment as well as the potential barriers to engagement among young adults. Second, the SURPS differs from other widely used measures of personality, such as the Big 5 model of personality (neuroticism, extraversion, openness, agreeableness, and conscientiousness). Numerous studies have demonstrated the SURPS to be a reliable tool for identifying personality traits associated with substance misuse and other emotional and behavioral problems among adolescents [15-17,56]. Noting this, a key advantage of the SURPS is that its items measure personality traits and not substance use. This enables the identification of adolescents at greater risk for substance use and related risk behaviors prior to their entrenchment, which is particularly beneficial for the implementation of selective or targeted preventive interventions.

Third, the original sample was designed as a cluster RCT for a school-based prevention program on harmful alcohol use rather than a representative sample of Australian young adults, and covariates included in the analyses were limited to those measured in the original study. There were a large number of schools in the trial, and they represented both independent and public schools in 2 states in Australia. However, the sample was largely Australian-born, English-speaking adolescents, and although this is in line with the general population [57], they were primarily well educated and employed, limiting the generalizability of our findings. This is particularly important, given the prevalence of risk factors is not uniform across populations. For example, low socioeconomic status youth in Australia are 22 times more likely to use alcohol at risky levels and 5 times more likely to smoke [58], and 12% less likely to be sufficiently physically active [59] than higher socioeconomic status youth. Co-designed interventions for disadvantaged populations are clearly needed, including interventions delivered in the home and school settings as well as public health initiatives to address the underlying structural and social determinants of health. Future research examining the associations between personality and chronic disease risk factors among young adults from diverse and disadvantaged backgrounds is required to inform such interventions, along with the inclusion of a broader range of potential covariates related to socioeconomic status and disadvantage.

Fourth, we note that there is considerable attrition at the time point when lifestyle risk behaviors were obtained compared to the baseline sample (55%), and therefore, some degree of response bias might limit our results. Comprehensive attrition analyses are reported elsewhere [26]; however, those who were missing at time points 6 and 7 compared to those who were retained were more likely to be male, less likely to have used alcohol or have hazardous levels of drinking at baseline, and demonstrated lower mean impulsivity and sensation-seeking scores at baseline. Replication of these findings in other samples would support the robustness of the findings reported here. Finally, this analysis was limited to cross-sectional examinations, as the lifestyle risk behaviors (ie, diet, PA, and SB) were only assessed at the early adulthood assessments of the RCT, limiting our ability to examine causal and bidirectional relationships between personality and lifestyle risk behaviors. Nonetheless, this study focuses on the critical and understudied emerging adulthood period and suggests that young adults exhibiting high levels of specific personality traits may benefit from targeted interventions to improve both physical and mental health. Further longitudinal research examining personality traits and energy balance–related behaviors across adolescence and into early adulthood will be important for understanding when to intervene.

Conclusions

This study provides new knowledge about the associations between personality and chronic disease risk factors among young adults. Given the high prevalence of these risk behaviors, their known relationship to important chronic disease outcomes, and the demonstrated effects of personality-targeted programs on other domains of health, the study suggests that personality should be considered when designing preventive interventions for lifestyle risk behaviors, especially high levels of SB, such as screen and sitting time, and low levels of PA. These findings have the potential to inform future development of programs tailored to particular personality styles to improve physical and mental health among young Australians.

Acknowledgments

We acknowledge the schools, students, and teachers who participated in this research. The research team also acknowledges Ms Anna Smout, Dr Siobhan Lawler, and Dr Jennifer Debenham for their assistance with data collection for this study. This study was funded through a project grant from the National Health and Medical Research Council (NHMRC; APP1124958), a Centre of Research Excellence Grant (PREMISE APP1134909), an NHMRC Career Development Fellowship to NCN (APP1166377), an NHMRC Early Career Fellowship to KEC (APP 1120641), and an NHMRC Leadership Fellowship (APP1195284) to MT. The funding body played no role in the design of the study and collection, analysis, and interpretation of data and in writing the manuscript.

Abstract

Background: Family health develops from the intersection of the health of each family member and their interactions and capacities as well as the family's internal and external resources. Frailty is the most prominent and typical clinical manifestation during population aging. Family health may be effective in addressing frailty, and this association may be mediated by health literacy and health behaviors. Until now, it is unclear whether and how family health affects frailty in older adults.

Objective: This study aimed to examine the associations between family health and frailty and the mediation roles of health literacy and health behaviors.

Methods: A total of 3758 participants aged ≥60 years were recruited from a national survey conducted in 2022 in China for this cross-sectional study. Family health was measured using the Short Form of the Family Health Scale. Frailty was measured using the Fatigue, Resistance, Ambulation, Illnesses, and Loss of weight (FRAIL) scale. Potential mediators included health literacy and health behaviors (not smoking, not having alcohol intake, physical exercise for ≥150 minutes per week, longer sleep duration, and having breakfast every day). Ordered logistic regression was applied to explore the association between family health and frailty status. Mediation analysis based on Sobel tests was used to analyze the indirect effects mediated by health literacy and behaviors, and the Karlson-Holm-Breen method was used to composite the indirect effects.

Results: Ordered logistic regression showed that family health is negatively associated with frailty (odds ratio 0.94, 95% CI 0.93-0.96) with covariates and potential mediators controlled. This association was mediated by health literacy (8.04%), not smoking (1.96%), longer sleep duration (5.74%), and having breakfast every day (10.98%) through the Karlson-Holm-Breen composition.

Conclusions: Family health can be an important intervention target that appears to be negatively linked to frailty in Chinese older adults. Improving family health can be effective in promoting healthier lifestyles; improving health literacy; and delaying, managing, and reversing frailty.

family health; frailty; health literacy; health behavior; healthy aging

Introduction

Background

The rapid aging of populations will lead to a greater chronic disease burden on the whole society [1]. Diseases such as hypertension, diabetes, cancer, stroke, arthritis, dementia, and related disease burdens will continue to increase [2]. From the perspective of disease occurrence and development, the immune functions of older adults gradually decrease with age, their susceptibility to adverse stimuli increases, and disease incidence rates will inevitably increase. However, there are substantially individual differences in the occurrence, development, prognosis, and progression of diseases and the consequent quality of life. These differences are mainly due to frailty [3,4]. *Frailty* refers to a homeostatic imbalance in the body, between unhealthy and serious damaging status due to a decline in physical, psychological, or cognitive function. It is the most prominent and typical clinical manifestation during population aging [5]. In addition, "prefrailty," which is defined as a complex multifactorial and multidimensional state associated with physiological and deleterious processes that develop over time, is an intermediate stage in the progression from robust to frailty [6]. Compared with frailty, prefrailty has a higher prevalence but a lower level of damage to older adults. In addition, prefrailty is more clinically reversible [7,8], which highlights the importance of early identification and intervention to reverse it or prevent the progression to frailty. Previous studies have shown that both prefrailty and frailty are associated with an increased risk of hospitalization, functional decline, progression to long-term care, and death [9]. Delaying the occurrence of prefrailty or frailty and promoting their reversal can play a substantial role in the promotion of healthy aging.

Family-oriented health promotions are promising and effective strategies because the family unit is both a resource and a priority group that needs preventive and curative services across its members' life course [10]. In particular, "family health" as a relatively new concept is receiving more attention from scholars. Weiss-Laxer et al [11] defined family health as a resource at the family unit level that develops from the intersection of the health of each family member and their interactions and capacities with the family's physical, social, emotional, economic, and medical resources. Family health integrates the key elements of the previous concepts of family structure, family function, and family social network; seeks to strengthen the ability of families to obtain external resources and sociality; and emphasizes health-related elements, linking individual health with social health. Therefore, family health may be an important target for health intervention. Regarding strategies for preventing and controlling frailty, researchers have yet to determine whether interventions through family health are effective.

Health literacy and health behaviors may be effective pathways to address the association between family health and frailty. Health literacy is defined as a cognitive and social skill that determines an individual's motivation and ability to access, understand, and use information in a way that promotes and maintains health. Low health literacy is associated with a poor understanding of one's medical condition, poor self-care, delayed care seeking, and lower use of preventive services; it can also affect disease management and outcomes in patients with chronic conditions [12,13]. Adequate health literacy can prevent frailty in older adults and plays a positive role in intervention and the management of frail, community-dwelling older adults [14,15]. Residents' health literacy may be affected by family structure, income level, information delivery, and other family members' education levels. Behaviors are the most concrete, visible aspect of family functioning. Family structure, processes, and cognitions are expressed through family behaviors [16]. There are a range of mechanisms underlying relationships between family and health behaviors, including promoting health-seeking or health treatment behaviors providing access, opportunities, and resources for a range of health behaviors [17]. Previous studies have also demonstrated the relationship between healthy behaviors, such as diet and exercise, and frailty [5,18]. Nevertheless, the associations between family health, health literacy, and health behaviors and frailty have not been explored.

Objective and Hypotheses

China is one of the countries with the fastest aging population and faces unprecedented challenges in the face of such a rapid aging process. Therefore, frailty prevention and management is essential and urgent in China, and family health may be an effective subject for intervention. This study explored whether and how family health could decrease the frailty risk in older populations. We proposed two hypotheses: (1) family health is positively associated with the prevalence of prefrailty and frailty and (2) the association between family health and frailty status is mediated by health literacy and health behaviors.

Methods

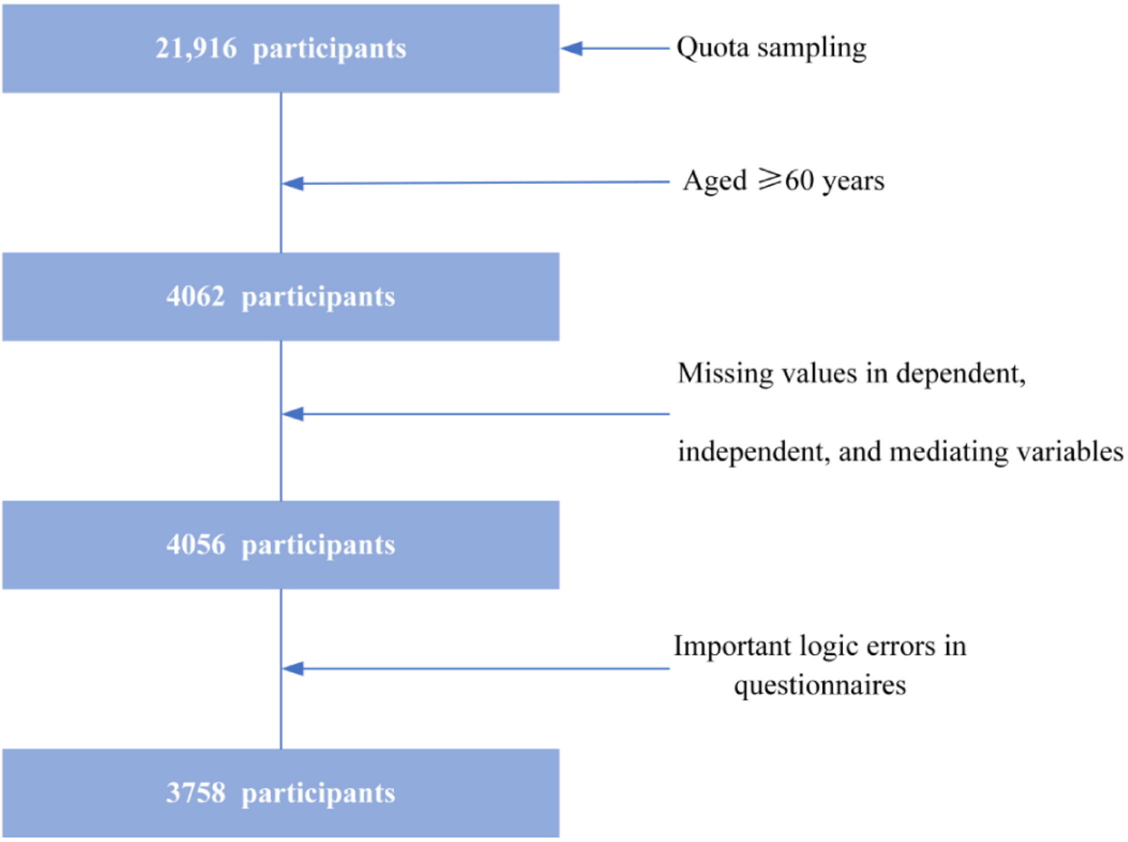
Sampling and Participants

The data are from a national survey, conducted from June 20, 2022, to August 31, 2022, in 148 cities; 202 districts and counties; 390 townships, towns, or streets; 780 communities or villages (excluding Hong Kong, Macao, and Taiwan) from 23 provinces; 5 autonomous regions; and 4 municipalities directly under the central government in China, initiated by the Peking University School of Public Health. The sampling ratio was determined based on the population proportion provided by the seventh national census data. At least 500, 1000, 1500, 2000, or 2500 individuals were sampled from each province, autonomous region, or municipality directly under the central government. The sample size was estimated to be 20,000. Finally, in the municipal, district, county, township or town, street, and community level, individual were sampled according to quota attribute, including sex and age.

To conduct the survey, the investigator set up a questionnaire survey site in the health service center or a relevant health service station of the sampling community in charge and then posted a poster and issued a paper or electronic invitation to recruit respondents. The investigator checked the identities of all respondents, solicited their informed consent, and determined whether the respondents met the inclusion criteria for the study participants. The targeted participants had to be aged >12 years, able to understand each item of the questionnaire, and able to complete the questionnaire on their own or with the help of an investigator. People who were confused, were experiencing mental health difficulties or cognitive impairment, or were unwilling to participate in the survey were excluded. All the participants voluntarily participated in the study and signed an informed consent form. In total, 21,916 questionnaires were collected after quota sampling. The survey protocol has been published [19].

In this study, the data of participants aged <60 years; those whose questionnaires did not include details on the independent, dependent, and potential mediating variables; and those whose questionnaires had logical errors (mainly contradictions and discrepancies between important variables such as age, family type, and marital status) were also excluded (details are shown in Figure 1). In total, 3758 participants were included in the final analysis.

Figure 1. Sample selection process for this cross-sectional study.



Variables

Frailty

Frailty was measured using the Fatigue, Resistance, Ambulation, Illnesses, and Loss of weight (FRAIL) scale [20], which has been validated in older Chinese populations (Multimedia Appendix 1) [21-23]. We assessed the presence of fatigue and loss of body weight by participants responding "yes" to the following items in the self-reported questionnaire: "Were you tired most of last week?" and "Have you experienced an unexplained loss of more than 5% of your body weight in the last year?" The presence of resistance and ambulation problems were assessed by a "yes" answer to the following questions: "Can you go up a staircase?" and "Can you walk a block (500 meters) away?" Illness was assessed based on the total number of chronic diseases that participants had (at least 5 diseases had to be present), and the number was then dichotomized into a binary variable. All the abovementioned 5 variables were coded as 0 ("no") or 1 ("yes"), with 1 indicating the presence of deficits. The total deficits were summed to calculate a frailty score that ranged from 0 to 5. On the basis of previous studies, participants who scored 0 were defined as robust, those who scored 1 or 2 were defined as prefrail, and those who scored ≥3 were defined as frail [24].

Family Health

Family health was measured using the Short Form of the Family Health Scale, which was translated into Chinese with the consent of the original author. The Chinese version of the Short Form of the Family Health Scale has good reliability and validity and can be used to assess the level of family health of Chinese residents [25]. It contains four dimensions: (1) family, social, or emotional health processes; (2) family healthy lifestyle; (3) family health resources; and (4) family external social support. The scores of the items and calculations for family health ranged from 10 to 50, with a higher score indicating better family health (Table 1). Cronbach α of the sample in this study was .634, which was deemed as indicating acceptable reliability, and the Kaiser-Meyer-Olkin value was 0.702, which was deemed as indicating acceptable validity.

Table 1. Short Form of the Family Health Scale.

Item number[a]	Dimensions	Items
1	Family, social, or emotional health processes	We support each other.
2	Family, social, or emotional health processes	I feel safe in my family relationships.
3	Family, social, or emotional health processes	We stay hopeful even in difficult times.
4	Family healthy lifestyle	We help each other in seeking health care services when needed (such as making physician's appointments).
5	Family healthy lifestyle	We help each other make healthy changes.
6	Family health resources	We do not trust doctors and other health professionals.
7	Family health resources	My family did not have enough money at the end of the month after bills were paid.
8	Family health resources	My family did not have adequate housing.
9	Family external social supports	We have people outside of our family we can turn to when we have problems at school or work.
10	Family external social supports	If we needed financial help, we have people outside of our family we could turn to for a loan (eg, for RMB 1000 [US $140]).

[a] Items 1 to 5 and 9 to 10 were positively scored (strongly disagree=1, somewhat disagree=2, neither agree nor disagree=3, somewhat agree=4, and strongly agree=5), and items 6 to 8 were negatively scored (strongly disagree=5, somewhat disagree=4, neither agree nor disagree=3, somewhat agree=2, and strongly agree=1). The total score is the sum of each item, with a score ranging from 10 to 50, with a higher score indicating better family health.

Mediators

The mediators measured in this study were health literacy and health behaviors. Health literacy was measured using the new short-form health literacy instrument, which included 9 items (Multimedia Appendix 2). Scores ranged from 9 to 36 points, with a high score indicating higher levels of health literacy. Health behaviors included smoking, alcohol intake, physical exercise, sleep, and diet. Smoking status and alcohol intake were set as binary variables (1=yes and 0=no). Physical exercise was assessed by weekly exercise time, including aggravating activities (power sports, fast running, ball games, aerobics, and fast cycling), moderate-intensity physical activity (handling goods, medium-speed cycling, jogging, and table tennis, excluding walking), and light aerobic exercise (walking for at least 10 min). Exercise time was calculated by summing up all activity time (minute), and ≥150 minutes was deemed as a healthy style (0: <150 minutes and 1: ≥150 minutes) [26]. Sleep behavior was assessed by sleep duration per night (1: <5 hours, 2: 5-6 hours, 3: 6-7 hours, and 4: >7 hours). Diet behavior was measured based on whether the participant had breakfast every day (1=yes and 0=no).

Covariates

The covariates were initially identified based on previous studies and general knowledge. Then, the enrolled covariates were selected based on their association with the independent variable and their impact on the change in the association between the independent and dependent variables. Age, sex, and potential mediators were included as fixed covariates to be controlled. Other covariates were included as potential confounders in the final models if they changed the estimates of the effect of family health on frailty status by >10% or were significantly associated with frailty status based on generalized linear regression [27]. The final covariates included age, sex (0=male and 1=female), family type (1=core family, 1=backbone family, 2=joint family, 3=conjugal family, 4=single-parent family, and 5=other), residence (0=urban and 1=rural), marital status (0=married and 1=divorced, widowed, or unmarried), number of children (grouped by 0, 1, 2, and ≥3), public insurance coverage (0=not covered and 1=covered), and BMI and self-rated health (scoring from 0 to 100).

Statistical Analysis

Sociodemographic characteristics, health literacy, health behaviors, and family health of participants were summarized using frequencies (percentages) or means and SDs, grouped by frailty status. Statistical differences were tested using Kruskal-Wallis one-way analysis for the continuity variables and chi-square tests for the categorical variables.

Ordered logistic regressions were applied to assess the association between family health, including its 4 dimensions; health behaviors; and frailty, with covariates controlled. Odds ratios (ORs) and 95% Cis for the risk of frailty were estimated. A generalized additive model and smoothing curve fitting were further used to address the potential nonlinear relationship between family health and the risk of frailty, with potential mediators and covariates controlled. The generalized additive model allows us to fit the model using a nonlinear smoothing term without prior knowledge of the relationship between the dependent and independent variables, which allows the association to be visualized more intuitively [28].

Sobel tests were then applied to measure the significance of the mediating effects of health literacy and health behaviors. To assess the effect sizes of the mediators, Karlson-Holm-Breen (KHB) methods were used to composite the indirect effects with the ordered logistic model. For health behaviors, the healthier groups were used as references.

The significance level was set at a *P* value of <.05 for all the hypothesis tests. Data were analyzed using Stata (version 17.0; StataCorp) [29] and R (version 3.6.3; R Foundation for Statistical Computing).

Sensitivity and Subgroup Analysis

Several sensitivity analyses were conducted to validate the results. First, as the prevalence of frailty was relatively low in this study, we set the absolute value of the frailty score (0-5 points) as the dependent variable and repeated the KHB decomposition methods. As the frailty score followed a Poisson distribution, we applied negative binomial regression as the model for analysis during the KHB decomposition. Second, in the questionnaire, physical exercise included some high-intensity exercises, which may not be universal or normal among older populations. Therefore, we used the number of days walking (at least 10 minutes) per week instead of physical exercise time. Third, the optimal sleep duration for older adults was not consistent with previous studies. Therefore, we used self-rated sleep quality (0=*very bad*, 1=*bad*, 2=*good*, and 3=*very good*) instead of sleep duration.

Furthermore, the definition of “older adults” was varied in recent studies. The participants in this study were adults aged ≥60 years, which was consistent with some previous studies and with the retirement policy in China [30,31]. However, in geriatrics, the definition for older adults is age ≥65 years [32]. In cardiovascular medicine, “older” was defined as age ≥75 years [33]. Therefore, to better clarify the association between family health and frailty in “true” older adults, we performed subgroup analysis in different age groups, including “≥65 years old” and “≥75 years old.”

Ethics Approval and Informed Consent

This quantitative study was performed in accordance with the guideline “involves people of biomedical research ethics review method (try out)” of the China Ministry of Health national drug supervision and administration of the quality control standard for clinical trials (2003), medical instrument clinical trial regulations (2004), and the Declaration of Helsinki. The investigators obtained ethics approval from the Shaanxi Institute of International Trade and Commerce (JKWH-2022-02). All applicable institutional and governmental regulations concerning the ethical use of human volunteers were followed over the course of this study. All interviewees provided written informed consent to participate in this study upon recruitment, and they participated voluntarily without compensation. All the study data were anonymous.

Results

Demographic Characteristics

Among the 3758 participants, 2327 (61.92%) were robust, 1342 (35.71%) were prefrail, and 89 (2.37%) were frail. The mean score of family health was 37.86 (SD 6.44), with 39.45 (SD 6.05), 35.18 (SD 6.25), and 36.63 (SD 5.53) in the robust, prefrail, and frail groups, respectively. We further compared the mean scores of family health between the prefrail and frail groups, and the difference was not significant (*P*=.237). Participants in the frail group were older than those in the other groups. The ratios for illiteracy; divorced, widowed, or unmarried; and smoking were also higher in the frail group than in the other groups, whereas self-rated health, health literacy, and the ratio of usually exercising (≥150 min/wk) were lower than those of the other groups (Table 2).

Table 2. Demographic characteristics and family health levels for participants aged ≥60 years by frailty status.

	All (N=3758)	Robust (n=2327)	Prefrail (n=1342)	Frail (n=89)	*P* value
Age (years), mean (SD)	68.81 (6.26)	68.28 (6.03)	69.37 (6.40)	74.33 (6.92)	<.001
Sex, n (%)					.51
Male	1866 (49.65)	1173 (50.41)	650 (48.44)	43 (48.31)	
Female	1892 (50.35)	1154 (49.59)	692 (51.56)	46 (51.69)	
Family type[a], n (%)					<.001

[a] "Core family" refers to a family consisting of parents and unmarried children; "Conjugal family" refers to a family consisting of parents and married children; "Backbone family" refers to a family consisting of only husband and wife; "Joint family" means a family of parents or more married children or siblings after marriage; "Single-parent family" means a family consisting of divorced, widowed, or unmarried single fathers or mothers and their children or adopted children; and "Other" consists of the following: "Intergenerational family," referring to a family with only 2 generations, and the parents left the family for some reasons; "Dink family," referring to a voluntary infertile family consisting of 2 couples; "Single family," referring to not being married at the age of marriage or not married after divorce but living alone; and reformed families, cohabitation families, and gay families.

The Association Between Family Health and Frailty

The ordered logistic regression (Table 3) showed that better family health was associated with a lower risk of frailty (OR 0.93, 95% CI 0.91-0.94), with covariates adjusted (model 1). After potential mediators were entered into the model (model 2), the association between family health and frailty was still significant (OR 0.94, 95% CI 0.93-0.96; $P<.001$). Model 2 had a greater pseudo R^2 and lower Akaike information criterion and Bayesian information criterion, which indicated better model fitting performance. Meanwhile, except for no alcohol intake ($P=.74$), high health literacy ($P=.01$), not smoking ($P=.009$), physical exercise for ≥150 minutes per week ($P<.001$), more than 5 hours of sleep (all $P<.05$), and having breakfast every day ($P<.001$) were significantly associated with a decreased risk of frailty.

After adjusting for covariates and potential mediators, the smooth curve based on the generalized additive model suggested that family health tended to be linearly associated with frailty risk, and frailty risk decreased with increased family health (Figure 2).

We further analyzed the associations between the 4 dimensions of family health and frailty; the increases in all dimensions were associated with decreased frailty risk (Multimedia Appendix 3).

Mediation Analysis

Mediation analysis revealed that the total effect of family health on frailty was −0.016, and the association between family health and frailty was mediated by health literacy, not smoking, sleep duration, and having breakfast every day. The Sobel test results were significant (*P*<.001). The KHB composition revealed that the 4 mediators reduced the total effect of family health on frailty by 26.72%. In addition, the mediating effects of health literacy and having breakfast constituted 8.04% and 10.98%, respectively, which were much higher than those of the other 3 mediators. Further details are presented in Figure 3 and Table 4.

We explored the mediating effects of health literacy, not smoking, sleep duration, and having breakfast on the 4 dimensions of family health and frailty (Table 5). The results were similar, although the mediating effect of sleep duration on the association between family health resources and frailty was not significant (*P*=.354).

Sensitivity Analysis

In sensitivity analysis (Multimedia Appendix 4), with deficits of frailty (scoring from 0 to 5) set as the dependent variable, KHB methods were used, and a negative abnormal regression model was used. The results were consistent with those of the main analysis. When using walking (at least 10 minutes) days per week to replace physical exercise time, the mediating effect was significant (*P*<.001), and the path to family health was positively associated with physical exercise and further decreased frailty risk. When using self-rated sleep quality to replace sleep duration, the results revealed that better family health was associated with better sleep quality and further decreased frailty risk, with a significant mediating effect (*P*<.001).

Subgroup Analysis

To better clarify the association between family health and frailty in “true” older adults, we performed subgroup analyses in different age groups, including “≥65 years old” and “≥75 years old.” First, through ordered logistic regressions, the negative associations between family health and frailty were significant in the 2 subgroups (for those aged ≥65 years: OR 0.94, 95% CI 0.93-0.96, *P*<.001; for those aged ≥75 years: OR 0.96, 95% CI 0.93-0.99, *P*=.007). For those aged ≥65 years, the mediating effects of health literacy, smoking status, sleep duration, and breakfast remained significant. However, for those aged ≥75 years, only the mediating effect of breakfast was significant (for health literacy: *P*=.554; for smoking status: *P*=.266; for sleep duration: *P*=.081). The details are presented in Table 6.

Discussion

Principal Findings

To our knowledge, this is the first study to assess and divide the effects of family health on frailty. The results demonstrate that family health is negatively associated with the prevalence of prefrailty and frailty, and this association can be mediated by health literacy and certain health behaviors (eg, not smoking, longer sleep duration, and having breakfast every day).

The prevalence of prefrailty and frailty in this study was 35.71% and 2.37%, respectively, which was lower than that reported in many previous studies in China. Furthermore, family health did not vary significantly between the prefrail and frail groups. This may be because the main survey method was conducted based on face-to-face reporting through an electronic questionnaire. If a respondent was mentally alert but not active enough to answer the questionnaire, the investigator conducted a one-on-one inquiry to complete the questionnaire on their behalf. Most participants were relatively healthy and less vulnerable than frail older adults. Therefore, the representativeness of the study sample might have been limited. In addition, frailty was measured using the FRAIL scale, which could not be validated by other frailty measures in this study, such as the frailty index proposed by Rockwood et al [34]. However, the findings of this study are important. Prefrail older adults are at a higher risk than robust older adults in experiencing frailty, adverse outcomes, and mortality [8]. In addition, older people with prefrailty are more likely to transition back to a state of robust health than those who are frail [35]. Therefore, health promotion for prefrail populations represents an important opportunity to prevent decline and dependence, enhance health, and reduce disability and the need for care. Therefore, the findings of this study provide important intervention strategies to manage frailty and have substantial implications for health policy and public health. Moreover, the results of the smooth curve and generalized additive model indicated a decreased risk of frailty and increased family health. Previous studies have indicated that both prefrail and frail older adults are highly susceptible to adverse health effects such as falls, disability, institutionalization, and hospitalization, all of which increase the social burden caused by population aging [36]. Therefore, improvement in family health is effective in preventing or delaying the onset of prefrailty or frailty.

Most studies associated with frailty management concentrated more on individuals, specifically exercise, nutritional intervention, multicomponent interventions, and individually tailored geriatric care models [37]. However, most individuals cannot exist away from their family, and family members are dependent on each other. Therefore, older adults may be far more affected by their family than by the outside world. As described by the family system theory, the family is a cohesive social unit that operates like a system with its own rules and responsibilities. Each family member has a profound impact on the choices of other members of the family, with the results passed on from generation to generation [38]. Therefore, frailty intervention in family units has great potential and may achieve twice the results with half the effort. This also indicates that promoting healthy aging through family health is effective and promising.

Previous studies have shown that the role of family is essential in predicting better health-related quality of life among older adults [39]. The presence of the family acts as the main source of social support in the acceptance of the aging process as well as helping to motivate participation in daily activities and improving self-esteem [40]. Psychosocial factors, such as individual preferences and values concerning food and sports or physical activities, affect health-related family interactions. Sociocultural factors indirectly affect family interactions via individuals who transfer these influences into their family lives [41]. In addition, the mediators in this study, including health literacy, smoking, sleep, and diet, have been shown to be effective in frailty interventions [42-44]. Family health, which covers a wider dimension of health-related social and internal support, interactions, and resources than family function or family climate [45], contributes to higher levels of health literacy and healthier behaviors and thus can decrease the risk of prefrailty and frailty. It is worth noting that in this study, the KHB composition revealed that the 4 mediators (health literacy, not smoking, sleep duration, and having breakfast every day) reduced the total effect of family health on frailty by only 26.72%, indicating that the proportion of mediated effects is not high. Family health is a comprehensive concept associated with individual's health in many aspects. The frailty status is also complex and is affected by many risk factors. Therefore, this study indicated potential paths for addressing the association between family health and frailty. Other mechanisms, especially the clinical, psychological, or physiological paths, should be explored in future research.

It is intriguing that the mediating effect of physical exercise on the association between family health and frailty was not significant when measured by weekly time ≥150 minutes but significant when measured by days of walking for at least 10 minutes per week. First, the negative association between physical exercise and frailty risk was significant in this study, which has also been supported by many previous studies [46-48]. Second, physical exercise, especially intensive and initiative exercises, was more popular among younger adults than older adults in China, and these exercise behaviors may be not easy to form among older adults, even when encouraged or urged by their family members. However, this study still indicated that some easy exercises, such as walking, which are also associated with decreased frailty risk [49], could be promoted by improving family health.

Family health resources, one of the dimensions of frailty, are negatively associated with health literacy and not smoking and also negatively associated with frailty. This may be because health sources mainly contribute to other behaviors, such as health-seeking behavior. Doctors' attempts to improve patients' health literacy and motivate them to quit smoking may be inadequate.

In addition, this study indicated that family health was associated with decreased frailty risk in older adults, which was validated in older adults aged ≥60 years, ≥65 years, and ≥75 years. However, the mediating roles of health literacy and health behaviors were not consistent. Most mediating effects in this study were not significant, particularly for those aged ≥75 years. A possible explanation may be found in the individual heterogeneity, complexity of disease conditions, and greater vulnerability to physical and psychological status for the relatively older populations [50]. Therefore, intervention in frailty status is more difficult in relatively older populations, and the associations between family health and frailty may be more significantly mediated by factors related to disease control and treatment. This also indicates that the mechanisms of the impact of family health on frailty are complex and require further exploration through prospective analyses within different age groups.

To improve family health, we suggest that it is necessary to broaden the previous perspective of family structure and family function, enhance the role of family health, make full use of and strengthen the internal relationships of the family, enhance the external support of the family, improve the family social network, and carry out health management of the older population with the family as the unit. Especially in China, with the acceleration of urbanization and the deepening of population aging, increasingly complex family structures and a broader range of social determinants of health have raised many challenges for health strategies. A family-centered healthy aging promotion strategy is feasible, but there is a need to consider the family's internal and social characteristics and to develop more scientific health promotion and management strategies suited to local conditions with the development of medical technology. Future research should further explore intervention strategies for family health and the causal effects of family health on individual health to promote healthy aging.

Limitations

This study has a few limitations. First, some participants were excluded from the data analysis because of missing data or logical errors. We compared our data with the population sample survey data from the National Bureau of Statistics (NBS) in China and found that the constituting ratio of the population aged ≥65 years among those aged ≥60 years (62.77%) was lower than that of NBS data (75.01%) and that the sex ratio (female or male) in this study was 0.99, which was slightly higher than that of NBS data (0.93). In addition, people who were confused, experienced mental health difficulties, or had cognitive impairments were not enrolled in the survey. However, mental or cognitive deficits are also risk factors for frailty. Therefore, the representativeness of the study findings should be interpreted with caution. Second, as mentioned earlier, the sample size of the frail population was small, making it difficult to conduct further analyses of the mechanism by which family health affects frailty. Third, all variables were self-reported, and some health-related variables may not be accurate because of recall bias. Fourth, this study had the inherent limitations of a cross-sectional study. Fifth, health behaviors that may be associated with frailty were not comprehensively or precisely determined in this survey. For example, the frequency of different physical exercises, nutritional intake, and self-adjustment of mood should be further explored. However, the association between family health and a decreased risk of prefrailty and frailty was consistently found across multiple models and subgroups, which offers important hints and inspiration for future studies. Longitudinal and prospective analyses of the causal effect of family health on frailty and its underlying mechanisms should be conducted in future studies.

Conclusions

In conclusion, family health can be an important intervention target that appears to be negatively linked to frailty in Chinese older adults. The mediation roles played by health literacy and health behaviors suggest that they can be effective in improving family health to promote healthier lifestyles as well as improving health literacy to delay, manage, and reverse frailty. The analysis related to the dimensions of family health may explain the mechanisms of the associations between family health, health literacy or behaviors, and frailty and guide future interventions. Strategies to intervene in frailty through family health in healthy aging and national public health strategies deserve more attention in the future.

Acknowledgments

The authors gratefully acknowledge the survey team for conducting the survey and for cleaning the data. The authors would also like to thank all the participants who participated in the study for their time and involvement. This work was supported by the China Scholarship Council (grant 202209095002) and the National Social Science Foundation (grant 16BGL150). The funders had no role in the study design, data collection, data analysis, data interpretation, or writing of the manuscript. The corresponding author had full access to all data in the study and had the final responsibility for the decision to submit for publication.

Data Availability

The data sets generated and analyzed during this study are not publicly available because the data still need to be used for other research but are available from the corresponding author on reasonable request.

Abstract

Background: Polymerase chain reaction (PCR) testing for COVID-19 was crucial in Australia's prevention strategy in the first 2 years of the pandemic, including required testing for symptoms, contact with cases, travel, and certain professions. However, several months into the pandemic, half of Australians were still not getting tested for respiratory symptoms, and little was known about the drivers of and barriers to COVID-19 PCR testing as a novel behavior at that time.

Objective: We aimed to identify and address COVID-19 testing barriers, and test the effectiveness of multiple eHealth interventions on knowledge for people with varying health literacy levels.

Methods: The intervention was developed in 4 phases. Phase 1 was a national survey conducted in June 2020 (n=1369), in which testing barriers were coded using the capability-opportunity-motivation-behavior framework. Phase 2 was a national survey conducted in November 2020 (n=2034) to estimate the prevalence of testing barriers and health literacy disparities. Phase 3 was a randomized experiment testing health literacy–sensitive written information for a wide range of barriers between February and March 2021 (n=1314), in which participants chose their top 3 barriers to testing to view a tailored intervention. Phase 4 was a randomized experiment testing 2 audio-visual interventions addressing common testing barriers for people with lower health literacy in November 2021, targeting young adults as a key group endorsing misinformation (n=1527).

Results: In phase 1, barriers were identified in all 3 categories: capability (eg, understanding which symptoms to test for), opportunity (eg, not being able to access a PCR test), and motivation (eg, not believing the symptoms are those of COVID-19). Phase 2 identified knowledge gaps for people with lower versus higher health literacy. Phase 3 found no differences between the intervention (health literacy–sensitive text for top 3 barriers) and control groups. Phase 4 showed that a fact-based animation or a TikTok-style video presenting the same facts in a humorous style increased knowledge about COVID-19 testing compared with government information. However, no differences were found for COVID-19 testing intentions.

Conclusions: This study identified a wide range of barriers to a novel testing behavior, PCR testing for COVID-19. These barriers were prevalent even in a health system where COVID-19 testing was free and widely available. We showed that key capability barriers, such as knowledge gaps, can be improved with simple videos targeting people with lower health literacy. Additional behavior change strategies are required to address motivational issues to support testing uptake. Future research will explore health literacy strategies in the current context of self-administered rapid antigen tests. The findings may inform planning for future COVID-19 variant outbreaks and new public health emergencies where novel testing behaviors are required.

Introduction

The Role of Polymerase Chain Reaction Testing in COVID-19

The behavior of individuals has been crucial to the control of COVID-19, from self-isolating and testing to vaccination uptake [1]. A key preventive behavior in the early stages of the pandemic was polymerase chain reaction (PCR) testing for COVID-19 [2]. From 2020 to 2021, COVID-19 prevention strategies were often reliant on people getting a PCR test. This could be required when community members had been in contact with a positive case, had COVID-19 symptoms (eg, fever, cough, or sore throat), needed to travel from an outbreak area to another region, or worked in certain professions (eg, health workers). In Australia, community members were required to self-isolate at home until they returned a negative PCR test result, and this test-trace-isolate strategy was used to determine the need for short-term localized restrictions until linked clusters of cases were brought under control [3].

Testing Barriers

In early 2020, there was little research on COVID-19 testing behaviors, given the very new nature of this issue, so little was known about the barriers to testing or how to address this. Media reports at this time suggested different barriers existed across countries, which was confirmed in subsequent research. For example, countries such as Tanzania had major issues with opportunity barriers in terms of limited access to COVID-19 tests and fake testing kits [4]. Cost was a barrier in other countries, such as the United States, where the government and health insurers did not cover the testing [5], disproportionately affecting certain groups such as immigrant and noncitizen communities, who may also fear financial and legal repercussions from testing positive [6]. Testing was sometimes limited to certain criteria (eg, only if you have symptoms or regardless of exposure to COVID-19 cases) because of the lack of supply or staff resource issues [7]. There were also issues with delivering tests and transporting samples to remote areas [8]. Inadequate communication and low community knowledge about which symptoms require testing and the process to follow also impacted uptake [7].

The Australian Context

Australia was fortunate to have efficient and free testing widely available from the start of the pandemic, although this varied by location. PCR testing clinics were established nationally, including drive-through options to minimize contact with others and results sent by SMS text messages within a short period [9,10]. However, despite the high accessibility of PCR testing, flu tracking data suggested that many more people had respiratory symptoms than were getting tested [11]. At the time of the study, it was unclear why the uptake was so low, but we hypothesized that COVID-19 testing communication did not address the needs of varying health literacy levels in the community. Similar to many other countries [12], Australian national surveys showed that people with lower health literacy were less likely to know about COVID-19 symptoms and prevention measures [13] and were more likely to agree with misinformation about COVID-19 [14].

Theoretical Framework

According to the capability-opportunity-motivation-behavior (COM-B) model [15], health prevention behaviors can be conceptualized in terms of 3 main drivers: physical and psychological *capability* (eg, having the physical ability to drive to or walk up the stairs to access a testing center and knowing what to do if you have symptoms), physical and social *opportunity* (eg, the availability of testing centers in your area and social norms that make testing and self-isolation acceptable), and automatic and reflective *motivation* (eg, fear of a painful test and an explicit belief that it is important to get tested for symptoms) [2]. In early 2020, we used this framework as the basis for a new research program on the novel behavior of COVID-19 PCR testing.

Objective

This program aimed to develop and test eHealth interventions to overcome COVID-19 PCR testing barriers and address the varying health literacy needs of the community. The interventions were developed and evaluated in 4 phases from June 2020 to November 2021.

- Phase 1, in June 2020, aimed to identify the *range* of barriers to COVID-19 testing.
- Phase 2, in November 2020, aimed to estimate the *prevalence* of barriers to COVID-19 testing and to target interventions for the most important issues.
- Phase 3, from February to March 2021, aimed to test the efficacy of providing health literacy–sensitive written information (ie, adapted for people with lower health literacy) for all capability and motivation barriers identified in phase 2, where individuals could view information to make a plan for their top 3 barriers to testing.
- Phase 4, in November 2021, aimed to address design issues in phase 3 and test the efficacy of providing health literacy–sensitive audio-visual interventions (simple animation or TikTok-style video) for a smaller selection of common barriers for people with lower health literacy, identified in phase 2.

Methods

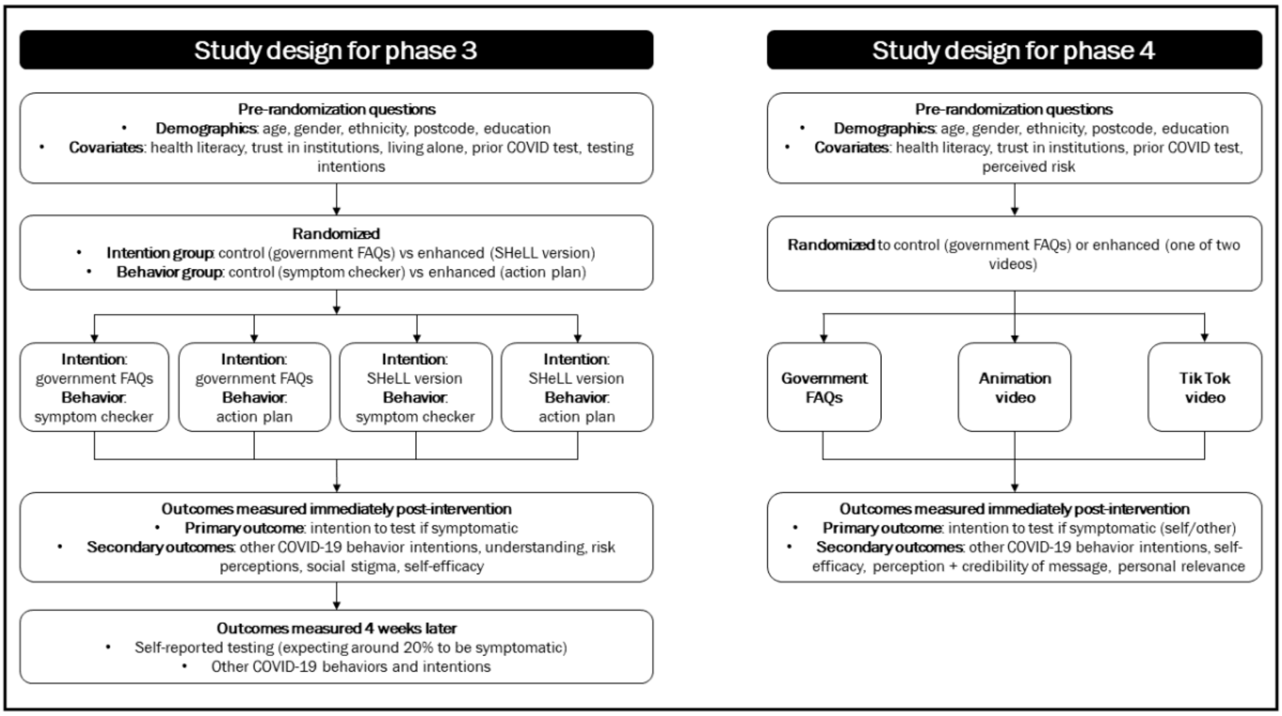
Ethics Approval

Ethics approval was obtained from the University of Sydney Human Research Ethics Committee (project number 2020/781), and the experiments were preregistered on the Australia New Zealand Trial Registry (ACTRN12621000876897 [16]; ACTRN12620001355965 [17]). All data were collected and stored anonymously, but participants could provide contact details to receive compensation via points for panel members and prize draws for gift vouchers if recruited via social media.

Study Design

The eHealth interventions were developed and tested in 4 phases. Phase 1 was a national survey conducted in June 2020, in which testing barriers were elicited and coded using the COM-B framework. Phase 2 was a national survey conducted in November 2020 to estimate the prevalence of testing barriers and health literacy disparities. Phase 3 was a randomized experiment testing health literacy–sensitive written information for a wide range of capability and motivation barriers from February to March 2021, in which participants chose their top 3 barriers to testing to view a tailored intervention. Phase 4 was a randomized experiment testing 2 audio-visual interventions addressing common testing barriers for people with lower health literacy in November 2021, targeting young adults as a key group endorsing misinformation (Figure 1).

Figure 1. Study design for phases 3 and 4. FAQ: frequently asked question; SHeLL: Sydney Health Literacy Lab.



Study Population

Phase 1 was open to any Australian adult who responded to the advertisements on social media. Phases 2 and 3 recruited a nationally representative sample of Australian adults based on age (equal groups above and below the age of 40 years), gender (equal groups for male and female; no quota for other categories), and education (equal groups for university degree and no degree). Phase 4 targeted younger Australian adults (aged <40 years) using the same market research panel.

Recruitment

Phase 1 used advertisements to target social media users, in which participants entered a prize draw to win a gift voucher. Phases 2 and 3 recruited a nationally representative sample via a market research panel company, where participants received points across multiple studies that they can redeem for various incentives including gift vouchers. Phase 4 involved both social media advertisements and panel recruitment. Different states in Australia were targeted at different times of recruitment so that participants were only recruited when there were very few or no cases in their state (when a test-trace-isolate strategy can be effective for containing spread).

Sample Size

For each phase, we recruited the following number of people: 1369 in phase 1; 20,349 in phase 2; 1314 in phase 3; and 1527 in phase 4.

Data Collection

All 4 phases involved piloting with a convenience sample from the target participant group before recruitment to identify and correct any grammar or navigation issues. The interventions were tested by a consumer representative who provided feedback to refine the study materials before formal data collection.

In phase 1, social media users were asked to participate in a series of 10-minute surveys, with COVID-19 testing questions included in June 2020. The New South Wales State Health Department provided a short list of testing barriers to be included along with an open response option for other perceived or experienced barriers. Phase 2 recruited a nationally representative sample, in which eligible panel members were invited to participate through the company's usual channels. After providing informed consent, participants completed a 10-minute survey, which included selecting COVID-19 testing barriers from a list and ranking them in order of importance.

A similar procedure was used for phases 3 and 4, with recruitment through a market research panel company, but participants were randomized to view different versions of COVID-19 testing information. In phase 3, they were randomized to view written government information or the intervention and completed the outcome questions. Those randomized to the intervention selected 3 relevant barriers, viewed health literacy–sensitive information about those issues, and created a plan for 1 chosen barrier. They were asked to create an action plan to help them overcome their barriers and received weekly reminders with a screenshot of their action plan by email. After 4 weeks, all participants received a 5-minute survey. In phase 4, social media users aged 18-39 years on Facebook and Instagram were targeted with advertisements, and further participants were recruited via the panel company. The following advertisement text was used for social media: “We want to hear from you! Complete a short survey about COVID-19 and be in with the chance to win a $20 gift card.” All participants answered a 10-minute survey. Those randomized to the intervention groups viewed a short audio-visual intervention, whereas those in the control group viewed standard written government information. Access to the outcome questions to complete the survey was enabled after 73 seconds for the animation and 65 seconds for the TikTok (the lengths of the audio-visual intervention) to increase the chance that participants viewed the intervention.

Outcomes

Survey questions for phases 1 and 2 are provided in Multimedia Appendix 1. In each phase, we measured variables shown to be associated with differences in the understanding of COVID-19 symptoms and prevention measures in our previous research [13,18]: age, gender, language, health literacy, trust, living alone, and prior COVID test. For the trials, our primary outcome was the intention to undergo testing for COVID-19 if symptomatic (measured in a broad way for phase 3 and a more specific way for phase 4 to increase sensitivity). The secondary outcomes included intentions about other prevention behaviors (self-isolation if symptomatic, social distancing of 1.5 m, washing hands regularly, and wearing masks in crowded indoor areas), understanding of messaging, risk perceptions, social stigma, and self-efficacy (ie, confidence in overcoming perceived barriers to testing). In phase 3 only, self-reported prevention behavior and intentions were assessed after 1 month, with our prior survey data suggesting that >20% of participants would experience symptoms over that time (Table 1).

Table 1. Primary outcome measures for phases 3 and 4.

Outcome and items	Response options	Phase 3	Phase 4
Intention to get tested for COVID-19			
Over the next 4 weeks I plan to get tested if I have COVID-19 symptoms (cough, sore throat, fever)	1=strongly disagree to 7=strongly agree	✓	✓
Imagine you woke up with a sore throat tomorrow. Would you get tested straight away?	1=extremely unlikely to 5=extremely likely		✓
Most people my age would get tested after seeing this information, if they develop symptoms	1=strongly disagree to 7=strongly agree		✓
Intention to engage in other preventive behaviors			
Over the next 4 weeks I plan to...Stay home if I have COVID-19 symptoms (cough, sore throat, fever)/Stay 1.5m away from others that I don't live with where I can/Wash my hands or use sanitiser to protect me and others from COVID-19/Wear a mask in crowded indoor areas	1=strongly disagree to 7=strongly agree	✓	✓
Knowledge			
Can you name 3 signs or symptoms that are associated with COVID-19?	Written answer	✓	
When someone has signs that they might have COVID-19 (e.g. a cough or a sore throat), they should...	Wait until their symptoms are bad enough, then get tested/get tested straight away and self-isolate at home until they get their test results/get tested straight away and carry on as normal until they get their test results/self-isolate at home until their symptoms go away	✓	
If someone has a sore throat and wants to get tested for COVID-19, they should go... (choose all that apply)	To the emergency department/to their GP[a]/to a COVID-19 testing center	✓	
If someone gets tested for COVID-19, and they need groceries while waiting for their result, they should ... (choose all that apply)	Ask someone to get the groceries for them/wear a mask at the shops/go to the shops quickly to get essentials/order online	✓	
What are the 6 main COVID-19 symptoms you should get tested for? Select from the list	Sore throat/loss of taste or smell/digestive issues/cough/muscle aches/vomiting/fever/conjunctivitis/runny nose/shortness of breath or difficulty breathing/diarrhea		✓
When do you need to get tested?	Any mild/slight symptoms/moderate/uncomfortable symptoms/symptoms are severe/disrupt your plans		✓
When do you need to get tested?	Any length of time with symptoms/symptoms lasting 2 days/symptoms lasting 3 days		✓
When do you need to get tested?	One or more symptoms in a single day/2 or more symptoms in a single day/3 or more symptoms in a single day		✓
If you have symptoms of COVID-19, you should get tested when... Select all that apply	There are hotel quarantine cases in your state/there are local cases in your community/there are no local cases in your community		✓
Should you get tested if you have unusual or new cold-like symptoms that you think are due to: Cold weather/a cold/flu/hayfever/allergies	1=yes definitely to 5=no definitely not		✓

[a] GP: general practitioner.

Analyses

For phases 1 and 2, participant characteristics and survey question responses were reported descriptively using a content analysis approach for open responses and chi-square tests to compare responses across health literacy levels. In total, 2 researchers mapped the text from open responses to the components of the COM-B model, with discussion to resolve discrepancies. For phases 3 and 4, analyses were conducted using planned contrasts between the intervention arms and control arm, implemented in the regression models. Continuous outcomes were analyzed using linear regression to estimate marginal mean differences, dichotomous outcomes were analyzed using generalized linear models with a modified Poisson approach (log link and robust SEs) to estimate relative risks, and count variables were analyzed using Poisson regression to estimate relative risks. In phase 3, analyses were controlled for age, gender, language, health literacy, trust, living alone, and previous COVID-19 testing. In phase 4, positive baseline intention, age, gender, language, health literacy, trust, and perceived COVID-19 risk in Australia were controlled for. Interactions between health literacy and randomized conditions were also explored.

Materials

Images and text for the intervention in phase 3 are provided in Multimedia Appendix 2. The health literacy–sensitive version of the text was developed by applying health literacy guidelines [18], using a web-based tool that provides objective feedback on the complexity of health information (eg, grade reading score, passive voice, and medical jargon) [19], and incorporating consumer feedback. We used the Sydney Health Literacy Lab Editor developed by our team [19] to meet the recommended grade 8 school level by simplifying complex words, sentences, and grammar. Participants randomized to the intervention were asked to choose their top 3 barriers to testing and then selected 1 barrier for the health literacy–sensitive action plan. This was adapted from our previous studies on health-related lifestyle changes to address intention-behavior gaps [20,21]. The web-based action plan used an *if-then* format (eg, “If I don’t want to get tested because there aren’t many cases in my area, then I will remind myself that every new outbreak of COVID-19 starts with one new case”), a format that has shown to improve various behavioral outcomes including smoking cessation, physical activity, and healthy eating [22-28]. Health literacy principles were applied to the if-then plan (eg, simple language, images, and breaking down tasks into smaller steps), as previous research has shown that this can improve the effectiveness of if-then plans for people with low health literacy [20,29]. The *if* options reflect the top 10 barriers for people with lower health literacy identified in phase 2:

- I would prefer to isolate instead.
- I’m not sure this symptom is one that needs testing.
- I have symptoms of COVID-19 but I don’t think they are bad enough.
- I have symptoms of COVID-19 but I think it’s a cold or hay fever.
- I’m worried the test is painful.
- I’m worried about spreading my illness on the way to the testing centre.
- There aren’t many cases in my area.
- I’m worried I will catch COVID-19 when I get tested or on the way to the testing centre.
- I’m not sure what to do.
- I’d like my doctor’s advice first.

Participants could then select a solution (*then* option). Solutions were generated in collaboration with our consumer representative.

Images and text for the phase 4 intervention are provided in Multimedia Appendix 3. There were 2 audio-visual interventions: one was an animation and the other was a TikTok-style video, which was more humorous. Both covered the following barriers to COVID-19 testing, which were identified as the most prevalent knowledge issues for people with lower health literacy in phase 2:

- I know what symptoms I have and don’t believe they are COVID-19 ones e.g. hay fever/normal cold.
- I’m not sure my symptoms are bad enough.
- It is unlikely I have COVID-19 because there aren’t many cases in my area.
- I’m not sure this symptom needs testing.

Results

Participant characteristics for each phase are provided in Multimedia Appendix 4.

Phase 1: Identification of COVID-19 Testing Barriers

Most people (1151/1369, 84.07%) agreed that they would get tested if they had COVID-19 symptoms (cough, fever, and sore throat), with 49.23% (674/1369) of people strongly agreeing. For self-isolation, 95.98% (1314/1369) of participants agreed to some extent that they would stay home if they had symptoms and 69.47% (951/1369) of participants strongly agreed. Most participants (982/1369, 71.73%) said they would get tested “no matter what.” The most common barriers selected from the list provided (Multimedia Appendix 1) were that testing is painful (153/1369, 11.18%), not knowing how to get tested (98/1369, 7.16%), and worry about getting infected at the testing center (81/1369, 5.92%). All other barriers were <3% (forgetting, worried what others think, too hard or expensive, doesn’t work or don’t trust results, and no one else getting tested). Many participants (136/1369, 9.93%) indicated other reasons, with 136 open responses that included many additional barriers to testing than those provided in the survey question. Table 2 maps all the barriers identified in open survey responses to the COM-B drivers of behavior (capability, opportunity, and motivation).

Table 2. Phase 1 COVID-19 testing behavior barriers mapped to the capability-opportunity-motivation-behavior (COM-B) model.

COM-B barriers	Example quotes from “other” barriers (10% of the sample)
Physical capability	
My disability means I can’t get a test	“Fear of injury from getting tested—I have a deviated septum and narrow sinuses.”
I need a ramp/disability provisions for the testing centre	“Mobility and suppressed immune system make travel difficult.” “Testing facilities can’t accommodate my disability so it’s better for me just to stay home.”
I physically can’t access testing centre	“I’m homebound due to severe disability so I know arranging testing will be super hard.”
Psychological capability	
I have been getting conflicting information or being told not to get tested even with symptoms	“When I first got sore throat, headache, aches, cough, and partner very lethargic I got tested, and had the impression from testers that it wasn’t necessary with only those symptoms.”
I’m not sure how to get tested	“I dont know how to drive so I dont know how to get to places that test.”
I’m not sure my symptoms are bad enough	“Believing that I don’t meet the threshold eg when is a cough a cough or a runny nose with spicy food a runny nose? Otherwise I would get tested.”
I’m not sure this symptom is one that needs testing	“I am not sure whether I would be eligible to be tested.”
Physical opportunity	
The testing centres are hard to access—too far away from me	“Hard to get to where I can get tested.”
The opening hours of the testing centres don’t suit me	“Being able to get to the testing clinic within opening hours when caring for children.”
I don’t want to take public transport	“Public transport required to get to testing centre is inappropriate.”
I will need to take time off work	“hard to find the time with increased workload.”
I don’t have enough time to get tested	“Just tooooo busy—work during COVID.”
I don’t have childcare	“Depends on if I can get childcare and can find the time.”
If I get tested, it will impact me financially	“My husbands test took 10 days to get results. Which meant he could not work. He is self employed which means he also did not get paid and lost 8 days of income.”
Social opportunity	
I am worried what others will think of me having a test/being positive	“I will certainly feel worried about what others think of me, especially people who lives in the same household.”
Reflective motivation	
I had a bad experience when I got tested previously	“we had a bad experience getting my son tested...I can’t afford to be off work for 5 days just to chase down a negative result.”
I think the process of testing or pre-testing requirements is too much hassle/pointless	“There is a very tiny chance it will actually be COVID-19 so waste of time.”
I think the test is painful	“It hurt last time I got tested.”
I am worried about spreading my illness	“Have to ask someone to take me to a clinic and don’t want to get them sick.”
I’m worried I will catch covid myself whilst getting tested or en route	“I’m immunocompromised so don’t want to be around others in case I get sick.”
I don’t want to hear that I’m positive	“Will only get tested if I have a fever. Also, ‘too scared’ to know the results!”
I don’t think the testing works or results are reliable enough	“the accuracy of tests does concern me a bit.”
I don’t want to self-isolate after the test	“requirement to quarantine between test & getting results.”
I would prefer to self-isolate instead (or do another type of test)	“Don’t think it’s necessary to test, just isolate.”
Symptoms due to something else	“The symptoms are the same as my normal June sniffles I wouldn’t bother, unless I get other unusual symptoms.”

COM-B barriers	Example quotes from “other” barriers (10% of the sample)
I have already got tested for these symptoms and was negative	“I was tested last week. If this residual cough remains I am unlikely to get retested. If I get new symptoms I would get retested.”
I have the symptoms but will wait for them to get worse first/threshold	“I’ll get tested if the symptoms last for more than 24 hours” “if its just something like runny nose but no other symptoms show up—No but if I have more than 1 then I’ll get tested.”
I don’t believe it can be covid as it’s so rare	“No community transmission, highly unlikely to be COVID-19.”
I will only get a test if advised to by my GP[a]	“Get tested if my dr refers me to be tested.”
I think getting tested may result in problems with my visa or job	“Might be excluded from starting a new job.”
Misinformation or myths/different views on managing COVID	“I believe in herd immunity.”
Automatic motivation	
I am scared of the test	“Afraid of the uncomfortable test.”

[a] GP: general practitioner.

Phase 2: Prevalence of Barriers to Testing for COVID-19

The aim of phase 2 was to estimate the prevalence of COVID-19 testing barriers in a nationally representative sample and explore health literacy disparities to identify priority issues for intervention.

Table 3 presents the prevalence and importance of barriers among the participants who selected any barrier (941/2034, 46.26%). The top barriers were related to motivation: “I know what symptoms I have and don’t believe they are COVID-19 ones e.g. hayfever/normal cold” (selected by 562/2034, 27.63%, with 200/2034, 9.83% ranking it most important) and “It is unlikely I have COVID-19 because there aren’t many cases in my area” (366/2034, 17.99% selected, with 104/2034, 5.11% ranking it most important). Capability issues were also common: “I’m not sure my symptoms are bad enough” (387/2034, 19.03% selected, with 109/2034, 5.36% ranking it most important) and “I’m not sure this symptom is one that needs testing” (306/2034, 15.04% selected, with 66/2034, 3.24% ranking it most important). Social opportunity issues were uncommon: 5.75% (117/2034) of participants were worried about what others might think if they got a positive COVID-19 test result, and 3.69% (75/2034) of participants worried about what others would think if they got tested at all. Physical opportunity issues included disabilities, access (especially the distance to travel to a testing center), and time restrictions.

When we compared participants with low health literacy versus high health literacy, we found similar results for the top 10 barriers, covering reflective motivation and psychological capability. However, there were significant differences between the 2 groups. People with low health literacy were more likely to select certain capability issues (I’m not sure how to get tested, $P<.001$; I’m not sure if this symptom needs testing, $P=.01$) and motivation issues (I would prefer to self-isolate instead, $P<.001$; I think the test is painful, $P=.002$; I’m worried about spreading my illness, $P<.001$, I’m worried I will catch COVID-19, $P=.001$; I don’t want to hear that I’m positive, $P<.001$; and I don’t trust people who are asking me to take a test, $P=.02$), compared with the people with higher health literacy (Table 3).

Table 3. Phase 2 prevalence of barriers in nationally representative sample and health literacy disparities (November 2020; n=2034).

Barrier[a]	Selections (n=2034), n (%)	People to rank it first (n=2034), n (%)	Low health literacy (n=334), n (%)	High health literacy (n=1681), n (%)	*P* value for health literacy
I would prefer to self-isolate instead	341 (16.8)	73 (3.6)	71 (21.3)	194 (11.5)	<.001
I know what symptoms I have and don’t believe they are COVID-19 ones e.g. hay fever/normal cold	562 (27.6)	200 (9.8)	61 (18.3)	241 (14.3)	.07
I think the test is painful	276 (13.6)	67 (3.3)	49 (14.7)	154 (9.2)	.002
I’m not sure my symptoms are bad enough	387 (19)	109 (5.4)	45 (13.5)	182 (10.8)	.16
I’m not sure this symptom is one that needs testing	306 (15)	66 (3.2)	41 (12.3)	134 (8)	.01
I am worried about spreading my illness on the way to the testing centre	207 (10.2)	39 (1.9)	39 (11.7)	105 (6.2)	<.001
It is unlikely I have COVID-19 because there aren’t many cases in my area	366 (18)	104 (5.1)	37 (11.1)	159 (9.5)	.36
I’m worried I will catch COVID-19 myself whilst getting tested or on the way to the testing centre	219 (10.8)	34 (1.7)	37 (11.1)	104 (6.2)	.001
I’m not sure how to get tested	123 (6)	27 (1.3)	36 (10.8)	59 (3.5)	<.001
I will only get tested if my GP[b] tells me I should	187 (9.2)	63 (3.1)	30 (9.0)	126 (7.5)	.35
I don’t want to take public transport	143 (7)	31 (1.5)	24 (7.2)	80 (4.8)	.07
I have already got tested for these symptoms and was negative	150 (7.4)	34 (1.7)	24 (7.2)	71 (4.2)	.02
I think the process of testing is too much effort	148 (7.3)	15 (0.7)	24 (7.2)	78 (4.6)	.05
I don’t want to hear that I’m positive for COVID-19	85 (4.2)	5 (0.2)	21 (6.3)	42 (2.5)	<.001
I have been told not to get tested even if I have symptoms	113 (5.6)	33 (1.6)	18 (5.4)	65 (3.9)	.20
I don’t trust people who are asking me to take a test	72 (3.5)	16 (0.8)	17 (5.1)	45 (2.7)	.02
I am worried what others will think of me being positive for COVID-19	117 (5.8)	29 (1.4)	16 (4.8)	66 (3.9)	.47
I don’t want to take up resources for testing so that others can’t get tested	88 (4.3)	8 (0.4)	15 (4.5)	41 (2.4)	.04
I am worried what others will think of me having a test	75 (3.7)	6 (0.3)	14 (4.2)	43 (2.6)	.10
I don’t think the testing works or results are reliable enough	66 (3.2)	15 (0.7)	13 (3.9)	44 (2.6)	.20
I had a bad experience when I got tested before	89 (4.4)	10 (0.5)	12 (3.6)	49 (2.9)	.51
I don’t understand why I need to get tested	48 (2.4)	12 (0.6)	9 (2.7)	34 (2)	.44
I don’t want to self-isolate after the test	118 (5.8)	16 (0.8)	9 (2.7)	46 (2.7)	.97
I have the symptoms but will wait for them to get worse first	88 (4.3)	9 (0.4)	6 (1.8)	45 (2.7)	.35
I think getting tested may result in problems with my visa or with official bodies	33 (1.6)	5 (0.2)	6 (1.8)	21 (1.2)	.43

[a] Ordered from highest to lowest frequency in the low health literacy group (top 10 used in phase 3); participants could select more than 1 barrier.

[b] GP: general practitioner.

Phase 3: Randomized Experiment to Test the Effect of Health Literacy–Sensitive Written Information About COVID-19 Testing Barriers

The aim of phase 3 was to address the top 10 testing barriers for people with lower health literacy. Opportunity barriers, such as physical inaccessibility, could not be addressed by a communication intervention, so this phase focused on capability and motivation issues. For the intervention, participants chose 3 relevant barriers from the 10 provided and viewed health literacy–sensitive versions of written government information about COVID-19 testing (eg, reading level reduced to grade 8 by replacing complex words and sentences with simpler options). Intervention participants then selected 1 barrier to make an "if-then" action plan for how they would get around this issue if they needed to get a COVID-19 test for symptoms. Immediately after the intervention, no differences were found for intervention versus control (written government frequently asked questions about COVID-19 testing) on intentions, knowledge, or any other psychological outcomes. After 4 weeks, 57.71% (790/1369) of respondents completed follow-up measures, but there were no differences between intervention and control (government tool that tailored information to the local context; eg, state-specific COVID-19 testing requirements). No significant differences were found in health literacy levels when included as an interaction term (Table 4).

Table 4. Phase 3 experiment results comparing intervention and control groups (February-March 2021; n=1314).

Outcomes[a]	Control (n=668), n (%)	Intervention (n=645), n (%)	Effect estimate (95% CI)	*P* value
Testing intentions (self—if symptomatic next 4 weeks; 7=strongest intentions)	5.8 (1.6)	5.8 (1.6)	0.07 (−0.09 to 0.22)	.40
Self-isolation intentions (7=strongest intentions)	6.2 (1.2)	6.1 (1.3)	−0.03 (−0.16 to 0.10)	.63
Knowledge total score (count/6)[b]	5.5 (0.9)	5.4 (1.0)	0.98 (0.94 to 1.03)	.42
Perceived risk (5=highest perceived risk)	2.8 (0.8)	2.8 (0.8)	−0.01 (−0.10 to 0.08)	.79
Threat to Australia (10=very serious threat)	6.7 (2.4)	6.7 (2.4)	0.04 (−0.21 to 0.29)	.77
Self-efficacy (7=highest self-efficacy)	5.8 (1.0)	5.7 (1.1)	0.00 (−0.11 to 0.11)	.96
COVID-19 stigma (7=highest stigma)	3.4 (1.2)	3.6 (1.3)	0.08 (−0.05 to 0.21)	.25
Distancing intentions (7=strongest intentions)	6.3 (1.1)	6.2 (1.2)	−0.03 (−0.15 to 0.08)	.56
Hand washing intentions (7=strongest intentions)	6.4 (1.0)	6.4 (1.1)	−0.04 (−0.14 to 0.07)	.49
Mask wearing intentions (7=strongest intentions)	6.0 (1.4)	6.0 (1.4)	0.02 (−0.13 to 0.16)	.81
Follow-up: Self-reported testing behavior[c]	39 (9.4)	39 (10.5)	1.00 (0.67 to 1.51)	.99
Follow-up: Testing intentions (7=strongest intentions)	5.8 (1.5)	5.7 (1.6)	−0.10 (−0.30 to 0.11)	.36
Follow-up: Testing intentions (controlling for baseline intentions) (7=strongest intentions)	—[d]	—	−0.11 (−0.30 to 0.08)	.26

Phase 4: Randomized Experiment to Test the Effect of Health Literacy–Sensitive Audio-Visual Interventions About COVID-19 Testing Barriers in Adults With Lower Health Literacy

The aim of phase 4 was to develop a more targeted communication intervention with further refined testing of outcome measures. We selected 4 capability (knowledge) barriers from the most prevalent issues for people with lower health literacy in phase 2 and developed 2 audio-visual intervention scripts to address these: a simple animation in the style of Australian government advertisements and a TikTok-style video developed from the same information by a pharmacist with a large social media following for COVID-19 information videos. Immediately postintervention, we found that the animation and TikTok versions were more effective than the written government information for increasing knowledge about COVID-19 testing but not testing intentions or other psychological outcomes (based on a multiple-comparison adjusted α level of .025). No significant differences were found in health literacy levels when included as an interaction term (Table 5).

Table 5. Phase 4 experiment results comparing intervention and health literacy groups (November 2021; n=1527).

Outcome[a]	Government text (n=509)	Animation (n=514)	TikTok (n=504), n (%)	Animation vs government text		TikTok vs government text		Condition × health literacy interaction (*P* value)
				Effect estimate (95% CI)	*P* value	Effect estimate (95% CI)	*P* value	
Positive testing intentions (self—if symptoms tomorrow)[b], n (%)	246 (48.3)	294 (57.2)	277 (55)	1.08 (0.99 to 1.17)	.08	1.10 (1.00 to 1.20)	.04	.70
Positive testing intentions (other—if symptoms tomorrow)[b], n (%)	270 (53)	264 (51.4)	260 (51.6)	0.93 (0.83 to 1.03)	.17	0.95 (0.85 to 1.07)	.40	.31
Positive testing intentions (self—if symptoms next 4 weeks)[b], n (%)	358 (70.3)	373 (72.6)	367 (72.8)	1.00 (0.93 to 1.07)	.97	1.02 (0.95 to 1.09)	.56	.24
Knowledge total score (count/6), median (IQR)[c]	3.0 (2.0 to 4.0)	4.0 (3.0 to 5.0)	4.0 (3.0 to 5.0)	1.33 (1.24 to 1.42)	<.001	1.25 (1.17 to 1.34)	<.001	.84

Discussion

This study aimed to identify and address barriers to COVID-19 testing and test the effectiveness of multiple eHealth interventions on knowledge for people with varying health literacy levels.

Principal Findings

Phase 1 identified a wide range of barriers to COVID-19 testing that had not been previously described in the COVID-19 literature. These covered all 3 behavioral drivers in the COM-B model. Phase 2 found that motivation and capability barriers were far more prevalent than opportunity barriers in Australia at the time of this study. Many barriers were reported as more prevalent among people with lower health literacy. Phases 3 and 4 tested different ways to address capability and motivation barriers. Phase 3 found no differences between standard government text about COVID-19 testing and a tailored text intervention that addressed many different barriers using health literacy design principles. Phase 4 found that audio-visual interventions to address key knowledge barriers are more effective than written government information for improving knowledge, but this was not enough to shift COVID-19 testing intentions in adjusted analyses.

Comparison With Prior Work

Since our Australian research was conducted, new papers have been published on the issue of COVID-19 testing, including the move from PCR to rapid antigen tests (RATs). Survey, interview, and media analysis studies have identified similar capability, opportunity, and motivation barriers in other countries, including the United States, the United Kingdom, the United Arab Emirates, and Jordan [30-34], as well as in

Australia (eg, in a recent qualitative study [35]). Sample populations have included the general public, parents, university students and staff, people experiencing homelessness, and specific cultural groups [36-44]. This study is unique in terms of mapping barriers to the COM-B theoretical framework, estimating the prevalence of key barriers to testing in people with diverse health literacy, and testing communication interventions to address capability and motivation barriers. We have shown that it is possible to increase COVID-19 testing knowledge when key barriers are explicitly addressed using simple audio-visual intervention formats that are cheap and quick to produce. However, it is important to acknowledge that a mass communication strategy will not address all barriers.

Interpretation and Implications

The results of this study provide new insights into identifying and addressing behavioral barriers to COVID-19 testing, which is central to understanding and controlling COVID-19 and future pandemics. The large range of barriers identified in this study reflects the fact that COVID-19 testing was a complex new behavior at the time of the research, requiring a multifaceted approach to improve uptake depending on key barriers in different communities. Although the Australian PCR testing system was free and widely accessible for the first 2 years of the pandemic, the shift to using RATs introduced new opportunity barriers that were not an issue at the time of these studies. For example, it was very difficult to locate RATs during a period of low supply and high demand in January 2022, and there were issues with price gouging that made this unaffordable for many Australians [45]. Government regulation and funded RATs were subsequently introduced to limited groups, such as schoolchildren and pensioners [46,47].

Future Research

The capability and motivation issues identified in this study apply to PCR testing, but there are likely to be additional barriers to RATs, which were not approved in Australia at the time of the study. Different barriers encountered for RATs are being investigated in subsequent research, including individuals' ability to understand instructions, perform self-testing, and interpret the results correctly (eg, see trial ACTRN12622001517763). Concerns have been raised about the misinterpretation of negative results from RATs, which have a high error rate if the test is not used within the recommended period after exposure to a COVID-19 case [48]. Another avenue for further work is to partner with the media to avoid the identification and stigmatization of individuals with positive test results in future disease outbreaks [49]. Media reports and anecdotal data from frontline health professionals may be a useful way to quickly identify emerging local issues that could inform the measurement of testing barriers to make them more relevant to local communities.

Strengths and Limitations

This research began as an unfunded and rapidly developing response to the COVID-19 pandemic. By addressing methodological issues and building on the findings in each phase, we were able to better target the final intervention and show the value of audio-visual formats in addressing common knowledge barriers among people with varying health literacy needs.

Phase 1 identified the range of barriers to COVID-19 testing in Australia for the first time, but the prevalence of the most important barriers could not be ascertained from these findings because of the reliance on open responses and a nonrepresentative sample. The next phase addressed these methodological issues. Phase 2 identified the prevalence of barriers to COVID-19 testing in a nationally representative sample and highlighted important health literacy disparities. However, even the second phase was not representative of all community groups, particularly those from culturally and linguistically diverse backgrounds, which has been identified as a key area of need in Australia and worldwide. We conducted a separate survey with these groups using interpreters to conduct the survey in phase 1 in preferred languages as a partnership with the Western Sydney Local Health District [50-52].

In phase 3, the intervention's highly tailored design meant that there was considerable heterogeneity in the intervention elements that participants received. This may have contributed to the lack of observed effect. It is possible that there were ceiling effects for testing intentions when participants assumed that they would get tested when they were not currently or recently thinking about the logistics of getting tested. It is also possible that participants did not engage with the text-based intervention content. We attempted to address these methodological issues in the final phase 4 by focusing on a consistent set of key knowledge barriers in a more targeted group with lower baseline testing intentions (younger and lower education), using a more engaging intervention format (animation with text and audio and a social media–style video), and including more sensitive measures of testing intention to avoid potential biases.

The audio-visual interventions produced for phase 4 have information that is specific to the Australian context and may not be useful in other countries but can be used as a starting point for new knowledge interventions. We found that a simple and relatively cheap animation focused on key messages or a TikTok-style video that incorporated humor was both effective for increasing knowledge but not testing intentions. However, the findings may not be generalizable to other contexts, particularly where opportunity issues such as cost or physical access to testing are a problem. We expect that there will be additional barriers to RATs. Nevertheless, this study provides a comprehensive list of testing barriers that may help us better prepare for future variants or the next pandemic.

Conclusions

To prepare for future pandemics, capability, opportunity, and motivation issues need to be addressed to increase testing behaviors for novel viruses, particularly in groups with lower health literacy. Audio-visual interventions can be used to address key knowledge issues in target populations. Our findings support broader advice from international experts on behavior change, highlighting the importance of diagnosing behavioral barriers to increase adherence to COVID-19 prevention behaviors.

Acknowledgments

The authors thank the participants of the longitudinal COVID-19 survey for their ongoing participation in this research, Wendy Liang for providing consumer input for the written intervention, and MD for developing the TikTok version of the intervention. The surveys were not specifically funded, but in-kind support was provided by the authors through research fellowships. The experimental trials were funded by the Marie Bashir Institute (now known as the Sydney Infectious Diseases Institute) at the University of Sydney. CB is supported by a National Health and Medical Research Council and Heart Foundation Early Career Fellowship (number 1122788).

KM is supported by a National Health and Medical Research Council Principal Research Fellowship (number 1121110).

Abstract

Background: Although the association between social isolation and the risk of subsequent cardiovascular disease (CVD) is well documented, most studies have only assessed social isolation at a single time point, and few studies have considered the association using repeatedly measured social isolation.

Objective: This study aimed to examine the association between social isolation trajectories and incident CVD in a large cohort of middle-aged and older adults.

Methods: This study used data from 4 waves (wave 1, wave 2, wave 3, and wave 4) of the China Health and Retirement Longitudinal Study. We defined the exposure period as from June 2011 to September 2015 (from wave 1 to wave 3) and the follow-up period as from September 2015 to March 2019 (wave 4). On the basis of the inclusion and exclusion criteria, our final analytic sample included 8422 individuals who had no CVD in the China Health and Retirement Longitudinal Study in waves 1 to 3 and were fully followed up in wave 4. Social isolation was ascertained using an extensively used questionnaire at 3 consecutive, biennial time points from waves 1 to 3, and individuals were assigned to 3 predefined social isolation trajectories based on their scores at each wave (consistently low, fluctuating, and consistently high). Incident CVD included self-reported physician-diagnosed heart disease and stroke combined. Cox proportional hazard models estimated the associations of social isolation trajectories with risks of incident CVD, adjusting for demographics, health behaviors, and health conditions.

Results: Of the 8422 participants (mean age 59.76, SD 10.33 years at baseline), 4219 (50.09%) were male. Most of the participants (5267/8422, 62.54%) had consistently low social isolation over time and 16.62% (1400/8422) of the participants had consistently high social isolation over the exposure period. During the 4-year follow-up, 746 incident CVDs occurred (heart disease: 450 cases and stroke: 336 cases). Compared with individuals with consistently low social isolation, those with fluctuating social isolation (adjusted hazard ratio 1.27, 95% CI 1.01-1.59) and consistently high social isolation (adjusted hazard ratio 1.45, 95% CI 1.13-1.85) had higher risks for incident CVD after adjusting for demographics (ie, age, sex, residence, and educational level), health behaviors (ie, smoking status and drinking status), and health conditions (ie, BMI; history of diabetes, hypertension, dyslipidemia, chronic kidney disease; use of diabetes medications, hypertension medications, and lipid-lowering therapy; and depressive symptoms scores).

Conclusions: In this cohort study, middle-aged and older adults with fluctuating and consistently high social isolation exposure had higher risks of the onset of CVD than those without the exposure. The findings suggest that routine social isolation screenings and efforts to improve social connectedness merit increased attention for preventing CVD among middle-aged and older adults.

Introduction

Background

Social isolation, defined as an objective reduction in social network size and frequency of social contact, has been shown to be a critical factor contributing to physical and mental health risks [1]. Previous evidence has suggested that it is particularly common in older adults, who may experience decreasing economic resources, physical impairment, or the loss of contemporaries, all of which can limit social contact [2,3]. As the global population ages, there has been an increasing interest in assessing the health effects of social isolation in older adults. The impact of COVID-19 has amplified concerns regarding social isolation among older adults, leading to greater public health awareness [4,5]. In China, it is projected that the proportion of empty-nest families (referring to older individuals with no children or whose children have already left home) will reach 90% [6], highlighting the need for increased attention to social isolation among middle-aged and older adults.

Cardiovascular disease (CVD) is one of the leading causes of global mortality and a major contributor to disability in older adults [7]. Several epidemiological studies have examined the association between social isolation and CVD; however, the results have been inconsistent. Some prospective studies have found that social isolation was associated with a higher risk of developing CVDs, such as coronary heart disease [8], heart failure [9], and stroke [10]. A meta-analysis with 16 cohorts from Europe, North America, Australia, Japan, and Asian Russia showed that social isolation and loneliness are associated with approximately 30% higher risk of coronary heart disease and stroke, even after controlling for age, sex, and socioeconomic status [3]. However, a study that included individuals from the UK Biobank found that the association between social isolation and incident acute myocardial infarction or stroke was attenuated after considering other risk factors, including biological factors (BMI, diastolic and systolic blood pressure, and grip strength), health behaviors (alcohol consumption, physical activity, and smoking), depressive symptoms, socioeconomic factors (education, household income, and Townsend Deprivation Index), and history of chronic illness [11]. A study using data from the English Longitudinal Study of Ageing (ELSA) did not observe a significant association between social isolation and incident CVD over a mean follow-up period of 5.4 years [12]. Similarly, another meta-analysis, including 5 longitudinal studies from Australian adults, reported no association between social isolation and the incidence of CVD [13]. Moreover, there is increasing evidence that social isolation is associated with CVD risk factors such as increased hypertension, smoking, psychological factors (eg, depression), and biological mechanisms (eg, inflammation and stress reactivity) [14-16]. It has been well established that lifestyle [17] and health conditions [18] are associated with an increased risk of CVD outcomes, and therefore, the confounding or covariate influences of these factors on the association between social isolation and incident CVD should be considered when estimating the aforementioned association between social isolation and CVD. Moreover, the level of exposure to social isolation may be dynamic and change over time, with some individuals experiencing long-term social isolation, whereas others experiencing a temporary increase in social isolation [19]. However, prior studies evaluating the association between social isolation and CVD have used social isolation at only a single time point [8-11], which may not provide a complete picture of the role of social isolation in CVD risk. An in-depth understanding of social isolation trajectories may provide clues for identifying individuals with different time-varying levels (eg, consistently high, fluctuating, or consistently low) over their life course. To reduce the risk of CVD in middle-aged and older people, it is crucial to identify its association with social isolation to facilitate research into the development of targeted prevention or early intervention programs.

Objectives

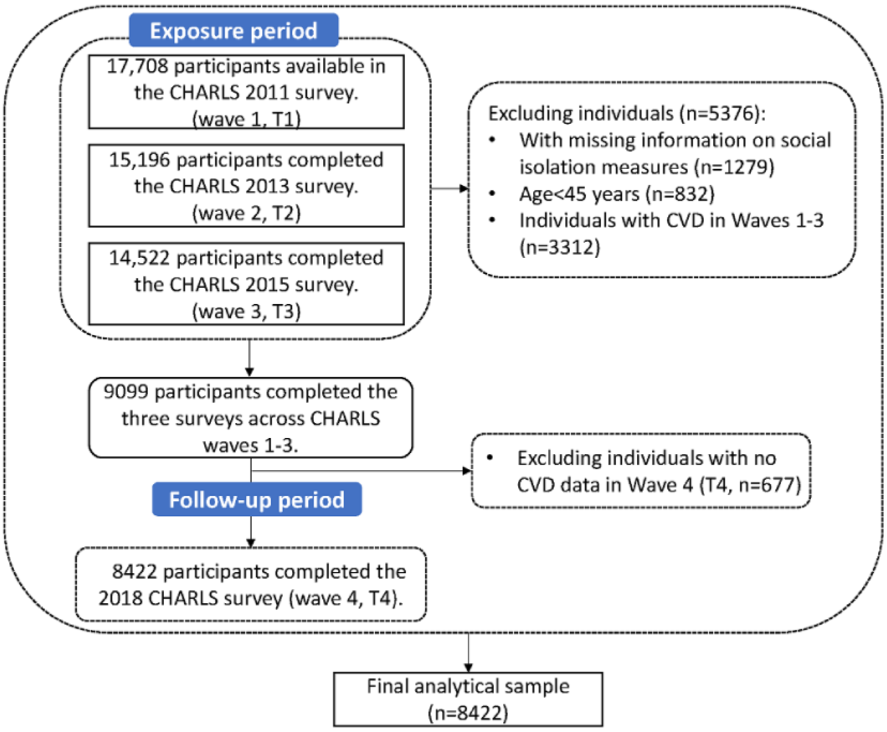
Therefore, to address this research gap, using the nationally representative data from the China Health and Retirement Longitudinal Study (CHARLS), we conducted longitudinal analyses to assess the associations of social isolation trajectories over a period of 4 years with incident CVD among the middle-aged and older Chinese population.

Methods

Study Population

This cohort study used data from CHARLS, an ongoing nationally representative cohort study of Chinese adults aged ≥45 years and their families, which has been previously described in detail [20]. The baseline survey was conducted between June 2011 and March 2012 using a multistage stratified probability-proportional-to-size (PPS) sampling method. In the first stage, 150 county-level units were randomly selected using a PPS sampling technique from a sampling frame containing all county-level units except Tibet. The sample was stratified by region and within each region by urban districts or rural counties and per capita gross domestic product statistics. The final sample of 150 counties was distributed across 28 provinces. The study sample used the lowest level of government organization consisting of administrative villages (*cun* in Chinese) in rural areas and neighborhoods (*shequ* or *juweihui* in Chinese) in urban areas as primary sampling units. A total of 3 primary sampling units within each county-level unit were selected using PPS sampling. At baseline, face-to-face computer-assisted personal interview data were collected from 17,708 participants in 10,257 households, who were recruited from 450 villages and resident communities across China. The response rate of the baseline survey was 80.5%. All participants were followed up every 2 years after the baseline survey using a face-to-face computer-assisted personal interview [20]. The CHARLS data include 4 waves of data (June 2011 to March 2019). We defined from June 2011 to September 2015 (from T1 to T3) as our exposure period (where T1 refers to wave 1, T2 to wave 2, and T3 to wave 3) and from September 2015 to March 2019 (T4, wave 4) as our follow-up period. On the basis of our inclusion and exclusion criteria, our final analytic sample included 8422 individuals who did not have CVD in CHARLS in waves 1 to 3 and were fully followed up in wave 4. Detailed process of participant selection is presented in Figure 1.

Figure 1. Flow diagram of participants included in the study. A total of 14,522 individuals had data available for waves 1-3. Individuals could be excluded due to multiple reasons. CHARLS: China Health and Retirement Longitudinal Study; CVD: cardiovascular disease.



Primary Exposure—Social Isolation Trajectories

In each biennial questionnaire, a social isolation index was generated based on social network ties and social activity or engagement [21]. Consistent with previous literature [22,23], the index consists of 4 indicators: currently unmarried (never married, separated, divorced, and widowed), living alone, having less than weekly contact (face-to-face, telephone, or email) with their children, and participating in social activities less than once a month. Detailed definitions of each indicator are provided in Methods in Multimedia Appendix 1 [22-27]. By summing the indicators, the total score ranged from 0 to 4, with higher scores indicating a greater level of social isolation. We performed Bartley sphericity test to analyze the validity structure of the social isolation index, and the *P* values across the first 3 waves were <.001. The rejection of the null hypothesis of Bartley sphericity test suggests that the validity structure of the social isolation index was good [28]. Participants were further categorized as nonisolated (score <2) and isolated (score ≥2) [22,23,29]. We created social isolation trajectories using the dichotomized social isolation variable for each wave (isolated vs nonisolated) [30]. Guided by theory and prior empirical work, we constructed 3 social isolation trajectories (consistently low, fluctuating, and consistently high) a priori based on combinations of social isolation status across the first 3 waves (wave 1 to 3) [31]. Consistently high was defined as isolated at 3 time points across the assessment period, consistently low was defined as nonisolated at 3 time points, and fluctuating encompassed the other social isolation trajectories that did not fit the above classifications. A visual depiction of the trajectories is provided in Table S1 in Multimedia Appendix 1.

CVD Outcomes

Incident CVD events were defined as the first occurrence of CVD during the follow-up period. In line with previous literature using CHARLS data [32,33], incident CVD events, including heart disease and stroke, were measured using the following standardized questions: “Have you been told by a doctor that you have been diagnosed with a heart attack, coronary heart disease, angina, congestive heart failure, or other heart problems?” or “Have you been told by a doctor that you have been diagnosed with a stroke?” Participants who reported heart disease or stroke during the follow-up period were defined as having an incident CVD.

Covariates

At baseline, information on the sociodemographic status and health-related factors was collected by trained interviews using a structured questionnaire. Demographic variables included age, sex, area of residence (rural or urban), and educational level (no formal education, primary school or below, middle or high school, and college or above). Health-related factors included smoking and drinking status (never, former, and current), BMI, depressive symptoms, hypertension, diabetes, dyslipidemia, chronic kidney disease, and the use of medications or therapies for hypertension, diabetes, and dyslipidemia. Detailed definitions of the covariates are provided in Multimedia Appendix 1.

Depressive symptoms were assessed using the 10-item Center for Epidemiology Scale for Depression (CESD-10), which has been validated and widely used among Chinese adults [34]. The CESD-10 consists of 10 items: (1) bothered by little things, (2) had trouble concentrating, (3) felt depressed, (4) everything was an effort, (5) felt hopeful, (6) felt fearful, (7) sleep was restless,

(8) felt happy, (9) felt lonely, and (10) could not get going. Each depressive symptom item in the past week was measured from 0 (rarely or none of the time [<1 day]) to 3 (most or all of the time [5-7 days]). The sum of CESD-10 scores ranges from 0 to 30, with higher scores indicating a higher level of depressive symptoms severity. A total score of ≥12 was used as the cutoff for having depressive symptoms [35]. Of note, subjective loneliness was measured using the CESD-10.

A subgroup of 5196 CHARLS participants underwent measurements of metabolic biomarkers, including fasting plasma glucose, total cholesterol, low-density lipoprotein cholesterol, high-density lipoprotein cholesterol, triglycerides, high-sensitivity C-reactive protein (hs-CRP), and serum creatinine. The estimated glomerular filtration rate was calculated using the Chronic Kidney Disease Epidemiology Collaboration’s 2009 creatinine equation [36].

Statistical Analysis

Data were described as mean (SD) or median (IQR) for continuous variables, and frequency with percentage was used to describe categorical variables. First, baseline characteristics were summarized based on the social isolation trajectory group and compared between participants using the chi-square test, ANOVA, or Kruskal-Wallis test, as appropriate. Second, we computed the incidence rates of CVD per 1000 person-years in CHARLS. We also calculated the follow-up time as the time elapsed from the date of the last interview, either the date of CVD diagnosis or the date of the latest interview (March 2019) in which the individual participated. Cox proportional hazard models estimated the hazard ratios (HRs) and 95% CIs for the associations between the social isolation trajectory group and incident CVD using the consistently low social isolation trajectory as the reference. Four models were estimated: model 1, an unadjusted model; in model 2, age and sex were adjusted; in model 3, age, sex, residence, educational level, smoking status, and drinking status were adjusted; and in model 4, the variables in model 3 plus BMI; history of diabetes, hypertension, dyslipidemia, and chronic kidney disease; use of diabetes medications, hypertension medications, and lipid-lowering therapy; and depressive symptoms scores were adjusted. We used interaction items and subgroup analyses to assess whether the potential association between the social isolation trajectory group and incident CVD was moderated by the following characteristics: age, sex, residence, educational level, smoking status, drinking status, diabetes, hypertension, dyslipidemia, chronic kidney disease, BMI, and depressive symptom scores. Four sensitivity analyses were conducted to assess the robustness of our study findings: (1) we further adjusted for metabolic biomarkers in the subgroup of 5196 participants who underwent metabolic examinations, (2) we additionally adjusted for health conditions and behaviors at wave 3 (T3) to estimate changes in associations due to potentially mediating health behavioral pathways, (3) we repeated analyses using the complete data set (7472 participants), and (4) we used inverse-probability weighting to examine the impact of potential selection bias by excluding individuals based on our exposure period [37]. All analyses were conducted using Stata (version 17.0; StataCorp) and R (version 4.2.1; R Foundation for Statistical Computing). Two-sided *P*<.05 was considered statistically significant.

Ethics Approval

The CHARLS study was approved by the Biomedical Ethics Review Committee of Peking University (IRB00001052-11015), and ethics approval for the use of the CHARLS data was obtained from the University of Newcastle Human Research Ethics Committee. This study was conducted in accordance with the Strengthening the Reporting of Observational Studies in Epidemiology reporting guidelines. All procedures were performed in accordance with the principles of the Declaration of Helsinki. Written informed consent was obtained from all the participants.

Results

Characteristics of Participants

Of the 8422 participants included in the primary analyses, the mean age of the study population at baseline was 59.76 (SD 10.33) years, and the proportion of male participants was 50.09% (4219/8422). Although the differences between included and excluded participants were relatively small, participants excluded from analyses were older and were more likely to be female; live in rural areas; and have a lower educational level, higher depressive symptoms scores, and lower BMI (Table S2 in Multimedia Appendix 1). Table 1 describes the characteristics of the participants according to their social isolation trajectory group. Among these middle-aged and older adults, the majority (5267/8422, 62.54%) had consistently low social isolation over time and 16.62% (1400/8422) had consistently high social isolation over the exposure period. Individuals with consistently high versus consistently low social isolation were more likely to be older (mean age 66.08, SD 10.55 years vs mean age 58.41, SD 9.88 years; *P*<.001), be female (811/1400, 57.93% vs 2592/5267, 49.21%; *P*<.001), live in rural area (1241/1400, 88.64% vs 3868/5267, 73.44%; *P*<.001), have no formal education (908/1400, 64.86% vs 2029/5267, 38.52%; *P*<.001), be a nonsmoker (855/1400, 61.07% vs 3130/5267, 59.42%; *P*=.04), be a nondrinker (897/1400, 64.07% vs 3148/5267, 59.77%; *P*=.002), have higher CESD-10 scores (mean 10.41, SD 6.70 vs mean 7.67, SD 5.98), have a history of hypertension (602/1400, 43% vs 1866/5267, 35.43%; *P*<.001), less use of diabetes mediations (29/1400, 2.07% vs 184/5267, 3.49%; *P*=.02), have higher systolic pressure (mean 135.65, SD 27.09 mm Hg vs mean 130.36, SD 24.88 mm Hg), have lower triglyceride (mean 118.71, SD 96.77 mg/dL vs mean 131.32, SD 101.87 mg/dL; *P*=.002) but higher high-density lipoprotein cholesterol (mean 54.11, SD 15.94 mg/dL vs mean 50.93, SD 15.28 mg/dL; *P*<.001), and have a lower estimated glomerular filtration rate (mean 88.42, SD 28.99 mL/min/1.73 m^2 vs mean 91.98, SD 36.09 mL/min/1.73 m^2; *P*=.02).

Table 1. Characteristics of the participants according to social isolation trajectory group.

Characteristics	Overall (N=8422)	Social isolation trajectory group			*P* value[a]
		Consistently low (n=5267)	Fluctuating (n=1755)	Consistently high (n=1400)	
Age (years), mean (SD)	59.76 (10.33)	58.41 (9.88)	58.78 (9.57)	66.08 (10.55)	<.001

eGFR[f] (mL/min/1.73 m^2), mean (SD)	90.82 (34.11)	91.98 (36.09)	89.36 (31.72)	88.42 (28.99)	.02

[a] *P* value was based on the chi-square test, ANOVA, or the Kruskal-Wallis test where appropriate.

[b] Missing data: 1 for the area of residence, 7 for educational level, 93 for smoking, 16 for drinking, 629 for depressive symptoms scores, 67 for diabetes medications, 37 for hypertension medications, and 178 for lipid-lowering therapy.

[c] Depressive symptom scores were measured using the 10-item Center for Epidemiology Scale for Depression, ranging from 0 to 30, with higher scores indicating a higher level of depressive symptom severity.

[d] Measured in the subpopulation of 5196 participants.

[e] hs-CRP: high-sensitivity C-reactive protein.

[f] eGFR: estimated glomerular filtration rate.

Associations of Social Isolation With Incident CVD

During the follow-up period between 2015 and 2019, a total of 746 incident CVDs occurred (heart disease: 450 cases and stroke: 336 cases). The incidence rate of CVD was 28.14 per 1000 person-years among individuals with consistently low social isolation, 34.81 per 1000 person-years among the fluctuating social isolation group, and 35.26 per 1000 person-years among those with consistently high social isolation. Table 2 shows that after adjusting for covariates in models 2 to 4, compared with individuals with consistently low social isolation (reference), those with fluctuating social isolation (adjusted HR 1.27, 95% CI 1.01-1.59; model 4) and those with consistently high social isolation (adjusted HR 1.45, 95% CI 1.13-1.85; model 4) had a higher risk for incident CVD. For CVD components, compared with the reference group, individuals with fluctuating social isolation (adjusted HR 1.59, 95% CI 1.16-2.17; model 4) and those with consistently high social isolation (adjusted HR 1.75, 95% CI 1.25-2.47; model 4) had a higher risk of stroke, but not heart disease (Table 2).

As shown in Figure 2, the association between the social isolation trajectory group and incident CVD events was not moderated by age, sex, residence, smoking status, drinking status, diabetes, hypertension, dyslipidemia, chronic kidney disease, BMI, and depressive symptoms scores. The association between consistently high social isolation and incident CVD was significant among participants with middle or high school or above educational level (adjusted HR 2.02, 95% CI 1.25-3.27; *P*=.03 for interaction). Moreover, we assessed the risk of incident CVD between fluctuating and consistently high social isolation subgroups. As shown in Table 3, we found that compared with individuals with fluctuating social isolation, those with consistently high social isolation were not significantly associated with an increased risk of incident CVD (*P*>.05).

Intercorrelations of the metabolic biomarkers used in this study are presented in Table S3 in Multimedia Appendix 1. Sensitivity analyses showed that after further adjusting for metabolic biomarkers, the associations of fluctuating social isolation and consistently high social isolation with incident stroke remained statistically significant (Table S4 in Multimedia Appendix 1). Our findings were not largely attenuated by health conditions and behaviors at wave 3 (Table S5 in Multimedia Appendix 1), and similar results were found when complete data analyses were performed (Table S6 in Multimedia Appendix 1) or using inverse-probability weighting (Table S7 in Multimedia Appendix 1).

[c] Model 3 was adjusted for age, sex, residence, educational level, smoking status, and drinking status.

[d] Model 4 was adjusted as model 3 plus BMI; history of diabetes, hypertension, dyslipidemia, chronic kidney disease; use of diabetes medications, hypertension medications, and lipid-lowering therapy; and depressive symptoms scores.

Discussion

Principal Findings

In this cohort study of middle-aged and older Chinese adults, individuals in the fluctuating and consistently high social isolation trajectory groups had a 27% and 45% higher risk for developing incident CVD than those with consistently low social isolation. The association between consistently high social isolation and incident CVD remained statistically significant after demographics, baseline health behaviors and conditions, and baseline depressive symptoms (including loneliness measurement) had been taken into account in multivariable models. However, after further adjusting for metabolic biomarkers, only the associations of fluctuating social isolation and consistently high social isolation with incident stroke remained statistically significant.

Several cross-sectional and longitudinal studies have suggested that the presence of social isolation is associated with a higher risk of coronary heart disease, heart failure [9], stroke [10], CVD diagnoses [38-40], and CVD risks [41]. Nagayoshi et al [10] demonstrated that community-dwelling men and women in the United States who reported having a small social network had an approximately 40% greater risk of incident stroke compared with their counterparts who reported a large social network, even after adjusting for demographics, socioeconomic variables, behavioral risk factors, and major stroke risk factors. Freak-Poli et al [40] reported a positive association between social isolation and incident CVDs, particularly stroke. However, these studies only assessed social isolation at a single time point, which may not provide a complete picture of the role of social isolation over the life span. In reality, the level of exposure to social isolation may be dynamic and vary over time [19]. Our study observed that 62.54% (5267/8422) of the study population had consistently low social isolation, 16.62% (1400/8422) had consistently high social isolation, and 20.83% (1755/8422) had fluctuating social isolation over the exposure period. Research on the longitudinal association between social isolation trajectories and CVD events is limited. Our study used repeated measures of social isolation and found that repeated occurrences of social isolation (ie, consistently high social isolation) may increase the risk of incident CVD, particularly stroke. The potential mechanisms underlying the association include elevated adrenaline levels in the blood, increased sympathetic nervous system activity, dysregulated heart rate and blood pressure, and modulated cardiovascular reactivity, as well as the activation of the hypothalamic-pituitary-adrenocortical axis and the sympathetic nervous system, or dysregulated inflammation [14,15,42]. In addition, social isolation is associated with unhealthy behavioral factors (eg, smoking, drinking, obesity, and lack of medication compliance) and psychological status (eg, depression), which may increase vascular risk and are considered CVD risk factors [43-47]. Consistent with previous literature [42,48-50], our study also observed that individuals in the consistently high social isolation group were more likely to be older, be female, live in more deprived areas, have higher systolic pressure, have higher depressive symptoms scores, and have poor medication compliance relative to those with consistently low social isolation. Our adjusted Cox regression models indicated that these factors might modestly explain the observed association between social isolation and CVD events. Furthermore, our sensitivity analysis, which was additionally adjusted for health conditions and behaviors at wave 3, resulted in attenuated risk estimates. Similarly, a large-scale prospective study using data from the UK Biobank reported that the association of social isolation with acute myocardial infarction and stroke was attenuated after adjusting for demographics, biological factors, health behaviors, and depressive symptoms [11]. Another large-scale prospective study using data from the UK Biobank and Million Women's study found that after controlling for established cardiovascular risk factors (eg, age, sex, and self-rated health) and health behaviors, no significant overall association between social isolation and nonfatal coronary heart disease and stroke was observed. However, in contrast, social isolation had clear associations with fatal coronary heart disease and stroke [49]. Furthermore, the association between social isolation and increased levels of inflammatory biomarkers, such as hs-CRP, are well documented [51,52]. In this study, after adjusting for hs-CRP and other metabolic biomarkers, the association of fluctuating social isolation and consistently high social isolation with incident stroke remained significant, suggesting that these findings are robust. Apart from the abovementioned mechanisms linking social isolation and CVD events, there may also be trajectory-specific mechanisms that require further investigation.

In addition, our study found that the association between the social isolation trajectory group and incident CVD events was not moderated by age, sex, residence, smoking status, drinking status, diabetes, hypertension, dyslipidemia, chronic kidney disease, BMI, and depressive symptoms scores. Only educational level modestly moderated the association between social isolation and incident CVD, with the highest HR observed in individuals with middle or high school education or above educational level. Similarly, Cené et al [9] did not observe the moderation effects of age, race, and ethnicity on the association between social isolation and incident heart failure among older women in the United States. Bu et al [39] reported no evidence of a moderation effect of age, sex, socioeconomic status, and CVD risk (established by obesity, high cholesterol, hypertension, diabetes, smoking, diet, physical activity, abnormal sleep, and depression) on the association between social isolation and CVD events among participants from the ELSA. Although we have no clear explanation for this finding, our study indicates that the social isolation trajectory and incident CVD may not differ in individuals with different ages, sexes, residences, BMI, or other abovementioned characteristics. However, for individuals with higher educational levels, the influences of social isolation trajectory on incident CVD may be greater than that for those with lower education levels. Nevertheless, the observed moderation effects of educational level or other unobserved findings still require further investigation.

Our study also found that individuals in the consistently high social isolation group did not have a higher risk of incident CVD than those with fluctuating social isolation. This result may be because individuals with fluctuating social isolation may also have increased risks of other health conditions, such as depressive symptoms, hypertension, and obesity, which may, in turn, increase their risk of developing CVDs [53,54]. Moreover, the fluctuating social isolation trajectory group in our study included a subgroup of individuals who were older, lived in rural areas, and had higher depressive symptoms scores than those with consistently low social isolation. On the basis of our findings, we recommend early identification and lifestyle interventions for socially isolated individuals as a means of combating CVDs and promoting healthy aging, with particular attention paid to the persistent occurrence of social isolation. Future research is needed to examine how frequently social isolation should be assessed and how many assessments would be sufficient to present the course of social isolation to determine high-risk groups for CVDs.

Strengths and Limitations

The strengths of our study include its prospective design, repeated measures of social isolation, a long follow-up period, and a wide range of covariates that include health conditions and behaviors and metabolic biomarkers. Repeated social isolation measurements over a long exposure period can minimize the likelihood of reverse causation or the potential bidirectionality of the estimated association between social isolation and CVD event. However, this study has several limitations. First, the diagnosis of CVD relied on self-reported data, which may be subject to reporting bias. Although medical records were not available in the CHARLS [33], previous large-scale studies using data from the Health and Retirement Study [55] or the ELSA [56] found that self-reported CVDs correspond well with CVDs coded according to the International Classification of Diseases in medical records. Second, individuals with missing social isolation measures and those who experienced CVD during the exposure assessment period were excluded from the analyses, which may limit the generalizability of our findings to middle-aged and older adults. Third, the predefined trajectory group definition of social isolation in our study may be only one possible representation of the accumulative progression of social isolation over time. Fourth, our study sample only included Chinese adults, and therefore our study findings may not be fully generalizable to other ethnicities. Fifth, although our social isolation index was based on previous research [22,23], it was not a standardized scale or instrument. Sixth, our analyses did not consider physical activity as a covariate because it was not assessed using a standardized scale and may be an intermediate variable between social isolation and CVD [57-61]. Finally, in one of our sensitivity analyses presented in Table S4 in Multimedia Appendix 1, all metabolic biomarkers were adjusted to test the robustness of our main findings. However, some of these markers appeared to be moderately correlated, which may have led to collinearity issues.

Conclusions

In this cohort study, both fluctuating and consistently high social isolation exposure were associated with a higher risk of incident CVD among middle-aged and older Chinese adults, especially for stroke. Our findings provide new evidence supporting the longitudinal link between social isolation trajectories and CVD, highlighting the importance of routine screening for social isolation, and providing preventive or intervention strategies to both fluctuate isolated or consistently isolated individuals to reduce the incidence of CVD and promote healthy aging. In addition, our results suggest that efforts to improve social connectedness and reduce social isolation among middle-aged and older adults are recommended.

Acknowledgments

The authors would like to thank the China Health and Retirement Longitudinal Study (CHARLS) research team for providing the data. LG and CL had full access to all the data in the study and took responsibility for the integrity of the data and accuracy of the data analysis.

Data Availability

The original data sets are publicly available on the website of the China Health and Retirement Longitudinal Study (CHARLS) [62]. The data sets generated and analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

LG and WW contributed equally to this work. All authors were equally involved in the concept and design of this study. All authors did data acquisition, analysis, or interpretation. LG drafted the manuscript. LG, WW, JS, XZ, and YH critically revised the manuscript for important intellectual content. LG performed the statistical analysis. CL and LG provided the administrative, technical, or material support. CL and LG supervised the study.

Conflicts of Interest

None declared.

Abstract

Background: Rapid increases in the morbidity and mortality of patients with upper gastrointestinal cancer (UGC) in high-incidence countries in Asia have raised public health concerns. Screening can effectively reduce the incidence and mortality of patients with UGC, but the low population uptake rate seriously affects the screening effect.

Objective: We aimed to determine the characteristics that influence residents' preference heterogeneity for a UGC-screening program and the extent to which these characteristics predict residents' uptake rates.

Methods: A discrete choice experiment was conducted in 1000 residents aged 40-69 years who were randomly selected from 3 counties (Feicheng, Linqu, and Dongchangfu) in Shandong Province, China. Each respondent was repeatedly asked to choose from 9 discrete choice questions of 2 hypothetical screening programs comprising 5 attributes: screening interval, screening technique, regular follow-up for precancerous lesions, mortality reduction, and out-of-pocket costs. The latent class logit model was used to estimate residents' preference heterogeneity for each attribute level, their willingness to pay, and the expected uptake rates.

Results: Of the 1000 residents invited, 926 (92.6%) were included in the final analyses. The mean age was 57.32 (SD 7.22) years. The best model contained 4 classes of respondents (Akaike information criterion=7140.989, Bayesian information criterion=7485.373) defined by different preferences for the 5 attributes. In the 4-class model, out of 926 residents, 88 (9.5%) were assigned to class 1, named as the negative latent type; 216 (3.3%) were assigned to class 2, named as the positive integrated type; 434 (46.9%) were assigned to class 3, named as the positive comfortable type; and 188 (20.3%) were assigned to class 4, named as the neutral quality type. For these 4 latent classes, "out-of-pocket cost" is the most preferred attribute in negative latent type and positive integrated type residents (45.04% vs 66.04% importance weights), whereas "screening technique" is the most preferred factor in positive comfortable type residents (62.56% importance weight) and "screening interval" is the most valued attribute in neutral quality type residents (47.05% importance weight). Besides, residents in different classes had common preference for painless endoscopy, and their willingness to pay were CNY ¥385.369 (US $59.747), CNY ¥93.44 (US $14.486), CNY ¥1946.48 (US $301.810), and CNY ¥3566.60 (US $552.961), respectively. Residents' participation rate could increase by more than 89% (except for the 60.98% in class 2) if the optimal UGC screening option with free, follow-up for precancerous lesions, 45% mortality reduction, screening every year, and painless endoscopy was implemented.

Conclusions: Public preference heterogeneity for UGC screening does exist. Most residents have a positive attitude toward UGC screening, but their preferences vary in selected attributes and levels, except for painless endoscopy. Policy makers should consider these heterogeneities to formulate UGC-screening programs that incorporate the public's needs and preferences to improve participation rates.

upper gastrointestinal cancer; screening programs; discrete choice experiment; latent class logit model; public preference heterogeneity; uptake rate

Introduction

Upper gastrointestinal cancer (UGC; including gastric cancer and esophageal cancer) is one of the most common malignant neoplasms worldwide, and 1.60 million new UGC cases were reported and 1.31 million UGC deaths occurred in 2020, with China alone accounting for more than half of the cases and deaths, respectively [1]. Among patients diagnosed with UGC, the 5-year survival rate is approximately 30% [2]. The main reason for the poor prognosis is that most patients are diagnosed at an advanced stage when tumors are not resectable and nonsurgical therapeutic modalities are ineffective [3]. Nevertheless, UGC can be detected and treated with endoscopic screening at an earlier stage, with a survival rate of >90% [4]. Endoscopic screening, the gold standard for the early diagnosis of UGC, has been widely adopted in many countries and proven to be highly effective in reducing the morbidity and mortality rates of UGC [5,6]. Furthermore, recent studies have confirmed that endoscopic screening is a more cost-effective screening method for UGC than no screening [7-9]. However, the effectiveness of endoscopic screening is reduced by the low population uptake rate.

In some high-income countries, such as Japan and South Korea, the participation rate is lower than 50% despite the launch of nationwide endoscopic screening programs for gastric cancer for a long time [10,11]. Similarly, as a low-income country with high UGC incidence and mortality, China has performed endoscopic screening for patients with gastric cancer and esophageal cancer in more than 110 high-risk areas throughout the country since 2005, but residents' compliance to date was still only 48.62% [6]. This low uptake rate for UGC screening has become a huge public health challenge and needs to be addressed to maximize the benefits that can be achieved by endoscopic screening. Recent studies have shown that the characteristics (attributes and levels) of the UGC-screening program may impact whether individuals participate in the screening [12-16]. Nevertheless, if and how these characteristics affect residents' screening preferences remains poorly understood.

The discrete choice experiment (DCE) is a stated preference method that has been used from 1990s to obtain individuals' preferences for health care and for a wide range of health care topics [17]. In a DCE, participants are presented with alternative options that are systematically described according to several attributes and are asked to make a choice among these options [18]. Their choice can be analyzed using a discrete choice model. The latent class logit (LCL) model is the most commonly used choice model for exploring individuals' preference heterogeneity, which permits the potential classification of the target population and estimation of their preference heterogeneity in different classes [19]. However, to date, no published studies have used LCL to explore individuals' UGC-screening preference heterogeneity.

Therefore, in this study, we constructed a DCE and used the LCL model to elicit public preference heterogeneity regarding UGC-screening programs and explore the influence of personal characteristics on the variation, willingness to pay (WTP), and uptake rate in their choices. These results will be helpful for policy makers in understanding the heterogeneity of public preferences, resulting in a sustainable and effective UGC-screening policy.

Methods

Sampling and Participants

This is an extension of our previously published study [12], which also used contemporaneous data but where the new methods are used to obtain more essential and meaningful findings and conclusions. In our study, a stratified (cluster) random sampling method was used to select participants. First, located in the east, central, and west of Shandong Province, 3 cities (Weifang, Taian, and Liaocheng) were chosen as sample areas, which represent high, medium, and low economic levels according to the gross domestic product (GDP) per capita (2020), respectively. Then, 3 counties (Linqu, Feicheng, and Dongchangfu) were selected from each sample area as the survey points, respectively. Finally, rural residents aged 40 to 69 years in 2 to 4 villages were randomly chosen from each county for a face-to-face DCE questionnaire survey.

DCE Design

Overview

In this study, a DCE was conducted to determine the factors (attributes and attribute levels) that influence residents' preference heterogeneity to participate in a UGC-screening program and the weightage that residents give to the selected attributes and attribute levels. The DCE was developed according to the methodological standards issued by the International Society for Pharmacoeconomics and Outcomes Research (ISPOR) [20]. The design process is as follows. More details on the DCE design process, sample size calculation, and data collection are available in our previously published study [12].

Selection of Attributes and Attribute Levels

The attributes and attribute levels of the DCE were derived from a literature review [5,12-14,21-29], expert interviews, and focus group discussions with residents of the target population.

Finally, the survey results described 5 attributes with 2 to 4 levels: out-of-pocket costs (CNY ¥0 [US $0], CNY ¥100 [US $15.503], CNY ¥300 [US $46.511], and CNY ¥500 [US $77.519]), screening interval (every year, every 2 years, every 5 years, and once in a lifetime), screening technique (endoscopy and painless endoscopy), mortality reduction (15%, 30%, 45%, and 60%), and regular follow-up for precancerous lesions (yes or no). Notably, the "mortality reduction" attribute in this study refers to the respondents' expected reduction extent of mortality because of UGC if they chose to participate in UGC screening.

Questionnaire Design

SAS (version 9.4) software was used to design the questionnaire. The combination of 5 attributes with 2 to 4 levels yielded 256 (ie, $4^3 \times 2^2$) possible scenarios using full factor design [30]. To minimize the respondents' burden, a smaller fractional factorial design was selected according to the D-efficiency criteria. The final design randomly generated 16 choice sets into 2 blocks with 8 choice tasks. For each choice task, 2 screening programs (options A and B) and an opt-out option (whether to choose to be screened in real life) were included. In addition, a rationality test (choice set 1=choice set 5) was included in the DCE to investigate residents' understanding of the questionnaire [31]. Table 1 presents an example of a discrete choice task.

The questionnaire also contained sociodemographic questions, including age, sex (male and female), educational level, and medical insurance. As a result, the questionnaire had 2 sections: the first section comprised sociodemographic questions and the second comprised information about the 9 DCE choice sets (Multimedia Appendices 1-4).

Table 1. Example of a discrete choice task[a].

Attributes	Option A	Option B
Out-of-pocket costs (CNY ¥ or US $)[b]	100 or 15.503	300 or 46.511
Screening interval	Every 2 years	Every year
Regular follow-up for precancerous lesions	Yes	No
Mortality reduction (%)	15	45
Screening technique	Endoscopy	Painless endoscopy
Which of these options would you prefer?	Option A	Option B
Would you screen as you choose in real life?	Yes	No

[a] See the study by Liu et al [12] for more details.

[b] CNY ¥6.45=US $1.00.

Pilot Study

Before the main study, we conducted a pilot test with residents of the target population to ascertain whether respondents could manage the length of the questionnaire and examine the validity, acceptability, and intelligibility of the questionnaire.

In total, 30 residents were recruited for the pilot test and interviewed by 8 trained investigators. Respondents were provided with descriptions of the attributes and levels and were given the opportunity to comment on the questionnaire design and layout. They found the questionnaire acceptable and easy to complete. No major changes were made to the questionnaires.

Sample Size and Data Collection

Calculating the optimal DCE sample size is complicated by the fact that it depends on the question format, complexity of the choice tasks, degree of heterogeneity in the target population, and need to conduct subgroup analyses [21,32]. However, there is a generally accepted rule of thumb proposed by Orem and Johnson [33,34] for calculating sample size:

The required sample size depends on the largest number of levels for any 1 attribute (*c*), number of alternatives per choice task (*a*), and number of choice tasks (*t*). Therefore, this questionnaire required at least 125 respondents [(500 × 4) / (8 × 2)] to estimate the main effect alone. Because 2 blocks were included in the design, there was a need for at least 300 respondents (125 × 2). Other studies found that the sample size of foreign DCE studies in the field of health care ranged from 150 to 1200, and 77% of the studies had a sample size 600, whereas most of the studies in China had a sample size below 600 [30,35,36]. Therefore, we combined the abovementioned literature reviews, the need for LCL model analysis, and an expected response rate of 20% to determine a total sample size of 1000 residents.

The final survey was conducted from April 1, 2021, to May 31, 2021. A total of 1000 permanent residents of the sample area were invited to participate in the survey, and they were assisted in completing the questionnaire by 8 trained investigators. A 2-step survey was conducted to interview the residents. In the first step, respondents were asked to describe their basic information, such as age, sex, and health insurance. In the second step, they were repeatedly asked to choose between 2 alternative options from the per-choice task (a total of 9 choice tasks).

Statistical Analysis

Overview

Statistical analyses were performed using Stata 16.0 software, with the commands *lclogit2* and *lclogitml2* for the analysis of the preference data. All attributes other than cost were treated as classification variables coded by dummy variables, whereas the cost parameter was modeled as a continuous variable to allow for WTP estimation. Sociodemographic data were summarized using descriptive statistics.

LCL Model and Model Fitting

The LCL model is the most commonly used preference heterogeneity model, assuming that preferences differ across respondents and that respondents can be grouped probabilistically according to distinct preference classes, each corresponding to a unique program preference [37,38]. It is based on random utility theory [39]:

$$U = ASC + \beta_1 \text{ (screening interval: every year)} + \beta_2 \text{ (screening interval: every 2 years)} + \beta_3 \text{ (screening interval: every 5 years)} + \beta_4 \text{ (follow-up: yes)} + \beta_5 \text{ (follow-up: yes)} + \beta_6 \text{ (mortality reduction: 30\%)} + \beta_7 \text{ (mortality reduction: 45\%)} + \beta_8 \text{ (mortality reduction: 60\%)} + \beta_9 \text{ (screening technique: endoscopy screening)} + \beta_{10} \text{ (screening technique: painless endoscopy screening)} + \beta_{11} \text{ (out-of-pocket costs)} + \varepsilon$$

where U refers to the utility of the respondents’ (in particular, latent class) choice of option across the different choice sets in the formal investigation stage; ASC (alternative specific constant) represents a fixed constant term (reflecting the screening attitudes of respondents in different classes), which was used to capture unobservable influences beyond attributes present in the choice sets; β provides quantitative information on the strength of preference for each attribute level; and ε is an unobservable random component. A positive β coefficient indicates that the attribute level combination is preferred relative to the reference level, whereas a negative β coefficient indicates the opposite. The higher the absolute value of β coefficient, the stronger is the preference for that level relative to the reference level. Then, using the expectation-maximization algorithm, we constructed an LCL model with different numbers of classes. The Akaike information criterion (AIC) and Bayesian information criterion (BIC) were used to compare the model fit, with lower AIC and BIC values indicating better models [40].

Parameter Estimation

Importance weights are a measure of the importance of an attribute relative to other attributes in the model for an individual’s preferences [41]. It is calculated by dividing the maximum utility of an attribute by the total utility of all the attributes.

WTP refers to the fee that residents of different classes were willing to spend or want to be compensated for the change in a certain attribute level in a specific program. To calculate the respondents’ WTP, the estimation of cost attributes was used as a measure of the marginal utility of money. The ratio of the value of the coefficient of other attribute levels to the negative of the cost attribute was calculated to elicit respondents’ WTP for contribution to a UGC-screening program.

From a policy perspective, the uptake rate is a useful output for estimating the effect of policies yet to be implemented, such as the change in the participation rate of rural residents with increasing screening costs [39]. The logit probability of choosing alternative *i* rather than alternative *j* is given by the following equation where *x* is a vector of the attribute coefficients:

With the level of attribute improving from *k* (baseline reference level) to *g*, the change in the uptake rate when choosing the baseline program is given by the following equation:

Ethics Approval

The Institutional Ethical Review Board of Shandong Cancer Hospital and Institute approved this study (reference no. SDTHEC201909001).

Results

Study Participation

A total of 959 of 1000 invited residents completed the questionnaire (for a response rate of 95.9%), of which 33 residents failed the consistency test. The sensitivity analysis indicated that there were no substantial differences in preference between the full sample and those who passed the consistency test. However, from the model fitting results, the likelihood, AIC, and BIC values of model 2 (removing samples of residents who did not pass the consistency test) were smaller than those of model 1, indicating that model 2 has a better fit (Multimedia Appendix 5). Considering the accuracy of the results, the 926 respondents who passed the consistency test were finally included in the preference estimation using the LCL model. Table 2 presents the characteristics of the 926 respondents. In all, 44.7% (414/926) of respondents were aged 50 to 59 years, and 95.9% (888/926) had a partner. Most respondents (743/926, 80.2%) had no family history of cancer, and 56.2% (520/926) had experience in cancer screening.

[b] Marital status: with a partner, reflecting that the individual is married and the spouse is alive; and without a partner, including single, divorced, and widowed.

[c] The per capita gross domestic product in 2020 in Linqu, Feicheng, and Dongchangfu was CNY ¥39,910, CNY ¥80,696, and CNY ¥50,726, respectively. The average exchange rate between US $ and CNY ¥ in 2021 was US $1=CNY ¥6.45.

[d] History of cancer in blood relatives, including parents, grandparents, siblings, uncles, aunts, and cousins.

Model Fitting Results

To select the appropriate number of classes, different numbers of classes were tested, from 2 to 5. The AIC and BIC values were used to select the final number of clusters that best fit the data. As presented in Table 3, there is a gradual decline in the values of AIC and BIC with an increase in the latent class number. When the number of latent classes is 4, the values reach a minimum (AIC=7140.989; BIC=7485.373) and subsequently increase. Accordingly, the 4-class model has the best fit for the data. The respondents’ preference heterogeneity was analyzed by constructing an LCL model with 4 classes.

Table 3. Results of model fitting under different classes.

Class	Observation, n	*df*	LL[a]	AIC[b]	BIC[c]
2	22,224	21	−4139.361	8320.722	8488.910
3	22,224	32	−3728.246	7520.492	7776.777
4	22,224	43	−3527.495	7140.989	7485.373
5	22,224	54	−3533.606	7175.213	7607.695

[a] LL: likelihood.

[b] AIC: Akaike information criterion.

[c] BIC: Bayesian information criterion.

Preferences Estimation

Table 4 shows that respondents' preferences varied at each attribute level, except for painless endoscopy. The detailed preference differences and the naming of different classes are as follows.

The residents (88/926, 9.5%) in class 1 responded negatively for UGC screening (β=3.372; *P*<.001), but they preferred lower screening costs. Theoretically, the respondents' negative screening attitudes can be changed once the cost of screening programs is reduced, so they were defined as the negative latent type (NLT).

Table 4. Parameters estimation results of latent class logit model.

[a] β coefficient: it reflects the values of each attribute level and the horizontal regression coefficient.

[b] Italicized *P* values denote a significance level at *P*<.05.

[c] ASC: alternative specific constant.

[d] Specific constant item for opt-out.

[e] Reference, reflecting the reference level for each attribute.

The residents (216/926, 23.3%) in class 2 responded most positively for UGC screening (β=−3.843; *P*<.001), and they preferred the program with every year, follow-up, 45% mortality reduction, and painless endoscopy, indicating that they had equal consideration in each attribute, so they were defined as the positive integrated type (PIT).

The residents (434/926, 46.8%) in class 3 responded positively for UGC screening (β=−2.165; *P*<.001), and they preferred follow-up, painless endoscopy, and lower out-of-pocket cost attribute levels over the screening interval and mortality reduction attributes. This group of people paid more attention to the comfort and experience of the screening process; therefore, they were defined as a positive comfortable type (PCT).

The residents (188/926, 20.3%) in class 4 had a neutral attitude toward UGC screening (β=.076; *P*>.05), and they preferred screening programs with shorter screening intervals, painlessness, follow-up, and a much lower risk of death regardless of the costs, indicating that they place more value on the quality and effect of the screening program, so they were defined as the neutral quality type (NQT).

Participants' WTP

Table 5 shows that NLT residents were willing to spend CNY ¥385.369 (US $59.747) to improve screening technique, that is, to upgrade endoscopy to painless endoscopy; PIT residents had more WTP for screening every year (CNY ¥65.966 [US $10.227]) compared with once in a lifetime, and they should be compensated CNY ¥41.776 (US $6.477) if there is no regular follow-up for precancerous lesions; PCT residents had the highest WTP for painless endoscopy (CNY ¥1946.482 [US $301.780]), and the participants should be compensated CNY ¥249.753 (US $ 38.721) if there is no follow-up after screening in theory. For the NQT population, there was no statistically substantial difference in costs attribute.

Table 5. Results of participants' willingness to pay (WTP).

[b] Reference, reflecting the reference level in each attribute; WTP reflects residents' willingness to pay for a certain screening program.

Personal Characteristics Influencing Factors

Sociodemographic characteristics influencing factors are presented in Table 6. Class 4 was automatically identified as the reference class in the LCL model. Accordingly, the residents living in Linqu were included in class 1 easily, whereas male respondents and those with an experience of UGC screening were more likely to be excluded from class 1. Residents who had a family history of cancer were more likely to be assigned to class 2 than those without a family history. Compared with female respondents, male respondents were less likely to be included in class 3, and residents aged 60 to 69 years were more likely to be included in class 3.

Table 6. Personal characteristics influencing factors.

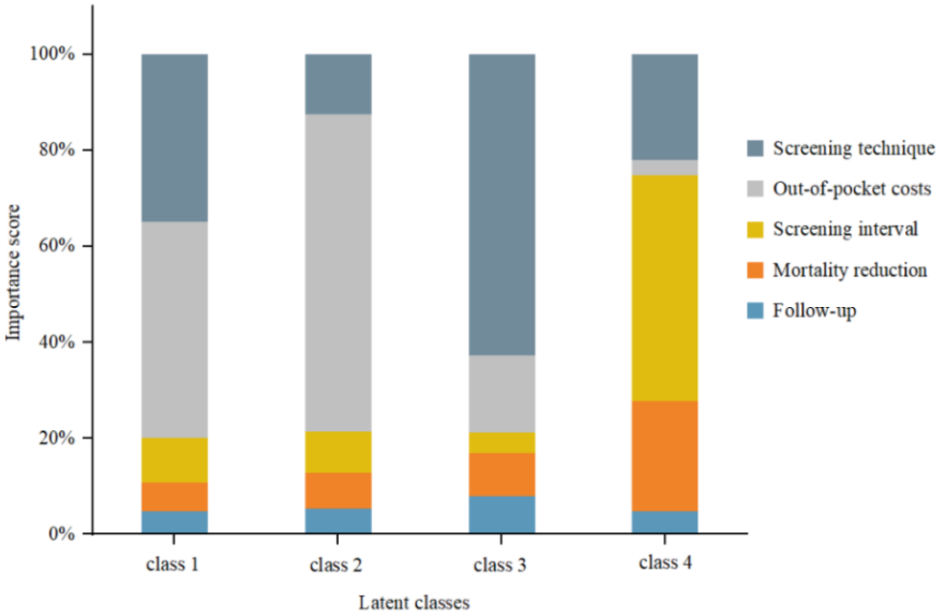
[e] Screening for cancer means attending endoscopy screening at any time in the past.

Relative Importance of Attributes

As presented in Figure 1, we calculated the importance weights for the 5 attributes in different classes. The out-of-pocket cost attribute was the factor that most influenced class 1 and class 2 residents' willingness to participate in UGC screening (45.04% and 66.04% importance weights, respectively). The screening technique was the most important for class 3 respondents (62.56% importance weight). The screening interval was the most important for class 4 residents (47.05% importance weight) and the out-of-pocket cost was not important (3.07% importance weight).

Figure 1. Relative importance of attributes in different classes. Relative scores expressed in percent as weighted out of 100.

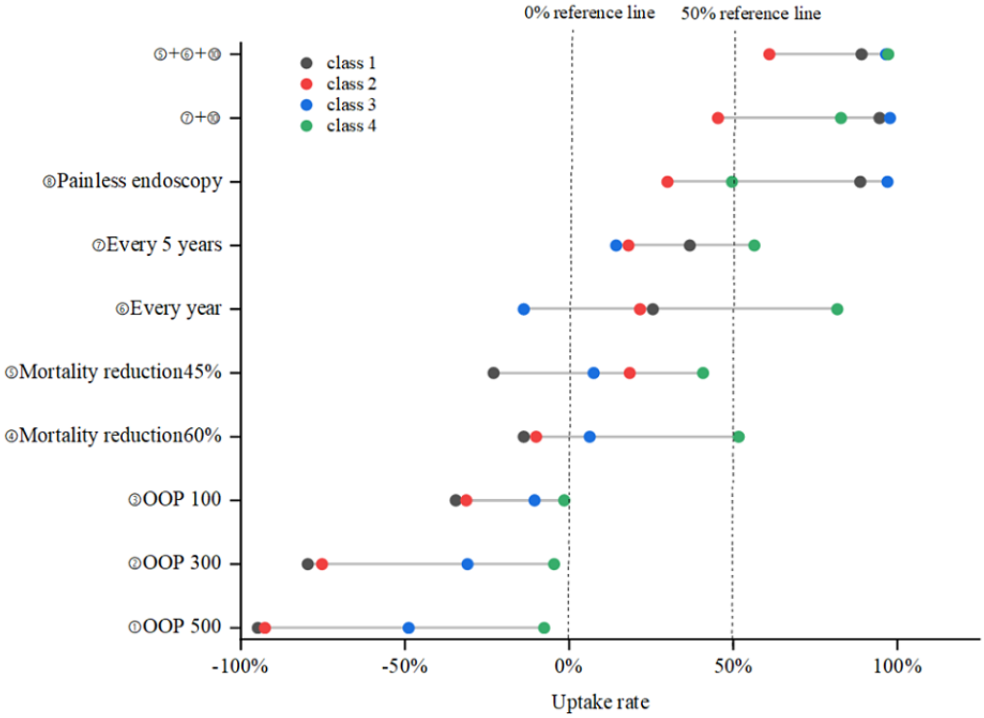


Uptake Rate

Figure 2 depicts the change in choice probability for different classes of respondents, as attributes and levels were changed at the baseline level (baseline: once in a lifetime, follow-up, 15% mortality reduction, endoscopy, and CNY ¥0). The screening uptake rate of residents in classes 1, 2, and 3 dramatically decreased by ≥48% (94.84%, 92.67%, and 48.91%, respectively) when the out-of-pocket costs increased to CNY ¥500 (US $71.903), whereas the uptake rate in class 4 remained constant.

For class 1 and class 3 residents, the participation rate was strongly driven by painless endoscopy, with an increase of 88.66% and 96.97%, respectively. Among residents in class 4, the participation rate would increase by 81.69% if the screening interval was improved from once in a lifetime to every year. The expected uptake rate for the best UGC-screening program (CNY ¥0, 45% mortality reduction, every year screening, and painless endoscopy) would increase by 89% and above in classes 1, 3, and 4, and class 2 residents' participation rate would remain ≥60%.

Figure 2. Uptake rate of residents in different classes. Null percent and 50% reference line represents the reference in uptake rate as 0% and 50%, respectively. The horizontal comparison between points can see the change of the participation rate of residents in different classes under the same attribute level, and the longitudinal comparison between points can show the change of participation rate of individuals in the same class under the change of different attribute levels. OOP: out-of-pocket costs.



Discussion

Principal Findings

To the best of our knowledge, this is the first study to explore public preference heterogeneity for a UGC-screening program by classifying the population. This study is a continuation and extension of our previous study [12]. We used novel analytic methods to explore population preference heterogeneity and found that preference heterogeneity exists when residents choose to participate in UGC-screening programs. Preference heterogeneity was explorable: the target population was divided into 4 categories, including NLT, PIT, PCT, and NQT. Residents in different classes had different preferences for the selected attributes and attribute levels, except for the screening technique attribute (preferably painless endoscopy). On the basis of this, we found that the optimal screening strategy with free, 45% mortality reduction, screening every year, and painless endoscopy could ensure that the screening participation rate of class 1, class 3, and class 4 residents reached ≥89%, and the screening uptake rate of residents in class 2 could reach 60.98%.

Nearly half (434/926, 46.8%) of the respondents were divided into the PCT group, indicating that they paid more attention to their experience and comfort levels regarding the screening procedure rather than the outcome. This is consistent with previous findings, in which the author found that residents' screening participation rate was significantly associated with severe pain and endoscopy experience [13]. Similarly, a DCE study of immediate family members with UGC indicated that participants preferred a pain-none program, increasing the participation rate by 58.85% compared with the reference level (pain-mild) [42]. Further analysis revealed that the uptake rate of residents of different classes was mostly driven by painless endoscopy. Accordingly, if painless endoscopic screening technology can be widely promoted, it will be able to satisfy the screening needs and preferences of residents in different categories, greatly improving population screening enthusiasm and participation rate. Areas with a good economic level and sufficient screening resources should take painless endoscopy as the essential element, paying more attention to the population screening experience.

Compared with other classes, NQT residents valued the screening quality and outcome most, such as screening interval and mortality reduction attributes (47.05% and 23% importance weights, respectively), and their screening compliance increased once the accuracy of endoscopy was improved. An unlabeled DCE assessing the attributes of an optimal esophageal adenocarcinoma screening test found that test accuracy generally outweighs the importance of potential pain and discomfort [13]. Consistent with our results, various DCEs evaluating preferences for breast, cervical, and colorectal cancer screening reported that attributes related to test accuracy were more important than attributes related to the screening procedure [43-45]. Although these studies targeted different cancer types and populations, their results provide face validity for the results of this study. This study provides an important reference for the clinical development of scientific and effective screening. Improving the accuracy of screening techniques and health care services is the main way to satisfy residents' growing demand for health care services and to increase their participation rate in a UGC screening program.

All residents, except those in class 4, strongly preferred the UGC-screening program with lower costs, particularly for the residents in class 1, and their negative attitude will be theoretically improved if the screening fee is reduced. These results are consistent with a recent South Australian study in which the uptake rate of participants decreased by 48% after the screening fee was changed from A$0 to A$500 (US $0 to US $328.62) [24]. Li et al [42] also pointed out that the probability of screening program selection increased by 11.30% when the cost changed from CNY ¥600 (US $86.28) to CNY ¥200 (US $28.76). Other studies regarding lung cancer screening and colorectal cancer screening found that cost-related attributes had an important impact on the residents' participation rate, and they all preferred the screening program with a lower cost [18,46]. However, it is unrealistic to provide a nationwide free UGC-screening strategy because of the large population size and limited medical resources. These results provide support and guidance for policy makers to explore the multifinancing and cost sharing of different interventions.

Only 9.5% of the respondents had a negative response for UGC screening, which is consistent with the screening status in rural China. These residents did not proactively seek medical attention or predisease screening influenced by their family income and the traditional concept of medical treatment. Other studies have also pointed out that some residents do not think it is necessary to screen before the onset of noticeable symptoms [47]. Therefore, policy makers should strengthen primary prevention and emphasize the importance of screening for cancer to promote more high-risk groups to take the initiative to screen, reduce their morbidity and mortality, and reduce the socioeconomic burden.

Differences in health care delivery systems across countries may affect public-related medical needs and preferences. A label DCE study conducted in the Netherlands indicated that respondents preferred video capsule over saliva swab and least preferred endoscopy, but a study performed in China showed that respondents have a strong preference for endoscopy [12,22]. In addition, we found that the population in different countries has a common preference for out-of-pocket cost attributes, preferring free or less-expensive screening programs [13,42,48,49]. Notably, in this study, we did not investigate the preference differences between health care systems in China and other countries. Accordingly, caution should be exercised when applying our results to other countries with different health care systems.

Limitations

This study has some limitations that should be considered. First, DCE as a stated preference method differs from revealed preferences (ie, a difference between what people say they will choose and what they actually choose) [50]. The revealed preferences should be examined after implementing the UGC-screening programs. Second, the development of UGC-screening programs depends not only on the population uptake rate but also on the cost-effectiveness of those programs.

In this study, we mainly analyzed the residents' screening uptake rate. However, other studies have reported that UGC screening is always more cost-effective than not screening [7,8]. Third, the respondents were selected from Shandong Province and interviewed during a specific period; thus, the results need to be carefully applied to all rural residents in China and other resource-limited countries.

Conclusions

Most rural residents have a positive attitude toward UGC screening, but they expressed preference heterogeneity in selected attributes and levels, except for painless endoscopy. The optimal UGC-screening program that is free with 45% mortality reduction, screening every year, and painless endoscopy should be implemented to maximize participation rates if resources permit. In areas with limited health resources, the population uptake rate can be controlled by adjusting steerable screening attributes such as screening intervals and out-of-pocket costs. In addition, differentiated screening programs suitable for residents belonging to different categories should be developed within certain regions. These findings will provide input for the design of a UGC-screening strategy that incorporates the public's preference heterogeneity to improve their participation rate and provide practical evidence for other resource-limited countries with high UGC incidence and mortality.

Acknowledgments

The authors wish to thank all the residents, collaborators, and graduate students who participated in the field survey and discrete choice experiment study, as well as the experts and work staff in the sample regions who assisted with participant recruitment and data collection.

Abstract

Background: Metabolic syndrome (MetS) is a constellation of risk factors increasingly present in the world's population. People with this syndrome are at an increased risk of cardiovascular disease and type 2 diabetes mellitus. Moreover, evidence has shown that it affects different organs. MetS and its risk factors are independently associated with impaired lung function, which can be quantified through spirometric variables.

Objective: This study aims to determine whether a high number of MetS criteria is associated with increased lung function decline.

Methods: We conducted a descriptive cross-sectional study with a random sample of 1980 workers. Workers with acute respiratory pathology (eg, influenza), chronic respiratory pathology (eg, chronic bronchitis), or exposure to substances harmful to the lungs (eg, organic and inorganic dust) were not included. MetS was established based on harmonized criteria, and lung function was assessed according to spirometric variables. On the basis of these, classification into restrictive lung disease (RLD), obstructive lung disease, and mixed lung disease (MLD) was performed. In addition, the association between MetS and lung function was established based on analysis of covariance, linear trend analysis, and multiple linear regression.

Results: MetS was associated with worse lung function according to all the spirometric parameters analyzed (percentage of predicted forced expiratory volume in 1 second: mean 83, SD 13.8 vs mean 89.2, SD 12.8; $P<.001$ and percentage of predicted forced vital capacity: mean 85.9, SD 11.6 vs mean 92, SD 11.3; $P<.001$). Moreover, those diagnosed with MetS had a higher prevalence of lung dysfunction (41% vs 21.9%; $P<.001$), RLD (23.4% vs 11.2%; $P<.001$), and MLD (7.3% vs 2.2%; $P<.001$). Furthermore, an increasing number of MetS criteria was associated with a greater impairment of pulmonary mechanics ($P<.001$). Similarly, with an increasing number of MetS criteria, there was a significant linear trend ($P<.001$) in the growth of the prevalence ratio of RLD (0 criteria: 1, 1: 1.46, 2: 1.52, 3: 2.53, 4: 2.97, and 5: 5.34) and MLD (0 criteria: 1, 1: 2.68, 2: 6.18, 3: 9.69, and 4: 11.37). Regression analysis showed that the alteration of all MetS risk factors, adjusted for various explanatory variables, was significantly associated with a worsening of spirometric parameters, except for forced expiratory volume in 1 second/forced vital capacity.

Conclusions: The findings have shown that an increase in cardiometabolic risk factors is associated with a more significant worsening of spirometric variables and a higher prevalence of RLD and MLD. As spirometry could be a crucial tool for monitoring patients at risk of developing chronic pathologies, we conclude that this inexpensive and easily accessible test could help detect changes in lung function in patients with cardiometabolic disorders. This highlights the need to consider the importance of cardiometabolic health in lung function when formulating public health policies.

Introduction

Background

The impact of noncommunicable chronic diseases worldwide is increasingly important. Their prevalence and social and economic impact have increased in the recent years, placing them at the center of public health interest [1-4].

Among the most worrying pathological conditions, metabolic syndrome (MetS) stands out because it is a risk factor for cardiovascular disease and type 2 diabetes mellitus (DM), which are, in turn, the noncommunicable chronic diseases with the most significant impact worldwide [5,6]. MetS, according to the harmonized definition, is characterized by the comorbid presence of ≥3 of the following risk factors: dysglycemia, increased blood pressure, hypertriglyceridemia, abdominal obesity, and altered high-density lipoprotein (HDL) cholesterol levels [6]. The prevalence of MetS exceeds 30% in several countries and is expected to increase in the coming years [7,8]. All these make MetS one of the public health challenges of the 21st century; therefore, early detection is essential to avoid associated complications, even at an early age [9,10].

Lung Dysfunction and MetS

In addition to cardiovascular pathologies and type 2 DM, MetS has been associated with alterations in other systemic organs, most notably alterations in lung function [11,12]. For example, researchers have observed that MetS is associated with the worsening of parameters measuring pulmonary mechanics, leading to respiratory diseases (asthma, chronic obstructive pulmonary disease, pulmonary hypertension, etc) [12-14]. Several MetS-related lung pathologies are currently the most prevalent, have significant morbidity and mortality, and are a major public health concern [15,16]. This link could be explained by insulin resistance, one of the main pathophysiological mechanisms of MetS, although its involvement in the modification of pneumocyte function is not yet clear [17-19].

Parameters for pulmonary function status are obtained through spirometry, which is the test of choice to assess lung function [20]. It is simple to execute for those who are well instructed and is routinely performed by health care professionals, for example, in primary care or during health examinations of workers [21,22]. A comparison of the values obtained in the test with the theoretical values, estimated from validated formulas (according to age, sex, height, etc), provides information on the lung condition [23,24]. It is, therefore, an essential public health tool for primary, secondary, and tertiary prevention of pathologies with a high impact on the population [25].

In this context, health care professionals, who play an essential role in disease prevention and health promotion, have a tool that, when used efficiently, would help to detect problems beyond pulmonary deterioration [26]. Regarding the latter, given that the onsets of MetS is reflected in spirometric variables, and its risk factors also do so independently, it is relevant to know whether a progressive deterioration of lung function is caused by the individual presence of the risk factors characterizing MetS. Thus, through public health programs (hospitals, communities, workplaces, etc) that include the study of these parameters from the perspective of cardiometabolic alterations, it would be possible to detect the risk factors and treat them early to prevent the development of MetS.

Therefore, the researchers hypothesized that the increase in the number of MetS components is associated with a greater decline in spirometric parameters and, therefore, an alteration in lung function. On this basis, the objective of this study was to determine how spirometric variables are affected because of the increase in the number of the MetS risk factors present.

Methods

Design, Population, and Sample

A descriptive cross-sectional study was conducted in the working population of the Cordoba City Council (Spain). The minimum sample size estimated was 1685 workers based on an expected prevalence of MetS of 14.9%, a power of 80%, a precision of 1.5%, and a confidence of 95%. The sample was randomly selected from workers who underwent a health examination between 2015 and 2019 at the occupational health unit of the City Council. All employees of the Cordoba City Council (blue-collar workers and white-collar workers) undergo an annual occupational health test. Each of the measurements carried out is stored in a computer program of the occupational health unit, which allows for the subsequent extraction of anonymized data. For this study, the number of workers selected was increased by 20% over the minimum sample size calculated to compensate for losses owing to noncompliance with the eligibility criteria.

Workers who were diagnosed with any acute respiratory pathology (influenza, common cold, etc) or chronic pulmonary disease (chronic bronchitis, emphysema, pneumonia, chronic obstructive pulmonary disease, etc) and those who could not perform the spirometry test according to the protocol were excluded from the study. In addition, the occupational risk of the positions held by the workers was assessed, and it was confirmed that there was no exposure to organic and inorganic dust or substances of high molecular weight that could lead to occupational lung pathologies or affect, transiently, the spirometry test results.

Variables and Measures

Lung function was studied through spirometric parameters: forced expiratory volume in 1 second (FEV1; in L), forced vital capacity (FVC; in L), and the FEV1/FVC ratio. To determine the status of pulmonary function, the expected values of FEV1 and FVC were estimated and related to those obtained in spirometry by calculating the percentage of predicted FEV1 (FEV1%) and percentage of predicted FVC (FVC%) [24].

In addition, the percentage reductions of FEV1 and FVC with respect to the theoretical or expected values of FEV1 and FVC were calculated:

FEV1 reduction (%) = ([FEV1 – expected FEV1]/FEVI) × 100 **(1)**

FVC reduction (%) = ([FVC – expected FVC]/FVC) × 100 **(2)**

Workers were also categorized according to their dysfunctional pattern [27]: normal: FEV1/FVC>0.7 and FVC%>0.8; restrictive lung disease (RLD): FEV1/FVC>0.7 and FVC%<0.8; obstructive lung disease (OLD): FEV1/FVC<0.7 and FVC%>0.8; and mixed lung disease (MLD): FEV1/FVC<0.7 and FVC%<0.8. In addition, the aforementioned categories were grouped into a new dichotomous variable with the following values: normal and lung dysfunction (encompassing RLD, OLD, and MLD).

The spirometry test was performed using the DATOSPIR 120 C spirometer (Silbemed) and following the recommendations of the Spanish Society of Pneumology and Thoracic Surgery [27]. Workers were instructed not to use bronchodilators during the previous 6 to 48 hours (depending on the drug), to avoid caffeine during the previous 8 hours, not to smoke during the previous 24 hours, avoid alcohol and sedatives during the last 4 hours, and not to exercise during the previous 30 minutes. During the measurement, the worker wore a nose clip and was seated upright with his back against the backrest. Once the posture was correct, the worker was asked to inhale as much air as possible and then exhale as fast and hard as possible until they were told to stop. Workers had to perform at least 3 valid tests, with the highest spirometric values being chosen. The researchers considered a test valid when the test had a rapid start (back-extrapolated volume <5% of the FVC) and was performed without hesitation, involved continuous expiration for a duration not <6 seconds, had no abrupt end (last changes in volume lower than 0.025 L for ≥1 s), and had no anomalies in the technique (cough, new inhalation, among others). Overall, 2 or 3 acceptable maneuvers were necessary for spirometry test's interpretation in which the difference between the 2 best FVC and FEV1 measures was not >0.2 L.

Moreover, risk factors included in the harmonized criteria for the diagnosis of MetS were considered: waist circumference (WC) ≥102 cm in men and ≥88 cm in women, triglycerides ≥150 mg/dL, HDL cholesterol <50 mg/dL in women and <40 mg/dL in men, blood pressure ≥130/85 mm Hg or being on treatment for high blood pressure and fasting glucose ≥100 mg/dL, being on antidiabetic treatment, or diagnosed with DM. Thus, the presence of ≥3 of these risk factors implies a diagnosis of MetS [6].

The independent variables collected were age (years), sex (female and male), smoking status (nonsmoker, ex-smoker, and smoker), physical activity level (light, moderate, and heavy), weight (kg), height (cm), BMI (kg/m^2), WC (cm), hip circumference (cm), body fat percentage (Equation Córdoba for Estimation of Body Fat [28]), waist to hip ratio, waist to height ratio, systolic blood pressure (mm Hg), diastolic blood pressure (mm Hg), fasting plasma glucose (mg/dL), HDL cholesterol (mg/dL), and triglycerides (mg/dL). In addition, the diagnoses of DM (yes or no) and hypertension (yes or no) were collected.

Anthropometric variables were measured according to international recommendations [29]. Weight and height were collected using an Atlántida S11 stadiometer and scale (Básculas y Balanzas Añó-Sayol), with an accuracy of 0.1 kg and 0.1 cm, respectively. BMI was calculated based on these variables, and workers were categorized into normal weight, overweight, and obese groups, as proposed by the World Health Organization. WC was measured at end-expiration at the midpoint between the last rib and the iliac crest. Hip circumference was assessed at the most prominent point of the buttocks. Both variables were measured using a flexible tape, with the worker standing and their feet placed together. Blood pressure was measured according to the recommendations of the manual of arterial hypertension in primary care clinical practice [30], with the patients seated, using a calibrated digital sphygmomanometer (Omron M3, Omron Healthcare). All measurements were performed by specialized personnel to minimize the coefficient of variation. Each measurement was repeated 3 times, and the mean was calculated. Finally, physical activity was estimated in metabolic equivalents using the International Physical Activity Questionnaire.

Ethics Approval

The study protocol complied with the Declaration of Helsinki for medical research involving human participants and was approved by the Andalusian Biomedical Research Ethics Committee (4427/Acta number 295).

Informed Consent

All participants were informed, verbally and in writing, about the objectives of the health study. The researchers obtained informed consent following the current regulations.

Statistical Analysis

Quantitative variables were presented as mean and SD, and qualitative variables were presented as absolute frequencies, percentages, and prevalence ratios. The goodness of fit of the quantitative variables to a normal distribution was studied using a Kolmogorov-Smirnov test with Lilliefors correction.

Hypothesis testing was performed with the 2-tailed Student *t* test for 2 means; *z* tests for independent proportions; and chi-square and Fisher exact tests, when necessary, for qualitative variables. In addition, linear trend tests, analysis of covariance, and multiple linear regression were used to determine the effect of other factors and covariates on the variation in spirometric parameters.

For all statistical analyses, an α error probability of <5% was accepted, and CIs were calculated at 95%. SPSS Statistics (version 22.0; IBM Corp) and EPIDAT 4.2 (Department of Sanidade, Xunta de Galicia) were used for statistical analysis.

Results

Description of the Sample

Of the 2069 randomly selected workers, 168 (8.12%) were excluded because they were diagnosed with an acute respiratory pathology or a chronic pulmonary pathology or were exposed to compounds that could alter their lung function, and in 41 (1.98%) other workers, it was impossible to assess MetS. Finally, 44 (2.13%) other workers were excluded because their clinical records did not include some spirometric variables. Thus, the final sample size was 1816.

The age of the sample ranged from 18.8 to 67 years. The prevalence of MetS was 18.3% (95% CI 16.5%-20.1%), being significantly higher in men (20.6%, 95% CI 18.5%-23.4%) than in women (16%, 95% CI 13.8%-18.5%; *P*<.001). BMI was higher among those with MetS (mean difference [MD] 7.1 kg/m^2; *P*<.001). This group showed a higher prevalence of overweight and obesity (95.9% vs 49.3%; *P*<.001). In addition, in the MetS group, higher abdominal adiposity was observed according to the following parameters: (1) WC (MD 19.5 cm; *P*<.001), (2) waist to hip ratio (MD 0.1; *P*<.001), and (3) waist to height ratio (MD 0.12; *P*<.001).

All the other variables analyzed showed differences between those with and those without MetS, except for height (MD 0.2 cm; *P*=.73). Table 1 summarizes the main variables according to the presence or absence of MetS.

Table 1. Characteristics of the sample according to the presence of metabolic syndrome (MetS).

Variables	Total (n=1816)	With MetS (n=329, 18.1%)	Without MetS (n=1487, 81.9%)	*P* value[a]

[a] With MetS versus without MetS.

[b] WHR: waist to hip ratio.

[c] WHtR: waist to height ratio.

[d] HDL: high-density lipoprotein.

[e] SBP: systolic blood pressure.

[f] DBP: diastolic blood pressure.

[g] HBP: high blood pressure.

[h] DM: diabetes mellitus.

[i] FEV1: forced expiratory volume in 1 second.

[j] FEV1%: percentage of predicted forced expiratory volume in 1 second.

[k] FEV1 reduction (%) = ([FEV1 – expected FEV1]/FEV1) × 100.

[l] FVC: forced vital capacity.

[m] FVC%: percentage of predicted forced vital capacity.

[n] FVC reduction (%) = ([FVC – expected FVC]/FVC) × 100.

MetS and Lung Function (Spirometric Parameters)

In relation to lung function, workers with MetS showed lower values of FEV1 (MD 0.3 L; *P*<.001), FVC (MD 0.32 L; *P*<.001), and FEV1/FVC ratio (MD 0.015; *P*<.001). Similarly, higher proportions of FEV1/FVC<0.7 (17.6% vs 10.8%; *P*<.001) and FVC%<0.8 (30.7% vs 13.4%; *P*<.001) were found among participants with MetS. This translated into the presence of MetS being associated with a higher prevalence of lung dysfunction (41% vs 21.9%; *P*<.001). Table 1 provides more detailed results.

Individual MetS Criteria and Lung Function (Spirometric Parameters)

Several adjusted multiple linear regression models are presented in Table 2, where the dependent variables, spirometric variables, are represented in the rows, and the independent variables are represented in the columns. The adjusted multiple linear regression study confirms that a quantitative modification of the variables related to MetS criteria (increased WC, elevated plasma triglycerides, raised blood pressure, increased blood glucose, and decreased HDL) causes an alteration of the spirometric variables (Table 2). Specifically, it is observed that an increase in abdominal adiposity and insulin resistance–related variables lead to a significant decrease in FVC and FEV1. Finally, MetS was associated with reductions of 0.220 L and 0.277 L in FEV1 and FVC, respectively.

Table 2. Multiple linear regression for spirometric parameters (n=1816)[a].

[a] The variables in the rows are the dependent variables, and the variables in the columns are the independent variables. Models were adjusted by age, height, smoking habit, sex, and physical activity (dichotomized: light and active [moderate and heavy]).

[b] HDL: high-density lipoprotein.

[c] FEV1: forced expiratory volume in 1 second (L).

[d] FEV1%: percentage of predicted forced expiratory volume in 1 second.

[e] FEV1 reduction (%) = ([FEV1 − expected FEV1]/FEV1) × 100.

[f] FVC: forced vital capacity (L).

[g] FVC%: percentage of predicted forced vital capacity.

[h] FVC reduction (%) = ([FVC – expected FVC]/FVC) × 100.

Number of MetS Criteria and Lung Function (Spirometric Parameters)

Table 3 shows the effect of the spirometric variables as a function of the number of MetS components.

FVC and FVC% showed a decrease in values with an increasing number of MetS criteria. However, the differences found between having 1 or 2 criteria (FVC: MD 0.046 L, *P*=.16; FVC%: MD 1.330, *P*=.08; FVC reduction: MD 1.481%, *P*=.13), 3 or 4 criteria (FVC: MD 0.107 L, *P*=.06; FVC%: MD 2.066, *P*=.13; FVC reduction: MD 3.257%, *P*=.07), 3 or 5 criteria (FVC: MD 0.165 L, *P*=.15; FVC%: MD 4.322, *P*=.21; FVC reduction: MD 7.228%, *P*=.11), and 4 or 5 criteria (FVC: MD 0.058 L, *P*=.16; FVC%: MD 2.256, *P*=.53; FVC reduction: MD 3.971%, *P*=.40) were not significant in any of the variables studied. Nevertheless, it is worth noting that the percentage reduction of FVC from what was expected showed a clear linear downward trend, with an MD of 16 (SD 20) percentage points between those with 0 criteria and those with 5 criteria (*P*<.001; Figure 1). These results were also observed for FEV1, FEV1%, and FEV1 reduction. These findings indicate that an increase in the number of MetS criteria is associated with a significant reduction in lung function.

Table 3. Lung function according to the number of metabolic syndrome criteria.

Variables	Number of components, mean (SD)						*P* value[a]
	0 (n=540)	1 (n=554)	2 (n=393)	3 (n=223)	4 (n=95)	5 (n=11)

FEV1/FVC	77.7 (6.6)	77.4 (6.5)	77 (6.5)	77.3 (6.5)	77.1 (6.5)	77.8 (6.5)	.73

[a] Analysis of covariance was adjusted for sex, age, height, smoking habits, and physical activity (dichotomized: light and active [moderate and heavy]).

[b] FEV1: forced expiratory volume in 1 second (L).

[c] The presence of the same symbol in the same row indicates that there were no significant differences between pulmonary function and the number of components.

[d] The presence of the same symbol in the same row indicates that there were no significant differences between pulmonary function and the number of components.

[e] FEV1%: percentage of predicted forced expiratory volume in 1 second.

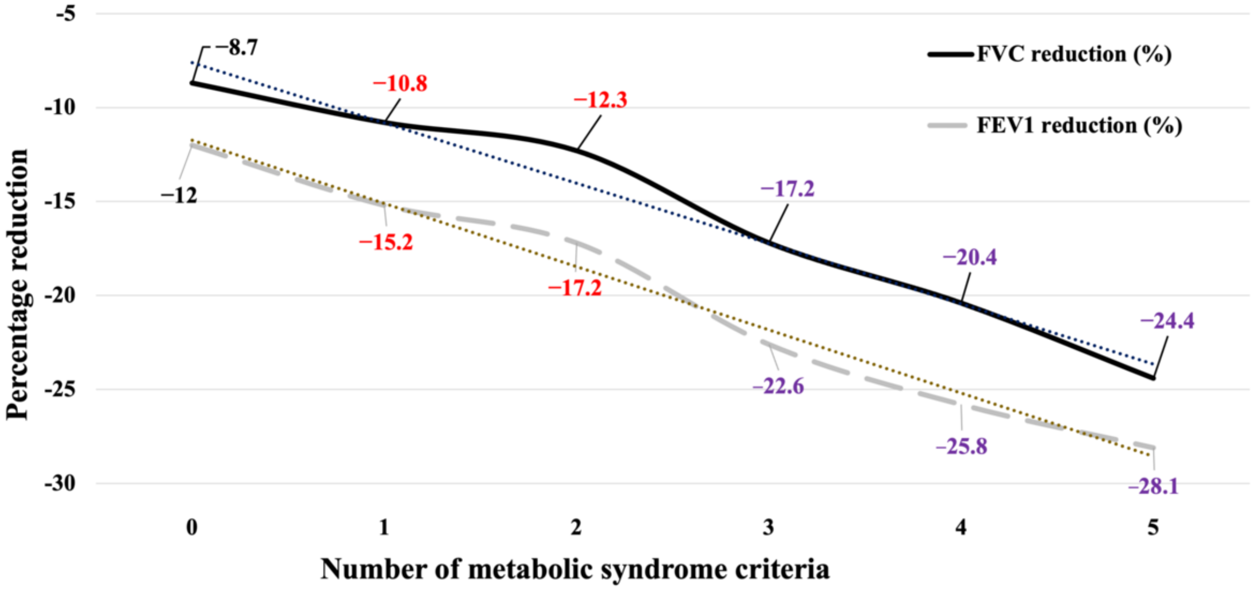
[f] FEV1 reduction (%) = ([FEV1 − expected FEV1]/FEV1) × 100.

[g] FVC: forced vital capacity (L).

[h] FVC%: percentage of predicted forced vital capacity.

[i] FVC reduction (%) = ([FVC − expected FVC]/FVC) × 100.

Figure 1. Percentage reductions of forced expiratory volume in 1 second (FEV1) and forced vital capacity (FVC) according to number of metabolic syndrome criteria. Same color means that there were no significant differences between values within a variable.



Number of MetS Criteria and Lung Dysfunction

This effect on pulmonary function variables was reflected in the distribution of the prevalence of respiratory disorders. In other words, the alteration of the spirometric values detailed in the *MetS and Lung Function (Spirometric Parameters), Individual MetS Criteria and Lung Function (Spirometric Parameters)* and *Number of MetS Criteria and Lung Function (Spirometric Parameters)* sections has clinical repercussions in the appearance of pathological respiratory patterns. In this respect, the proportion of participants who presented FEV1/FVC<0.7 (0: 8.9%, 1: 11.2%, 2: 12.7%, 3: 16.6%, 4: 21.1%, 5: 9.1%; *P*=.006) and FVC%<0.8 (0: 9.3%, 1: 14.4%, 2: 17.6%, 3: 28.7%, 4: 33.7%, 5: 45.5%; *P*<.001) was significantly higher among those with the most risk factors. This trend was also observed in the rates of lung dysfunction (0: 17.4%, 1: 23.6%, 2: 25.7%, 3: 38.1%, 4: 46.3%, 5: 45.5%; *P*<.001), in RLD (0: 8.5%, 1: 12.5%, 2: 13%, 3: 21.5%, 4: 25.3%, 5: 45.5%; *P*<.001), and in MLD (0: 0.7%, 1: 2%, 2: 4.6%, 3: 7.2%, 4: 8.4%, 5: 0%; *P*<.001) but not in OLD (0: 8.1%, 1: 9.2%, 2: 8.1%, 3: 9.4%, 4: 12.6%, 5: 9.1%; *P*=.79). Table 4 shows the prevalence ratios as a function of the number of components. The results show a significant linear increase in the prevalence ratio of all the pulmonary disorders studied with an increasing number of components (*P*<.001), except for OLD.

Table 4. Prevalence ratios for lung disorders according to the number of metabolic syndrome criteria.

Variables	Number of components, prevalence ratios (95% CI)						*P* value[a]	*P* value[b]

[a] Chi-square test.

[b] Linear trend.

[c] FEV1: forced expiratory volume in 1 second (L).

[d] FVC: forced vital capacity (L).

[e] Reference category in statistical analysis.

[f] FVC%: percentage of predicted forced vital capacity.

[g] RLD: restrictive lung disease.

[h] OLD: obstructive lung disease.

[i] MLD: mixed lung disease.

Discussion

Principal Findings

This study aimed to identify the association between MetS and changes in spirometric parameters and precisely determine whether a higher number of MetS components is related to a worse state of lung function.

The results show that the presence of MetS is associated with worse lung function. In this study, participants with MetS showed lower mean FEV1, FEV1%, FVC, and FVC%. These findings were confirmed when adjusting for different explanatory variables, showing a clear effect of MetS on different spirometric parameters. In the case of FEV1/FVC, although its mean was lower in the MetS group, this association was lost when adjusting for other independent variables. This trend has been evidenced in populations of different ethnicities across cross-sectional and longitudinal designs, although discrepancies in FEV1/FVC have been observed [31-36]. Kim et al [32] showed that after 6 years of follow-up, participants who had MetS at the beginning of the study or developed MetS during the study had a greater decline in FVC and FEV1 than those who were healthy. However, the difference was not significant in the case of FEV1. Ford et al [33] found that participants with MetS had lower FEV1, FEV1%, FVC, and FVC% and higher FEV1/FVC.

These changes in spirometric parameters have clinical relevance, as they translate into the development of lung dysfunction. However, there are inconsistencies in the type of alteration most present in participants with MetS. Some authors state that OLD is more prevalent [12,34,37], whereas others show that RLD is predominant [12,33,36,38-40]. The results of our study show a higher proportion of participants with FEV1/FVC<0.7 and FVC%<0.8 among those diagnosed with MetS. This was reflected in a higher prevalence of lung dysfunction, RLD, and MLD, with no difference observed in OLD. In contrast to our results, Buchman et al [34] found that among men and women aged >60 years with MetS, there was no higher prevalence of FEV1/FVC<0.7 compared with those without MetS. However, we did not analyze by age group, so we do not know what happens specifically in those aged >60 years. Scarlata et al [39] observed that participants with RLD had 3-fold higher odds of MetS (95% CI 1.16-7.89) than those with normal spirometry, similar to findings by other authors [33]. Inconsistencies in the obstructive pattern may be (1) because some studies do not consider the mixed pattern, which may increase the percentage of patients with an obstructive pattern [37] or (2) because of the noninclusion of the restrictive pattern in the study [34]. However, it seems clear that there is a greater tendency for the presence of RLD in people with MetS [12,33,36,40].

Despite the clear association of MetS with lung dysfunction, the pathophysiological process remains unclear. However, several mechanisms that could be crucial in the process have been described, such as insulin resistance and low-grade inflammation, both of which are present in MetS [17,18,41], which is reflected in the lungs through different markers [42]. Therefore, it seems reasonable to state that damage in other body systems, identified according to MetS risk factors, is associated with lung damage [41]. In this regard, our results have shown that each MetS component (WC, triglycerides, HDL, glucose, and high blood pressure) can significantly modify each spirometric parameter once adjusted for explanatory variables. This fact has also been evidenced by other authors [37,38,43,44].

The accumulation of systemic damage, measured by the number of MetS criteria, has been associated with more significant organ damage [45-48]. In this regard, we have shown that having a higher number of MetS criteria was related to a significantly worse lung function (spirometric parameters, except for FEV1/FVC), although no statistically significant differences were found between some analysis groups defined by the number of MetS criteria. In addition, linear percentage reductions of FVC and FEV1 were observed among the different groups. This inverse relationship has been observed in other populations, highlighting the association of central obesity with lung function decline [31,33,35-38,49,50].

These findings are essential for public health in any country. Therefore, it could be recommended that when health care professionals observe a progressive loss of lung function in a patient, they should be alerted and explore for possible cardiometabolic impairment. Concerning the latter, it is noteworthy that a significant linear increase in the prevalence ratios of pulmonary disorders was observed when the number of MetS components increased. Specifically, the decreases in FVC% below 80% and in the restrictive pattern stand out. In this regard, Lee et al [38] found a linear growth trend in the prevalence of RLD in men but not in women. Chen et al [50] reported a significant linear trend between the accumulation of MetS components and the decline in FVC% and FEV1% in both men and women. Similar results were found by Yoon et al [36]. They also reported that a significant increase in the odds ratio for RLD was observed with an increasing number of risk factors, with the magnitude varying according to the adjustment made. This trend was not observed for OLD [36].

Regardless of the type of lung disorder associated with MetS, several researchers have highlighted the need to intervene in these patients to ensure better respiratory health [12,32,33,50]. From our perspective and based on the results obtained, we believe that governments should promote public health programs that include the detection of cardiometabolic disorders and their impacts on lung health. Although some organizations consider the magnitude of the most critical public health problems as risk factors for lung disease [15,51,52], only a few consider metabolic disorders such as obesity [53]. The accumulation of visceral fat, the primary pathophysiological mechanism in the development of insulin resistance and thus of major metabolic disturbances, requires public health attention [54]. Therefore, metabolic disorders, such as MetS, should be included in the programs more concretely, as the evidence is increasingly strong regarding the relationship between metabolic disorders and lung disorders [55,56], even pointing to lung cancer [57].

With this inclusion, health professionals could be encouraged to perform routine spirometry in health examinations to detect early lung disorders, both those of both respiratory origin and those of cardiometabolic origin, not only in the working population (higher risk) but also in the general population [25]. Health professionals are on the frontline, and public health must provide strategies to diagnose and prevent lung disorders and protect and promote health [58], which has been advocated for years [59,60]. This idea gains relevance in a context where spirometry may be underused or, when used, misused [61,62].

Limitations and Strengths

Owing to the epidemiological design, it is impossible to establish a cause-effect relationship between the increase in the number of cardiometabolic risk factors and the progressive alteration of spirometric variables. It would be interesting to conduct a retrospective cohort study to determine whether exposure to different cardiometabolic alterations modifies lung function and increases pulmonary disease incidence. Another possible limitation is the small number of participants in the group with 5 MetS criteria, which makes it difficult to analyze their lung function status. However, given the sample's representativeness, we consider that its small size is linked to what can be found in real settings, where the presence of these individuals is scarce. Moreover, given the particular characteristics of the sample (workers, ie, the working population), extrapolation to the general population (more sedentary) is challenging. However, workers represent a significant proportion of the people, meaning that the participants analyzed cover an essential demographic stratum. Although workers' smoking habits have been controlled, including the number of annual packs of cigarettes in data collection could improve the accuracy of the analysis. Despite the limitations, the robustness of the statistical tests, the control of confounding variables, and the large sample size make the results consistent. Furthermore, the methodology used has facilitated comparison with similar studies, making it possible to reinforce knowledge on the topic.

Conclusions

The presence of a greater number of MetS criteria (cardiometabolic risk factors) has been associated with increased lung dysfunction and a higher prevalence of pulmonary impairments, especially those of the restrictive and mixed types. In addition, the findings show that the comorbid occurrence of risk factors leads to a deterioration of FVC and FEV1. The findings highlight the need for governments to consider the importance of cardiometabolic health in lung function when formulating public health policies that are to be implemented in hospitals, health centers, companies, etc. In this context, spirometry could be crucial for health professionals to monitor patients at a risk of developing chronic pathologies. In addition, routine spirometry helps detect changes in lung function related to cardiometabolic disorders. In short, spirometry is an accessible method that should be used to prevent and provide early care for diseases, including those not of pulmonary origin.

Abstract

Background: A clear understanding of the anthropometric and sociodemographic risk factors related to BMI and hypertension categories is essential for more effective disease prevention, particularly in India. There is a paucity of nationally representative data on the dynamics of these risk factors, which have not been assessed among healthy reproductive-age Indian women.

Objective: This cross-sectional polycystic ovary syndrome (PCOS) task force study aimed to assess the anthropometric and sociodemographic characteristics of healthy reproductive-age Indian women and explore the association of these characteristics with various noncommunicable diseases.

Methods: We conducted a nationwide cross-sectional survey from 2018 to 2022 as part of the Indian Council of Medical Research–PCOS National Task Force study, with the primary aim of estimating the national prevalence of PCOS and regional phenotypic variations among women with PCOS. A multistage random sampling technique was adopted, and 7107 healthy women (aged 18-40 years) from 6 representative geographical zones of India were included in the study. The anthropometric indices and sociodemographic characteristics of these women were analyzed. Statistical analysis was performed to assess the association between exposure and outcome variables.

Results: Of the 7107 study participants, 3585 (50.44%) were from rural areas and 3522 (49.56%) were from urban areas. The prevalence of obesity increased from 8.1% using World Health Organization criteria to 40% using the revised consensus guidelines for Asian Indian populations. Women from urban areas showed higher proportions of overweight (524/1908, 27.46%), obesity (775/1908, 40.62%), and prehypertension (1008/1908, 52.83%) categories. A rising trend of obesity was observed with an increase in age. Women aged 18 to 23 years were healthy (314/724, 43.4%) and overweight (140/724, 19.3%) compared with women aged 36 to 40 years with obesity (448/911, 49.2%) and overweight (216/911, 23.7%). The proportion of obesity was high among South Indian women, with 49.53% (531/1072) and 66.14% (709/1072), using both World Health Organization criteria and the revised Indian guidelines for BMI, respectively. BMI with waist circumference and waist-to-height ratio had a statistically significant linear relationship (r=0.417; P<.001 and r=0.422; P<.001, respectively). However, the magnitude, or strength, of the association was relatively weak ($0.3<|r|<0.5$). Statistical analysis showed that the strongest predictors of being overweight or obese were older age, level of education, wealth quintile, and area of residence.

Conclusions: Anthropometric and sociodemographic characteristics are useful predictors of overweight- and obesity-related syndromes, including prehypertension, among healthy Indian women. Increased attention to the health of Indian women from public health experts and policy makers is warranted. The findings of this study can be leveraged to offer valuable insights, informing health decision-making and targeted interventions that mitigate risk factors of overweight, obesity, and hypertension.

Introduction

Background

Over the past few decades, a disturbing epidemiological transition has revealed that chronic noncommunicable diseases (NCDs) are on the rise both at the global and regional levels. The etiology of NCDs has remained vague and has been attributed to many factors, ranging from genetic predispositions to human lifestyles. The lack of physical exercise, high BMI, increased blood pressure (BP), and obesity are a few factors that affect people's health and predispose them to the risk of NCDs [1,2]. Obesity has now emerged as a major worldwide health concern and is probably the main cause of the deranged metabolism leading to metabolic syndrome, including insulin resistance (IR), type 2 diabetes mellitus, hypertension, and dyslipidemia [3,4]. Scientific evidence reveals that women with obesity are more vulnerable to infertility, miscarriage, and other reproductive complications [5]. Researchers have brought to light the fact that a fast-paced lifestyle has taken a toll on human health and is a contributor to the rise of various diseases and disorders. The issue of obesity and overweight has increased to epidemic proportions; one-third of the global population is overweight or obese, and according to the global burden of disease, >4 million people die each year as a result of these issues. According to the Indian Council of Medical Research (ICMR)–India Diabetes study 2015, the prevalence rates of obesity and central obesity vary from 11.8% to 31.3% and from 16.9% to 36.3%, respectively [6]. Another cross-sectional study reported an age-adjusted prevalence of hypertension of 10.9% in women, 12.5% in urban areas, and 10.6% in rural areas [7]. Recent reports from the World Health Organization (WHO) revealed that, among adults aged ≥18 years, 13% are obese and 39% are overweight [8]. The 2019 to 2021 National Family Health Survey (NFHS)–5 anthropometric data revealed that 19% of women aged between 15 and 49 years are underweight, 24% are overweight or obese, and 57% have a BMI within the normal range [9].

A global strategy for improving health, early detection, and prevention of disease epidemics can be developed by adopting appropriate, accessible, affordable, and scalable health solutions. Anthropometry is the single most universally applicable, inexpensive, noninvasive, and reliable method available for the assessment of body composition, size, and proportions among other methods such as biochemical and radiological assessments. Anthropometric indices are being used to predict the increased risk of several diseases at both the individual and population levels [10-12]. These indices are combinations of anthropometric measurements (BMI, waist circumference [WC], and waist-to-hip ratio [WHR]) that are vital for the interpretation of measurements and assessment of NCD risk factors in the population [13,14]. The most frequently used anthropometric indices are BMI and WC as predictors of overweight- and obesity-related syndromes, including hypertension. The existing literature includes waist-to-height ratio (WHtR) as an additional anthropometric indicator for the assessment of overweight- and obesity-related syndromes, including hypertension [9,15,16]. Several epidemiological studies have consistently reported an association between hypertension and BMI, WC, WHR, and WHtR [17,18].

The correlation between obesity and hypertension is a major concern worldwide. The prevalence of obesity in India is not uniform and varies according to age, gender, geographical environment, and socioeconomic status (SES). Furthermore, many sociodemographic indicators such as education, SES, and occupation and ethnic and racial differences are linked to health status through multiple pathways; however, their clear relationships have not yet been fully elucidated and hitherto remain obscure. The NFHS conducted in India has depicted substantial differences using WHO criteria in the prevalence of overweight and obesity among adults across regions, implying the role of geographic and regional factors. However, there is a paucity of similar literature among reproductive age–matched healthy women using revised consensus guidelines for Indian populations. Myriad previous studies have revealed that the prevalence of prehypertension is an important risk and predisposing factor for developing hypertension in the future [19]. Making use of Western anthropometric standards for low- and middle-income countries (LMICs) has remained controversial [20]; hence, country-specific anthropometric data become indispensable in this regard. It has been very well acknowledged that no standard is universally acceptable as the definition of indices such as optimal growth differs with ethnicity and genetic makeup. In addition, these anthropometric parameters are not uniform and vary considerably from population to population. However, these anthropometric indicators have high predictive value for assessing risk factors of NCDs, thus offering a robust mechanism for the identification of risk factors in relatively easy and cost-effective ways in a local setting.

Objectives

The pattern of overall lifestyle varies from region to region, which necessitates a comprehensive national-level research study, especially among young, healthy reproductive-age women across diverse regions of the country. India has called for the highest priority for the health needs of women, who constitute nearly 50% of the country's population. Taking a cue, the ICMR has taken an initiative under the ICMR–polycystic ovary syndrome (PCOS) Task Force study to address women-centric issues, wherein attention has also been paid to the assessment of various aberrations among women from representative regions of India using anthropometric indices. As the prevalence of overweight, obesity, and hypertension is rising in LMICs such as India, it becomes imperative to understand the dynamics of the various sociodemographic factors and their association with the incidence of overweight, obesity, and BP profile among age-matched healthy women from representative regions of India. With this endeavor, this study attempted to address the gaps in NFHS anthropometric data using nationally representative data through the adoption of revised country-specific guidelines.

Methods

Setting

We used data from the ICMR-PCOS Task Force study conducted across representative regions of India [21]. The data were collected from both rural and urban areas in 6 geographical zones of the country.

Ethics Approval

The study was conducted in accordance with the Helsinki Declaration of 1975 and has been approved by the institutional ethics committees at all 10 study sites as: 131/IEC-SKIMS/2017-101- Sher-i-Kashmir Institute of Medical Sciences, Srinagar; PGI/IEC/2017/47-Postgraduate Institute of Medical Education and Research, Chandigarh;IEC-34/09.02.2017- All India Institute of Medical Sciences, Delhi; IEC/2017/057- Institute of Post Graduate Medical Education and Research, Kolkata; NEIGR/IEC/2018/02- North Eastern Indira Gandhi Regional Institute of Health and Medical Sciences; ECR/300/Inst/AP/2017-Osmania Medical College, Hyderabad; IEC/MHRT/302- Maternal Health and Research Trust, Hyderabad;173/IEC-AIIMSRPR/2017- All India Institute of Medical Sciences, Raipur; D/ICEC/Sci-33/37/2017- National Institute for Research in Reproductive Health, Mumbai and IEC.No.07/09/2017/MCT- Government Medical College, Trivandrum.

Informed Consent and Safety Measures

Written informed consent was obtained from the participants, ensuring their understanding of the purpose of the study and the obligations and possible consequences of their participation. During the data collection process, face masks, hand gloves, and hand sanitizer were provided to the data collection team and study participants to protect the data collectors and participants from COVID-19 infection.

Study Sites

This study involved the participation of the following sites: All India Institute of Medical Sciences, Delhi; All India Institute of Medical Sciences, Raipur; Government Medical College, Trivandrum; Institute of Post Graduate Medical Education and Research, Kolkata; Maternal Health and Research Trust, Hyderabad; North Eastern Indira Gandhi Regional Institute of Health and Medical Sciences, Shillong; National Institute for Research in Reproductive Health, Mumbai; Osmania Medical College, Hyderabad; Postgraduate Institute of Medical Education and Research, Chandigarh; and Sher-i-Kashmir Institute of Medical Sciences, Srinagar.

Sampling Design

This multicenter study involved the recruitment of apparently healthy women aged 18 to 40 years using a multistage sampling technique from randomly selected polling booths across urban and rural areas from the 6 zones (ie, North, South, East, West, Northeast, and Central India) of the country. The states and union territories were grouped into 6 geographical regions based on their sociocultural similarities, with a small change from the grouping (Table 1 shows the composition of each zone). Details of the sample size and sampling plan are available in our published protocol in *JMIR Research Protocols* [21].

Table 1. States and union territories in each region.

Region or zone	State and UT[a]
East	West Bengal
West	Maharashtra
North	Jammu and Kashmir (UT), Chandigarh (UT), and Delhi (UT)
Northeast	Meghalaya
Central	Chhattisgarh
South	Telangana

[a] UT: Union Territory.

Study Population

We approached a total of 13,166 women as per the voter ID list, of whom 3137 (23.83%) were either not eligible or refused to give consent and were excluded. Of the total 10,029 women, 2922 (29.14%) were excluded using the inclusion and exclusion criteria (Textbox 1). A total of 7107 women were enrolled as apparently healthy controls with complete sociodemographic details, and after considering the missing clinical information, our analysis included 3877 (54.55%) apparently healthy women from representative regions of the country (Figure 1).

Textbox 1. Inclusion and exclusion criteria.

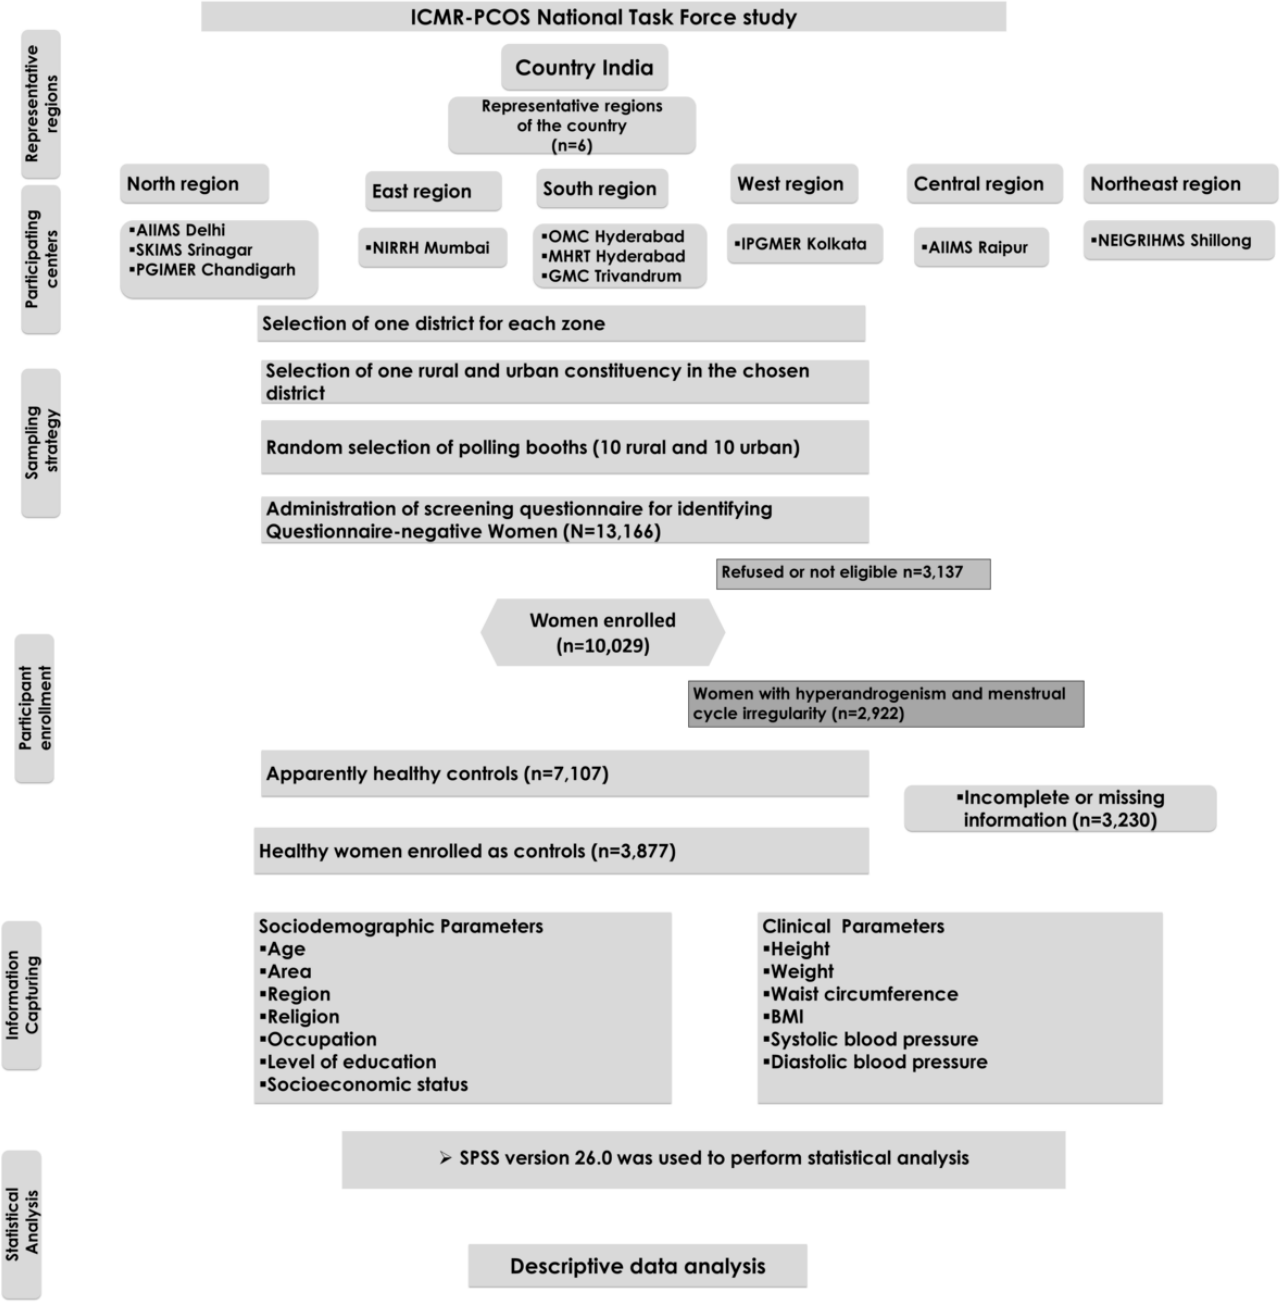
Inclusion criteria

- Healthy women aged between 18-40 years
- Women who were permanent residents of that area (>1 y)
- Willingness to participate in the study and sign an informed consent form

Exclusion criteria

- Participants with hypothyroidism, subclinical hypothyroidism, hyperthyroidism, hyperprolactinemia, type 2 diabetes, exogenous Cushing syndrome, premature ovarian failure, and hypopituitarism
- Pregnant or lactating women and those with cognitive or physical limitations that prevented them from answering the questionnaire

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) diagram showing selection of participants in the cross-sectional polycystic ovary syndrome (PCOS) Task Force study. AIIMS: All India Institute of Medical Sciences; GMC: Government Medical College; ICMR: Indian Council of Medical Research; IPGMER: Institute of Post Graduate Medical Education and Research; MHRT: Maternal Health and Research Trust; NEIGRIHMS: North Eastern Indira Gandhi Regional Institute of Health and Medical Sciences; NIRRH: National Institute for Research in Reproductive Health; OMC: Osmania Medical College; PGIMER: Postgraduate Institute of Medical Education and Research; SKIMS: Sher-i-Kashmir Institute of Medical Sciences.



Data Collection

Well-trained research staff collected the requisite data as appropriate at each study site. After obtaining written consent, an in-depth questionnaire was presented to each woman enrolled from the community (rural and urban) to obtain demographic information about her age, religion, marital status, level of education, SES, occupation, and type of family. Anthropometric data collected included height, weight, WHR, and WC. BP readings were taken at 5-minute intervals. The junior medical officers were responsible for the overall management of the field team at all sites. The investigators at all participating centers monitored the data collection process and checked the data during entry.

Tools and Techniques

Sociodemographic Information

Sociodemographic information pertaining to age, sex, address, occupation, education, SES, marital status, and religion was obtained using a paper-based questionnaire. Information related to anthropometric and related parameters in study participants was obtained through in-person physical evaluation during community visits.

Anthropometric Measurements

Participants included in the study underwent a range of anthropometric measurements in accordance with the instruction manual designed before the initiation of the study. Trained research staff were engaged to take the measurements and record the clinical data from all participants, including age, body weight (kg), height (cm), BMI (kg/m^2), WHR, and BP. The anthropometric measurements were performed using anthropometric tools (SECA 213, 813, and 203 scales) with similar specifications at all participating sites. The equipment was maintained and calibrated as per the manufacturer's instructions. BMI was calculated using the following formula: $BMI = weight\ (kg) / height^2\ (m^2)$. BP was measured 3 times with an automated sphygmomanometer in a sitting position after at least 5 minutes of rest.

Height was measured using a portable stadiometer (SECA 213) with precision nearest to 0.1 cm. Before measurement, the stadiometer was checked using calibration rods. During measurement, the participants were asked to take off their shoes. To ensure correct measurements, the shoulder, buttocks, calf, heel, and back of the head of each participant were to touch the vertical stand of the stadiometer.

Body weight was measured using a digital scale (SECA 813) with a precision of 0.1 kg. The accuracy of the scale was checked by weighing an object of known weight. The participants were asked to stand straight on the electronic weighing scale barefoot and with light clothing, and the weight displayed on the screen was recorded.

WC was measured using nonstretchable measuring tape (SECA), and the participants were asked to raise their clothing above the waist to avoid any interference with the measurements. WC was measured on bare skin with the participant in a standing position and at the narrowest indentation at the midpoint between the costal margin and iliac crest.

BP was measured using an automatic BP monitor (OMRON HEM-7124). To ensure adherence to WHO criteria for the measurement of BP, the participants were asked to sit on a chair and allowed to rest as required with their feet on the ground and their palm facing upward. All BP measurements were performed preferably on the left arm, ensuring that the cuff was wrapped over the bare upper arm, 2 to 3 cm above the antecubital fossa. The average of 3 consecutive measurements was taken as the BP of the participant.

Categorization of Variables

The primary outcome variables of our study included prevalence of overweight, obesity, and hypertension. The variables used were age; place of residence; geographical region; marital status; occupation; SES; and biological risk factors such as BMI, WC, and WHtR of the study participants. BMI was calculated as the ratio of weight (in kg) to the square of height (in m; $BMI = weight / height^2$). For the WHR, WC was divided by hip circumference. BMI was categorized as healthy, underweight, overweight, and obese. According to the WHO classification of obesity, BMI is categorized as healthy (<24.9 kg/m^2), overweight (25-29.9 kg/m^2), and obese (>30 kg/m^2) [22]. However, in this study, BMI was calculated based on the revised consensus guidelines for India [23,24]. Using this scale, the participants were categorized as underweight (<18.5 kg/m^2), healthy (18.5-22.9 kg/m^2), overweight (23.0-24.9 kg/m^2), and obese (≥25 kg/m^2).

The explanatory variables were selected based on published reports and the data set's structure. The study collected information pertaining to the participants' age (18-23, 24-29, 30-35, and 36-40 y), place of residence (urban and rural), geographical location (East, West, North, South, Northeast, and Central India), marital status, educational level (ie, illiterate, up to primary school, up to secondary school, up to high school, and above), SES using the BG Prasad scale (eg, lower class, middle class, lower middle class, and upper class), and religion (ie, Hindu, Muslim, Christian, Sikh, and others).

Definition and Categorization of Hypertension

Hypertension was defined according to the Eighth Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 8) criteria. All the participants with a systolic BP (SBP) of ≥140 mm Hg or a diastolic BP (DBP) of ≥90 mm Hg or who reported taking medication at present for the treatment of high BP were classified as having hypertension. As per the JNC 8, (1) stage-1 hypertension was defined as an SBP of 140 to 159 mm Hg or DBP of 90 to 99 mm Hg, and (2) prehypertension was defined as an SBP of >120 mm Hg but less than the cutoff for hypertension or DBP between 80 and 89 mm Hg in the absence of a diagnosis of hypertension or treatment with medication for high BP [23].

Statistical Analysis

The data from all study participants were entered into Excel (Microsoft Corp) sheets, and we used SPSS (version 26.0; IBM Corp) for data analysis. Descriptive statistical analysis was performed, and categorical variables were stratified into groups and then presented as numbers and percentages. Pearson correlation analysis was performed between BMI and WC and WHtR. A logistic regression model was used to determine the influence of demographic characteristics on general and central obesity. Variables included in the multivariate logistic regression analysis were age, region, SES, education, religion, marital status, and occupation. The data on the distribution of BMI categories using WHO criteria and the revised consensus guidelines for India were presented using bar charts. A 2-tailed P value of <.05 was considered statistically significant.

Results

Description

Apparently healthy women who met the inclusion criteria were enrolled as controls in the study. The sociodemographic information (age, sex, address, occupation, education, SES, marital status, and religion) of the study participants is shown in Table 2. Of the 7107 study participants, 3585 (50.44%) were from rural areas and 3522 (49.56%) were from urban areas. Most of the women (2323/7107, 32.69%) were aged 30 to 35 years, followed by 24 to 29 years (1869/7107, 26.3%), 36 to 40 years (1609/7107, 22.64%), and 18 to 23 years (1306/7107, 18.38%). Most women (4851/7107, 68.26%) were Hindu, followed by Muslim (1300/7107, 18.29%), Christian (837/7107, 11.78%), Sikh (88/7107, 1.24%), and other religions (31/7107, 0.44%). Approximately 73.8% (5245/7107) of women were married, and 24.22% (1721/7107) were unmarried, with approximately 1.98% (141/7107) of women being either widowed or un-remarried. Among the enrolled women, 22.37% (1590/7107) had a high school education, 18.62% (1323/7107) had a middle school education, 20.22% (1437/7107) had a postgraduate education, only 2.41% (171/7107) had received a professional education or honors, and 14.65% (1041/7107) were uneducated. Furthermore, 82.43% (5858/7107) of women were unemployed or unskilled, and 2.41% (171/7107) were in some profession. Most of them (2176/7107, 30.62%) belonged to the middle class, followed by the lower-middle class (1721/7107, 24.22%). Of all the enrolled women, 13.02% (925/7107) belonged to the upper class, 22.39% (1591/7107) belonged to the upper-middle class, and 9.62% (684/7107) belonged to the lower class.

Table 2. Sociodemographic characteristics of the study population from representative regions of the country (n=7107).

In addition, we observed that the prevalence of overweight, obesity, and hypertension among women showed an association with sociodemographic and other characteristics. We analyzed how overweight, obesity, and prehypertension varied when nonmodifiable factors such as age and modifiable factors such as educational level were considered in accordance with the revised consensus guidelines for India. A rising trend of obesity was observed with an increase in age. Women aged between 36 and 40 years (448/911, 49.2%) were more obese compared with those in other age groups. As expected, we observed the lowest percentage of obesity among women aged 18 to 23 years. The incidence of overweight was highest (341/1289, 26.45%) among women aged between 30 and 35 years and lowest among women aged between 18 and 23 years. In addition, we found a lower percentage of prehypertension (324/1946, 16.65%) among younger women aged between 18 and 23 years than in those aged between 30 and 35 years.

Using the revised consensus guidelines for India, we found varying proportions of BMI categories and prehypertension across rural and urban areas. Urban areas showed the highest proportions of women with obesity (775/1908, 40.62%), overweight (524/1908, 27.46%), and prehypertension (1008/1908, 52.83%) compared with women from rural areas. The proportion of underweight showed an almost decreasing trend with an increase in SES and vice versa for obesity rates. Upper-class and upper–middle-class women presented the lowest rates of underweight (17/308, 5.5% and 25/740, 3.4%, respectively). However, middle-class women presented a high incidence of underweight, obesity, and prehypertension (80/1331, 6.01%; 552/1331, 41.47%; and 738/1946, 37.92%, respectively). Women with a higher level of education (professional or honors) showed the lowest rates of overweight (6/34, 18%) and prehypertension (14/1946, 0.72%), and none were underweight. Women with a middle school education and illiterate women had higher obesity rates (299/665, 45% and 269/614, 43.8%, respectively). Women who had received a high school, graduate, or postgraduate education showed high rates of prehypertension (482/1946, 24.77% and 359/1946, 18.45%, respectively). Predictably, we observed high percentages of prehypertension (1409/1946, 72.4%) and overweight (706/2836, 24.89%) among unemployed women and the lowest rates of prehypertension (31/1946, 1.59%) among women who were either semiprofessional or professional (Table 3).

Table 4 shows the pattern of BMI and hypertension categories in each zone stratified by BMI, central obesity (WHtR and WC), and BP profiles. The comparative distribution of BMI categories of the 3877 women using the WHO and revised consensus guidelines for India are shown in Tables 4 and 5, in which regional variations are quite evident. Using WHO criteria and the revised consensus guidelines for India, the highest proportion of healthy women was observed in the Northeast (126/164, 76.8% and 99/164, 60.4%, respectively), and the proportion of overweight women was 42.1% (59/140) and 27.9% (39/140) in the East region, respectively. Accordingly, we found the highest rates of obesity in southern India (151/1072, 14.09% using the WHO criteria and 531/1072, 49.53% using the revised consensus BMI guidelines for India).

Table 3. Association between sociodemographic variables and BMI categories stratified by the revised consensus guidelines for India and stages of hypertension.

Normotensive	1173 (53)	134 (81.7)	70 (50)	73 (57.9)	363 (33.9)	118 (73.3)
Prehypertension	1041 (47)	30 (18.3)	70 (50)	53 (42.1)	709 (66.1)	43 (26.7)

[a] No participant identified in this category.

[b] WHtR: waist-to-height ratio.

[c] WC: waist circumference.

[d] JNC 8: Eighth Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure.

Table 5. Comparative distribution of BMI categories (obese, overweight, healthy, and underweight) of the women using the World Health Organization (WHO) criteria and the revised consensus guidelines for India (n=3877).

	Participants, n (%)
BMI (WHO)	
Obese	312 (8.05)
Overweight	1240 (31.98)
Healthy	2121 (54.71)
Underweight	204 (5.26)
BMI (Indian)	
Obese	1552 (40.03)
Overweight	941 (24.27)
Healthy	1180 (30.44)
Underweight	204 (5.26)

A clear variation in the frequency of central obesity, WHtR, and WC was noted among women across the regions. The central obesity WHtR and WC were highest among Central Indian women (80/126, 63.5% and 38/126, 30.2%, respectively).

We also analyzed how BP profile varied across regions using JNC 8 criteria. After stratifying by region, our analysis showed that the women who were enrolled as healthy controls in the study either were normotensive (healthy BP profile) or fell under the prehypertension category. The Northeast region (Shillong) showed the highest incidence of normotensive women (134/164, 81.7%) and the lowest rates of women with prehypertension (30/164, 18.3%). However, prehypertension was found to be highest among South Indian women (709/1072, 66.14%), followed by women from East (70/140, 50%), North (1041/2214, 47.02%), and Central (53/126, 42.1%) India, as well as 26.7% (43/161) from the Western region of the country. Table 6 shows the multivariate logistic regression analysis on the association between demographic characteristics (age, region, residence, occupation, SES, education, marital status, and religion of participants) and general and central obesity. We observed that age, region, religion, and occupation were significantly associated with obesity. Obesity was significantly higher in older age groups (36-40 y; odds ratio [OR] 2.57, 95% CI 1.906-3.471; *P*<.001), central regions (OR 1.76, 95% CI 1.144-2.719; *P*=.01), and the Muslim population (OR 2.73, 95% CI 2.245-3.313; *P*<.001).

Table 6. Multivariate logistic regression analysis on the association between demographic characteristics (age, region, residence, occupation, socioeconomic status, education, marital status, and religion of the participants) and general and central obesity.

[a] WC: waist circumference.

[b] WHO: World Health Organization.

[c] OR: odds ratio.

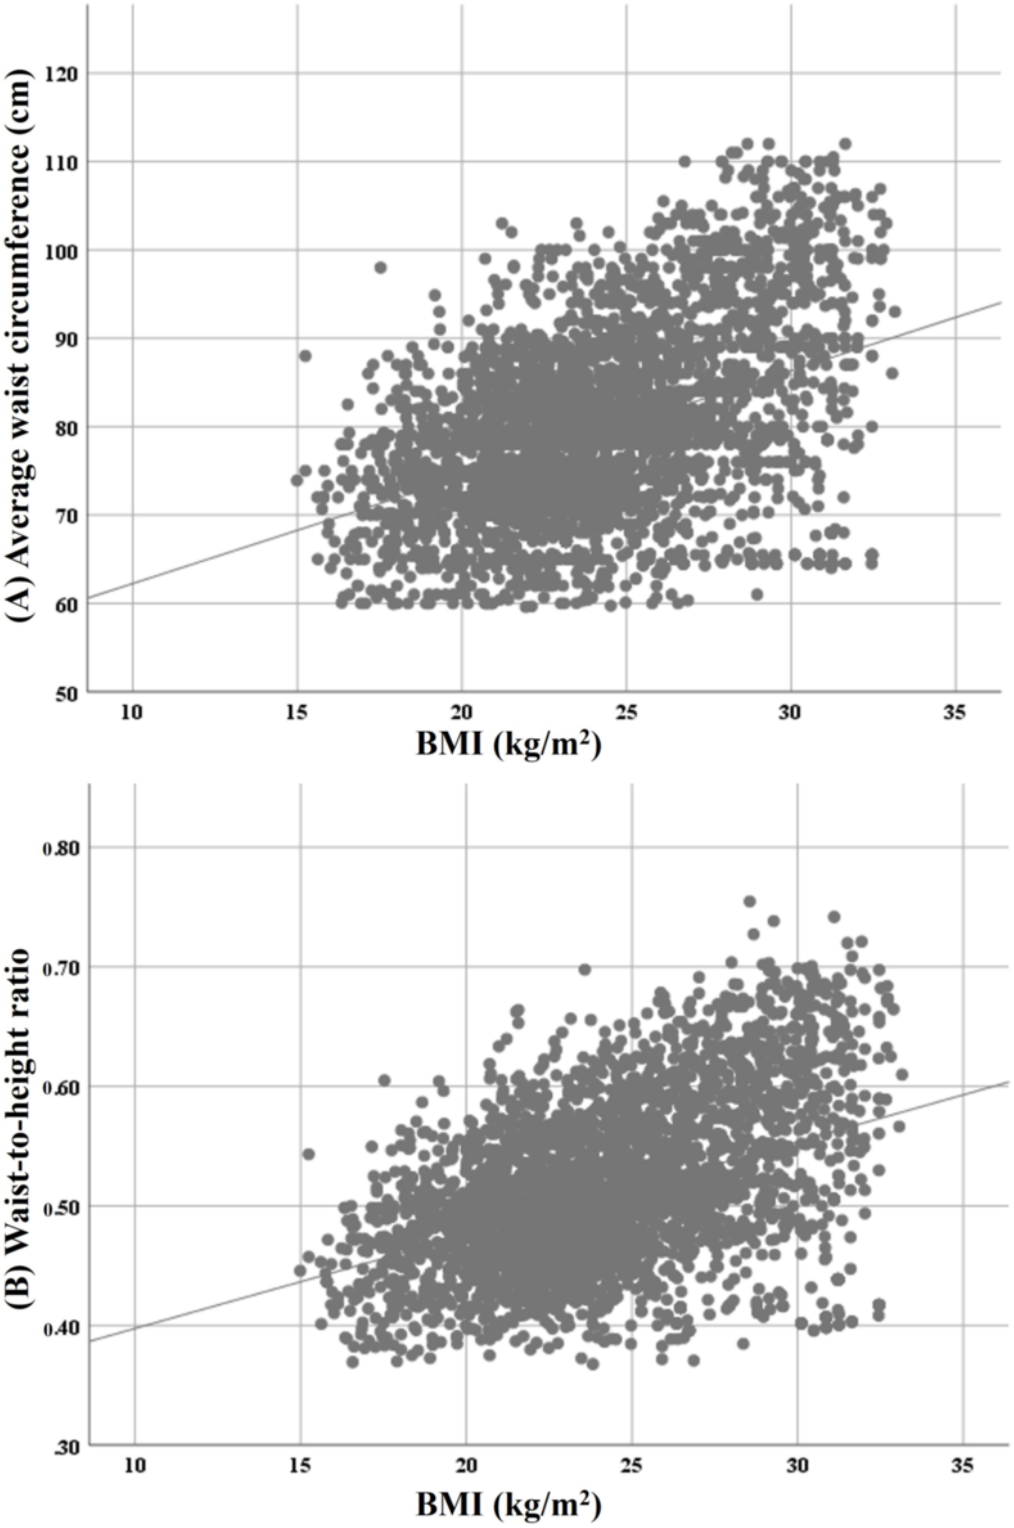
[d] Reference group.

[e] N/A: not applicable.

Correlation Between BMI and Overweight Indicators

Pearson correlation analysis was conducted, and we observed a positive but weak association between these variables. Figure 2 illustrates the correlation between BMI and (1) WC and (2) WHtR of the participants.

Figure 2. Correlation between BMI and (A) waist circumference and (B) waist-to-height ratio.



BMI and WC

BMI and WC showed a statistically significant linear relationship (*r*=0.417; *P*<.001). The direction of the relationship was positive, meaning that these variables tended to increase together (ie, greater WC was associated with greater BMI). However, the magnitude, or strength, of the association was relatively weak (0.3<|*r*|<0.5).

BMI and WHtR

Similarly, BMI and WHtR showed a statistically significant linear relationship (*r*=0.422; *P*<.001). The direction of the relationship was positive, implying that these variables tended to increase together (ie, greater WHtR was associated with greater BMI). However, the magnitude, or strength, of the association was relatively weak (0.3<|*r*|<0.5).

Discussion

Principal Findings

The ongoing ICMR-PCOS Task Force study is the first pan-Indian study conducted among urban and rural women across representative geographical regions. To the best of our knowledge, this is the first report on the pattern and prevalence of overweight, obesity, and hypertension among apparently healthy women with region-wise categorization into North, East, West, South, Northeast, and Central India. This part of the study uses a specific scenario of the risks to women's health, such as overweight and obesity, influenced by multiple determinants of health. Although the prevalence of overweight and obesity affects all segments of the population, there are notable trends among certain sections wherein women are more likely to be obese or gain weight. There are a number of studies available in the literature that use the WHO criteria for BMI cutoffs for defining overweight and obesity prevalence in India. However, these are scientifically challenged as these guidelines are based on studies of White individuals (defined as BMI ≥30 for obesity). Our study provides the comparative estimates of overweight and obesity based on the revised consensus guidelines for India, that is, it defines BMI as underweight (<18.5 kg/m^2), healthy (18.5-22.9 kg/m^2), overweight (23.0-24.9 kg/m^2), and obese (≥25 kg/m^2).

Our results showed that overweight, obesity, and hypertension are also prevalent among apparently healthy women across the country. Health concerns in women start to creep in when entering their second and third decades of life. Our results also showed a rising trend of obesity with an increase in age. While going through age categories, we found that women aged between 36 and 40 years were more obese (448/911, 49.2%). Overweight was observed more among women aged between 30 and 35 years. A significant proportion of women from other age groups was found to be either overweight or obese. The rising incidence of overweight and obesity is a challenge across all age groups [24].

Our findings showed a high proportion of healthy women across rural and urban areas using the revised Indian criteria (647/1969, 32.86% and 533/1908, 27.94%, respectively). These findings are in agreement with the statement under "Patterns by background characteristics of NFHS-5," which states that the proportion of healthy women was higher in rural areas than in urban areas. Our results show higher rates of obesity among urban women than in women from rural areas. These results are in agreement with the data analysis of the NFHS for the epidemiology of obesity in Indian adults and similar to the findings of other studies [9,25-28]. Mishra et al [29] also revealed that the urban population was at a higher risk of obesity than the rural population, in consonance with our findings. We believe that lifestyle and behavioral factors are the main reasons for the differences between urban and rural populations.

Our results showed that both obesity and overweight are significantly prevalent, along with cross-regional variations. The revised consensus guidelines for BMI in Indians showed an increased proportion of obese women in South India (531/1072, 49.53%), followed by East (62/140, 44.3%) and North (841/2214, 37.99%) India, whereas Northeast India showed the lowest rates of obesity (25/164, 15.2%). These findings are partially in agreement with the findings of the NFHS-5, which reported the highest proportion of obese women in Puducherry (south), followed by Chandigarh and Delhi (north). These cross-regional variations highlight the role of geographical factors in these disorders. Levels of urbanization may be the reason for the lower prevalence in the northeastern and eastern regions than in other regions. The northeastern, eastern, and central regions are the 3 least urbanized regions in India [30]. A systematic review reported that variations in the prevalence of obesity in India are due to diverse geographical conditions, lifestyles, and dietary patterns. As expected, we found that only a small proportion of women belonging to the upper class were underweight, and a good proportion (125/308, 40.6%) of women from the same class presented obesity. These findings are similar to those of a cross-sectional study that reported high rates of overweight and obesity (71.8%) among the socioeconomically well-off community of Marwaris, West Bengal, India. This can be attributed to their sedentary lifestyle and high-calorie food intake compared with women of lower SES. Obesity is a triggering factor for various diseases; we used Homeostatic Model Assessment of IR as an indicator of IR and found that 49.77% (661/1328) of participants had IR, with Homeostatic Model Assessment of IR of >2.

Our results showed that women with the highest level of education (with a profession or honors) were not underweight and showed the lowest rates of overweight (6/34, 18%) and prehypertension (14/1946, 0.72%) incidence compared with women who were illiterate or had other levels of education. These trends resemble the findings in other regions of the world, wherein a better education appears to be associated with a lower likelihood of obesity, especially among women. Data analyses of individual-level national health surveys in countries such as Australia, Canada, England, and Korea also reported a linear relationship between the number of years spent in full-time education and the probability of obesity, with most educated individuals displaying lower rates of the condition [31]. Several other studies have reported a strong education gradient in BMI or obesity, with better educated women being less likely to be overweight or obese [32-34]. Our results suggest that general education campaigns and the design and implementation of effective policies can play a significant role in reducing obesity to curb the epidemic.

Hypertension is of particular importance to public health because of its association with a number of diseases contributing to premature deaths. The incidence of hypertension has increased drastically in many LMICs, including India. Our analysis showed patterns of higher incidence of prehypertension among urban women compared with rural women, and a rising trend was observed with an increase in age. These findings refute the age-old concept that hypertension is not a major problem in rural India. The increasing trend of prehypertension with age is in agreement with the NFHS-5, which reported an increase in all categories of hypertension, including prehypertension, with age for both women and men. We also found patterns of greater prevalence of prehypertension among women belonging to the middle class (738/1946, 37.92%) and the lower middle class (461/1946, 23.69%) than among women from the upper class, with an incidence rate of 6.89% (133/1931). This may be linked to the tendencies toward sedentary living and eating unhealthy foods, among other things. These findings are in contradiction to the findings of studies from Nigeria and Kenya that reported a greater prevalence of hypertension among wealthier groups [35,36]. Prehypertension was found to be more prevalent in women who had a lower educational level (high school) and women who were illiterate (379/1946, 19.48%) compared with women with higher levels of education (professional or honors). These findings support the belief that a higher educational level increases awareness and information regarding hypertension and, subsequently, encourages adaptation to healthy lifestyles, and that could be the possible reason behind it. Reddy et al [37] reported based on a cross-sectional study that hypertension was significantly more prevalent in the group with a lower educational level compared with that with a higher educational level. Our results showed that age, level of education, occupation, geographical background, and SES were significant predictors of hypertension. The possible explanations for the lower incidence rates of overweight, obesity, and hypertension in women with a higher education and from the upper socioeconomic class in this study may be attributed to good awareness of preventive measures, better adherence to medical advice, and lifestyle modifications. We believe that there is an urgent need to implement strategies to increase awareness of hypertension and promote healthier lifestyles.

Region-wise categorization into North, East, West, South, Central, and Northeast India allowed us to capture and present the regional estimates of prehypertension and BMI categories among healthy subsets of women, which showed the highest rates of prehypertension among women from southern parts of India (709/1072, 66.14%) followed by East Indian women (70/140, 50%) and the lowest rates among Northeast Indian women. Overall, the identification of women who might face greater challenges with their disease management suggests a role for relevant health authorities in executing appropriately targeted public health measures and policies to ensure good hypertension management in this population.

Strengths

The major strength of our study is its large sample size with apparently healthy reproductive-age women recruited from the 6 regions of India. Hence, it provides region-specific incidences of overweight, obesity, and prehypertension. The findings of our study may be used to plan interventions or policies for the prevention and control of obesity and hypertension among different populations. The results of this study should be interpreted in the context of the potential limitations. Furthermore, we adopted a common instruction manual and standard equipment of similar specifications at all study centers to ensure the accuracy and reliable quality of all the measurements throughout the entire study period so as to generate quality data.

Limitations

There are some limitations to our study. First, to overcome population heterogeneity, we attempted to divide the study areas geographically into North, East, West, South, Northeast, and Central India and arrive at region-specific rates. However, the cultural and dietary practices vary drastically state-wise, and this may have a bearing on the results. Second, we did not report on the awareness and control of obesity and BP and the association of sociodemographic factors such as SES and nutrition with height. We used the BG Prasad social classification, which is applicable to rural and urban areas, but it only considers income and excludes the other SES criteria. In addition, this study provides estimates from 6 regions that include only a few states and union territories and did not include several major Indian states such as Rajasthan and Madhya Pradesh. Above all, the findings are limited to only feminine (female individuals) aged between 18 and 40 years.

Conclusions

To conclude, overweight, obesity, and hypertension epidemics are highly prevalent among healthy subsets of reproductive-age Indian women across rural and urban strata with cross-regional variations. Age, level of education, geographical background, and SES were found to be predictors of BMI and hypertension categories. Genetic and environmental factors such as diet and activity level are likely contributors to these aberrations; however, role of the type of family and marital status need to be explored further. Our results highlight the importance of both nonmodifiable (such as age) and modifiable (such as educational level) factors in determining patterns of overweight, obesity, and hypertension. Education plays an important role in tackling overweight and obesity. This study may serve as an indicator providing early clues and recommending further research using more rigorous scientific methods. In light of our findings, there is a need for targeted attention to both prevent future epidemics in a population that has not developed obesity or hypertension and help maintain healthy weight and BP in individuals with hypertension. Public health awareness regarding overweight, obesity, and BP needs to be tailored differently for women considering the regional, rural, and urban dimensions. We advocate for multidisciplinary efforts to address these issues, and policy makers need to consider what level of evidence should be deemed sufficient to prompt action and tackle these issues.

Acknowledgments

The authors are grateful to the Indian Council of Medical Research, New Delhi, India, for financial assistance in carrying out the study. They acknowledge the expert committee for their valuable suggestions and appreciate the assistance of the clinical and nonclinical staff of all the participating sites in collecting the data. The authors also thank the Multidisciplinary Research Unit, Sher-i-Kashmir Institute of Medical Sciences, funded by the Department of Health Research, Government of India, for providing the necessary support during the study. All authors declare that they had insufficient funding to support the open-access publication of this manuscript, including from affiliated organizations or institutions, funding agencies, or other organizations. JMIR Publications provided article processing fee support for the publication of this paper. The Indian Council of Medical Research–polycystic ovary syndrome study group members were Mohd Ashraf Ganie, Bharati Kulkarni, Amlin Shukla, Taruna Arora, Subhankar Chowdhury, Vanita Suri, Beena Joshi, Prasanta Kumar Bhattacharya, Sarita Agrawal, Neena Malhotra, Rakesh Sahay, Puthiyaveettil Khadar Jabbar, Roya Rozati, Imtiyaz Ahmad Wani, Gaivee Vinam Meshram, Shouvik Choudhury, V Sreenivas, Mukesh Srivastava, Abilash Nair, Parvaiz Koul, Zafar Amin Shah, Shariq Masoodi, Tabassum Parvez, and Ghulam Nabi Yatoo, Naseer Ahmed, Tariq Gojwari, Muzafar Maqsood Wani, Seema Qayoom, Wahid Khan, Rama Walia, Dipankar De, Aashima Arora, Tulika Singh, Neena Khanna, Nitish Naik, Shyam Prakash, Nandita Gupta, Rajesh Sagar, Jai Bhagwan Sharma, Devasenathipathy Kandasamy, Narendra Kuber Bodhey, Eli Mohapatra, Sabah Siddiqui, Gourisankar Kamilya, Archana Singh, Pradip Mukhopadhyay, Mousumi Mukhopadhyay, Nehar Ranjan Sarkar, Alice Abraham Ruram, Jessy Abraham, Saroj Kumar Pati, Dibakar Sahu, Lokesh Kumar Singh, Donboklang Lynser, Manika Agrawal, Ashok Anand, Shahina Begum, Anushree Patil, Shrabani Mukherjee, Hemangini Thakkar, Aruna Ramaiah, Lakshman Rao, Sudha Bindu, Malathi Ponnuru, Nadeem Ahmad, Sujatha Rani, Aleem Ahmed Khan, Sultan Rizwan Ahmed, Prabhakar Rao, Nirmala C, Anuja Elizabeth George, Jayasree Leelamma, Jayakumari, Gaurav thakur, Saba Noor, Shaikh Sharmeen, Aafia Rashid, Wasia Showkat, Rohina Bashir, Pieu Adhikary, Subhasish Pramanik, Rahul Harish, Mudasir Makhdoomi, Mudasir Fayaz, Nafeez Rehman, Neha Ravi, Ajay Kumar, Siffali Chandrakar, Nithlesh Kumar, Sudipta Banerjee, Gazala Hasan, Nitin Deshpande, Himali Vadhan, Rita Parab, Humaira Minhaj, Balaji Bhasker, Shaik Iqubal Ahmed, Ram Babu, and Arya Suresh.

Abstract

Background: Although many studies have reported on the associations between the amount of physical activity (PA) and the transitions of cardiometabolic multimorbidity (CMM), the evidence for PA intensity has not been fully evaluated.

Objective: This study aimed to explore the impact of PA intensity on the dynamic progression of CMM.

Methods: The prospective cohort of this study using data from the UK Biobank included 359,773 participants aged 37-73 years who were recruited from 22 centers between 2006 and 2010. The diagnoses of CMM, which included the copresence of type 2 diabetes (T2D), ischemic heart disease, and stroke, were obtained from *first occurrence fields* provided by the UK Biobank, which included data from primary care, hospital inpatient record, self-reported medical condition, and death registers. The PA intensity was assessed by the proportion of vigorous PA (VPA) to moderate to vigorous PA (MVPA). Multistate models were used to evaluate the effect of PA intensity on the dynamic progression of CMM. The first model (model A) included 5 transitions, namely free of cardiometabolic disease (CMD) to first occurrence of CMD (FCMD), free of CMD to death, FCMD to CMM, FCMD to mortality, and CMM to mortality. The other model (model B) used specific CMD, namely T2D, ischemic heart disease, and stroke, instead of FCMD and included 11 transitions in this study.

Results: The mean age of the included participants (N=359,773) was 55.82 (SD 8.12) years at baseline, and 54.55% (196,271/359,773) of the participants were female. Compared with the participants with no VPA, participants with intensity levels of >0.75 to <1 for VPA to MVPA had a 13% and 27% lower risk of transition from free of CMD to FCMD (hazard ratio [HR] 0.87, 95% CI 0.83-0.91) and mortality (HR 0.73, 95% CI 0.66-0.79) in model A, respectively. The HR for the participants with no moderate PA was 0.82 (95% CI 0.73-0.92) compared with no VPA. There was a substantially protective effect of higher PA intensity on the transitions from free of CMD to T2D and from T2D to mortality, which reveals the importance of PA intensity for the transitions of T2D. More PA and greater intensity had a synergistic effect on decreasing the risk of the transitions from free of CMD to FCMD and mortality. Male participants, younger adults, adults with a higher BMI, current or previous smokers, and excessive alcohol drinkers could obtain more benefits from higher PA intensity for the lower risk of at least 1 transition from free of CMD, then to CMM, and finally to mortality.

Conclusions: This study suggests that higher PA intensity is an effective measure for preventing CMM and mortality in the early period of CMM development. Relevant interventions related to higher PA intensity should be conducted.

Introduction

Background

Multimorbidity, defined as the coexistence of ≥2 chronic conditions from noncommunicable disease, mental disease, or infectious disease of long duration, is an unignorable public health issue that brings great physical and mental burden to families [1]. Cardiometabolic multimorbidity (CMM), namely the copresence of type 2 diabetes (T2D), ischemic heart disease (IHD), and stroke, is associated with significantly multiplicative mortality risk and lower life expectancy [2,3]. The prevalence of CMM for adults in the United States is 14.4% and is higher among the male population and older adults [4]. Previous studies characterized a troubling rise in the prevalence of CMM from 1999 to 2018 [4]. Early prevention is needed in consideration of the many adverse health outcomes related to CMM, such as cognitive decline, dementia, depression, and even a worse COVID-19 prognosis [5-8]. Previous studies have mentioned that many variables such as handgrip strength, sleep pattern, beverage consumption, shift work, and ambient air pollution are independent factors for predicting CMM [9-13]. Exploring more factors affecting the early stage of CMM, which means free of cardiometabolic disease (CMD) or first occurrence of CMD (FCMD), is necessary for preventing adverse and severe outcomes in the future.

A high level of physical activity (PA), especially for a longer duration of moderate to vigorous PA (MVPA), has been shown to be the common protective factor for CMD, including T2D [14-16], IHD [17-19], stroke [20-22], CMM [23-26], and death [27-30]. Previous studies also reported that a higher intensity of PA, namely a higher proportion of vigorous PA (VPA), could bring additional benefits for reducing the risk of mortality [31-34]. However, there is limited evidence for the associations of PA intensity with CMD and CMM. In other words, it is unclear whether a higher intensity of PA has a positive effect on decreasing the risk of mortality among the participants with CMD or CMM. Furthermore, previous studies also reported that the amount of PA, namely the duration or metabolic equivalent task (MET) for PA, could affect all the stages from healthy status to CMD, then to CMM, and finally to mortality [23,24]. To the best of our knowledge, no previous studies have evaluated the association of PA intensity with all the transitions simultaneously. Considering the studies focusing on a single transition might overlook some competing risks of mortality, future studies should investigate how PA intensity affects the dynamic progression from the free of CMD status to CMM and from other status to mortality.

Objectives

This study aimed to explore the associations of PA intensity with the dynamic progression of CMM, namely from free of CMD to FCMD, then to CMM, and finally to mortality. In addition, the effect of PA intensity on the transitions from specific CMD, namely T2D, IHD, and stroke, to CMM and mortality was further assessed. Furthermore, the effect of modification by sociodemographic factors and the amount of PA was also assessed. The findings of this study would provide some evidence of the benefits and help relevant departments to develop some interventions related to the PA intensity for CMM and mortality.

Methods

Study Design and Participants

The UK Biobank (UKB) is an ongoing population-based and prospective cohort, which includes >500,000 participants aged 37 to 73 years. The details of recruitment for the UKB can be found elsewhere [35]. The main aims of the UKB are to explore genetic and nongenetic determinants of the diseases among middle-aged adults and older adults. Briefly, UKB participants were recruited from 22 centers in the United Kingdom (England, Wales, and Scotland) between 2006 and 2010 at baseline. After obtaining electronic consent for the use of deidentified data, every participant finished a self-completed touchscreen questionnaire, including socioeconomic factors and lifestyles. In addition, computer-assisted interviews, physical measurements, and sample collection were also conducted. The records from national health-related hospitals, primary care, and death registers were also matched with the included participants, which could help us comprehensively understand their health status.

In this study, we excluded participants whose records were withdrawn or could not be followed up from the cohort. In addition, the participants with missing PA data at baseline were also excluded. Finally, we excluded the participants with CMD at baseline to avoid inverse causality. Finally, 359,773 participants were included in this study (Figure S1 in Multimedia Appendix 1).

Measures

Exposures

In this study, PA was assessed by using the short-form International Physical Activity Questionnaire, which has good validity and reliability [36]. The MET of moderate PA (MPA) and VPA calculated by the UKB was used in this study (data field 22038 and 22039). MVPA, which is the sum of MET associated with MPA and VPA, was used to assess the amount of PA according to the recommendations of the World Health Organization PA guidelines [37]. First, the amount of PA was categorized into <600, 600 to 1200, and >1200 MET minutes per week associated with MVPA. Second, PA intensity, which is the ratio of VPA to MVPA, was measured by using the MET of VPA to MVPA as follows: MET (VPA) / MET (MVPA). The PA intensity ranged from 0 to 1, and a higher ratio indicated higher PA intensity. Different categories (0, >0 to 0.25, >0.25 to 0.5, >0.5 to 0.75, >0.75 to <1, and 1) of PA intensity were used to assess the associations with all the transitions from the free of CMD status to FCMD, then to CMM, and finally to mortality. In addition, the ordinal scale, which coded the PA intensity from 0 to 5, was also used to measure the associations.

Outcomes

The incidence, progression, and prognosis of CMM, namely the occurrence of at least 2 diseases of T2D, IHD, and stroke, were the main outcomes in this study. The diagnoses and time of occurrence were obtained from *first occurrence fields* provided by UKB (data category: 2409) and were coded using the International Classification of Disease, 10th version, which included data from primary care, hospital inpatient record, self-reported medical condition, and death registers. T2D was coded by E11 and E14, as recommended in previous studies related to CMM diagnoses [9,24]. IHD was coded by I20-I25, and stroke was coded by I60-I69.

The records related to all-cause mortality were identified by linking to death registries of the National Health Service Information Centre for participants from England and Wales and the National Health Service Central Register for participants from Scotland [35]. The participants entered the cohort from the date of being recruited at the centers and exited at the date of death, occurrence of outcomes at respective progression, or censorship.

Covariates

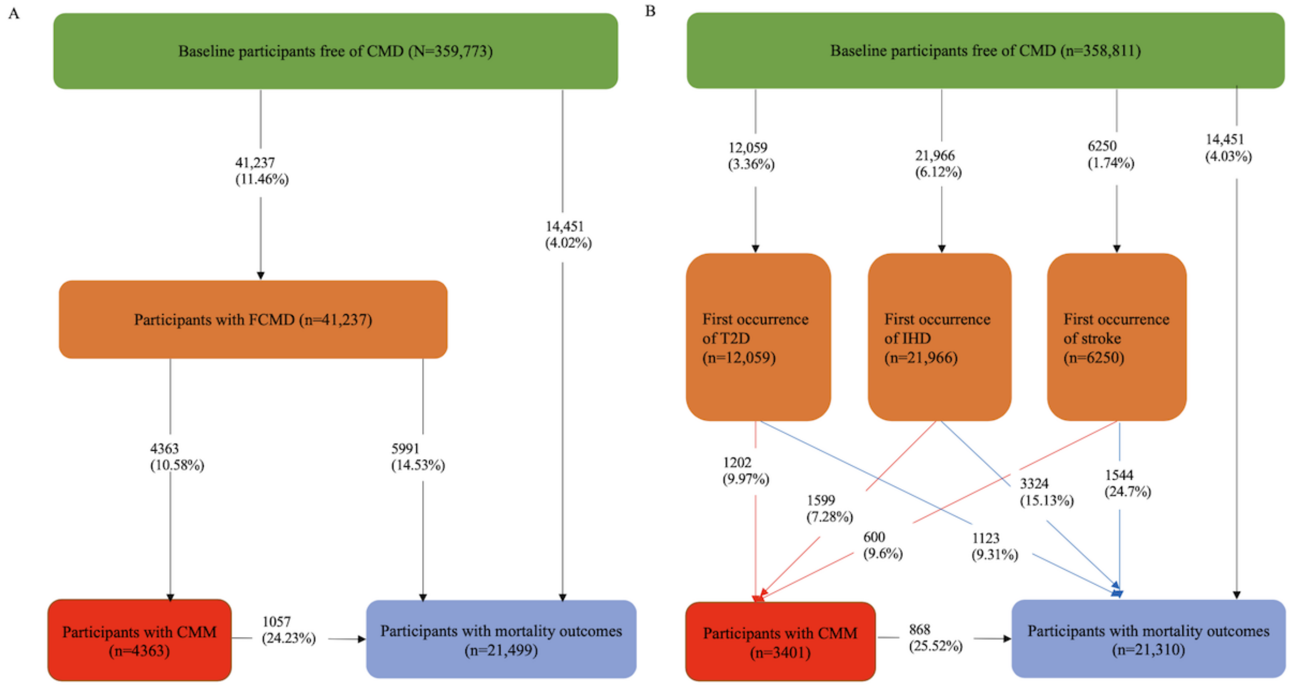
The covariates in this study, which were chosen according to previous studies on CMM [9,23,24], included age, sex, ethnicity, socioeconomic status (SES), BMI, household income before tax per year, study center region, education group, smoking status, and alcohol drinking status. According to previous studies [38,39], an a priori–defined directed acyclic graph [40] was drawn to show the relationship between the covariates and outcomes (Figure S2 in Multimedia Appendix 1). Ethnicity was classified as either White or Others. The SES was measured using the Townsend area deprivation index [41]. Higher scores indicated greater socioeconomic deprivation and lower SES, and quartiles of the score for SES were included in the analyses. The data field and definition of other included covariates are shown in Table S1 in Multimedia Appendix 1. Missing values for the covariates were regarded as a classification when performing the analyses.

Statistical Analysis

We used R (version 4.1.2; R Foundation for Statistical Computing) software to perform statistical analyses. Initially, traditional Cox proportional hazards models were used to explore the association of the amount of PA and intensity with FCMD, CMM, and all-cause mortality. No obvious violations to the proportional hazards assumption were noted for interested exposures. All the models were adjusted for age, sex, ethnicity, SES, BMI, household income before tax per year, study center region, education group, smoking status, and alcohol drinking status.

Furthermore, multistate models [42,43] were used to assess the effect of PA amount and intensity on the transitions from free of CMD to FCMD, then to CMM, and finally to mortality. The multistate model, which was an extension of the traditional Cox proportional hazards model and competing risk model, was widely used to explore the effect of interested risk factors on multiple transitions related to multistate outcomes. In this study, we adopted 2 series of multistate models, as recommended by previous studies [9,23,24]. The first model (model A) included 5 transitions, namely free of CMD to FCMD, free of CMD to death, FCMD to CMM, FCMD to mortality, and CMM to mortality (Figure 1). The other model (model B) used specific CMD, namely T2D, IHD, and stroke, instead of FCMD and included 11 transitions (Figure 1). When the participants had the same date for different transitions, we adopted a theoretically time of pushing entering date forward by 0.5 day, which was based on previous studies related to a similar topic [9,24]. When performing model B, we excluded 962 participants with the same date of diagnosis for T2D, IHD, or stroke to explore disease-specific associations, as we were unsure which disease occurred first.

Figure 1. Transitions from free of cardiometabolic disease (CMD) to mortality outcomes: (A) 5-transition model and (B) 11-transition model. CMM: cardiometabolic multimorbidity; FCMD: first cardiometabolic disease; IHD: ischemic heart disease; T2D: type 2 diabetes.



A series of subgroup analyses related to age (≤60 vs >60 y), sex (female vs male), BMI (underweight or normal weight vs overweight), smoking status (never vs previous or current), and alcohol drinking status (daily or almost daily vs ≤1-3 times/wk) were performed to identify the susceptible populations associated with PA intensity. *Z* test was used to compare the estimates of different subgroups, as recommended by Altman and Bland [44].

We performed several sensitivity analyses to verify the robustness of the estimates of model A. First, we used different time intervals (0.5 y, 1 y, 2 y, 3 y, and 5 y) to theoretically change the entering time to test the stability of the estimates. Second, we excluded the participants who entered different transitions on the same day. Third, we omitted the participants with FCMD for the first 2 years of follow-up to account for reverse causality. Fourth, considering the interactive effect of cancer and CMD, we reanalyzed the associations by omitting the participants with cancer at baseline. In addition, the participants with missing covariate values were excluded from the analyses. Finally, considering the correlation of air pollution with PA and CMM, we separately added particulate matter 2.5, particulate matter 10, nitric oxide, and nitrogen dioxide at baseline in the multistate models. The data of air pollution were estimated using the Land Use Regression model developed as part of the European Study of Cohorts for Air Pollution Effects and can be found in the UKB database (field id: 24003, 24004, 24005, and 24006).

Ethical Considerations

UKB received ethics approval from the North West Multi-centre Research Ethics Committee (reference 21/NW/0157). All participants provided written informed consent before enrollment in the study, which was conducted in accordance with the principles of the Declaration of Helsinki. The data used in this study were anonymized and deidentified for privacy and confidentiality protection. More details about ethics approval can be found on the UKB website.

Results

Participant Characteristics at Baseline and Transitions From Baseline to Mortality

Of the included participants, 54.55% (196,271/359,773) were female and 94.91% (341,474/359,773) were White. The mean age of the participants was 55.82 (SD 8.12) years at baseline. Moreover, 64.12% (230,676/359,773) of the participants were overweight and obese, and 88.68% (319,043/359,773) of the participants were recruited from England; 56.06% (201,671/359,773) of the participants never smoked, and 70.21% (252,589/359,773) of the participants drank daily, almost daily, or more than once per week. Furthermore, 38.9% (139,963/359,773), 19.55% (70,329/359,773), and 41.55% (149,481/359,773) of the included participants had MVPA of <600, 600 to 1200, and >1200 MET minutes per week, respectively. The participants with lower PA intensity were more likely to be female; be of younger age, belong to a different ethnicity, have a lower SES, have a higher BMI, have lower income, have a lower education level, engage in more frequent drinking, and have less PA; and be current smokers. All the differences for different groups of PA intensity were statistically significant. More characteristics for included participants are shown in Table 1.

There were 2 patterns for the transitions from free of CMD to FCMD, then to CMM, and finally to mortality. The 5-transition model and 11-transition model are shown in Figure 1. For pattern A, 11.46% (41,237/359,773) of the participants developed FCMD and 4.02% (14,451/359,773) of the participants among baseline participants free of CMD died eventually. Moreover, 10.58% (4363/41,237) of the participants developed CMM, and 14.53% (5991/41,237) of the participants died after FCMD. Finally, 24.23% (1057/4363) of the participants died after a CMM diagnosis. For pattern B, 3.36% (12,059/358,811), 6.12% (21,966/358,811), and 1.74% (6250/358,811) of the participants, among the baseline participants free of CMD, first developed T2D, IHD, and stroke, respectively. Moreover, 8.44% (3401/40275) of the participants developed CMM, and 14.88% (5991/40275) of the participants died after a diagnosis of T2D, IHD, and stroke. Eventually, 25.52% (868/3401) of the participants died after having a diagnosis of CMM. More details are presented in Figure 1.

[a] Unknown included prefer not to answer, do not know, and missing values in the UK Biobank database.

[b] MVPA: moderate to vigorous PA.

[c] VPA: vigorous PA.

[d] Socioeconomic status was measured by using the Townsend area deprivation index.

[e] A currency exchange rate of £1=US $1.26 is applicable.

[f] A-level: Advanced level.

[g] AS-level: Advanced Subsidiary level.

[h] O-level: Ordinary level.

[i] GCSE: General Certificate of Secondary Education.

[j] CSE: General Certificate of Education.

[k] NVQ: National Vocational Qualification.

[l] HND: Higher National Diploma.

[m] HNC: Higher National Certificate.

[n] MET: metabolic equivalent task.

Traditional Cox Proportional Hazards Model

The estimates of the associations of PA amount and intensity with FCMD, CMM, and mortality are presented in Table S2 in Multimedia Appendix 1. More MVPA with 600-1200 and >1200 MET minutes per week lowered the risk of FCMD, CMM, and mortality than MVPA with <600 MET minutes per week. A decreased risk of FCMD, CMM, and mortality was also found in the participants with more VPA to MVPA (>0 to <1) than in the participants with no VPA. However, the associations of no MPA, namely total VPA with FCMD (*P*=.073), CMM (*P*=.294), and mortality (*P*=.123), were not statistically significant compared with no VPA. Similar results were found when the ordinal scale of PA intensity was used in the models.

Multistate Models

Multistate models for the associations of PA amount (Table S3 in Multimedia Appendix 1) and intensity (Table 2) with all the transitions were performed. First, meeting the recommendations of the World Health Organization, namely no less than 600 MET minutes per week for MVPA were found to be negatively associated with transitions from free of CMD to FCMD and mortality. In addition, >1200 MET minutes per week for MVPA was significantly associated with a decreased risk of transition from FCMD to CMM. When focusing on specific FCMD, more PA was found to be associated with a decreased risk of transitions from free of CMD to T2D, IHD, stroke, and mortality as well as transitions from stroke to CMM and from T2D to mortality.

A greater proportion of VPA to MPA, namely >0.5 for the proportion of VPA to MVPA, was associated with a lower risk of different transitions. Our analyses showed that compared with the participants with no VPA, participants with >0.75 to <1 of VPA to MVPA had a 13% and 27% lower risk of transition from free of CMD to FCMD (hazard ratio [HR] 0.87, 95% CI 0.83-0.91) and mortality (HR 0.73, 95% CI 0.66-0.79), respectively. Furthermore, the HR for the participants with no MPA was 0.82 (95% CI 0.73-0.92) compared with those with no VPA. The participants with >0.75 to <1 VPA to MVPA had the lowest risk of transitions from free of CMD to FCMD and mortality. The decreased risk of transitions from free of CMD to FCMD and mortality was also related to higher PA intensity in consideration of the ordinal scale. However, we did not find significant associations of PA intensity with other transitions in model A.

Model B showed different associations of PA intensity with the transitions related to specific FCMD. Specifically, a greater proportion of VPA to MPA was associated with a lower risk of transitions from free of CMD to T2D and stroke. In addition, a decreased risk of transitions from stroke to CMM and from T2D to mortality was found to be associated with >0.5 to 0.75 of VPA to MVPA. It was noted that lower PA intensity, that is, >0 to 0.5 of VPA to MVPA, was also found to be associated with a lower risk of transition from T2D to mortality. The ordinal scale of higher PA intensity was significantly associated with a lower risk of transition from free of CMD to T2D, stroke, and mortality.

Table 2. Associations of physical activity (PA) intensity with transitions from free of cardiometabolic disease (CMD) to first occurrence of CMD (FCMD), cardiometabolic multimorbidity (CMM), and mortality.

[a] VPA: vigorous PA.

[b] MVPA: moderate to vigorous PA.

[c] HR: hazard ratio.

[d] The models were adjusted for age, sex, ethnicity, socioeconomic status, BMI, household income, study center region, education group, smoking status, alcohol drinking status, and PA amount. Model A included 5 transitions from free of CMD to FCMD, then to CMM, and finally to mortality (Figure 1A), and model B included 11 transitions by including specific FCMD (Figure 1B).

[e] *P*<.001.

[f] *P*<.01.

[g] T2D: type 2 diabetes.

[h] IHD: ischemic heart disease.

[i] *P*<.05.

Subgroup Analyses

Several important findings were involved in the subgroup analyses of PA amount, and details are presented in Table 3. First, lower PA (<600 MET min/wk) accompanied by lower PA intensity, that is, >0 to 0.25 of VPA to MVPA, was not significantly associated with a decreased risk of any transition compared with no VPA. Second, the participants with a greater proportion of VPA to MPA were highly associated with a reduced risk of transitions from free of CMD to FCMD and mortality regardless of the amount of PA. Third, higher PA intensity was associated with a decreased risk of transitions from free of CMD to T2D and stroke for the participants with the recommended amount of PA (no less than 600 MET min/wk) and IHD for the participants under the threshold of the recommended amount of PA (<600 MET min/wk). These findings were similar when using the ordinal scale of PA intensity.

A significant effect of modification related to age, sex, PA amount, BMI, smoking, and alcohol drinking status was found among at least 1 transition (Table 4; Tables S4 and S5 in Multimedia Appendix 1). The protective effect of higher PA intensity on the transition from free of CMD to FCMD was larger among younger participants, participants with overweight, and previous or current smokers. Specifically, the decreased risk of the transitions from free of CMD to IHD and stroke associated with higher PA intensity was only found in previous or current smokers. Male participants, current or previous smokers, excessive alcohol drinkers, and participants with more PA could have more benefits of higher PA intensity for reducing mortality from free of CMD. In addition, the protective effect of higher PA intensity on the transitions from FCMD to mortality was more pronounced among the current or previous smokers. Younger populations aged ≤60 years could benefit from higher PA intensity when having CMM.

Table 3. Associations of physical activity (PA) intensity with transitions from free of cardiometabolic disease (CMD) to first occurrence of CMD (FCMD), cardiometabolic multimorbidity (CMM), and mortality by PA amount.

[a] The models were adjusted for age, sex, ethnicity, socioeconomic status, BMI, household income, study center region, education group, smoking status, alcohol drinking status, and PA amount. Age, sex, BMI, smoking status, and alcohol drinking status were not included in the models for the subgroup analyses. Model A included 5 transitions from free of CMD to FCMD, then to CMM, and finally to mortality (Figure 1A). PA intensity refers to the proportion of vigorous PA to moderate to vigorous PA, and an ordinal scale of PA intensity was used in the subgroup analyses.

[b] HR: hazard ratio.

[c] *P*<.001.

[d] *P*<.05.

[e] *P*<.01.

Sensitivity Analysis

We did not find substantial changes for the associations of PA intensity with the transitions from free of CMD to FCMD, then to CMM, and finally to mortality by performing additional analyses (Table S6 in Multimedia Appendix 1) using different time intervals (0.5 y, 1 y, 2 y, 3 y, and 5 y) for the participants entering different transitions on the same day, excluding the participants who entered different transitions on the same day, excluding FCMD in the first 2-year follow-up, excluding the participants with cancer, and excluding the participants with missing values at baseline for the covariates, which revealed robust estimates in this study.

Discussion

Principal Findings

This is the first prospective cohort study using large-scale population–based data to explore the associations of PA intensity with different transitions from free of CMD, then to CMM, and finally to mortality. This study reported the effect of the proportion of VPA to MVPA on the incidence, progression, and prognosis of CMM using multistate models, and the principal findings are discussed next. Compared with the participants with no VPA, the participants with >0.75 to <1 of VPA to MVPA had the lowest risk of transitions from free of CMD to FCMD and mortality regardless of model A or B. The protective effect of higher PA intensity on the transitions from free of CMD to T2D (*P*<.001) and from T2D to mortality (*P*<.001) was statistically significant, which revealed the importance of PA intensity for the transitions of T2D. More PA and greater intensity had a synergistic effect on decreasing the risk of transitions from free of CMD to FCMD and mortality. Male participants, younger adults, participants with a higher BMI, current or previous smokers, and excessive alcohol drinkers could obtain more benefits from higher PA intensity for the lower risk of at least 1 transition from free of CMD, then to CMM, and finally to mortality.

Interpretations, Implications, and Comparisons With Existing Literature

In line with previous studies focusing on PA amount, this study had similar findings that meeting the recommendations of PA amount could significantly decrease the risk of FCMD, CMM, and mortality, regardless of whether the traditional Cox proportional hazards regression model or multistate model was used [23-30]. This study also provided some evidence for the additional benefits of more PA (>1200 MET min/wk) for FCMD, CMM, and mortality. It is worth noting that more PA did not provide a lower risk of mortality when including CMM in the consideration of estimates from the multistate model. The aforementioned findings might be explained by the fact that the participants with CMM might have cardiovascular organic lesions and the benefits from more PA might be offset.

In line with previous studies [31-34], this study also found that higher PA intensity was significantly associated with all-cause mortality. In addition, this study added new evidence to recent knowledge that a greater proportion of VPA to MVPA (>0.75 to <1) could provide more benefits, including a decreased risk of 27% and 13% for the transitions from free of CMD to mortality and FCMD, respectively. Simultaneously, it was noted that no strong evidence was observed that a higher proportion of VPA to MVPA was associated with a lower risk of transition from free of CMD to IHD, which indicated that a suitable intensity was more effective for preventing IHD than no VPA. Another important finding in this study was that median PA intensity (the proportion of VPA to MVPA >0 to 0.75) was associated with a lower risk of transition from T2D to mortality, which suggests that stronger interventions of higher PA intensity for the participants with T2D are necessary to decrease all-cause mortality. In addition, we did not find that higher PA intensity was associated with other transitions related to CMM, which emphasizes that higher PA intensity at baseline plays an important role in the primary and secondary prevention for CMM and has a weaker role in the prognosis of CMM.

A national cohort study of >400,000 US adults reported a decreased risk of all-cause mortality associated with the synergistic effect of more PA and greater intensity [32]. This study reported similar results for the associations of an interactive effect of PA amount and intensity on transitions from free of CMD to mortality. The aforementioned associations were also significant in the transition from free of CMD to FCMD, which not only emphasized the importance of PA amount but also highlighted the importance of higher PA intensity for healthy outcomes and the development of CMM.

Inconsistent with a previous study reporting no interactions for the associations of sex with all-cause mortality [31,32], this study found that male participants could benefit more from higher PA intensity for reducing mortality from the free of CMD status. In line with the study by Wang et al [32], we also found significant interactions of current or previous smoking status and PA intensity with all-cause mortality. These differences might be caused by the different models used in this study. Instead of traditional Cox proportional hazard models used in previous studies, this study used the multistate models, which introduced a competing risk for all-cause mortality and could more validly show the transitions from free of CMD to mortality. In addition, this study provided additional evidence for identifying sensitive populations for other transitions in the incidence, progression, and prognosis of CMM, which could help develop preventive, targeted strategies for sensitive populations in the transitions.

Strengths and Limitations

This study has several strengths. First, this study used multistate models considering the competing risk for all-cause mortality to assess the associations of PA intensity, namely the proportion of VPA to MVPA with the transitions from free of CMD to FCMD, then to CMM, and finally to mortality. Second, this study used a large-scale population–based cohort, which allowed us to explore the associations among different transitions using the prospective design. Third, long-term follow-ups of UKB in this study could provide a sufficient duration to observe the incidence, progression, and prognosis of CMM. Certain limitations should be approached with caution when interpreting the results of this study. First, the PA amount and intensity were self-reported, and more studies using portable equipment are needed to verify these associations. In addition, we only captured the baseline characteristics of PA in this study. Further studies should focus on the effects of the trajectory of PA on the transitions. In addition, although UKB had a low recruitment rate [35] and a limited age group from 37 to 73 years, a previous study proved that the associations of PA with mortality were not materially changed [45].

Clinical Implications and Conclusions

This study suggests that higher PA intensity is an effective measure for preventing CMM and mortality in the early period of CMM development. Higher PA intensity accompanied by higher PA levels could provide the lowest risk of all-cause mortality and FCMD. Targeted populations including male participants, younger adults, people with overweight, current or previous smokers, and excessive alcohol drinkers could obtain more benefits from higher PA intensity for FCMD and all-cause mortality. Relevant interventions related to higher PA intensity should be performed.

Acknowledgments

The authors would like to thank the participants of the UK Biobank. This research was conducted using the UK Biobank Resource under application number 91536. B-PL was supported by the National Natural Science Foundation of China (NSFC; #82103954) and Shandong Provincial Natural Science Foundation (#ZR2021QH310). C-XJ was supported by the NSFC (#81761128033). The funding sources were not involved in the study design; in the collection, analysis, and interpretation of data; in the writing of the report; or in the decision to submit the paper for publication.

Data Availability

UK Biobank data can be accessed by submitting an application through the UK Biobank website.

Authors' Contributions

B-PL and C-XJ conceptualized the research question. B-PL conducted data analysis and managed the data. B-PL, J-HZ, L-PW, Z-YZ, and XW drafted the paper. All authors provided critical feedback on the paper at various stages and approved the final version of the paper.

Conflicts of Interest

None declared.

Abstract

Background: Esophageal cancer (EC) is the sixth leading cause of cancer-related burden with distinct regional variations globally. Although the burden of EC has decreased, the specific reasons for this decline are still unclear.

Objective: This study aims to uncover the spatiotemporal patterns of EC risk–attributable burden in 204 countries and territories from 1990 to 2019 so that prevention and control strategies of EC can be prioritized worldwide.

Methods: We extracted EC risk–attributable deaths, disability-adjusted life years (DALYs), age-standardized mortality rates (ASMRs), and age-standardized DALY rates (ASDRs) from the global burden of disease (GBD) study from 1990 to 2019, in terms of behavioral, metabolic, and dietary factors by age, sex, and geographical location. Average annual percentage change (AAPC) was used to assess the long-term trends in the ASMRs and ASDRs of EC due to specific risk factors.

Results: Between 1990 and 2019, the greatest decrease in EC burden was attributed to low intake of fruits and vegetables. An AAPC of –2.96 (95% CI –3.28 to –2.63) and –3.12 (95% CI –3.44 to –2.79) in ASMR and ASDR was attributable to a low-fruit diet, while an AAPC of –3.60 (95% CI –3.84 to –3.36) and –3.64 (95% CI –3.92 to –3.35) in ASMR and ASDR was attributed to a low-vegetable diet. However, the trends in ASMRs and ASDRs due to high BMI showed significant increases with an AAPC of 0.52 (95% CI 0.29-0.75) in ASMR and 0.42 (95% CI 0.18-0.66) in ASDR from 1990 to 2019 compared to significant decreases in other attributable risks with AAPC<0 ($P<.05$). East Asia had the largest decrease in EC burden due to low-vegetable diets, with an AAPC of –11.00 (95% CI –11.32 to –10.67) in ASMR and –11.81 (95% CI –12.21 to –11.41) in ASDR, followed by Central Asia, whereas Western Sub-Saharan Africa had the largest increase in ASMR and ASDR due to high BMI, with an AAPC of 3.28 (95% CI 3.14-3.42) and 3.09 (95% CI 2.96-3.22), respectively. China had the highest EC burden attributed to smoking, alcohol use, high BMI, and low-fruit diets. Between 1990 and 2019, there was a significant decrease in EC burden attributable to smoking, alcohol use, chewing tobacco, low-fruit diets, and low-vegetable diets in most countries, wherein a significant increase in the EC burden was due to high BMI.

Conclusions: Our study shows that smoking and alcohol consumption are still the leading risk factors of EC burden and that EC burden attributable to low intake of fruits and vegetables has shown the largest decline recently. The risks of ASMRs and ASDRs of EC showed distinct spatiotemporal patterns, and future studies should focus on the upward trend in the EC burden attributed to high BMI.

KEYWORDS

esophageal cancer; age-standardized mortality rate; disability-adjusted life years; attributable risk; average annual percentage change

Introduction

In 2019, esophageal cancer (EC) was the sixth leading cause of cancer deaths and disability-adjusted life years (DALYs), with over 0.54 million deaths and 1.17 million DALYs, representing 50% of all cancers worldwide [1]. Early diagnosis and treatment have been implemented to reduce EC incidence and mortality rates and to improve survival rates over years. However, patients with EC still have low 5-year survival rates (about 30.3%) due to unclear and nonspecific early clinical symptoms, and most patients are diagnosed at an advanced stage [2]. Therefore, EC is still an important public health and clinical challenge for early diagnosis and prevention, especially in low-income countries. Besides, EC burden greatly varies with geographical locations, and the "EC belt" has substantially high EC incidence and mortality rates worldwide [3]. The disparities in the burden of cancer and the poor treatment outcomes across regions worldwide are reflected in the Sustainable Development Goal target 3.4 that focuses on reducing premature mortality from noncommunicable diseases (eg, cancers) by one-third by promoting mental health and well-being by 2030 through prevention and treatment [4].

EC has 2 main histological subtypes, that is, esophageal squamous cell carcinoma (ESCC) and esophageal adenocarcinoma (EAC), which have analogous and distinct etiologies with modifiable risk factors (eg, smoking, alcohol use, obesity, diet) [5,6]. EC cases with over 85% ESCC histological subtype cluster in low-income countries and has recently shown a significantly downward trend worldwide [7,8]. Previous studies have reported the epidemiological characteristics of EC, such as incidence, mortality, and DALY rates in several countries or regions over several years [9,10]. Age-standardized incidence rates of EC in China have declined significantly from 1990 to 2019, and the decrease is more pronounced among females than among males [11]. Moreover, there are significant differences in the risk factors between sexes [11]. There was a significant male predominance in EC cases with a male-to-female incidence ratio of 3.3:1 for ESCC and 6.7:1 for EAC [8]. Further, the interaction effect of sex and smoking in ESCC has been reported in a cohort study with 13 years of median follow-up [12]. However, comprehensive understanding of EC risk–attributable burden does not exist in many countries, leading to a void in the up-to-date prevention strategies and adjustment in the EC treatment research focus. At this point, the latest changes in the specified risk-attributable burden of EC should be scheduled at global, regional, and national scales to elucidate the trend in EC cases that are attributable to primary factors (eg, smoking, alcohol use, metabolism, diet). Addressing the primary factors contributing to EC burden can lead to advances in the prognosis and treatment of EC in countries worldwide that require EC prevention and control measures.

To date, the Global Burden of Disease (GBD) study has assessed cancer burden by broadly considering the major modifiable risk factors across countries, ages, and sexes worldwide over time. To our knowledge, GBD is the only database that quantifies and provides a comprehensive picture of the cancer burden attributable to a set of risk factors through stringent quality assurance procedures to model at different scales over time. Further, GBD 2019 provides the latest information on each risk-outcome pair for EC in 204 countries and territories and its aggregation regions from 1990 to 2019, which enables the evaluation of the risk-attributable burden for low-income countries. Herein, we analyzed the spatiotemporal patterns in the burden of EC attributable to specific behavioral, metabolic, and dietary risk factors at global, regional, and national levels over 3 decades, which can help policy makers implement prevention measures and tackle the growing EC burden driven by specific risk factors.

Methods

Data Source

We collected the annual number of EC (International Classification of Diseases 10th revision code C15) deaths, DALYs, age-standardized mortality rates (ASMRs), and age-standardized DALY rates (ASDRs) related to risk-attributable factors by sex and age at global, regional, and national levels from GBD 2019 estimations from 1990 to 2019. The data included EC risk–attributable deaths, DALYs, ASMRs, and ASDRs in 204 countries and territories and were clustered in 21 GBD regions according to geographical proximity and economic similarities [13]. Subsequently, according to the sociodemographic index (SDI) ranging from 0 to 1, 204 countries and territories were classified under 5 SDI levels: low SDI (<0.45), low-middle SDI (≥0.45 to <0.61), middle SDI (≥0.61 to <0.69), high-middle SDI (≥0.69 to <0.80), and high SDI (≥0.80). The SDI is a composite indicator of a country's lag-distributed income per capita, average years of schooling (aged >15 years), and fertility rate in females younger than 25 years [14].

Exposure Selection and Definition

By reviewing previous literature and studies in terms of the leading risk factors of EC burden, we targeted the EC burden attributable to the most prominent risk factors, including behavioral risk (ie, smoking, alcohol use, and chewing tobacco), metabolic risk (ie, high BMI), and diet risk (ie, diet with less vegetables and fruits) [15,16]. We focused on these leading factors (established EC risk factors with available data in GBD) to analyze the spatiotemporal patterns of EC burden in different regions in order to implement EC prevention and intervention measures. In this study, smoking is defined as the prevalence of current use of any smoked tobacco product and prevalence of the former use of any smoked tobacco product. Alcohol use is defined as the average daily alcohol consumption of pure alcohol (measured in grams per day) by current drinkers who had consumed alcohol during the past 12 months. Chewing tobacco is defined as the current use of any chewing tobacco product. High BMI is defined as BMI above the normal range (18.5-24.9 kg/m^2). Diet low in vegetables and fruits is defined as the average daily consumption of vegetables and fruits (measured in grams per day). These variables are well-established risk factors for EC with available data in GBD and whose detailed definitions and risk gradients for EC are elaborated elsewhere [17]. Because EC incidence and mortality have been hardly reported among individuals younger than 40 years [18], we considered 0-39 years old as one age group, individuals aged 40-94 years as smaller subgroups each with an age range of 5 years, and >95 years old as the last age group.

Statistical Analysis

Estimation of the EC Burden

Data on deaths, DALYs, ASMRs, and ASDRs were reported with numbers and their 95% uncertainty intervals (UIs), generating values at the 2.5th and 97.5th percentile from 1000 draws. The methods for the estimation of explaining uncertainty in the risk-attributable burden have been described in detail elsewhere [15]. Briefly, the GBD comparative risk assessment was divided into 6 key processes for each risk-outcome estimation. First, we identified convincing or probable evidence for causal association with EC based on systematic reviews and meta-regression. Second, we estimated the relative risks for each risk-outcome pair as risk-attributable function of EC by using GBD's meta-regression-Bayesian, regularized, and trimmed method. Third, we analyzed the model risk exposure level and distribution by age, sex, location, and year by using Bayesian meta-regression modelling (DisMod-MR 2.1). Fourth, we determined the theoretical minimum risk exposure level based on a counterfactual scenario (a given population receives the optimal level of risk exposure) and the 85th percentile of exposure in cohorts and trial studies. Fifth, we calculated the population attributable fractions for each risk-outcome pair by age, sex, location, and year. Sixth, we estimated the EC burden attributable to specified risk factors, wherein deaths and DALYs were multiplied by the corresponding risk factor population attributable fraction [19,20].

Analysis of the Time Trends of EC Burden

An average annual percentage change (AAPC) was used to estimate the long-term trends in ASMR and ASDR in EC cases attributable to each risk factor from 1990 to 2019. In this study, AAPC was widely used to analyze a summary measure of time trend over an entire period, which was fitted in a regression by the natural logarithm of the ASMR and ASDR from 1990 to 2019, that is, $y = \alpha+\beta x+$, where $y = \ln$ (ASMR or ASDR) and x = calendar year. The AAPC was calculated as $100 \times (\exp(\beta)-1)$, and its 95% CI can also be obtained from the fitted regression model. The time trend of ASMR or ASDR was defined as a significant increase if AAPC>0 and its lower boundary of 95% CI>0 (*P*<.05). Inversely, the time trend of ASMR or ASDR was defined as a significant decrease if the AAPC<0 and its upper boundary of 95% CI<0 (*P*<.05). Otherwise, it was not a significant trend over time. In addition, we assessed the time trends of ASMR and ASDR attributable to each specific risk factor for EC by age group and sex at regional, SDI, and national levels from 1990 to 2019. These statistical analyses were conducted using Joinpoint trend analysis software (version 4.9.1.0; Statistical Methodology and Applications Branch), and corresponding geographical patterns were presented by ArcGIS 10.6 (ESRI). A *P* value less than .05 was considered statistically significant.

Ethical Considerations

This study did not involve human participants and animals. Ethics approval was not applicable for this study, as this study used existing good quality modeled data that were aggregated at the population level.

Results

Global Trends in EC Risk–Attributable Burden

As Table 1 shows, although the total number of EC risk–attributable deaths and DALYs globally increased in both sexes combined between 1990 and 2019, the corresponding ASMRs and ASDRs decreased. The deaths attributable to smoking increased from 134,682 (95% UI 105,311-152,927) in 1990 to 203,328 (95% UI 170,461-236,522) in 2019, while the corresponding ASMR decreased from 3.42 (95% UI 2.69-3.86) per 100,000 people in 1990 to 2.48 (95% UI 2.08-2.89) per 100,000 people in 2019. The DALYs and ASDRs attributable to smoking followed a similar pattern during the same period. Besides, in 2019, the higher global EC burden was attributable to specifically behavioral, metabolic, and dietary factors among males (Table 1).

Table 1. Global burden of esophageal cancer attributable to behavioral, metabolic, and diet factors in 1990 and 2019.

Risk factor	1990				2019			
	Death (persons, 95% UI[a])	ASMR[b] (95% UI)	DALY[c] (95% UI)	ASDR[d] (95% UI)	Death (persons, 95% UI)	ASMR (95% UI)	DALY (95% UI)	ASDR (95% UI)

[a] UI: uncertainty interval.

[b] ASMR: age-standardized mortality rate per 100,000 people.

[c] DALY: disability-adjusted life year of persons.

[d] ASDR: age-standardized disability-adjusted life year rate per 100,000 people.

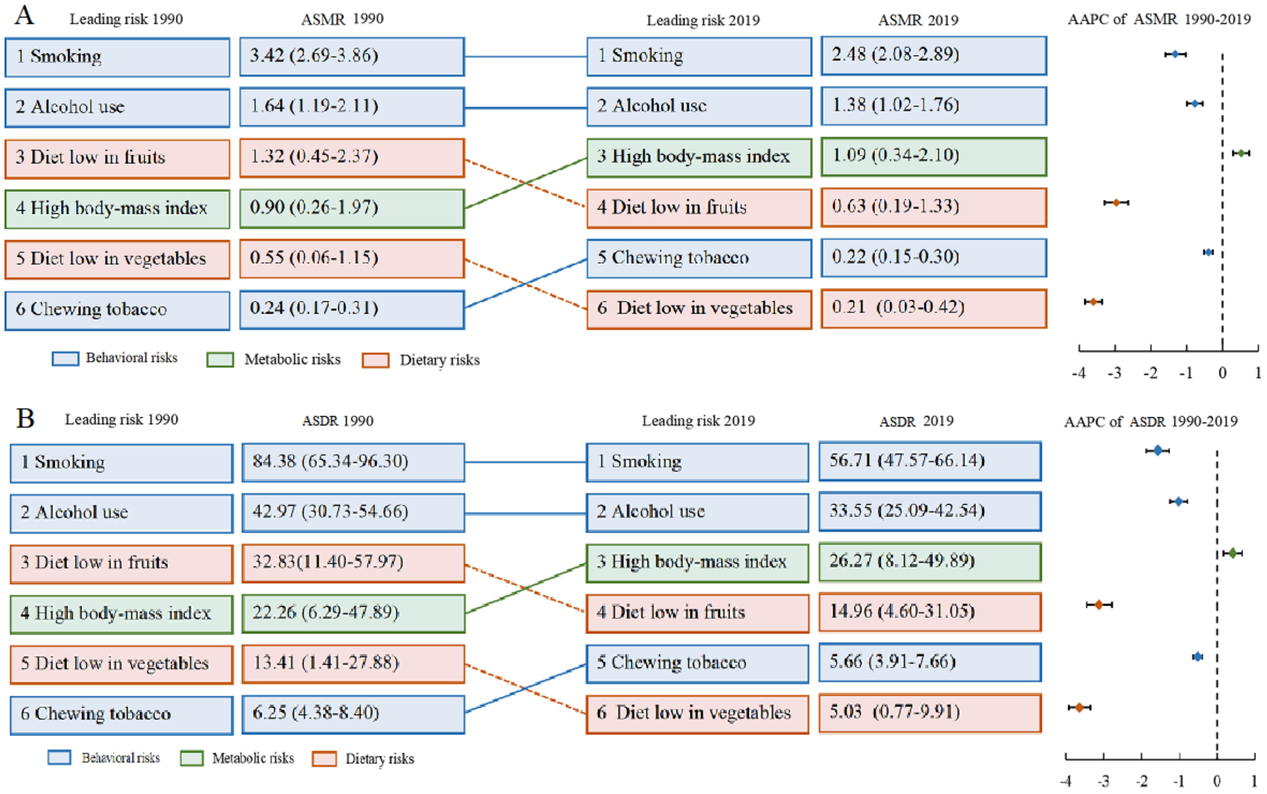
[e] B: both male and female.

[f] M: male.

[g] F: female.

Behavioral risks include smoking, alcohol use, and chewing tobacco; metabolic risks include high BMI; and diet risks include diets low in fruits and vegetables. Figure 1 shows the changes in EC ASMR and ASDR by specific risk factors for both sexes combined from 1990 to 2019. Globally, smoking and alcohol use were the leading risk factors for EC burden, which declined significantly in the past 3 decades. The ASMRs attributable to diets low in fruits and vegetables had the most significant decrease, falling from the third and fifth positions in 1990 to the fourth and sixth positions in 2019, respectively. However, EC burden related to high BMI ranked third during this period. Notably, although the ranks of ASMR and ASDR attributable to chewing tobacco increased, the burden of EC attributed to chewing tobacco declined significantly (*P*<.05).

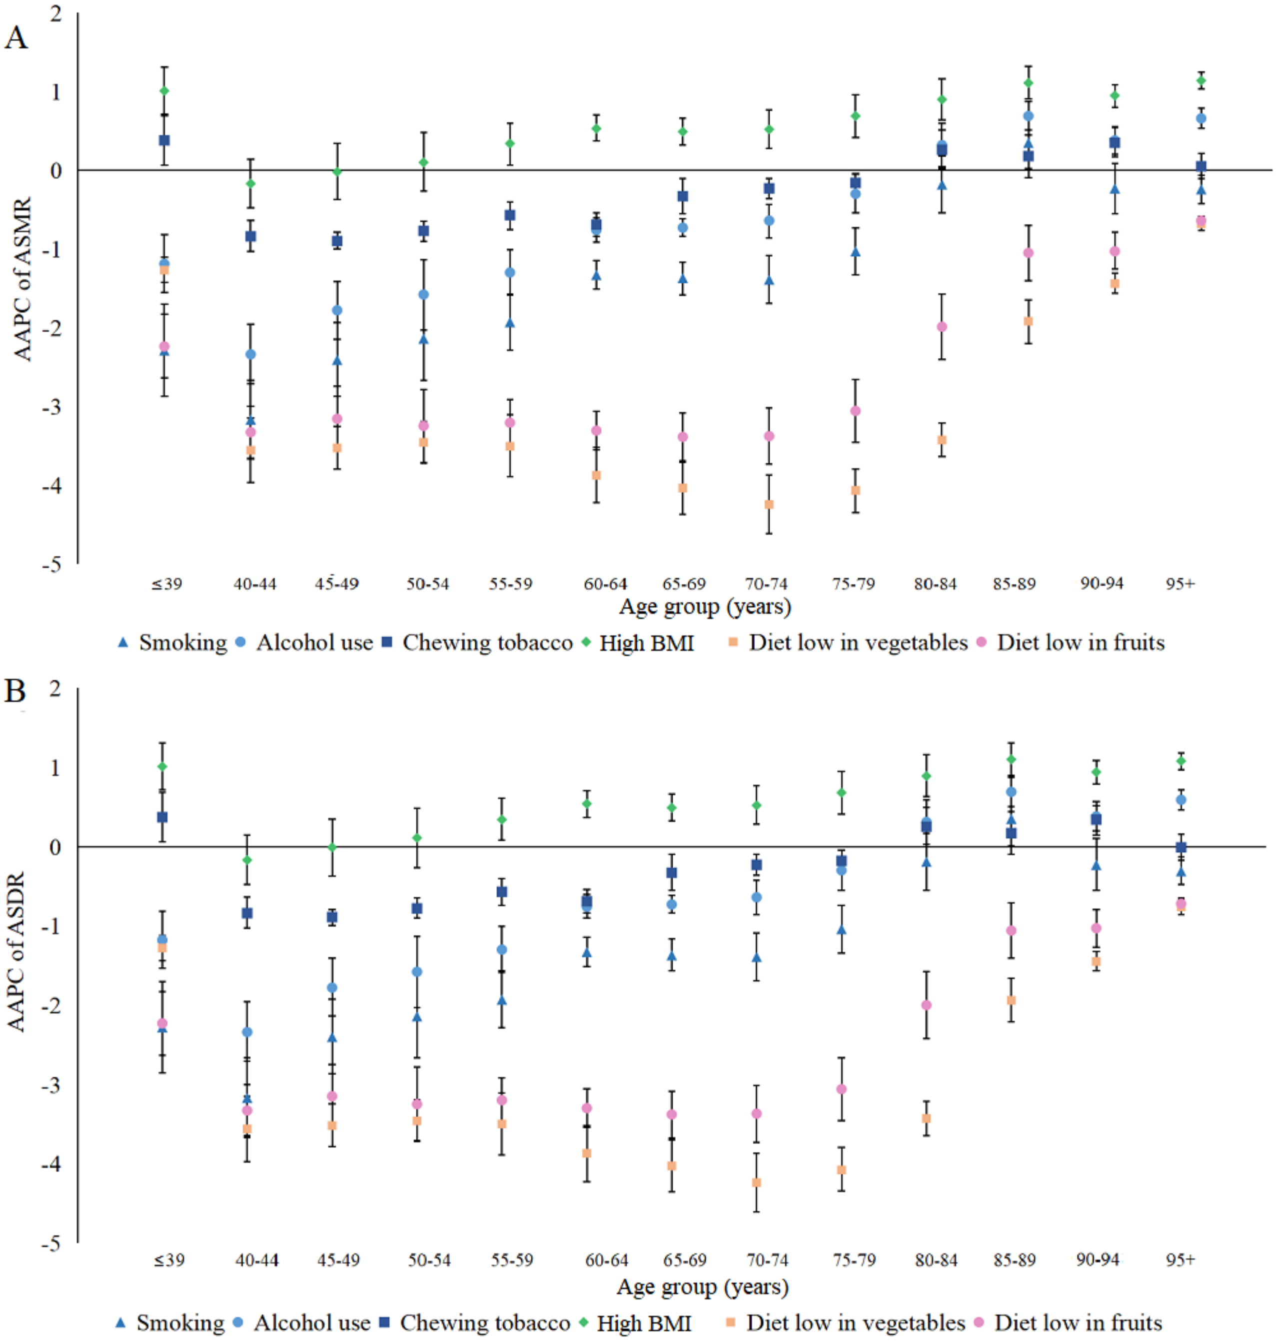
Figure 1. The changes in esophageal cancer (A) age-standardized mortality rate and (B) age-standardized disability-adjusted life year rate attributable to specific risk factors for both sexes combined in 1990-2019 globally. Dashed lines indicate decrease in rank. Solid lines indicate increase or no change in rank. Data in parentheses are 95% CIs. AAPC: average annual percentage change; ASDR: age-standardized disability-adjusted life year rate; ASMR: age-standardized mortality rate.



Global Trends in EC Risk–Attributable Burden by Age Groups

Figure 2 shows that smoking-related ASMRs and ASDRs declined in each age group except for the 85-89 years age group, with the highest decrease noted in the 40-44 years age group. Similarly, alcohol-related ASMR and ASDR declined in the 40-44 years age group, while it increased in the >80 years age group and peaked in the 85-89 years age group. The ASMRs and ASDRs attributable to diets low in fruits and vegetables declined in all age groups, but that attributable to high BMI increased in most age groups outside the subgroups within the age range of 40-54 years significantly (*P*<.05). The AAPCs of ASMR and ASDR for males and females are presented in Figures S1-S2 of Multimedia Appendix 1.

Figure 2. The average annual percentage change of (A) age-standardized mortality rate and (B) age-standardized disability-adjusted life year rate for both sexes combined by age groups in 1990-2019 globally. AAPC: average annual percentage change; ASDR: age-standardized disability-adjusted life year rate; ASMR: age-standardized mortality rate.



Regional and SDI Trends in EC Risk–Attributable Burden

As Figure 3 shows, there were significant downward trends in risk-attributable ASMRs and ASDRs in most regions with AAPC<0 compared to significant increases in high BMI–related ASMRs and ASDRs (*P*<.05). The EC burden attributable to each risk factor increased in Western Sub-Saharan Africa, while it declined significantly in Central Asia, Central Latin America, Eastern Europe, high-income Asia–Pacific, and Southern Latin America (*P*<.05). Among the risk factors, diets low in vegetables caused the most decline in the EC burden in East Asia and Central Asia, while high BMI caused the most increase in the ASMRs and ASDRs in Western Sub-Saharan Africa. Southern Sub-Saharan Africa and Central Asia showed the highest decline in smoking-related and alcohol use–related ASMRs and ASDRs, respectively. Figure 3 shows that the most dramatic decrease in EC burden was ascribed to low-vegetable diets in countries with middle SDI, followed by countries with high-middle SDI. In contrast, countries with low-middle SDI showed a sharp increase in EC burden, which is attributable to high BMI. In addition, Figures S1-S2 of Multimedia Appendix 1 show the changes in ASMRs and ASDRs attributable to risk factors among males and females in 21 GBD regions and 5 SDI levels. Table S1 of Multimedia Appendix 1 shows that the preponderance of EC burden for both sexes combined, in terms of the number of deaths and DALYs, were attributable to smoking, alcohol use, high BMI, and low-fruit diets in East

Asia, while the highest number of deaths and DALYs attributable to chewing tobacco and low-vegetable diets occurred in South Asia in 2019 (Multimedia Appendix 1). Table S2 in Multimedia Appendix 1 shows distinct differences and risk gradients of ASMRs and ASDRs in 21 GBD regions and 5 SDI levels.

Figure 3. The average annual percentage change for esophageal cancer risk–attributable age-standardized mortality rate and age-standardized disability-adjusted life year rate in 21 global burden of disease regions classified by 5 sociodemographic index levels for both sexes in 1990-2019. Dark green indicates the highest decline in the average annual percentage change, dark red indicates the highest increase in the average annual percentage change, and grey indicates no significant average annual percentage change. AAPC: average annual percentage change; ASDR: age-standardized disability-adjusted life year rate; ASMR: age-standardized mortality rate; SDI: sociodemographic index.

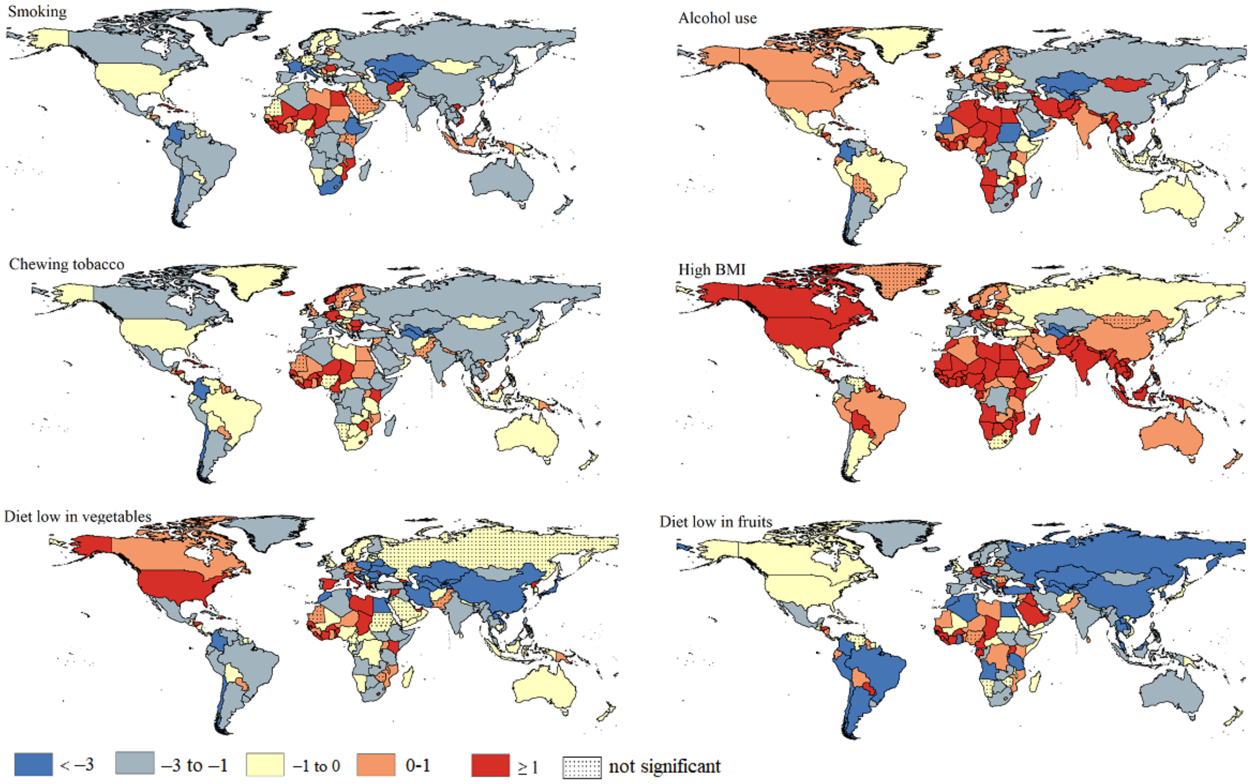
National Trends in EC Risk–Attributable Burden

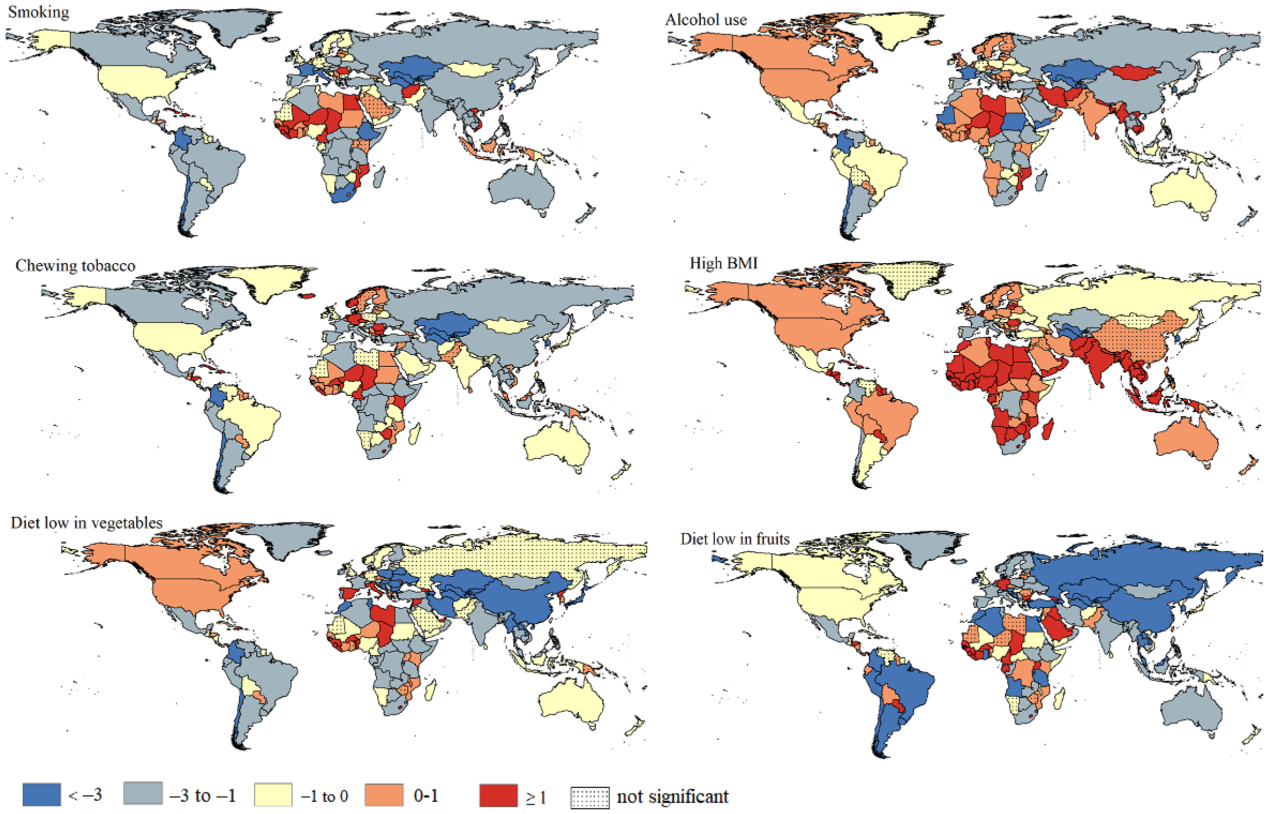
Figure 4 shows the trends in risk-attributable ASMR in both sexes combined in 204 countries and territories from 1990 to 2019. There was a significant downward trend in ASMRs attributable to smoking, alcohol use, chewing tobacco, low-vegetable diets, and low-fruit diets in 136 (66.7%), 93 (45.6%), 118 (57.8%), 141 (69.1%), and 137 (67.2%) countries of all the 204 countries and territories, respectively. In contrast, a significantly upward trend in ASMR attributable to high BMI was observed in 139 (68.1%) countries and territories. Turkmenistan showed the highest decline in ASMRs attributable to smoking (AAPC=–5.21, 95% CI –5.99 to –4.42), high BMI (AAPC=–3.21, 95% CI –4.03 to –2.39), chewing tobacco (AAPC=–4.77, 95% CI –5.51 to –4.03), and low-vegetable diets (AAPC=–13.67, 95% CI –14.69 to –12.64), while the highest decline in ASMR attributable to alcohol use (AAPC=–8.02, 95% CI –10.94 to –5.00) and low-fruit diets (AAPC=–7.99, 95% CI –8.63 to –7.34) occurred in Sudan and Albania. São Tomé, Príncipe, and Northern Mariana had the highest increase in ASMR attributable to smoking (AAPC=3.40, 95% CI 3.17-3.62) and chewing tobacco (AAPC=3.58, 95% CI 3.08-4.08). Besides, Vietnam had the highest increase in ASMR attributable to alcohol use (AAPC=8.61, 95% CI 7.77-9.45) and high BMI (AAPC=5.94, 95% CI 5.55-6.34), but United Arab Emirates had the highest increase in ASMR attributable to low-vegetable diets (AAPC=11.01, 95% CI 9.47-12.56) and low-fruit diets (AAPC=5.10, 95% CI 4.50-5.72).

Figure 4. The average annual percentage change of esophageal cancer age-standardized mortality rate attributable to specific risk factors for both sexes combined in 204 countries and territories from 1990 to 2019.



As Figure 5 shows, from 1990 to 2019, significant decreases in ASDR attributable to smoking, alcohol use, chewing tobacco, low-vegetable diets, and low-fruit diets were found in 143 (70.1%), 96 (47.1%), 116 (56.9%), 145 (71.1%), and 143 (70.1%) countries of the 204 countries and territories, while 124 (60.7%) countries and territories experienced significant increases in ASDR attributable to high BMI. During this period, Turkmenistan had the highest decrease in ASDR attributable to smoking (AAPC=–5.31, 95% CI –6.09 to –4.53) and low-vegetable diets (AAPC=–14.49, 95% CI –15.66 to –13.31), while Uzbekistan had the highest decrease in ASDR attributable to chewing tobacco (AAPC=–4.97, 95% CI –5.48 to –4.26) and high BMI (AAPC=–3.37, 95% CI –3.89 to –2.84). The changes in the risk-attributable burden in other countries and territories are presented in Figure 5.

Figure 5. The average annual percentage change of esophageal cancer age-standardized disability-adjusted life year rate attributable to specific risk factors for both sexes combined in 204 countries and territories from 1990 to 2019.



As Table S3 of Multimedia Appendix 1 shows, globally in 2019, China was the worst affected country with the highest number of EC deaths and DALYs attributable to smoking, alcohol use, high BMI, and low-fruit diets due to its large population and aging, accounting for about 50% of the total number of EC deaths and DALYs. China was followed by India, which had the highest number of EC-related deaths and DALYs attributable to chewing tobacco and low-vegetable diets.

Discussion

Principal Findings

This study uses the latest GBD 2019 data to analyze the spatiotemporal patterns in the burden of EC attributable to specific risk factors from 1990 to 2019, and our results show that the burden of EC varied with different risk factors at regional and national levels, among which EC disparities had different gradients of risk factors during this period. EC risk–attributable burden declined in most regions, countries, and territories, except for the increasing burden of EC attributed to high BMI. Our findings may be useful for the prognosis and treatment of EC by identifying the burden of modifiable risk factors worldwide for making clinical decisions about the risk attribution, stratification, and prevention.

Although the past 3 decades have witnessed a significant decrease in smoking-related EC burden, smoking still dominates among the risk-attributable factors. Moreover, the risk rank of EC burden attributable to chewing tobacco increased by 1 gradient from 1990 to 2019. The DALY of EC is estimated to be driven by tobacco smoking and chewing tobacco worldwide [10]. Compared with those in 1990, EC deaths and DALYs reduced by 55.9% and 42.1% in 2019, respectively, along with the corresponding ASMRs and ASDRs that annually declined by –1.18% and –1.41%, respectively, of which smoking resulted in 40.6% deaths [21]. Between 1990 and 2019, the trends in EC burden attributable to smoking largely varied across geographical locations, and there was a significant decrease mostly in regions outside the Caribbean and Western Sub-Saharan Africa. In 2003, the World Health Organization issued the “Framework Convention on Tobacco Control,” in which 168 countries joined this action and further worked out their own tobacco control strategies. EC deaths attributable to smoking continue to decrease with the reduction of smoking prevalence in high-income countries, paralleling with a decrease of 32.2% for males and 28.8% for females in age-standardized prevalence of smoking since 1990 [22,23]. Therefore, reducing smoking prevalence is an effective way to mitigate the EC burden.

Alcohol consumption still remains the second leading risk factor for EC burden from 1990 to 2019. The clear differences in EC burden over time attributable to alcohol use in GBD regions, as shown in our study, provides the most up-to-date information on the trends in EC risk–attributable burden. Approximately 22.6% of the deaths and 33.8% DALYs in EC are attributed to alcohol use worldwide [10,22]. Although alcohol-related EC deaths and DALYs increased by 13.1% and 8.3%, the change in the percentage of alcohol-related EC deaths and DALYs reduced by 14.4% and 17.1% from 1990 to 2017 [10,24]. The EC burden attributable to alcohol use declined in most regions (eg, Eastern Europe) concomitantly with the decrease in alcohol per capita consumption (from 11.2 L per capita to 9.8 L per capita) [25,26]. In contrast, a significant increase in EC burden related to alcohol use was observed in Southeast Asia, South Asia, Western Sub-Saharan Africa, and North America, largely because alcohol per capita consumption was high from 1990 to 2017 and is expected to remain high till 2030 [27-29]. For example, alcohol per capita consumption increased by 34% in Southeast Asia, ranging from 3.5 L per capita in 2010 to 4.7 L per capita in 2017 [27]. Thus, alcohol-related EC burden largely varies across geographical locations, and this variation should be carefully analyzed in the future.

The EC burden attributable to high BMI, in comparison with other risk factors, increased in most regions. This is consistent with the rising incidence of high BMI reported across the world, which has increased from 1975 to 2016 by nearly 12% for males, 24% for females, and 40% for both sexes combined [30]. Geographical differences in EC burden related to high BMI followed a geographical pattern of increasing obesity prevalence, with the largest absolute increase in high-income western countries, Central Asia, Middle East, and North Africa, and with the most relative increase in East and South-Eastern Asia [31]. However, previous studies have indicated that high BMI (or obesity) was a driver for EAC and not for ESCC [23]. This study also found that the geographical pattern of EC burden related to high BMI with AAPC>3 was generally consistent with that of EAC [32,33]. The slightly increased burden of EC attributable to high BMI, especially in typical ESCC high-risk regions such as China, suggest that EAC may show an upward trend due to increased prevalence of high BMI.

Consistent with that reported in previous studies [21,34], the burden of EC attributable to low-fruit and low-vegetable diets declined significantly, even if it remained stable or increased slightly in some regions. This aligns with the globally low consumption of fruits by 16.58% and vegetables by 25.60% from 1990 to 2017 [34,35]. The high dietary fibers of vegetables and fruits show a protective effect by generating inositol hexaphosphate to curb the growth rate of EC cells by reducing cellular proliferation and stimulating apoptosis [36]. Another plausible explanation is that high dietary fibers in vegetables and fruits decrease the levels of systemic inflammation factors such as tumor necrosis factor-α receptor-2 and interleukin-6, which may cause carcinogenesis [37]. The largest decrease in EC burden attributable to low intake of fruits and vegetables occurred in East Asia because of higher incomes and better health care. However, an upward trend in EC burden associated with low intake of vegetables occurred in North America and that associated with low intake of fruits occurred in Western Sub-Saharan Africa. In light of these variations, policy makers in each country should tailor related measures to promote well-balanced diets according to the local risk factors.

Risk Exposure of EC burden Among Sexes and Age Groups

In terms of the spatiotemporal pattern in the risk exposure of EC burden, important differences in the EC burden between sexes and age groups in different locations should be mentioned. The time trend in EC burden attributed to smoking and chewing tobacco among sexes and age groups followed a similar pattern with a significant decrease, but the gradient showed a distinct difference among locations. This is possibly caused by the reduction of smoking prevalence in different regions, wherein males in 135 countries and females in 68 countries showed a prominent decrease in smoking prevalence [22]. Similarly, the greater decreases in EC burden due to alcohol use among females and in the 40-44 years age group indicate that interventions should target males and >45-year-old populations. Besides, the time trends of the EC burden attributable to high BMI for males and females did not follow the same pattern—with an increasing AAPC for males and a decreasing AAPC for females within the 40-64 years old subgroups. A previous study documented that high BMI resulted in ASDR increase of 12.7% for males and 26.8% for females, accounting for nearly 20% of the EC burden [38]. In the past decades, the prevalence of obesity increased by quadruple in men and more than double in women, and the time trend of ASMR attributable to high BMI showed a significant upward trend in 170 countries and territories, a downward trend only in 8 countries and territories, and a stable trend in 26 countries and territories [31,39]. The reason for this phenomenon is not completely understood, but the global prevalence of high BMI and obesity as well as deaths and DALY-related overweight are observed to be parallel with our findings across age groups, implying that sex differences in the prevalence of high BMI and obesity in the age groups are a potential risk factor [38,40]. Accordingly, the sex differences in EC burden related to high BMI should be addressed by ad hoc strategies, which are imperative for implementing regulations and policies targeting specific disorders.

Public Health Implications

Our findings provide important evidence for tailored, country-specific policy development and inventions to address the geographical disparities in the EC burden, which can be used by governments at the national level to meet the challenges of the substantial burden of EC and develop strategies based on the priority of specific risk-attributable EC burden. Strategies such as behavioral and metabolic modifications (including smoking control, alcohol control policies and regulations, weight management tips) and access to abundant fruits and vegetables are imperative to face the challenges of EC. In light of the increase in EC burden related to high BMI in most countries, we recommend that public health policy makers and decision makers should prioritize their agenda by designing and implementing ad hoc effective policies to restrain the upward momentum of EAC. Moreover, encouraging balanced diets and reducing alcohol consumption and tobacco should constitute the essential component of EC prevention strategies. Educating the general public regarding risk factor modification is urgently needed in countries with heavy EC burden. Although it is not clear how diet influences EC development and progression, our study shows that EC burden attributable to low intake of fruits and vegetables has decreased significantly.

Strengths and Limitations

This study provides a comprehensive spatiotemporal analysis of the EC burden attributable to specific risk factors, thereby becoming a potential reference for developing interventions that address similar health problems by identifying the most prominent risk factor and monitoring the effectiveness of the change of risk-attributable burden of EC over time. Further studies are required to conduct early interventions targeting behavioral and metabolic risk factors of individuals based on our findings. Moreover, the accelerating growth of EC burden related to high BMI alerts us to prevent and curb this issue as early as possible. We hope these limitations can be solved in the future. The 2 distinct histological subtypes of EC, that is, ESCC and EAC, have completely different risk factors, trends, and geographical patterns, but data on ESCC and EAC are unavailable in GBD. Thus, we did not analyze the changes of EC burden attributable to risk factors by subtype. Second, some countries had no EC data because of the lack of registries, or even if they had data in several registries that did not cover the whole country and territory, the estimates were obtained by modelling. The EC data in countries without cancer registries were modeled, but the model did not solve the geographical approximates of EC, because the distribution of EC showed clear clusters. Third, we did not analyze the spatiotemporal changes of EC burden attributable to other risk factors such as consumption of hot meals, eating red or processed meat, physical activity, and infectious agents, because GBD has no data on these variables. This may overestimate the burden of EC attributable to the included risk factors in this study. Fourth, this study did not capture the potential synergy effects between risk factors in which some combinations might be multiplicative. For some risk factors such as behavior and diet, the joint effect of smoking and alcohol use on the burden of EC is very important for framing public policy. Further, more detailed work is needed to strengthen the evidence base for understanding the mediation effects of sex, age, and geographical locations on the risk-attributable burden of EC.

Conclusion

This study analyzes the spatiotemporal patterns in the risk-attributable burden of EC over the past 3 decades, suggesting that smoking and alcohol use remained the dominant risk factors and drive the burden of EC compared with other risk-outcome pairs. The EC burden caused by smoking, alcohol use, chewing tobacco, low-fruit diets, and low-vegetable diets has decreased over the last 3 decades, but the EC burden attributable to high BMI has increased significantly. In addition, changes in the burden of EC due to modifiable risk factors varied widely across regions, with the largest decrease in EC burden in East Asia, especially in China. Although the exact reasons for the marked geographical differences are still unclear, a large number of epidemiological studies are ongoing to yield valuable findings. Our findings targeted specific risk factors of EC burden at different geographical scales to elucidate the key modifiable risk factors for the prevention and control of EC in line with achieving the target 3.4 of the Sustainable Development Goals. Further, understanding the epidemiological trend and risk factor stratification of EC are the key pathways for public health and clinical decisions regarding risk stratification, screening, and prevention. These results might be conducive for identifying the leading modifiable risk factors for countries that might not have previous local research on EC burden and risk factor exposure.

Acknowledgments

We greatly appreciate the works of the Global Burden of Disease Study 2019 collaborators and thank all the researchers and collaborators who were involved in this study for their efforts and contribution. This work was funded by the Shanxi Provincial Administration of Traditional Chinese Medicine, Esophageal Cancer Comprehensive Treatment and Accelerated Recovery Innovation Team (grant 2022-SLRH-LJ-009), and the National Youth Science Foundation (grant 82102976).

Data Availability

Publicly available data sets were analyzed in this study. The processed data sets and statistical methods in the analysis are available from the corresponding author upon reasonable request.

Authors' Contributions

PL and GZ designed the study. PL drafted and revised the manuscript. JJ and WL collected and cleaned the data. JW checked the accuracy of data and prepared the tables. XQ performed statistical analysis. All authors reviewed the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Sleep is an important physiological behavior in humans that is associated with the occurrence and development of various diseases. However, the association of sleep duration with health-related outcomes, including obesity-related factors, musculoskeletal diseases, and mortality because of different causes, has not been systematically reported.

Objective: This study aims to systematically investigate the effect of sleep duration on health-related outcomes.

Methods: Overall, 54,664 participants with sleep information from 8 survey cycles of the National Health and Nutrition Examination Survey (2005-2020) were included in the analysis. Health-related outcomes comprised obesity-related outcomes (ie, BMI, obesity, waist circumference, and abdominal obesity), metabolism-related outcomes (ie, uric acid, hyperuricemia, and bone mineral density [BMD]), musculoskeletal diseases (ie, osteoarthritis [OA] and rheumatoid arthritis [RA]), and mortality because of different causes. The baseline information of participants including age, sex, race, educational level, marital status, total energy intake, physical activity, alcohol consumption, smoking, hypertension, and diabetes was also collected as covariates. Information about the metabolism index, disease status, and covariates was acquired from the laboratory, examination, and questionnaire data. Survival information, including survival status, duration, and cause of death, was obtained from the National Death Index records. Quantile regression models and Cox regression models were used for association analysis between sleep duration and health-related outcomes. In addition, the threshold effect analysis, along with smooth curve fitting method, was applied for the nonlinear association analysis.

Results: Participants were divided into 4 groups with different sleep durations. The 4 groups showed significant differences in terms of baseline data (*P*<.001). The quantile regression analysis indicated that participants with increased sleep duration showed decreased BMI (β=−.176, 95% CI −.220 to −.133; *P*<.001), obesity (odds ratio [OR] 0.964, 95% CI 0.950-0.977; *P*<.001), waist circumference (β=−.219, 95% CI −.320 to −.117; *P*<.001), abdominal obesity (OR 0.975, 95% CI 0.960-0.990; *P*<.001), OA (OR 0.965, 95% CI 0.942-0.990; *P*=.005), and RA (OR 0.940, 95% CI 0.912-0.968; *P*<.001). Participants with increased sleep duration also showed increased BMD (β=.002, 95% CI .001-.003; *P*=.005), as compared with participants who slept <5.5 hours. A significant saturation effect of sleep duration on obesity, abdominal obesity, and hyperuricemia was detected through smooth curve fitting and threshold effect analysis (sleep duration>inflection point). In addition, a significant threshold effect of sleep duration on BMD (*P*<.001); OA (*P*<.001); RA (*P*<.001); and all-cause (*P*<.001), cardiovascular disease−cause (*P*<.001), cancer-cause (*P*=.005), and diabetes-cause mortality (*P*<.001) was found. The inflection point was between 6.5 hours and 9 hours.

Conclusions: The double-edged sword effect of sleep duration on obesity-related outcomes, embolism-related diseases, musculoskeletal diseases, and mortality because of different causes was detected in this study. These findings provided epidemiological evidence that proper sleep duration may be an important factor in the prevention of multisystem diseases.

Introduction

Background

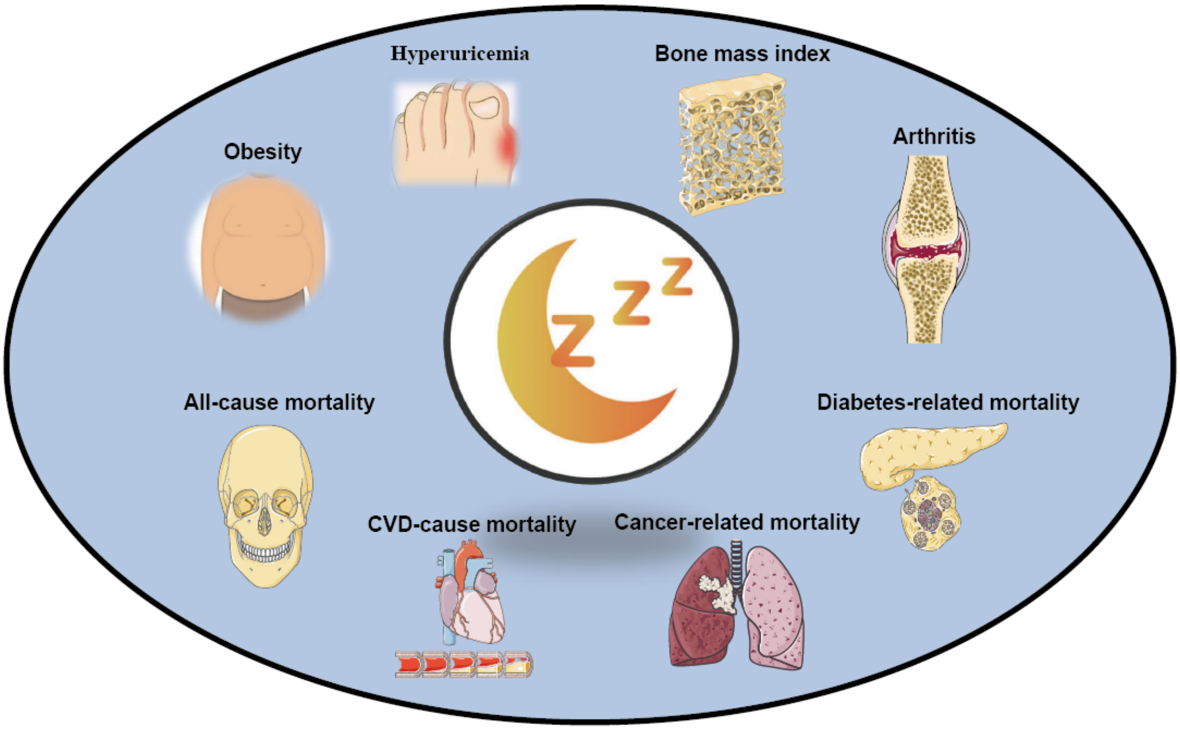
A third of our lives is spent sleeping, a crucial activity for maintaining our physiological functions. It is increasingly believed to influence the development of many diseases such as diabetes and death. Some studies have found that sleep deprivation can reduce energy expenditure by slowing metabolism and may also increase the risk of cardiovascular disease (CVD) [1]. Many meta-analyses have shown that short and long sleep durations are associated with all-cause mortality [2-4]. Moreover, sleep may improve musculoskeletal disease at the psychological level [5-8]. It has also been reported that sleep duration is associated with obesity and diabetes [9-11]. However, the problems that cannot be ignored are that there are opposite results reported, differences between different types of studies, diverse target populations and reference groups, insufficient sample size, and other factors; therefore, the benefits of sleep duration on human disease and mortality are still in an uncertain stage.

In addition, different ages, sex, race, education, marital status, body size, lifestyle habits, and the presence of chronic diseases all influenced the outcome variables [12,13]. They are similar to spiderwebs, which have complex connections and restrict or promote each other. At present, few studies include multiple influential factors to establish a prediction model of multiple-disease and multiple-factor mortality and a large sample size to evaluate the correlation between sleep duration and obesity, metabolism-related factors, musculoskeletal disease, and different types of mortalities.

Objectives

The US National Health and Nutrition Examination Survey (NHANES) database collected sleep data from participants in the survey program between 2005 and 2020. We used these data to evaluate the complex relationship between sleep duration and obesity metabolism, musculoskeletal disease, and mortality and to elaborate on their essential roles systematically (Figure 1).

Figure 1. The schematic graph of the relationship between sleep duration and metabolism, musculoskeletal disease, and mortality in the general US population. CVD: cardiovascular diseases.



Methods

Data Source and Population

All data used in this study were acquired from 8 survey cycles (2005-2006, 2007-2008, 2009-2010, 2011-2012, 2013-2014, 2015-2016, 2017-2018, and 2019-2020) of the NHANES program. The NHANES database is designed to survey the nutritional health of the US population every 2 years. It uses a stratified sampling strategy that includes certain groups, such as people aged >60 years and other ethnic groups in the United States. The project includes demographic, inspection, laboratory, and questionnaire data. All data used in this study are available on the NHANES website [14].

Ethical Considerations

The investigation protocol for this national health program in the United States was reviewed and approved by the National Center for Health Statistics, as one of the departments of the Centers for Disease Control and Prevention. All participants were given an informed consent form outlining the program details, and they would sign it before being included [15]. Furthermore, this study was reviewed and approved by the ethics committee of Xiangya Hospital (202309188).

Measure of Sleep Duration

In the NHANES program, 8 survey cycles (2005-2020) monitored sleep disorders in people aged >16 years. A detailed measurement method for testing sleep disorders can be found on the website [14]. Sleep information survey collected the enrolled population's sleep duration and wake duration, including sleep and wake duration on weekdays and weekends. Statistical sleep time was rounded to the nearest half hour. The questions were asked at home by trained interviewers using a computer-assisted personal interview system to ensure data integrity, consistency, and analysis usefulness.

Obesity Evaluation

BMI assesses obesity, which is obtained as weight/square of height (kg/m^2), and participants' obesity status was then determined by BMI, with a BMI of ≥30 being considered obese. For the assessment of abdominal obesity, each participant's waist circumference (WC; in cm) was obtained for each survey period. Abdominal obesity was defined as WC of >102 cm for men and >88 cm for women. Bone mineral density (BMD) was measured using the dual-energy x-ray absorptiometry method, which has the advantages of high speed, ease of use, and low radiation [16]. Blood uric acid (UA) detection is based on UA oxidation by uricase, under the action of 4-aminophenazone, to produce color products, which the instrument can detect.

Assessment of Musculoskeletal Diseases

We evaluated musculoskeletal diseases including hyperuricemia (HUA), osteoarthritis (OA), and rheumatoid arthritis (RA). The diagnosis of HUA is determined using the enrolled patient's serum UA concentration. HUA is diagnosed with serum UA >7mg/mL in men or 6 mg/mL in women. The OA or RA status of participants was obtained through a questionnaire survey. The questions included the following: Have you ever been diagnosed with arthritis? Once the answer was confirmed, they were asked what type of arthritis was diagnosed. Participants were divided into OA, RA, and other groups based on their answers to these 2 questions. A previous study showed an 81% agreement between self-reported OA and clinically diagnosed OA [17].

Determination of Mortality Outcomes

Mortality information for NHANES program participants is available for download on the National Death Index website, the database used by the National Center for Health Statistics to register death certificate records. The mortality data used in this study were followed up to 2019. National Death Index mortality data included the number of NHANES participants, mortality status, causes of death, and survival time since enlisting in the NHANES program. The cause of death was determined according to the International Statistical Classification of Diseases, 10th edition. The National Institute of Health divided the causes of death into heart disease (054-068) and cancer (019-043). In addition, whether the participants died because of high blood pressure and diabetes was included in the data. In this study, all mortality rates were identified as all-cause mortality, and those related to malignancy were identified as cancer-cause mortality. In addition, deaths related to heart disease or hypertension were identified as CVD-cause mortality. Finally, diabetes-related deaths were identified as diabetes-cause mortality [18].

Assessment of Covariates

Covariate data were collected and included demographic data such as age, sex, race, education, and marital status. The race consisted of Mexican American, non-Hispanic Black, non-Hispanic White, other Hispanic, and other race. Education level included <9th grade, 9th to 11th grade, high school graduate, some college or Associate of Arts degree, college graduate or above, and others. Marital status included married, widowed, divorced, separated, never married, living with a partner, and others. Data also included BMI, total energy intake, physical activity, alcohol consumption, smoking, high blood pressure, and diabetes. There are subdivisions for each type of data. For example, hypertension is defined as a systolic blood pressure >140 mm Hg and a diastolic blood pressure >90 mm Hg. Diabetes is diagnosed by fasting blood glucose >7.0 mmol/L or the use of hypoglycemic drugs.

Statistical Analysis

This study aimed to investigate the association between sleep duration and various health-related outcomes using cross-sectional and follow-up data. The analysis between sleep duration and mortality information owing to different causes belongs to the prospective part, as the mortality information was collected after some period of follow-up, whereas the analysis between sleep duration and the other outcomes belongs to the cross-sectional part, as the information of these outcomes was collected at the same time with that of sleep duration and the covariates information. For the prospective part, the Cox quantile regression risk model was used for association analysis between sleep duration and mortality, and the hazard ratio (HR) was used for assessing the effect of sleep duration on mortality-related outcomes. For the cross-sectional part, the quantile regression model was used to analyze the correlation between sleep duration and other outcomes, and the odds ratio (OR) was used for assessing the effect of sleep duration on other health-related outcomes. For continuous variables, β values were used to measure the effect of risk factors on outcome measures. An OR or HR value >1 indicates that the factor is a risk factor. An OR or HR value <1 indicates that the element is protective. A β value of >0 indicates that the factor positively correlates with the outcome measure and vice versa. First, all the participants were equally grouped into 4 quantiles from short to long sleep duration, and the incidence or effective size of clinical outcomes in the first quantile (Q1) was set as the reference. Second, 3 regression models (Cox quantile or quantile regression model) with different covariables were constructed. A nonadjusted model without covariates is first used for the analysis. Model 1 was adjusted for age, sex, race, education, and marital status, and model 2 was adjusted for age, sex, race, education, marital status, BMI, total energy intake, physical activity, smoking, alcohol consumption, hypertension, and diabetes. In addition, baseline data between the 4 groups of participants were compared using the chi-square test (classified data) and the Kruskal-Wallis test (quantitative data). The smooth curve fitting method was used to analyze the nonlinear relationship between sleep duration and these outcomes. According to the results of the smooth curve fitting, the threshold effect analysis was used to investigate whether there were significant differences between the linear model and the 2-piecewise model. A *P* value of <.05 for logarithmic likelihood ratio test was considered to detect the threshold effect of sleep duration on outcomes. A *P* value <.05 was considered statistically significant in all statistical analyses. R software (R Foundation for Statistical Computing) was used for statistical analysis [19].

Results

Baseline Data of Participants in Different Sleep Duration

A total of 54,896 participants with sleep questionnaire information in the NHANES (2005-2020) were included. After excluding 232 participants with insufficient sleep questionnaire information, 54,664 participants were finally included (Figure 2). Significant differences between the 4 groups were detected in terms of various baseline data, including race composition, educational background, marital status, BMI, total energy intake, physical activity, alcohol consumption, smoking, hypertension, and diabetes (Table 1).

In addition, significant differences between the 4 groups were detected in terms of analyzed outcomes, including obesity-related outcomes, musculoskeletal index, and diseases, as well as mortality because of different causes (Table 2).

Figure 2. The flow diagram of screening eligible participants from 8 survey cycles (2005-2020) of the National Health and Nutrition Examination Survey (NHANES) program and research structure of association analysis between sleep duration and various clinical outcomes. BMD: bone mineral density; CVD: cardiovascular disease; HUA: hyperuricemia; OA: osteoarthritis; RA: rheumatoid arthritis; UA: uric acid.

Correlation Between Sleep Duration and Musculoskeletal Diseases, Obesity, and Metabolism-Related Outcomes

As shown in Tables 3-6, a negative association between sleep duration and negative association was detected in the whole quantile of all the 3 models. In model 2, the β values of sleep duration on BMI in Q2, Q3, and Q4 were −.308, −.687, and −.931, respectively, and the ORs for obesity in Q2, Q3, and Q4 were 0.924, 0.874, and 0.810, respectively. The β values of sleep duration on WC in Q2, Q3, and Q4 of model 2 were −.593, −1.449, and −1.456, respectively. A negative correlation with abdominal obesity in Q3 (OR 0.898, 95% CI 0.831-0.971) and Q4 (OR 0.871, 95% CI 0.809-0.937) in model 2 was also detected. In contrast, a positive correlation with BMD in Q3 (OR 0.012, 95% CI 0.006-0.008) and Q4 (OR 0.008, 95% CI

0.002-0.013) in model 2 was found, whereas no significant association was detected between sleep duration and UA as well as HUA. In addition, a negative correlation between sleep duration and OA was detected in Q2 (OR 0.839, 95% CI 0.733-0.959), Q3 (OR 0.780, 95% CI 0.686-0.887), and Q4 (OR 0.771, 95% CI 0.683-0.870) in model 2. Similarly, a negative association between sleep duration and RA was detected in the whole quantile of all the 3 models. Subsequently, the nonlinear association using the smooth curve fitting method indicated that sleep duration showed a negative association with BMI, obesity, WC, and abdominal obesity (Figures 3A and 4D). In addition, a n-shaped association between sleep duration and BMD and HUA was detected (Figures 3E and 4F). However, an L-shaped association was observed between sleep duration and OA and RA (Figures 3G and 4H). The threshold effect analysis detected a significant threshold effect of sleep duration on BMI, obesity, and WC (Table 7) as well as on BMD, HUA, OA, and RA (Table 8). The relative inflection points in BMI, obesity, and WC were 8 hours. The relative inflection points in BMD, HUA, OA, and RA were 7.5 hours, 5 hours, 8 hours, and 6.5 hours, respectively. Below the inflection point, negative correlations were detected with BMI, obesity, WC, OA, and RA, whereas a positive correlation was observed between BMD and HUA.

Table 3. The association between sleep duration and obesity-related outcomes using the quantile regression method among 51,416 participants in 8 survey cycles of the National Health and Nutrition Examination Survey program (2005-2020). Model 1 was adjusted for age, sex, race, educational level, and marital status; model 2 was adjusted for age, sex, race, educational level, marital status, total energy intake, physical activity, alcohol consumption, smoking, hypertension, and diabetes.

Association Between Sleep Duration and Mortality in General Population

As shown in Table 9, a significantly negative correlation between sleep duration and all-cause mortality was found in Q2 (HR 0.844) and Q3 (HR 0.749) of model 2, respectively. Consistently, a significantly negative correlation with CVD-cause mortality in Q2 (HR 0.773) in model 2 was discovered. For cancer-cause mortality, a significant HR in Q2 (HR 0.801) and Q3 (HR 0.798) of model 1 was detected, which was absent in model 2. For diabetes-cause mortality, a significantly negative HR was detected in Q2 (HR 0.654) and Q3 (HR 0.0.562) of model 1 as well as Q3 (HR 0.633) of model 2. The analysis results of smooth curve fitting indicated an L-shaped association between sleep duration and all-cause, CVD-cause, cancer-cause, and diabetes-cause mortality (Figures 3I and 4L). The threshold effect analysis detected a significant threshold effect of sleep duration on all-cause, CVD-cause, cancer-cause, and diabetes-cause mortality, and an inflection point of 6.5 hours was detected (Table 10). When below the inflection point, a significantly protective HR of sleep duration was detected in terms of all-cause, CVD-cause, cancer-cause, and diabetes-cause mortality. However, when above the inflection point, a significant risk HR of sleep duration was detected in terms of all-cause, CVD-cause, cancer-cause, and diabetes-cause mortality.

Table 9. The association between sleep duration and hazard ratios for mortality in population using the quantile regression method among 51,416 participants in 8 survey cycles of the National Health and Nutrition Examination Survey program (2005-2020).

Association Between Sleep Duration and Mortality in RA, OA, and HUA Populations

As shown in Table 11, in the HUA population, the HR of all-cause mortality in Q2, Q3, and Q4 was 0.784 (95% CI 0.633-0.972; *P*=.03), 0.669 (95% CI 0.538-0.832; *P*<.001), and 0.786 (95% CI 0.649-0.953; *P*=.01), respectively. The HR of CVD-cause mortality in Q3 was 0.667 (95% CI 0.471-0.944; *P*=.02). The HR of diabetes-cause mortality in Q2 and Q3 was 0.587 (95% CI 0.345-0.996; *P*=.048) and 0.464 (95% CI 0.266-0.810; *P*=.007), respectively. In the OA population, sleep duration was identified as a protective factor for OA in Q3 of all-cause mortality. The HR for all-cause mortality in Q3 was 0.647 (95% CI 0.487-0.861; *P*=.003). In the RA population, sleep duration was identified as a protective factor for RA in Q3 (HR 0.500, 95% CI 0.338-0.742; *P*<.001) of all-cause mortality and Q3 (HR 0.302, 95% CI 0.143-0.638; *P*=.002) of CVD-cause mortality. The analysis results of the smooth curve fitting showed an L-shaped association between sleep duration and mortality in participants with HUA (Figure 4) and a n-shaped association between sleep duration and cancer-cause mortality in the OA population. The threshold effect analysis found a significant threshold effect of sleep duration on all-cause, CVD-cause, cancer-cause, and diabetes-cause mortality in the HUA population, which was also detected for all-cause and CVD-cause mortality in the OA and RA populations as well as diabetes-cause mortality in the OA population. In the OA population, the detected inflection points of sleep duration for all-cause, CVD-cause, and diabetes-cause mortality were 6.5 hours, 8.5 hours, and 7.5 hours, respectively (Table 12).

Table 11. The effect of sleep duration on mortality of population experiencing musculoskeletal disorders using the quantile regression method among 5538 participants in 8 survey cycles of the National Health and Nutrition Examination Survey program (2005-2020). The model was adjusted by age, sex, race, educational level, marital status, total energy intake, physical activity, alcohol consumption, smoking, hypertension, and diabetes.

Below the inflection point, a significantly decreased HR for all-cause mortality was detected, whereas a significantly increased HR for all-cause, CVD-cause, and diabetes-cause mortality was detected above the inflection point. In the RA population, the detected inflection point of sleep duration for all-cause and CVD-cause mortality was 6.5 hours. Below the inflection point, a significantly decreased HR for all-cause and CVD-cause mortality was detected. Above the inflection point, a significantly increased HR for all-cause and CVD-cause mortality was detected. In the HUA population, the inflection point of sleep duration for all-cause, CVD-cause, cancer-cause, and diabetes-cause mortality in model 2 was 7.5 hours, 7.5 hours, 9 hours, and 7.5 hours, respectively. Below the inflection point, a significantly decreased HR for all-cause, CVD-cause, and diabetes-cause mortality was detected. Above the inflection point, a significantly increased HR for all-cause, CVD-cause, cancer-cause, and diabetes-cause mortality was detected.

Discussion

Principal Findings

In this study, we found that increased sleep duration was associated with decreased BMI, obesity, WC, abdominal obesity, OA, and RA but increased BMD. The nonlinear analysis indicated that sleep duration caused a saturation effect on obesity, abdominal obesity, and HUA. In addition, a significant threshold effect of sleep duration on BMD; OA; RA; and all-cause, CVD-cause, cancer-cause, and diabetes-cause mortality was found.

Sleep is an indispensable physiological activity for human beings that is closely associated with physical and mental health and the incidence and development of various diseases. Despite the critical significance of healthy sleep, sleep disorders have gradually increased over the past 2 decades, with more than a third of adults and 57% of teenagers in the United States experiencing insomnia [20]. With aggravating the worrying sleep dilemma, accumulating interests have been aroused in exploring sleep's physiological and pathological role in human beings. According to the International Classification of Sleep Disorders published by the American Academy of Sleep Medicine, the diagnosis of sleep disorders can be divided into 7 types, including insomnia, sleep-related breathing disorders, central disorders of hypersomnolence, circadian rhythm sleep-wake disorders, parasomnias, sleep-related movement disorders, and other sleep disorders [21]. These sleep disorders would significantly impair sleep duration, which is essential to maintain mental health [22,23].

Many studies have investigated the association between obesity and sleep duration, with controversial conclusions achieved. A negative association between obesity and sleep duration has been detected in some studies [24-27], whereas none of these studies have a sample size of>10,000 participants. In addition, Kripke et al [28] reported a U-shaped association between BMI and sleep duration in 636,095 female participants in the United States, with an inflection point of sleep duration (7 to 8 hours). In comparison, no significant association between BMI and sleep duration was detected in 480,841 male participants. To the best of our knowledge, we are the first to find the saturation effect of sleep duration on obesity-related outcomes, indicating a negative association between obesity and sleep duration when sleep duration is <8 hours. Some epidemiological studies have pointed out that sleep duration may cause obesity and endocrine changes such as decreased glucose tolerance and insulin sensitivity, increased evening concentrations of cortisol, increased levels of ghrelin, decreased levels of leptin, and increased hunger and appetite [29,30]. Although only a few experimental studies have explored the underlying mechanism behind this phenomenon, it could be hypothesized that the underlying mechanism is complex and works in multiple networks.

In this study, we have found a n-shaped association between BMD and sleep duration, with the inflection point of 7.5 hours sleep duration detected. On the basis of the NHANES program 2017-2018, Lee et al [6] found that the osteoporosis incidence of female participants aged >50 years with a sleep duration of <5 hours was significantly higher than that of normal participants (OR 7.35) in the NHANES program 2005-2010, which was almost consistent with the findings of Shiao et al [31]. In addition, Tang et al [32] found that participants with shorter or longer sleep durations showed lower BMD than those with normal sleep duration (7 to 9 hours), which was consistent with our findings. It should not be ignored that some studies reported no significant association between sleep duration and BMD [33] and osteoporosis [34]. These epidemiological studies revealed that sleep duration seems to be a double-edged sword in affecting the change of BMD. However, more experimental evidence should be provided to demonstrate this phenomenon. Swanson et al [35] found that the level of P1NP, a biomarker of bone formation, decreased when the sleep circadian rhythm was disrupted, which was more pronounced among younger people and indicated a detrimental effect of sleep disorders on normal bone turnover. In addition, it was reported that growth hormone might be an important effective agent involving sleep duration affecting bone mass [36]. In general, many epidemiological studies have demonstrated the detrimental effect of sleep disorders on BMD, although exploring specific molecular mechanisms needs further work.

UA is the terminal metabolite of purine compounds, of which approximately 80% are endogenous and 20% are derived from exogenous food rich in purine or nucleic acid proteins [37]. Under normal physiological conditions, the production and catabolism of UA are in dynamic homeostasis, mainly regulated by liver synthesis and excretion from or absorption in the kidney and intestine [38]. Excessive serum UA, HUA, was reported to be closely associated with various diseases, including gout, chronic kidney disease, and CVD [39,40]. A few epidemiological studies have investigated the association between sleep duration and UA or HUA. Lee et al [41] found a U-shaped association between sleep duration and UA in Korean women, indicating that female individuals with a sleep duration of 7 to 8 hours showed the lowest UA level. In addition, many related studies have reported the negative association that increased sleep duration was significantly associated with a lower risk of HUA [42-44]. However, in this study, we found a threshold effect between sleep duration and HUA, indicating a positive association between HUA and sleep duration when sleep duration was <5 hours. This finding was different from that of previous studies. Owing to the lack of experimental evidence and controversy regarding epidemiological studies, it could be challenging to draw an affirmative conclusion related to the association between sleep duration and UA level up till now.

OA is one of the most common musculoskeletal diseases, seriously impairing the health and social functioning of the US population. Recent epidemiological studies have investigated the association between sleep duration and OA. On the basis of the Korea NHANES program, Park et al [45] found a U-shaped association between sleep duration and OA in the older woman population (aged >50 years), with a lower incidence of OA occurring in the group reporting a 7 to 8 hours sleep duration. Ni et al [46] found that the increased OA incidence was positively correlated with a shorter sleep duration. These studies were conducted within a specific population in Korea. At the same time, there were few studies to investigate the association between sleep duration and OA in the general US population. What we performed in this study tried to answer this question, and we found a threshold effect of sleep duration on OA incidence in the US population. The OA incidence increased with the increase in sleep duration; however, this synergistically positive association disappeared when sleep duration increased to 8 hours. It is worth noting that Ni et al [46] found that patients with OA aged >60 years in the NHANES program (2011 to 2018) experienced a higher incidence of sleep trouble [46]. These studies and our findings have demonstrated a positive association between sleep duration and OA incidence, although the causal association between them is yet to be clarified. It is well known that progressing OA pathology into the advanced stage causes severe pain and impairs the patient's function and sleep quality [47,48]. Therefore, the more profound association between sleep duration and OA, such as a causal relationship, should be verified by more prospective clinical studies.

As an autoimmune disease, RA is caused by multiple factors, including genetic susceptibility and environmental factors [49]. Kim et al [50] found that the RA incidence in the Korean population decreased with an increase in sleep duration when sleep duration was <6 hours. They also found that severe RA pain was closely associated with sleep duration when it was <6 hours [50]. Meanwhile, Wu et al [51] found that shorter sleep duration, <6 hours, and poor sleep quality were positively associated with RA incidence. This study found that increased sleep duration was negatively associated with RA. A threshold effect (inflection point: 6.5 hours) was detected in the association analysis between sleep duration and RA. The association we detected between sleep duration (<6.5 hours) and RA was almost consistent with the aforementioned studies. It is worth noting that we were the first to find that excessive sleep duration (>6.5 hours) was a risk factor for RA. However, the causal relationship between sleep duration and RA was challenging to be verified because the pain symptom was one of the main characteristics of RA, which could also cause detrimental influences on sleep quality. Notably, Gao et al [52] performed a Mendelian randomization study to investigate the causal relationship between sleep traits and RA. They found no association between sleep duration and frequent insomnia, any insomnia, sleep duration, or snoring, although the casual effect of shorter sleep duration (<6 hours) on RA was detected through inverse variance weighted and weighted median methods, which provided further evidence to support our findings. Despite this accumulating epidemiological evidence and continuous insight into the pathogenesis of RA, research on how sleep duration or traits affect the occurrence and development of RA still needs to be completed. Further experimental studies focusing on this perspective may yield a new understanding of the pathogenesis of RA.

Many epidemiological studies have widely investigated the association between sleep duration and mortality [2,53,54]. The U-shaped association (inflection point: 6.5 hours) detected in this study between sleep duration and all-cause, CVD-cause, and cancer-cause mortality was first detected in the general US population, which was consistent with a previous study involving a specific population, such as older or woman populations [55-57]. With the change in dietary structure, diabetes has gradually become one of the most common aging diseases, causing serious detrimental effects on health and longevity [58,59]. However, mortality, mainly or partly because of diabetes, has been less investigated, especially for investigating the effect of life behaviors on diabetes-cause mortality in the general or specific population. Hou et al [60] investigated the association between diabetes-cause mortality and carbohydrate intake behaviors and found that low-quality carbohydrates at dinner were positively associated with diabetes-cause mortality. We first explored the association between sleep duration and diabetes-cause mortality, with a U-shaped association detected in the general US population. We also detected a similar U-shaped association between sleep duration and diabetes-cause mortality in the OA and HUA populations. These findings provide a strong epidemiological evidence that lifestyle behaviors, such as dietary and sleep behaviors, may have played an essential role in affecting poor diabetes-related outcomes. A large amount of epidemiological evidence have been provided to demonstrate that shorter or excessive sleep duration causes a detrimental effect on mortality outcomes. Unlike previous studies, we are the first to identify a threshold effect of sleep duration on mortality in the OA, RA, and HUA populations. This discovery offers new clinical evidence about the impact of sleep duration on mortality outcomes within these specific populations, highlighting the potential benefits of maintaining an appropriate sleep duration for individuals in these groups. There are some potential explanations from the perspective of mechanisms to clarify the negative association between shorter sleep duration and mortality, including increased cortisol secretion, altered growth hormone metabolism, inflammation activation, and changes in circulating leptin and ghrelin [2,61,62]. Although no such hypothesis has been provided to clarify the detrimental effect of excessive sleep duration on mortality in the general or specific population, further experimental studies must be conducted.

Study Limitations

Some limitations should be addressed when generalizing the conclusions. First, as a cross-sectional study, this study highlighted the association between sleep duration and various outcomes; however, it was not possible to infer the causal association between sleep duration and these outcomes. Mendelian randomization analysis could be an alternative method to investigate their causal association, which may be conducted to further determine their causal association in the US population. Second, the diagnosis of OA and RA was defined through a questionnaire survey method, which may lead to misdiagnosing or missed diagnosis of some participants and impair the evidence level of our conclusion. Third, although we included various covariates for adjustment in the analysis, there must be missing covariates associated with the outcomes analyzed in this study. For example, genetic factors, family history, and environmental exposures have been considered as the risk factors for some diseases, such as RA and obesity. Owing to the limitation of data availability, it was difficult to include these individual information as covariates. Furthermore, the sleep duration information of children was absent in the NHANES program. Therefore, we should be careful when generalizing the conclusions to specific populations. In addition, the quality of sleep is an important factor influencing the health status; however, the lack of this individual information in the NHANES program makes it difficult to analyze the role of sleep quality on individual health, which should be investigated in future studies. In general, more prospective and related experimental studies or Mendelian randomization studies are needed to further validate the conclusions of this study.

Conclusions

In our study, which included a total of 54,664 participants across 8 survey cycles of the NHANES program, we observed that longer sleep duration was associated with decreased BMI, obesity, WC, abdominal obesity, OA, and RA but increased BMD. Furthermore, we found that sleep duration caused a saturation effect on obesity, abdominal obesity, and HUA. In addition, a significant threshold effect of sleep duration on BMD; OA; RA; and all-cause, CVD-cause, cancer-cause, and diabetes-cause mortality was found. In conclusion, this study provided further evidence about the double-edged sword effect of sleep duration on health, and proper sleep duration plays a critical role in maintaining good health status. These findings suggested that ensuring adequate sleep duration should be an integral part of public health programs.

Acknowledgments

This study was supported by the Natural Science Foundation of China (grant 82360437). The authors would like to thank the National Health and Nutrition Examination Survey (NHANES) team and its participants.

Data Availability

All data used in this study are available on the National Health and Nutrition Examination Survey (NHANES) website [63].

Authors' Contributions

TL, ML, HQ, and JY collected and analyzed the data. TL was a major contributor to this manuscript. ML contributed to the ethics approval progress. LH takes full responsibility for the work, including the study design, access to data, and the decision to submit and publish the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Cataracts now account for the largest proportion of the global burden of blindness and vision loss. Understanding the changing trends in the global burden of cataracts over the past 30 years and the next 15 years is of clear significance for the prevention and control of cataracts in key populations. As far as we know, research on the future burden of cataracts is lacking.

Objective: This study aims to assess the global burden of cataracts over the past 30 years by using age-period-cohort modeling and to estimate trends in the next 15 years.

Methods: Data were obtained from the Global Burden of Disease Study 2019, the United Nations Development Programme, and the WHO (World Health Organization) Global Health Observatory data repository. The assessment of trends and disparities in the number and rate of disability-adjusted life years (DALYs) for cataracts from 1990 to 2019 was conducted. The association between the age-standardized DALY rate (ASDR) and the socio-demographic index (SDI), human development index (HDI), national levels of particulate matter <2.5 µm in diameter ($PM_{2.5}$), and ambient ultraviolet radiation (UVR) was determined using linear regression analysis. Additionally, we used the Nordpred (Harald Fekjær and Bjørn Møller) age-period-cohort model to predict the cataract burden from 2020 to 2034.

Results: Globally, the number of DALYs due to cataract increased from 3,492,604 (95% uncertainty interval [UI] 2,481,846-4,719,629) in 1990 to 6,676,281 (95% UI 4,761,210-9,006,193) in 2019. The ASDRs due to cataract decreased from 93.17 (95% UI 66.14-125.32) in 1990 to 82.94 (95% UI 59.06-111.75) in 2019, with an average annual percentage change of –0.37 (95% CI –0.44 to –0.3; $P<.001$). Age, female sex, air pollution, smoking, high fasting plasma glucose levels, and a high body mass index were risk factors for the burden of cataracts. SDI and HDI were negatively correlated with ASDRs of cataracts, while $PM_{2.5}$ and UVR were positively associated with them. Higher DALY rates were also associated with lower SDI ($R^2=0.1939$; $P<.001$), lower HDI ($R^2=0.2828$; $P<.001$), national $PM_{2.5}$ concentration ($R^2=0.1874$; $P<.001$), and ambient UVR levels ($R^2=0.2354$; $P<.001$). The prediction model suggested that the number of DALYs due to cataract will continue to rise globally, while the cataract DALY rate will continue to decrease.

Conclusions: While the ASDR of cataracts has decreased, there has been a notable increase in the number of DALYs over the past 30 years. Projections suggest that the global burden of cataracts will continue to rise over the next 15 years. To address this challenge, appropriate prevention and treatment policies must be implemented.

KEYWORDS

burden; cataract; disability-adjusted life-years; human development index; prediction; risk factor

Introduction

With the progressive aging of the world's population, health issues, such as ocular health, have drawn more attention [1]. Cataracts are among the main causes of blindness globally, accounting for nearly half of all cases of blindness in low-income countries and 5% in high-income countries [2,3]. Recently, researchers have focused on the disability-adjusted life years (DALYs), which are defined as the sum of years lived with disability and years of life lost due to premature death and reflect the difference between the real state of health and the standard condition [4,5]. Moreover, DALYs attributed to cataracts exceed 90% in low-income countries and generally indicate the sum of years lived with disability, underscoring the significant impairments cataracts deal to the patients' quality of life [4]. As the global burden of cataracts continues to grow due to the rise in global population and aging, this phenomenon will inevitably increase the economic burden, decrease the quality of life, and lead to cognitive function impairments [3,5]. Therefore, investigating the trends in the global cataract burden and associated risk factors will allow more targeted prevention strategies to be initiated, thereby promoting targeted prevention and treatment of cataracts.

A trend analysis of the Global Burden of Disease (GBD) Study 2019 data showed that the global burden of visual impairment due to cataracts exhibited a substantial increase, with the prevalence rate rising by 58.45% and the DALY rate increasing by 32.18% over the past 30 years [6]. Cataract is a multifactorial disease manifested by transparency loss of the eye lens, owing to tissue degradation and protein clumping, as well as pathogenic environmental and genetic factors [7]. Previous publications have reported risk factors such as aging, female sex, diabetes, excess weight, diet and nutritional status, smoking, drinking, exposure to ultraviolet light, socioeconomic status, and air pollution [8-23]. In addition, cataracts can also be innate, owing to a variety of genetic and molecular mechanisms [7]. However, the extent to which these risk factors affect cataracts remains unclear. Additionally, the long-term global trend of DALYs due to cataracts has not been visually demonstrated and analyzed, necessitating further research.

To address these gaps, we conducted an evaluation of the global trend in the DALYs of cataract by year, age, and sex from 1990 to 2019 and estimated its prediction over the next 15 years. Additionally, we conducted correlation analyses between age-standardized DALY rates (ASDRs) and the socio-demographic index (SDI) and human development index (HDI) separately. We then estimated the proportion of DALYs that could be attributed to several important risk factors for cataracts, including air pollution, smoking, high fasting plasma glucose, and a high BMI. Finally, the association between HDI, particulate matter <2.5 µm in diameter ($PM_{2.5}$), and ultraviolet radiation (UVR) and ASDRs of cataracts was analyzed. Our results represented a significant extension of previous reports and offered valuable insights for future initiatives aimed at preventing cataracts.

Methods

Data Sources

This study was based on the GBD Study 2019, the United Nations Development Programme, and the WHO (World Health Organization) Global Health Observatory data repository. We collected related data on cataracts and SDI from the GBD database. The HDI data were obtained from the United Nations Development Programme, and concentrations of $PM_{2.5}$ and average daily UVR data were collected from the WHO Global Health Observatory data repository. We estimated the global population using data from the GBD database.

Study Variable Description

Study results are presented by number of DALYs, ASDRs, crude DALY rates, and average annual percentage changes (AAPCs) between 1990 and 2019 using 95% uncertainty intervals (UIs) and 95% CIs, age, sex, SDI, HDI, $PM_{2.5}$ concentration, and UVR. The SDI gauges a nation's economic development using per capita income distribution, average schooling years, and the fertility rate of women under 25 years of age [24]. The SDI ranges from 0 to 1, with higher values indicating greater economic advancement. The HDI was used as a measure of health, education, and living conditions [25]; it is calculated from life expectancy, education years, schooling expectancy, and per capita gross national income. HDI values range from 0 to 1, with higher values indicating greater socioeconomic development. The UNDP classifies countries into subgroups based on HDI: low (<0.550), moderate (0.550-0.699), high (0.700-0.799), and very high (≥0.800). The $PM_{2.5}$ concentration is a common measurement for air pollution in a country and is defined as the annual average concentration of suspended fine particulate matter smaller than 2.5 µm in diameter. The UVR was defined as the average daily level of ambient solar UVR (in J/m^2).

Statistical Analysis

Temporal trends in DALYs due to cataract were assessed using the Joinpoint regression software (version 4.9.0.0; National Cancer Institute). This model uses segmented regression to capture disease distribution patterns over time. For each juncture point, the annual percentage change (APC) was computed, accompanied by a 95% CI. Additionally, the AAPC was determined as the weighted mean of individual APCs, offering a consolidated overview of the study period's overall trend. In summary, a rising cataract rate was noted if both the APC and the lower 95% CI bound exceeded 0, while a declining rate was indicated if both values fell below 0. Linear regression analysis was used to determine the relationship between ASDR and SDI, HDI, national $PM_{2.5}$, and ambient UVR. To predict DALYs due to cataract from 2020 to 2035, we used the Nordpred age-period-cohort model implemented in the Nordpred package in R (version 4.2.2; R Foundation for Statistical Computing). To validate the stability of the prediction results, the Bayesian age-period-cohort model was further applied to perform a sensitivity analysis using the R package "BAPC." All statistical analyses and data visualization were conducted using R, the Joinpoint Regression Program, and GraphPad Prism 9.0

(GraphPad Software, Inc). A significance level of α=.05 was used, with *P*<.05 indicating statistical significance.

Ethical Considerations

The authors received an exemption from ethical review from the institutional review board of the First Affiliated Hospital of Soochow University, and the study was also exempt from ethical review by the National Health Research Ethics Council of China. The research adhered to the principles of the Declaration of Helsinki. Due to the retrospective nature of the study, the requirement for informed consent regarding data processing and disease models was waived.

Results

Temporal Trends of Disease Burden Due to Cataract From 1990 to 2019

Globally, the number of DALYs due to cataracts increased from 3,492,604 (95% UI 2,481,84-4,719,629) to 6,676,281.11 (95% UI 4,761,210-9,006,193) in 2019 (Table 1). The ASDR exhibited a dramatic decrease from 1990 to 1995 (APC=–0.63; *P*<.05), a dramatic increase from 1995 to 2000 (APC=1.05; *P*<.05), and another dramatic decrease from 2000 to 2010 (APC=–0.56; *P*<.05), followed by a slight increase from 2010 to 2017 (APC=0.25; *P*>.05). However, a remarkable decrease in ASDR was observed between 2017 and 2019 (APC=–3.21; *P*<.05) (Figure 1).

Table 1. Disability-adjusted life years (DALYs) of cataract and its average annual percentage changes from 1990 to 2019 at the global and regional levels.

Characteristics	1990		2019		1990-2019	*P* value
	Value (95% UI[a])	ASDR[b] (95% UI)	Number (95% UI)	ASDR (95% UI)	AAPC[c] (95% CI)

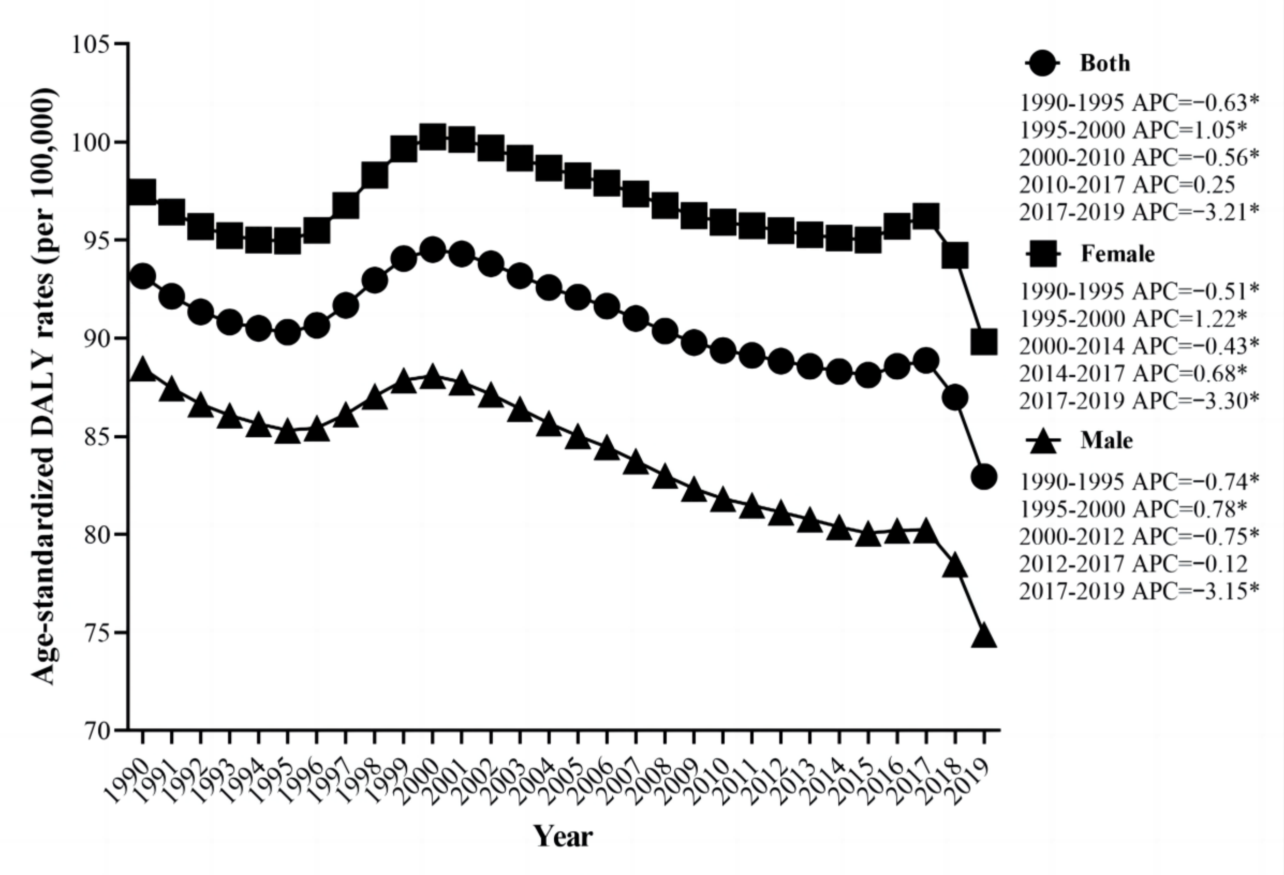
[a] UI: uncertainty interval.

[b] ASDR: age-standardized DALY rate.

[c] AAPC: average annual percent change.

[d] SDI: socio-demographic index.

Figure 1. Joinpoint regression analysis of global age-standardized disability-adjusted life-years (DALYs) rates due to cataract for both female and male from 1990 to 2019. **P*<.05; APC: annual percentage change.



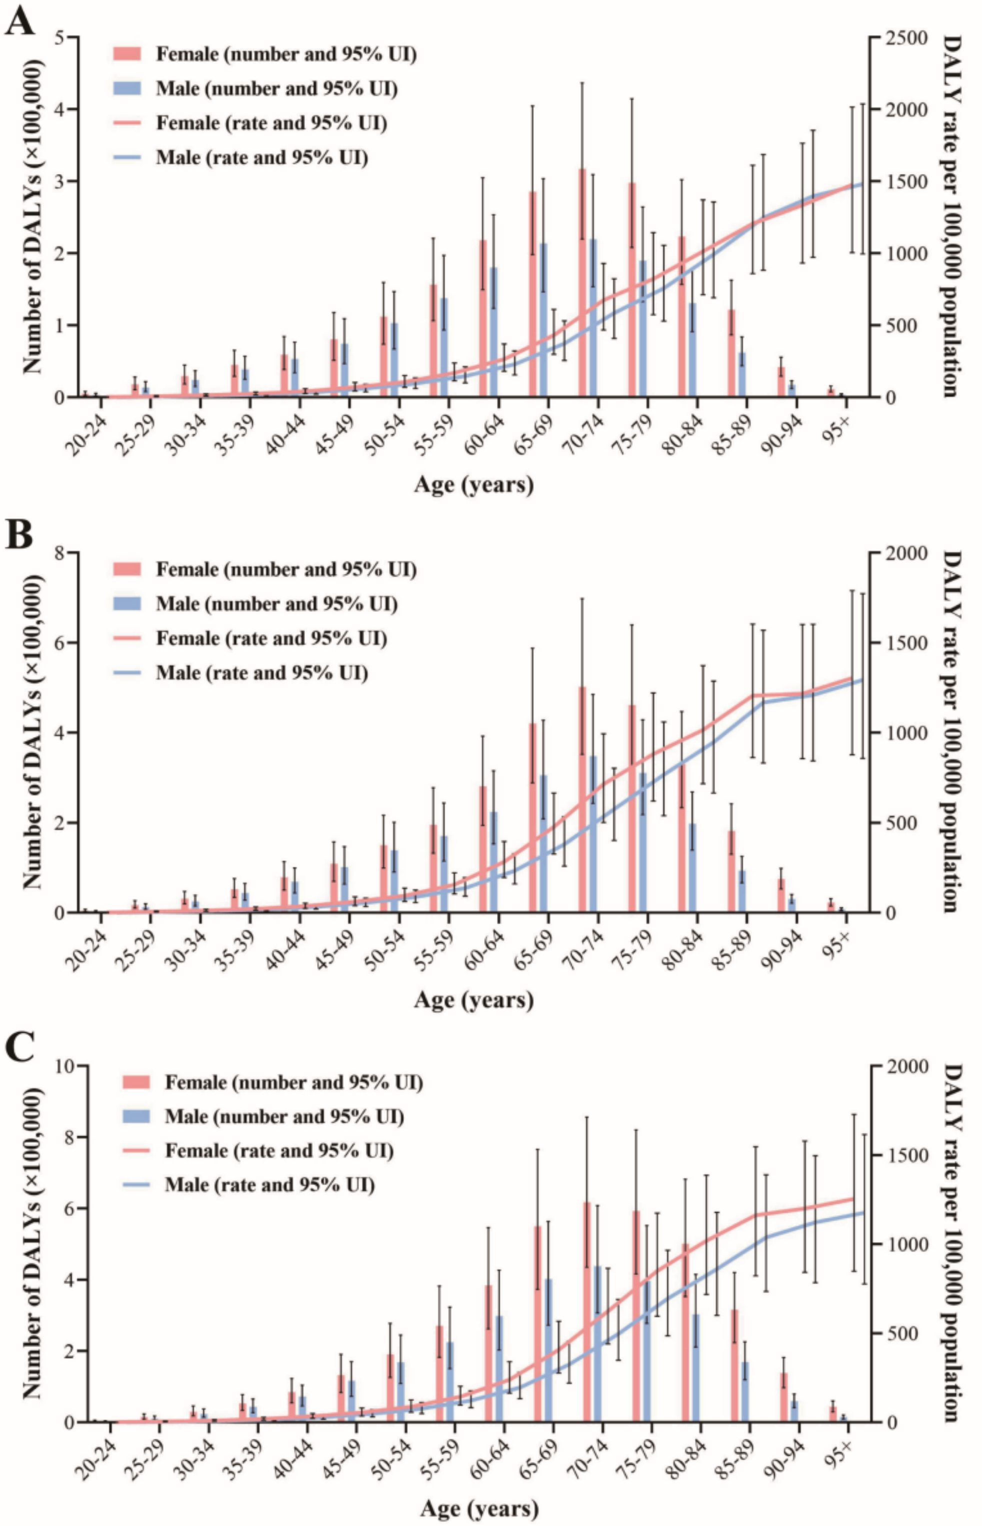
Regional Differences in Disease Burden Due to Cataract

At the regional level in 1990 and 2019, the number of DALYs due to cataracts was highest in South Asia and lowest in Oceania (Table 1). The ASDR was highest in Southeast Asia in 1990 and highest in South Asia in 2019. From 1990 to 2019, the AAPC of ASDR in Southern Sub-Saharan Africa was lowest at –1.35 (95% CI –1.38 to –1.33; *P*<.001), followed by Andean Latin America at –1.31 (95% CI –1.45 to –1.17; *P*<.001). In contrast, the AAPC of ASDR in North America was highest at –0.12 (95% CI –0.15 to –0.08; *P*<.001).

Age-Specific and Gender-Specific Disease Burden Due to Cataract

With increasing age, the global number of DALYs due to cataracts gradually increased (up to the age of 75 years) in 1990, reaching a peak at the ages of 70-74 years, after which it declined with increasing age. Similar trends were observed in 2005 and 2019. The DALYs due to cataracts were relatively low in individuals aged less than 30 years or more than 95 years. The crude DALY rates of cataracts rose with increasing age, with the fastest increment observed between the ages of 60 and 85 years in 1990. In 2005 and 2019, the general trend of the crude DALY rates was similar to 1990; however, the rate of increase after the age of 85 years slowed down more significantly (Figure 2). The global number of DALYs due to cataracts was lower in males than in females in 1990 and 2019, while ASDR was also smaller in males (Table 1). Moreover, the ASDR of male cataracts decreased more than that of females between 1990 and 2019, with AAPCs of –0.54 (95% CI –0.60 to –0.49; *P*<.001) and –0.25 (95% CI –0.33 to –0.16; *P*<.001), respectively (Table 1 and Figure 1).

Figure 2. Global number of disability-adjusted life years (DALYs) and crude DALY rates due to cataract by age and sex in (A) 1990, (B) 2005, and (C) 2019. The black bar indicates the upper and lower limits of the 95% uncertainty intervals (UIs) for females and males, respectively.



Characteristics of the Cataract Burden Attributable to Risk Factors

Areas with high SDI have lower ASDRs for cataracts than those with low SDI, with high-income North America having the lowest ASDRs and South Asia having the highest between 1990 and 2019 (Table 1 and Figure 3A). In addition, the ASDRs of cataracts were lower in countries with a high SDI than in those with a low SDI. Linear regression analysis revealed that ASDRs were negatively correlated with SDI (R^2=0.1939; P<.001; Figure 3B). ASDRs of cataracts due to air pollution, smoking, high fasting plasma glucose, and high BMI in 21 GBD regions in 2019 were obtained and presented in Figure 4. Apart from high SDI regions, air pollution accounted for the largest proportion of the 4 listed factors leading to cataracts, which increased as the SDI declined. The scatter plots between ASDRs of cataract and other country-level indicators were presented in Multimedia Appendix 1, and a linear trend was observed between ASDRs of cataract and HDI level (R^2=0.2828; P<.001), national $PM_{2.5}$ concentration (R^2=0.1874; P<.001), and ambient UVR (R^2=0.2354; P<.001). Based on the aforementioned results, HDI, national $PM_{2.5}$ concentration, and ambient UVR were included as independent variables to construct the multivariate linear regression model for ASDRs. A significant relationship was identified (P<.001), and this model accounted for 37.6% of the variance in the national differences in cataract burden.

Figure 3. Age-standardized disability-adjusted life year (DALY) rate (per 100,000 persons) of cataract by socio-demographic index (SDI) for (A) 21 Global Burden of Disease (GBD) Study regions from 1990 to 2019, and (B) 204 countries and territories in 2019. The black line represents the expected values based on age-standardized DALY rates and SDI in all locations.

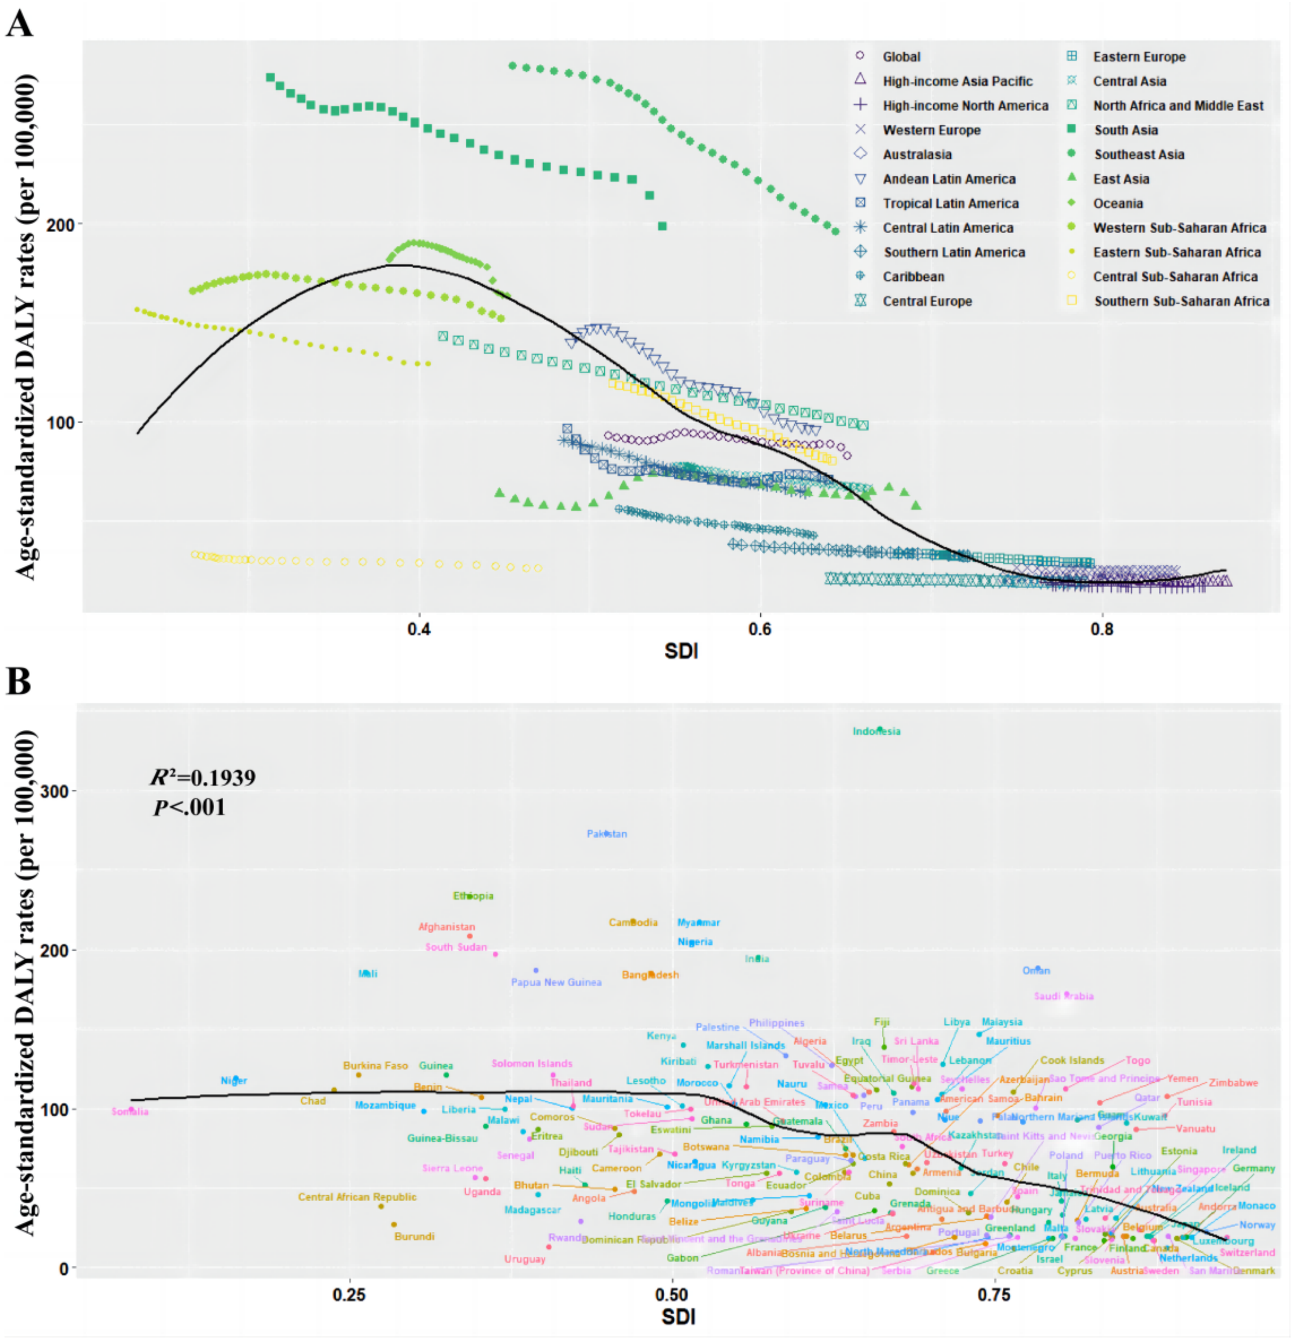


Figure 4. The proportion of cataract disability-adjusted life year (DALY) attributable to air pollution, smoking, high fasting plasma glucose, and high body-mass index for (A) 21 Global Burden of Disease (GBD) Study regions in 1990 and (B) 2019. SDI: socio-demographic index.

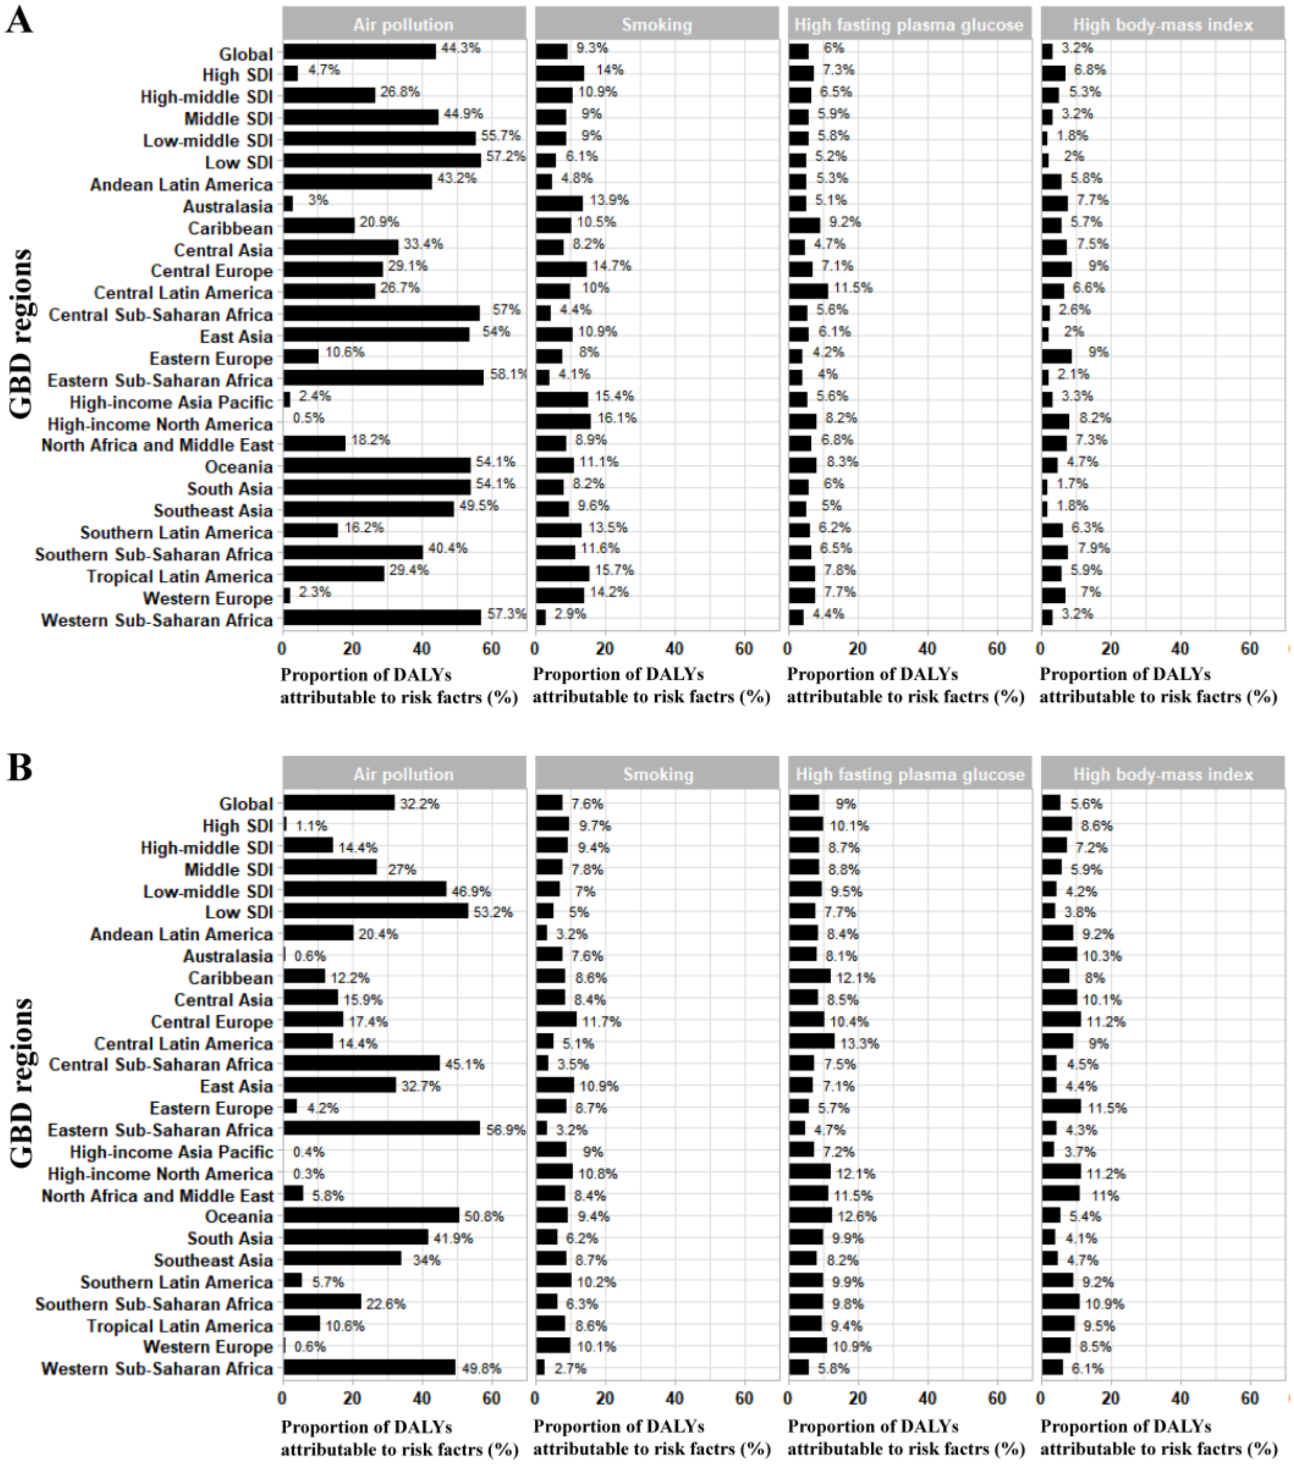
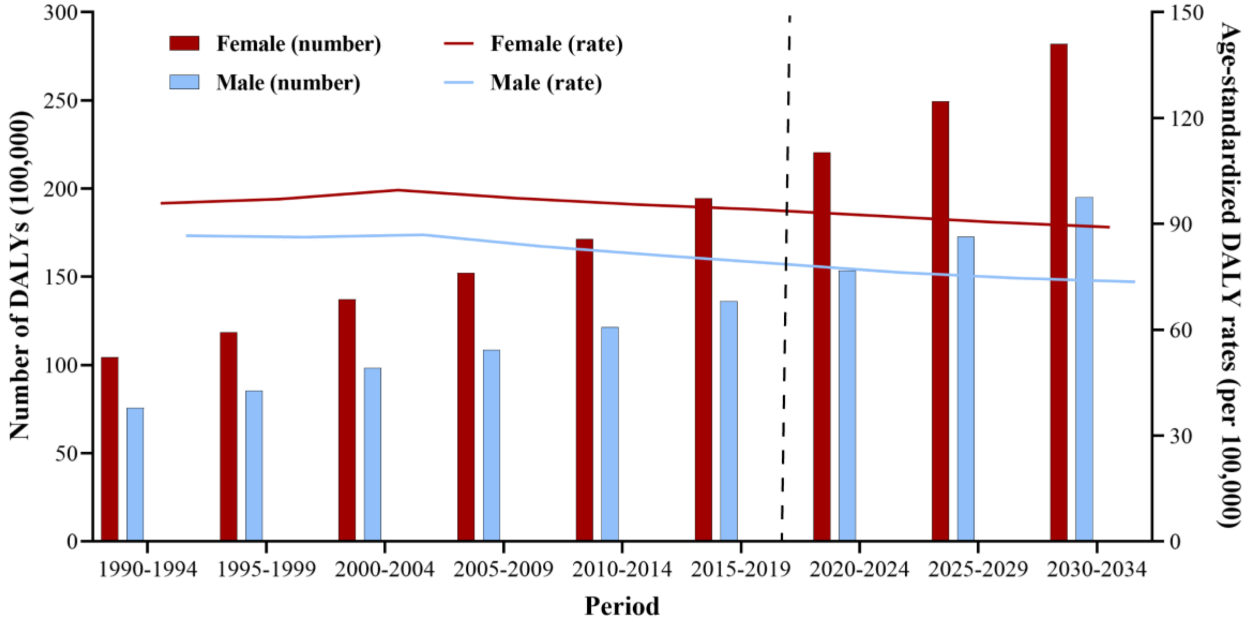


Predictions of DALYs Due to Cataract

We predicted that, due to population growth and aging, the DALYs due to cataracts for both sexes are expected to continue to increase over the next 15 years. Further, over the next 15 years, a decrease in the ASDRs of cataracts is expected, particularly among women (Figure 5 and Multimedia Appendix 2). While the patterns of changes in DALY rates in men were similar to those in women, the DALY rates of cataracts were notably lower among men. To assess the robustness of our predictions, we further performed a sensitivity analysis using the BAPC package to predict the future global burden of cataracts; the results showed consistent trends with the abovementioned results (Multimedia Appendix 3).

Figure 5. Trends in global number of disability-adjusted life years (DALYs) and age-standardized DALY rates (per 100,000 persons) due to cataract by sex: observed (1990-2019) and predicted (2020-2034).



Discussion

Principal Findings

This study reported on the number of DALYs and ASDRs due to cataracts from 1990 to 2019, revealing disparities by region, nation, age, and sex. Although the ASDRs decreased overall, the overall DALYs due to cataracts still increased. Our findings showed that over the last 3 decades, higher DALY rates were also associated with lower SDI, HDI, national $PM_{2.5}$, and ambient UVR. Furthermore, we predicted that the global burden of cataracts will continue to increase over the next 15 years due to the growth and aging of the global population. To the best of our knowledge, this report acts as an essential complement to previous studies, and the results of our research can provide crucial insights into evidence-based health care planning and reduce the global burden of cataracts by allocating resources to cataract prevention.

Global policy making and economic restructuring can guide the prevention and treatment of cataract. Initially, the WHO and International Agency for the Prevention of Blindness started the VISION 2020 global initiative in 1999 to prevent, control, and eliminate avoidable blindness at the national level by 2020 [26]. In line with earlier studies, the number of DALYs in cataracts has increased globally over the last 30 years, although the ASDRs fell between 1990 and 2019 [6,10,20]. According to our findings, low-income regions exhibited higher ASDRs compared to high-income regions, indicating a greater burden of cataract in the former. Several factors could potentially explain this pattern, including elevated UVR levels in southern countries and the prevalence of conditions such as arterial hypertension and diabetes, which might contribute to the proliferation of this ailment. Notably, in response to VISION 2020, high-income regions allocated funding for diverse programs aimed at reducing rates of low vision and blindness. The adoption of more proactive diagnostics, early detection, and treatment strategies could potentially bolster the performance of high-income regions [27]. Addressing this phenomenon warrants increased attention and further investigations into the mechanisms underlying these disparities.

Although previous studies have implicated many risk factors for cataracts, age is uniquely important. Cataracts can be divided by age-related, pediatric, and secondary causes. Age-related cataract is the most common type in adults, starting between the ages of 45 and 50 years [28]. Aging is the most meaningful risk factor for cataract because structural and functional changes to the lens can promote cataract development. The lens consists of soluble proteins, and the fiber cell organization in the lens is tight, which enables intercellular space reduction. These mechanisms prevent light content and support lens transparency. Increasing age leads to slower protein metabolism, reducing their solubilization, which in turn impairs lens transparency and may cause other pathological risk factors to have cumulatively detrimental effects [29,30].

According to our findings, both the number of DALYs and ASDRs caused by cataracts in females was greater than that in males from 1990 to 2019. The following is consistent with other studies that found similar situations of sex disparity in ocular diseases, such as cataracts, age-related macular degeneration, and diabetic retinopathy [5,21,30,31]. Possible explanations for these results include differences in follow-up time points and longer life expectancies in female patients [10]. Another explanation could be related to the inequality between men and women, as women can be disadvantaged in terms of access to education, employment opportunities, income distribution, and health care services [32]. Other research has also focused on the function of estrogen in cataract formation, which has been shown to play a role due to antioxidant effects on reactive oxygen species, which are important factors for cataracts. Menopause is hypothesized to cause an elevated risk of cataract in older females, caused by the withdrawal effect [9]. More attention and further studies regarding female eye care are required to explore the possible mechanisms between sex and cataract.

Furthermore, health inequalities are largely caused by socioeconomic disparities. According to our findings, the ASDRs of cataracts varied significantly between regions and nations and were lower in high-income regions and countries, while SDI and HDI were negatively correlated with cataract ASDR. A higher quality of eye care and increasing opportunities for cataract surgery may explain this association in countries with high SDI and HDI scores. Although surgery is the definitive therapy for cataract, many major barriers to cataract treatment still exist [33]. One aspect is that the outcome of cataract surgery is related to the quality of the surgery. Access to quality cataract surgery remains difficult in many countries, while the coverage of cataract surgery is influenced by GDP and health expenditure [18,20]. The lack of education and medical knowledge, as well as the cost of surgery, may discourage patients in low-income areas from choosing treatment [19]. As a result, the cataract surgical rate is over 10,000 in developed countries and below 500 in low-income countries [34]. Thus, in low-income countries, the emphasis on reducing the burden of cataracts in the formation of health policies should be as important as in high-income countries.

We also found that air pollution, smoking, high fasting plasma glucose, and high BMI were all significant cataract risk factors that contributed to most of the burden. In this study, air pollution referred mainly to household air pollution from solid fuels, which was associated with a higher risk of cataracts in agreement with previous studies [35,36]. Smoking is a risk factor for many diseases, including cataracts, glaucoma, and age-related macular degeneration, with studies reporting an elevated risk of nuclear sclerotic cataract in patients of both sexes [37-39]. Tobacco contains large quantities of toxic heavy metals, including cadmium, lead, and copper, and the accumulation of these metals on the lens can eventually contribute to cataract development [15,40,41]. More specifically, the ratio of the indirect impact of tobacco to the total impact of cadmium exceeded 50% [42]. This study also indicated that high fasting blood glucose levels were correlated with cataracts. The Blue Mountains Eye Study recently demonstrated that fasting blood glucose levels were associated with long-term cortical cataract formation and long-term progression of cortical, nuclear, and posterior subcapsular cataracts, which is consistent with our findings [43]. Similarly, the Beaver Dam Eye Study evaluated diabetic participants as having an increased risk of developing cataracts [44]. The study proposed strategies to address the increased risk of cataracts in diabetic patients, which include targeting the polyol pathway, oxidative stress, and nonenzymatic glycation of lens proteins [45,46]. Moreover, a study indicated that diabetic retinopathy is an independent risk factor for cataract formation in patients with type 2 diabetes, alongside BMI, HbA_{1c}, and insulin usage [12]. The Blue Mountain Eye Study also showed an increased risk of cataract in relation to metabolic syndrome [47]. Therefore, obesity is correlated with increased DALY rates in cataract. Obesity, especially central obesity, is associated with insulin resistance, which indirectly leads to type 2 diabetes [48]. In addition, the lipid composition of the lens changes during cataract formation, possibly because high BMI and excess body weight alter lipid metabolism in the lens [14]. The results of this study may have implications for public health, as cataracts are susceptible to air pollution, smoking, high fasting plasma glucose, and high BMI, and increased health awareness may be a cost-effective intervention to prevent blindness in patients with cataract.

This study illustrated that exposure to $PM_{2.5}$ and solar UVR accelerated cataract development. Current evidence suggests that air pollution may affect ocular diseases, including cataracts, age-related macular degeneration, and glaucoma [22]. After exposure to air pollutants such as $PM_{2.5}$, NO_2 (nitrogen dioxide), and NO_x (nitrogen oxide), the risk of cataract surgery increased by 5%, but the effects were relatively small [49]. The most common assessment of air pollution is $PM_{2.5}$. The Canadian Longitudinal Study on Aging illustrated that $PM_{2.5}$ had a borderline-adjusted correlation with cataracts [23]. Evidence suggests that exposure to high-dose UVR can cause acute photokeratitis and photoconjunctivitis while chronic exposure to low-dose UVR can cause cataract, pterygium, and corneal and conjunctival squamous cell carcinoma [50]. Interestingly, cataract DALY rates were lower in urbanized areas because the work of most individuals could be completed indoors, and their UVR exposure could be at a lower level [51]. Evidence suggests that oxidation accumulation, antioxidant potential, and repair function of the lens decrease with age, which are all related to age-related cataracts. The most significant cause of cataract may be the formation of reactive oxygen species caused by UVR. This decreased the activity of a series of enzymes that catalyze the reduction of hydrogen peroxide and peroxide radicals [50]. Our results indicate that improving the living environment and increasing UV radiation protection may be effective interventions to delay the occurrence of cataract blindness, while the pathogenic roles of $PM_{2.5}$ and UV light in cataracts require further study.

While the DALY rates for cataract decreased overall in most age and sex groups between 1990 and 2019, there was a significant increase in the total number of DALYs due to cataract. This upward trend in cataract DALYs, coupled with an aging population and expanding economy, is likely to lead to a greater economic burden on health care. We anticipate that the number of DALYs due to cataract will continue to rise steadily from 2020 to 2034. In light of the anticipated increase in the global burden of cataract, efforts should be made to strengthen prevention and management strategies for both established and emerging risk factors such as air pollution, smoking, and UV radiation. Effective global policies aimed at reducing the prevalence of these risk factors could play a critical role in mitigating the impact of cataract and reduce its burden.

Study Limitations

Although this study enabled us to examine the global cataract burden and its relationship to risk factors with high confidence, some limitations should be noted. First, all data come from the GBD 2019, UNDP, and GHO. As such, the authenticity and reliability of the results depend on the data source. Second, cataract is a multifactorial disease, and some key factors, such as congenital, traumatic, and drug-induced factors, have not been analyzed in this study; therefore, the factors included in our model may also be affected. Third, the prevalence and incidence of cataracts were not investigated in this study. Moreover, this study did not conduct a decomposition analysis of the disease burden of cataract over time. This omission indicates a potential gap in understanding the complex dynamics underlying the changing disease burden of cataract. Therefore, it is essential to explore and gather more information on cataract to improve our understanding of this important public health issue.

Conclusions

Over the past 3 decades, the global burden of cataract has increased, as evidenced by the increasing number of DALYs. Furthermore, given the changing demographics of the world, this trend is expected to persist over the coming 15 years. Age, female sex, air pollution, smoking, high fasting plasma glucose, high BMI, UVR, and low socioeconomic status were risk factors for the burden of cataracts. Our findings showed that the older adults and female populations in low-income countries have a greater burden caused by cataract; therefore, health services for cataract should be strengthened for these populations. Effective resource allocation and health-service planning will be essential in managing the anticipated increase in the global burden of cataract in the next 15 years.

Acknowledgments

We highly appreciate the work done by the Global Burden of Disease, the United Nations Development Programme, and the WHO (World Health Organization) Global Health Observatory. This work was supported by the Jiangsu Provincial Medical Innovation Team (CXTDA2017039) and the National Natural Science Foundation in China (81671641, 82271113, and 81970830).

Data Availability

The data analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

PRL and BJ had full access to all the data in the study and took responsibility for the integrity of the data, the accuracy of the data analysis, and the concept and design of the study. All authors were responsible for the acquisition, analysis, or interpretation of data. PRL, BJ, and THW drafted the manuscript. PRL, GQL, and BJ were responsible for the critical revision of the manuscript for important intellectual content. BJ did the statistical analysis. PRL and GQL obtained the funding. PRL was responsible for administrative, technical, or material support and supervision.

Abstract

Background: Over-the-counter (OTC) medications are frequently used to self-care for nonspecific ovarian cancer symptoms prior to diagnosis. Monitoring such purchases may provide an opportunity for earlier diagnosis.

Objective: The aim of the Cancer Loyalty Card Study (CLOCS) was to investigate purchases of OTC pain and indigestion medications prior to ovarian cancer diagnosis in women with and without ovarian cancer in the United Kingdom using loyalty card data.

Methods: An observational case-control study was performed comparing purchases of OTC pain and indigestion medications prior to diagnosis in women with (n=153) and without (n=120) ovarian cancer using loyalty card data from two UK-based high street retailers. Monthly purchases of pain and indigestion medications for cases and controls were compared using the Fisher exact test, conditional logistic regression, and receiver operating characteristic (ROC) curve analysis.

Results: Pain and indigestion medication purchases were increased among cases 8 months before diagnosis, with maximum discrimination between cases and controls 8 months before diagnosis (Fisher exact odds ratio [OR] 2.9, 95% CI 2.1-4.1). An increase in indigestion medication purchases was detected up to 9 months before diagnosis (adjusted conditional logistic regression OR 1.38, 95% CI 1.04-1.83). The ROC analysis for indigestion medication purchases showed a maximum area under the curve (AUC) at 13 months before diagnosis (AUC=0.65, 95% CI 0.57-0.73), which further improved when stratified to late-stage ovarian cancer (AUC=0.68, 95% CI 0.59-0.78).

Conclusions: There is a difference in purchases of pain and indigestion medications among women with and without ovarian cancer up to 8 months before diagnosis. Facilitating earlier presentation among those who self-care for symptoms using this novel data source could improve ovarian cancer patients' options for treatment and improve survival.

ovarian cancer; early diagnosis; transactional data; health informatics; cancer risk; medication; self-medication; self-care; over-the-counter medication; nonspecific symptoms; pain medication; indigestion medication

Introduction

Ovarian cancer is the eighth most common cancer in females worldwide and is the sixth most common cause of cancer-related death in females in the United Kingdom [1,2]. There is an urgent need for earlier diagnosis to improve survival outcomes since 5-year survival rates decrease from 93% for women diagnosed at the earliest stage to 20% for women diagnosed at the latest stage[2]; however, a population-based ovarian cancer screening program is not currently recommended in the United Kingdom [3]. One possible approach for improvement is to encourage earlier help-seeking behavior among women experiencing symptoms such as abdominal/pelvic pain, bloating, loss of appetite, and urinary symptoms, which can often be associated with other more common illnesses [4]. Awareness of these nonspecific symptoms among women in the United Kingdom is low [5,6]; consequently, the average time between experiencing a symptom and presenting to primary care with these symptoms is 39 days [7].

A proof-of-concept study conducted in 2019 concluded that there may be an increase in purchases of pain and indigestion medications 10-12 months before ovarian cancer diagnosis to treat symptoms [8], although larger studies were needed to validate this finding. The Cancer Loyalty Card Study (CLOCS) was therefore proposed to investigate this further through an observational case-control study design, which hypothesized that a significant change in purchasing behavior, specifically an increase in self-medication prior to presentation in primary care, could be an indication for early signs of ovarian cancer [9]. The primary objective of the CLOCS is to investigate the purchasing behaviors of women with and without ovarian cancer using commercial data collected through loyalty card use at two participating high street retailers in the United Kingdom with the aim to reduce delays in ovarian cancer diagnosis.

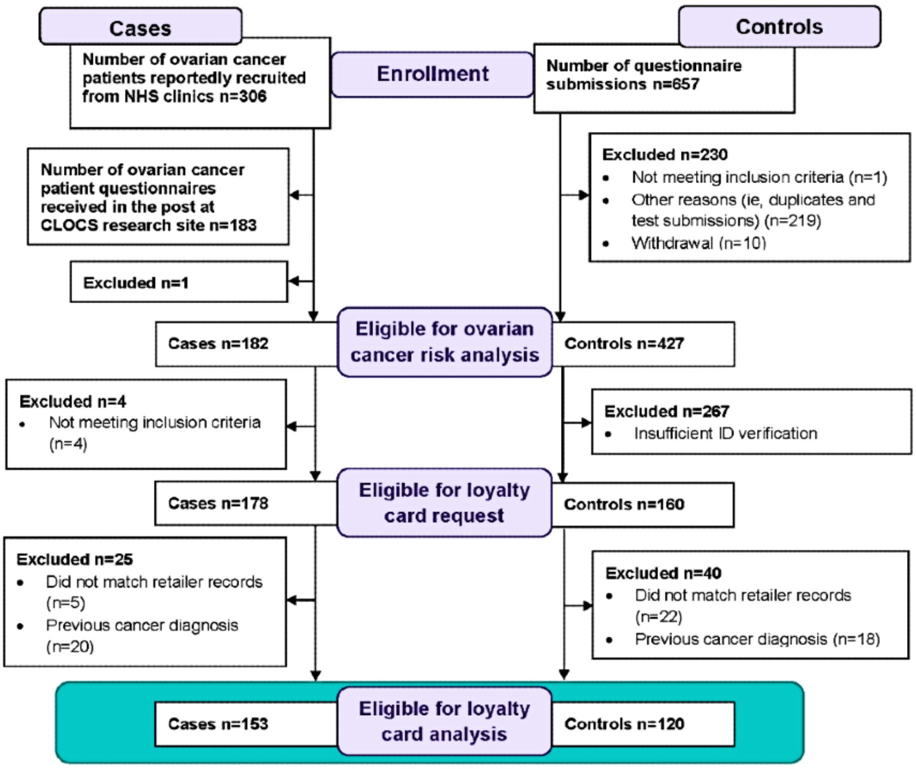
Methods

Study Design, Setting, and Participants

The CLOCS case-control study design and protocol have been described previously [9]. Eligible participants were women in the United Kingdom, 18 years or older, who owned at least one of the participating retailers' loyalty cards. Patients diagnosed with ovarian cancer within 2 years of recruitment to the study until January 31, 2022, were considered cases, whereas controls did not have a previous diagnosis of ovarian cancer. When face-to-face interactions between patients with ovarian cancer and clinics were minimized due to the COVID-19 pandemic, the protocol was amended to allow for patients to be recruited from National Health Service (NHS) clinics over the phone.

Patients were recruited from 12 NHS clinic sites in England, Wales, and Scotland from November 1, 2019, to January 31, 2022. Participants without ovarian cancer were recruited indirectly through an online experiment that investigated the effects of an animated decision aid on willingness to take part in the CLOCS in July 2020 (unpublished), and directly through paid social media advertisements using Meta (formerly known as Facebook), a test recruitment email from one of the participating retailers, word of mouth, and the advocate network VOICE [10] from September 1, 2020, to May 31, 2021. A CONSORT (Consolidated Standards of Reporting Trials) diagram of CLOCS participant recruitment and eligibility for analysis is shown in Figure 1.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) diagram for Cancer Loyalty Card Study (CLOCS) case-control recruitment and loyalty card data collection. NHS: National Health Service.



After obtaining explicit consent, up to 6 years of loyalty card purchase history, starting from the date of recruitment, was requested from two high street retailers, hereafter referred to as high street retailer 1 (HSR1) and high street retailer 2 (HSR2), for eligible participants using the name and number on their loyalty card(s). One of the participating retailers offers a supply of health and beauty items, while the other stocks a wider range of health, beauty, and grocery items, thereby providing CLOCS with a variety of purchases related to the participants' intentions to shop at either retailer. If these details matched the retailers' records, then the participant purchase history was transferred to the CLOCS team. If the details did not match, then the purchase history was not shared, and the participant was recontacted up to two times to clarify their details. Once clarified, the participant's card history was requested once again as described previously [9].

Patient and Public Involvement

The CLOCS team included two ovarian cancer patient advocates who were involved in the project from the inception of the idea to study design, ethical approval applications, and development of recruitment strategies throughout the CLOCS. We presented two public-facing seminars to engage with the wider audience about the CLOCS in December 2020 and March 2021 during Ovarian Cancer Awareness month. Furthermore, we held three annual scientific meetings inviting academics, patient representatives, and participating high street retailers.

Variables

Participants completed a short questionnaire about ovarian cancer risk factors, including ethnicity, marital status, BMI, age at menarche, menopausal status, age at menopause, parity, breastfeeding, hysterectomy, tubal ligation, cancer history, endometriosis, aspirin use, oral contraceptive (OC) use, hormone replacement therapy (HRT) use, family history of ovarian and breast cancers, vaping, and cigarette smoking. The questionnaire also requested information about the symptoms experienced (if any) and number of visits to the general practitioner (GP) in the year before participating in the study for controls or leading up to cancer referral or diagnosis for cases.

In addition, participants were asked about which food and pharmacy stores they shop at regularly, at which stores they own a loyalty card, frequency of use of those loyalty cards, and where they heard about the study (for controls only). The questionnaire was amended to include a question about the number of people in their household. To gain a better understanding of the impact of COVID-19 on purchase history patterns and ovarian cancer diagnosis delays, the questionnaire was amended to include a question about whether participants had been diagnosed with COVID-19 (responses limited to the following: diagnosed and recovered, diagnosed and still ill, suspected but not formally diagnosed, did not have COVID-19). The date of diagnosis, type, stage, grade, *BRCA1* and *BRCA2* mutation status, and any surgical outcomes for cases were provided by the clinical team at their respective recruitment sites.

Statistical Methods

Ovarian Cancer Risk

Unconditional logistic regression was used to calculate the risk of ovarian cancer among CLOCS participants, first using an unadjusted model and then with adjustment for age, OC use (ever/never), menopausal status (premenopausal/postmenopausal), and HRT use (ever/never).

An ovarian cancer risk score was calculated for all participants stratified by age (<50 years and ≥50 years) using an additive model described previously [11]. The risk score was the sum of the product of the median log odds ratio (OR) and the values of the following risk factors: low- and high-dose aspirin use (regular use ever/never), BMI (continuous), breastfeeding (ever/never), number of months breastfeeding (continuous), endometriosis (ever diagnosed/never), family history of breast cancer in first-degree relative (ever/never), family history of ovarian cancer in first-degree relative (ever/never), hysterectomy and no HRT use (ever/never), age at the end of the last pregnancy (continuous), age at menarche (continuous), menopausal status (pre-/postmenopausal), OC use (ever/never), duration of OC use (continuous), number of nonfull-term pregnancies (continuous), number of full-term pregnancies (continuous), and tubal ligation status (ever/never). Instead of limiting the analysis to participants with complete data or eliminate risk factors from the risk score, missing values were imputed using the k-nearest neighbors imputation method in the Visualization and Imputation of Missing Values (*vim*) package in R. Participants were grouped into low-, medium-, or high-risk score groups using cut-off points based on tertiles of the risk score among controls.

Purchase History Analysis

For purchase history analyses, two controls were matched with each case according to age (continuous) and which HSR loyalty card they had (HSR1 only, HSR2 only, HSR1 and HSR2), with replacement. The analysis was focused on the period of 24 months prior to diagnosis for cases to maximize the amount of purchase history data available from participants and to detect a difference in purchases between cases and controls up to 10 months before diagnosis, according to the prior power calculations [9]. Owing to the differing periods of recruitment of cases and control, where possible, the same 24 months of purchases from controls were aligned with each matched case leading up to diagnosis; otherwise, the latest 24 months of purchases were used for controls. Purchases of items commonly used to treat symptoms of ovarian cancer, such as stomach pain and indigestion, were averaged and cumulatively summed for each participant per month over 24 months. Pain and indigestion medication purchases were selected using the categories predetermined by the retailers.

For statistical analysis, purchases for each individual were summed on a sliding 3-month window to smooth the signal and to represent a pattern of individual purchase behavior for cases and controls comparing all purchases to the purchase of both pain and indigestion medication bought together. The Fisher exact test was used to calculate the ORs, 95% CIs, and significance of enrichment at each month prior to diagnosis.

A conditional logistic regression model was used to investigate the association between purchase of medications that treat pain and indigestion over the 24-month period as well as pain and indigestion medication purchases separately, where the medication purchase was the exposure and ovarian cancer diagnosis was the outcome.

A receiver operating characteristic (ROC) analysis was performed for purchases of pain and indigestion medications separately at each month prior to diagnosis for cases and the latest 24 months available for controls. For cases, the ROC analysis was repeated and stratified by stage at diagnosis, where stages 1 and 2 were grouped together and considered the early stage and stages 3 and 4 were considered the late stage.

Sensitivity analyses were performed to assess the impact of several factors on purchase behaviors among CLOCS participants. First, conditional logistic regression was used to assess the association between ovarian cancer diagnosis and purchases of pain and indigestion medications before and after the COVID-19 pandemic (before and after March 2020). Second, to account for seasonal purchase behaviors (eg, painkillers linked to flu and cold season in autumn and winter), the conditional logistic regression model was repeated with adjustment for seasons. Finally, to investigate whether the number of members in a household affects the association between ovarian cancer and purchases, the model was run with adjustment for the number of members in the household and OC use.

Further sensitivity analyses related to ovarian cancer symptom behaviors were performed using the same conditional logistic regression model with adjustment for whether participants reportedly attended the GP in the 12 months prior to diagnosis for cases and prior to participation for controls, as well as with adjustment for whether participants reported experiencing nonspecific ovarian cancer symptoms.

All statistical analyses were conducted in the ISO27001-certified Secure Enclave environment at Imperial College London using R (version 4.1.2).

Ethics Considerations

The CLOCS was reviewed and approved by the North West-Greater Manchester South Research Ethics Committee (19/NW/0427). Explicit consent for the research team to request loyalty card data from participating retailers and to take part in the study was given from all participants.

Results

Participant Characteristics

As of January 31, 2022, 182 cases and 441 controls consented to take part in the CLOCS. As shown in the CONSORT diagram in Figure 1, one case was excluded for providing insufficient consent and 14 control participants withdrew or were excluded. Of the remaining 427 controls, only 160 (37.5%) provided sufficient ID verification and were therefore eligible for loyalty card data requests. There were 4 cases who completed the risk factor questionnaire but did not provide loyalty card details and therefore were excluded from purchase history requests.

The characteristics of CLOCS participants are shown in Table 1. On average, cases were about 13 years older than controls. In terms of loyalty card ownership, 47% of cases and 33% of controls owned cards from both retailers, while the remaining participants had one or the other. The majority of cases who took part in the CLOCS were diagnosed with serous ovarian cancer (75.8%) and of those, 94% were diagnosed at stage 3 or 4 (see Table S1 in Multimedia Appendix 1 for details).

Ovarian cancer risk and risk scores among participants are shown in Table S2 and Table S3, respectively, of Multimedia Appendix 1. The majority of cases (46.7%) fell into the high ovarian cancer risk score tertile, while 24.7% had a medium risk score and 28.6% of cases were in the low risk score tertile.

Purchase histories were requested for 178 cases and 160 controls from HSR1 and HSR2, as described in Figure 1. After consent, ID verification, matching loyalty card details with retailers' records, and recontacting participants who did not match to clarify loyalty card details, purchase histories from 173 (97.2%) cases and 138 (86.3%) controls were transferred to the CLOCS team for analysis. There were 5 (2.8%) cases and 22 (13.8%) controls whose loyalty card details did not match the records at either HSR1, HSR2, or both. There were 20 cases and 18 controls with a previous cancer diagnosis before participating in the study and were excluded from all purchase history analyses (participants with a previous nonmelanoma skin cancer were included). After exclusion of participants with a previous cancer diagnosis and matching cases and controls on age and cardholder status, purchase histories of 153 cases and 306 controls (77 unique individuals) were included in purchase history analyses. The median age difference for matched pairs was 0.3 years (IQR –0.4 to 1.7 years). Among this reduced set of participants, only OC use was associated with ovarian cancer risk and was therefore the only risk factor adjusted for in subsequent purchase history analyses.

Table 1. Characteristics of participants.

Characteristic	Cases (n=182)	Controls (n=427)
Age (years), mean (SD)[a]	64.7 (10.9)	51.6 (13.7)
Age group (years), n (%)		
18-39	6 (3.6)	61 (16.2)
40-49	7 (4.7)	96 (23.8)
50-59	32 (21.3)	125 (31.8)
60-69	64 (36.7)	107 (21.2)
≥70	73 (33.7)	33 (5.9)

Missing	8 (5.6)	2 (0.7)

[a] Missing data for n=5 (0.9%) controls.

[b] HSR1: high street retailer 1.

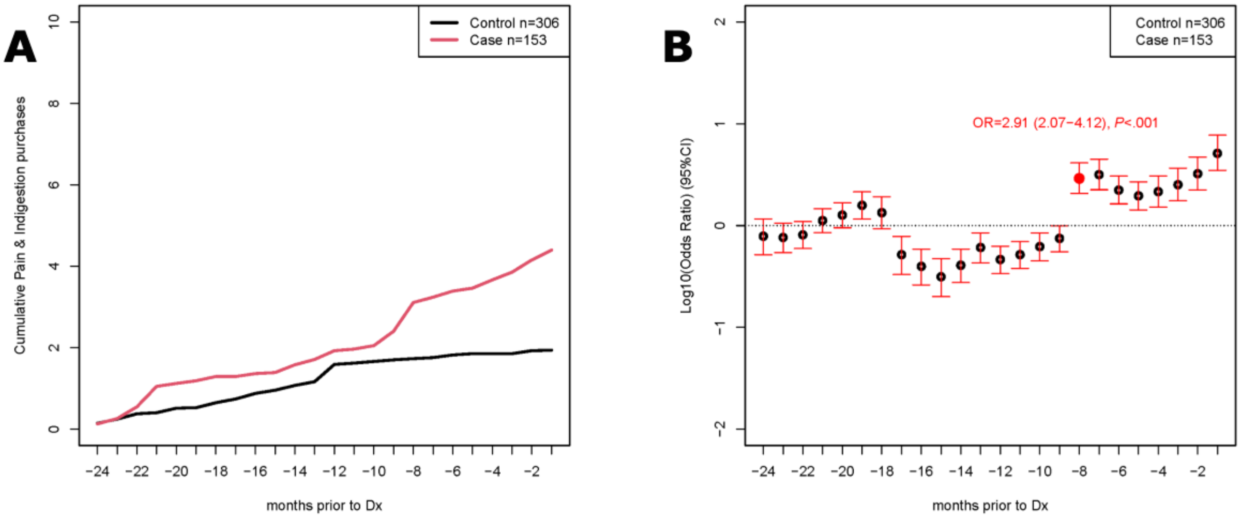
[c] HSR2: high street retailer 2.

[d] Number of members in the household question was added to the questionnaire after amendment and during active recruitment. Missingness describes those who participated before the question was available.

Cumulative Purchases

The average cumulative number of purchases of pain and indigestion medications together are shown in Figure 2A. Throughout the 24 months, there was an increased number of these purchases among cases before diagnosis compared with that of controls, with an increased rate of purchases 8 months before diagnosis. The mean numbers of purchases of pain and indigestion medications were greater for cases in the 6 months, 12 months, and 24 months before diagnosis, with a significant association between these purchases and ovarian cancer diagnosis in the 6 months before diagnosis (OR 1.05, 95% CI 1.01-1.10; Table S4 in Multimedia Appendix 1). The Fisher exact test (Figure 2B) showed maximum discrimination between cases and controls 8 months before diagnosis (OR 2.91, 95% CI 2.07-4.12).

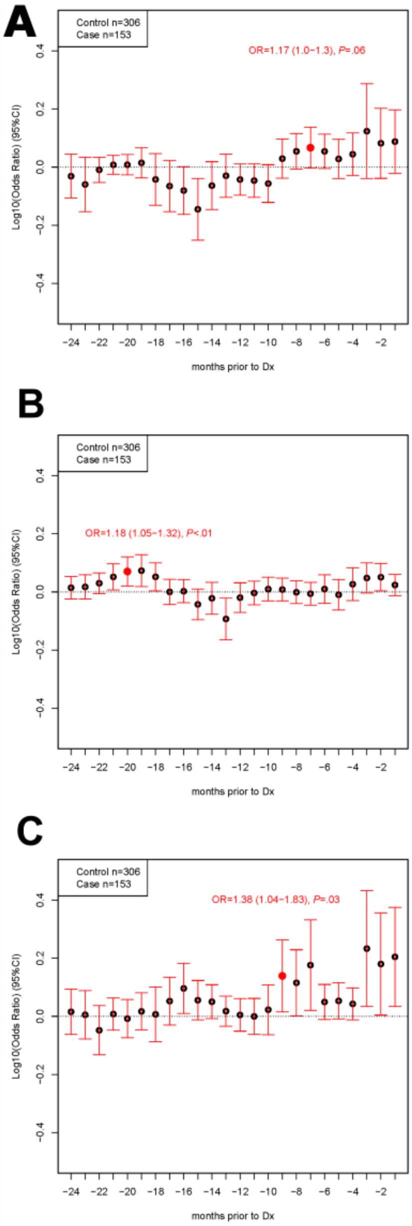
Figure 2. Combined pain and indigestion medications in the Cancer Loyalty Card Study (CLOCS). Cases (n=153) were matched with controls with respect to age and store card use (HSR1 only, HSR2 only, or HSR1+HSR2) at a 2:1 ratio with replacement (n=306 controls in matched analysis, 77 unique individuals). Participants with a previous diagnosis of cancer were excluded. Where possible, the same 24 months of purchases from controls were aligned to each matched case leading to their diagnosis (–24 months to –1 month on the X-axis); otherwise, the last 24 months of purchases were used for controls. (A) Average cumulative purchases of combined pain and indigestion medications in cases (red) and controls (black). (B) Purchases summed on a sliding 3-month window for cases and controls comparing all purchases to purchase of both pain and indigestion medication bought together. The Fisher exact test was used to calculate the odds ratios and significance of enrichment at each month prior to diagnosis. Dx: diagnosis; HSR: high street retailer.



Adjusted Models

As shown in Figure 3A, the likelihood of being diagnosed with ovarian cancer was significantly lower at 15 months before diagnosis in combined purchases of pain and indigestion medications, and there was no significant increase in risk of ovarian cancer diagnosis. However, when pain medication purchases were considered alone, there was a significantly increased likelihood of ovarian cancer 19 months before diagnosis (OR 1.18, 95% CI 1.05-1.32), as shown in Figure 3B. There was a significantly increased association between ovarian cancer diagnosis and indigestion medication purchases alone 9 months before diagnosis (OR 1.38, 95% CI 1.04-1.83), as shown in Figure 3C and Table S5 of Multimedia Appendix 1.

Figure 3. Conditional logistic regression for purchases prior to diagnosis (Dx). Cases (n=153) were matched with controls according to age and store card use (HSR1 only, HSR2 only, or HSR1+HSR2) at a 2:1 ratio with replacement (n=306 controls in matched analysis, 77 unique individuals). Participants with a previous diagnosis of cancer were excluded. Where possible, the same 24 months of purchases from controls were aligned to each matched case leading to their diagnosis (–24 months to –1 month on the X-axis); otherwise, the last 24 months of purchases were used for controls. Conditional logistic regression of matched case-control sets adjusting for oral contraceptive pill use and household number for combined sum of pain and indigestion medication (A), pain medication only (B), or indigestion medication only (C). HSR: high street retailer; OR: odds ratio.

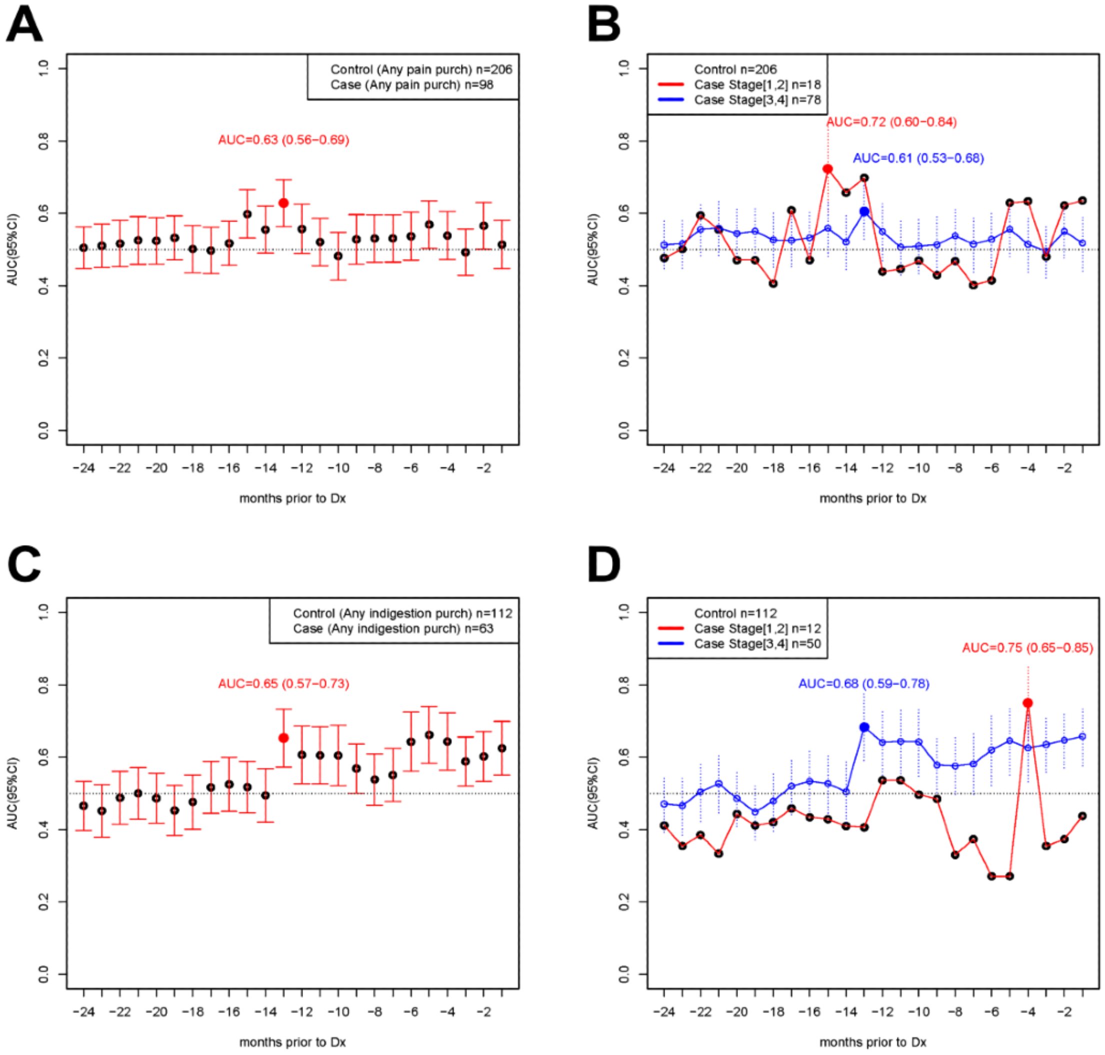


ROC Analyses

Restricting the analysis to only participants who purchased any pain medication over the 24-month period, 98 cases and 206 controls remained. The ROC analysis for pain medication purchases alone (Figure 4A and Table S6 in Multimedia Appendix 1), excluding participants who did not purchase any pain medication, showed a maximum area under the curve (AUC) at 13 months before diagnosis (AUC=0.63, 95% CI 0.56-0.69). When further stratified on early stage at diagnosis, the AUC reached a maximum of 0.72 (95% CI 0.60-0.84) 15 months before diagnosis (Figure 4B).

Among those who only purchased any indigestion medication over the 24-month period, 63 cases and 112 controls remained. The ROC analysis for indigestion medication purchases alone (Figure 4C and Table S6 of Multimedia Appendix 1) also showed a maximum AUC at 13 months before diagnosis (AUC=0.65, 95% CI 0.57-0.73), and this further improved when restricted to late-stage ovarian cancer diagnosis (AUC=0.68, 95% CI 0.59-0.78), as shown in Figure 4D. Overall, the AUC was greater for late-stage diagnosis than early-stage diagnosis in all 24 months before diagnosis.

Figure 4. Receiver operating characteristic (ROC) analysis stratifying by stage of diagnosis (Dx). Purchases in cases and controls were aligned as per Figure 3. (A) ROC analysis of pain medications at each month prior to diagnosis in cases (n=98) and controls (n=206) that purchased any pain medication in the 24-month period. Area under the curve (AUC) and 95% CIs are presented. (B) Stratification into cases diagnosed at a low stage (1,2) (n=18, red line) or high stage (3,4) (n=78, blue line). (C) ROC analysis of indigestion medications at each month prior to diagnosis in cases (n=63) and controls (n=112) that purchased any indigestion medication in the 24-month period. AUC and 95% CIs are presented. (D) Stratification into cases diagnosed at a low stage (1,2) (n=12, red line) or high stage (3,4) (n=50, blue line).



Sensitivity Analyses

Adjusting for purchase behaviors before and after the COIVD-19 pandemic, different seasons, number of household members, and OC use showed little to no effect on the association of purchases with ovarian cancer over 24 months before diagnosis (Tables S7-S9 in Multimedia Appendix 1).

After adjustment for the ovarian cancer risk score (Tables S10-S12 in Multimedia Appendix 1), there was no significant change in the OR for detecting cancer symptoms among CLOCS participants who purchased pain and indigestion medications compared with only adjusting for OC use and number of household members.

Discussion

Principal Results

The primary aim of the CLOCS was to investigate purchasing behaviors of women with and without ovarian cancer before diagnosis to determine whether there is a difference in purchases of OTC medications among ovarian cancer patients before diagnosis. Purchases among CLOCS participants indicated an increase of pain and indigestion medication purchases prior to diagnosis of ovarian cancer. Specifically, we detected an increase in purchases of pain and indigestion medications bought together at 8 months before diagnosis. When considered separately in conditional logistic regression models adjusting for confounders, the signal for increased purchases of indigestion medications occurred from 9 months before diagnosis. For pain medication, we observed a period of increased purchases at 19 months prior to diagnosis, but no significant differences in the 12 months leading up to diagnosis. This suggests that there may be a difference in the timeline along which the patients with ovarian cancer included in this study may have experienced and cared for symptoms that can be treated with pain or indigestion medication.

Comparison With Prior Work and Clinical Implications

The guidelines for investigation and initial assessment of ovarian cancer in symptomatic women vary greatly internationally partially due to the nonspecific nature of symptoms [12], and almost 1 in 4 cancer patients present with a broad range of abdominal symptoms before diagnosis [13]. Specifically, for an effective treatment of ovarian cancer, while symptom presentation may not always correlate with early-stage diagnosis, an earlier diagnosis even at stage IV could mean that patients may receive treatments that could improve their chances of surviving 1 year or longer. In the context of this study, when stratified by stage of diagnosis, for those diagnosed at an early stage, we identified that the purchase of pain medications occurred at 15 months before diagnosis, whereas indigestion medications were much more closely associated to diagnosis, at 4 months. For those diagnosed at a late stage, we identified indigestion medication purchases as early as 13 months prior to diagnosis and then in every month from 6 months up to diagnosis, but no significant change in pain medication purchases was found in the 12 months prior to diagnosis. From a clinical point of view, this highlights a unique interval in the tumor development where symptoms are presenting at different times. However, our sample sizes were too small to further stratify according to patient characteristics based on their OTC use associated with reported symptoms and stage at diagnosis.

While these differences could reflect the nonspecific nature of symptoms that occur during the development of ovarian cancer, they could also indicate the complex symptom appraisal processes for nonspecific cancer symptoms and presentation in health care [14]. For example, patients with pain 1 year before diagnosis might have already seen a health care professional following the initial presentation of their symptoms. However, in the absence of other symptoms not warranting an urgent cancer referral (ie, diagnostic pathway in the United Kingdom where patients with suspected cancer are seen within 2 weeks of presentation), patients' symptoms may have been treated for other illnesses, resulting in a longer diagnostic interval from the first onset of symptoms [15]. In fact, we identified no differences in the number of GP visits in the 12 months leading up to diagnosis or participation in the study between cases and controls, indicating that transactional data could be useful to further explore self-care behaviors even after patients may have presented in health care for their symptoms. A previous study reported that 36% of ovarian cancer patients presented to their GP at least three times before diagnosis [16], while approximately 25.8% of cases in the CLOCS reported attending three or more visits to the GP before diagnosis (see Table S3 in Multimedia Appendix 1). Much lower rates of help-seeking behaviors could be attributed to the fact that approximately 64% of cases were diagnosed with ovarian cancer throughout the COVID-19 pandemic, during which many people avoided contacting or seeking help about their symptoms from their local GP [17]. Our results further emphasize the importance of safety nets to be in place between community pharmacies and primary care to ensure that patients who continue to care for their ongoing symptoms are identified and referred promptly.

Alternatively, the duration and the effectiveness of self-care using OTC indigestion and pain medication may be related to the type of abdominal symptom experienced [13]. However, there is little qualitative evidence on patients' accounts of when they experienced pain and indigestion, or how they coped with these symptoms and cared for them before they received a diagnosis [18]. Nevertheless, the number of cases in the CLOCS with early-stage diagnosis was small; therefore, further studies with a larger number of patients with early-stage diagnosis would be needed to verify if self-care behaviors and earlier presentation are moderated by symptom development and individuals' symptom appraisal processes.

Strengths and Limitations

The main strength of this study is that this is the first study to investigate transactional data for understanding individuals' self-care behaviors prior to a cancer diagnosis using a case-control study design. The use of prospectively collected data prior to cancer diagnosis avoids potential recall bias that would have occurred from querying as to when patients purchased OTC products for nonspecific symptoms using questionnaires. In the CLOCS, exposure to pain and indigestion medication purchases was measured using loyalty card data that are recorded by retailers, thereby adjusting for the potential recall bias as well as respondents' bias to provide desirable outcomes. For example, although there was a significant difference between purchases of indigestion medications among cases and controls, the self-reported indigestion symptoms were not significantly different between cases and controls in this study (see Table S13 in Multimedia Appendix 1). Recall bias is a common issue reported for case-control studies; thus, to overcome recall bias associated with symptoms experienced before diagnosis, we aimed to recruit patients soon after their cancer diagnosis and/or exclude patients diagnosed before 2018.

One of the main limitations of this study is that purchase of an item is not the same as consumption of the item. The majority of participants reported that they lived with others in their household, and therefore could have been purchasing pain and indigestion medications for others instead of directly consuming these themselves. This limitation is applied equally to cases and controls who might also be buying products for others. There was no difference in the effect of purchases and ovarian cancer diagnosis when adjusting for other household members. Similarly, the analysis was restricted to purchases recorded only when participants used their loyalty cards, and any items purchased without the loyalty card were not recorded. However, 85% of participants reported that they used their loyalty card often or all the time. It is also likely that participants could be shopping for these medications at other retailers not included in this study, resulting in an underrepresentation of purchases with the limited participating retailers. Therefore, it is possible that the significant association observed here could be stronger with the inclusion of purchases of these items from other retailers, although further studies including more retailers are needed to verify this possibility.

Furthermore, most of the timeline for recruitment of cases and controls to this case-control study occurred during the COVID-19 pandemic. As a result of the paused recruitment and necessary amendments, the study did not meet the original goal to recruit 500 cases and 500 controls, and the sample size for analysis was smaller than originally intended. Due to the nature of recruitment of cases and controls, there was on average a 13-year age difference between cases and controls, reflecting an age bias in acceptability of sharing data, participating in research, and online recruitment of controls (HRB, YH, and JMF preliminary data, August 8, 2022). However, this age difference was accounted for in all analyses either through age adjustment or matching on age.

Future Research

This study highlights the significant timeframe (9 to 19 months prior to diagnosis) in the patient interval in cancer diagnosis for when individuals who have yet to receive an ovarian cancer diagnosis and may have been reacting to the bodily changes and caring for their symptoms using OTC medications to maintain their health status. In the landscape of cancer epidemiology and symptom presentation research [5,6], this result contradicts with the timelines reported for the first symptoms recorded on primary care–based records to calculate the patient interval, which potentially highlights the need to have better data collection methods on patient well-being.

Likewise, this study only reported the temporal associations between OTC purchases and ovarian cancer diagnosis, and future data analyses will include understanding the characteristics of changing patterns of purchases, as well as combining other purchase categories that are not linked to symptom management using unbiased machine-learning approaches. Future analysis may also consider the association between OTC purchases and other diseases with similar symptoms, such as gastrointestinal diseases. With growing literature on utilizing other data sources in health research, transactional data have already been used to evaluate dietary patterns, and such analysis is considered to be a tool that can supplement our understanding of people's dietary behaviors [19,20]. Similarly, this type of surveillance could provide an opportunity to utilize loyalty card programs, where available around the world, to assess purchases related to OTC treatment of many cancer types to improve earlier detection.

Conclusions

To date, the CLOCS has identified an increase in purchases of OTC pain and indigestion medications among ovarian cancer patients before diagnosis compared with those of women without ovarian cancer. Further studies with larger numbers of ovarian cancer patients, diagnosed at different stages, and more participating retailers are needed to verify these findings, which can lead to the future development of an alert system for individuals to seek medical attention for the symptoms they are experiencing sooner than they might otherwise.

Acknowledgments

The authors would like to acknowledge all of the participants in the Cancer Loyalty Card Study (CLOCS), the participating retailers, and the National Health Service (NHS) sites that recruited ovarian cancer patients to this study. We would like to acknowledge Deborah Tanner and Fiona Murphy who have acted as ovarian cancer patient representatives since the inception of the CLOCS project. This study was funded by Cancer Research UK Early Detection and Diagnosis Project (grant C38463/A26726) with additional support from the Cancer Research UK Imperial Centre, National Institute for Health Research Imperial Biomedical Research Centre, and Ovarian Cancer Action Research Centre.

Data Availability

Access to all Cancer Loyalty Card Study (CLOCS) purchase history data collected from the retailers is restricted due to the data sharing agreements in place and the sensitive nature of the data. However, we welcome other researchers to contact us for collaborations. The principal investigator and research team will review each proposal and, if approved, the analysis will be conducted by a member of the CLOCS team.

Authors' Contributions

JMF, YH, and HRB conceived the study. HRB and JMF conducted all statistical analyses. HRB, JMF, and YH reviewed the results. EJ provided expertise in information governance and data management. HRB wrote the first draft of the manuscript. YH, JMF, SS, and MC-H commented on and reviewed the final draft of the manuscript. All authors agree on the final version of the manuscript.

Conflicts of Interest

SS declares receiving honoraria from Astra Zeneca, Glaxo Smith Kline and MSD (Merck & Co) for speakers fees. The author has no conflicts in relation to this manuscript. All other authors declare no conflicts of interest.

Abstract

Background: Unintentional injury is the leading cause of death in young children. Emergency department (ED) diagnoses are a useful source of information for injury epidemiological surveillance purposes. However, ED data collection systems often use free-text fields to report patient diagnoses. Machine learning techniques (MLTs) are powerful tools for automatic text classification. The MLT system is useful to improve injury surveillance by speeding up the manual free-text coding tasks of ED diagnoses.

Objective: This research aims to develop a tool for automatic free-text classification of ED diagnoses to automatically identify injury cases. The automatic classification system also serves for epidemiological purposes to identify the burden of pediatric injuries in Padua, a large province in the Veneto region in the Northeast Italy.

Methods: The study includes 283,468 pediatric admissions between 2007 and 2018 to the Padova University Hospital ED, a large referral center in Northern Italy. Each record reports a diagnosis by free text. The records are standard tools for reporting patient diagnoses. An expert pediatrician manually classified a randomly extracted sample of approximately 40,000 diagnoses. This study sample served as the gold standard to train an MLT classifier. After preprocessing, a document-term matrix was created. The machine learning classifiers, including decision tree, random forest, gradient boosting method (GBM), and support vector machine (SVM), were tuned by 4-fold cross-validation. The injury diagnoses were classified into 3 hierarchical classification tasks, as follows: injury versus noninjury (task A), intentional versus unintentional injury (task B), and type of unintentional injury (task C), according to the World Health Organization classification of injuries.

Results: The SVM classifier achieved the highest performance accuracy (94.14%) in classifying injury versus noninjury cases (task A). The GBM method produced the best results (92% accuracy) for the unintentional and intentional injury classification task (task B). The highest accuracy for the unintentional injury subclassification (task C) was achieved by the SVM classifier. The SVM, random forest, and GBM algorithms performed similarly against the gold standard across different tasks.

Conclusions: This study shows that MLTs are promising techniques for improving epidemiological surveillance, allowing for the automatic classification of pediatric ED free-text diagnoses. The MLTs revealed a suitable classification performance, especially for general injuries and intentional injury classification. This automatic classification could facilitate the epidemiological surveillance of pediatric injuries by also reducing the health professionals’ efforts in manually classifying diagnoses for research purposes.

Introduction

Unintentional injury is the leading cause of morbidity and mortality in children worldwide [1]. An injury is defined as tissue damage that occurs secondary to acute exposure to physical agents (eg, thermal, kinetic, chemical, electrical, or electrical energy or water) or chemicals (eg, poisoning). An injury can be fatal or nonfatal and can occur unintentionally or as a result of purposeful acts of harm (intentional) [2]. Unintentional injuries can be prevented or controlled because they are potentially understandable and predictable [3].

In 2013, 15.4% of 2.6 million unintentional injuries worldwide involved a fatal outcome for children between 1 and 14 years of age [1]. In Europe, 42,000 children and adolescents aged 0-19 years died of unintentional injuries in 2004 [4]. Moreover, a considerable number of children may incur some form of disability as a result of injury, often with lifelong consequences [5]. Decreasing the injury burden is the main challenge for child and adolescent public health policies over the next century [6]. For this reason, public health departments must pay more attention to the problem to implement prevention policies [6].

Injury surveillance is made difficult by a series of logistic and structural challenges, the most important of which is the accurate coding of injury mechanisms, products involved, types of injury, and body parts involved, given that emergency department (ED) admission and discharge records are largely based on narrative free-text notes [7]. Injury surveillance integrated with timely data dissemination is crucial for planning and evaluating prevention policies [8] and quantifying injury burden and related risk factors [9,10].

In Italy and other European and newly developed countries [11], narratives and free-text records are standard tools for reporting patient diagnoses. Automatic classification of such free-text information using machine learning techniques (MLTs) would be a powerful tool to improve injury surveillance [12].

This is true, especially for the ED, where physicians and medical personnel often face stressful situations from a clinical and management perspective [13]. Within this general framework, it could be promising to provide an automated MLT-based system aimed at facilitating free-text diagnosis encoding, by also limiting an additional burden for the overwhelmed medical staff. This MLT-based system could be tailored for research and epidemiological surveillance purposes. Furthermore, this surveillance system could be promising for pediatric injury surveillance purposes because most of the incidents that occur on the ground are referred to such departments, especially large pediatric EDs [13].

The literature over the past 10 years indicates an increasing interest in the automated categorization of free-text diagnoses due to the increased availability of documents in digital form [14,15]. Automatic MLT classifiers can learn (during the training phase) from a set of manually classified documents with complex free-text lexical patterns. A properly trained MLT tool can categorize a free-text record into its corresponding class. The advantages of this approach over manual methods are efficiency and saving time (in terms of expert labor) for free-text classification [15].

Statistical text mining methods can also be useful tools to classify electronic ED admission records and properly identify unintentional injury events [15].

This study represents, to our knowledge, the first effort in the literature in proposing an automatic injury classification system based on the free-text data of pediatric ED diagnoses. We propose this algorithm to facilitate injury epidemiological surveillance. The system is aimed at limiting the burden of health care professionals, who are overburdened by patient care and management tasks, in manually classifying diagnoses for epidemiological research.

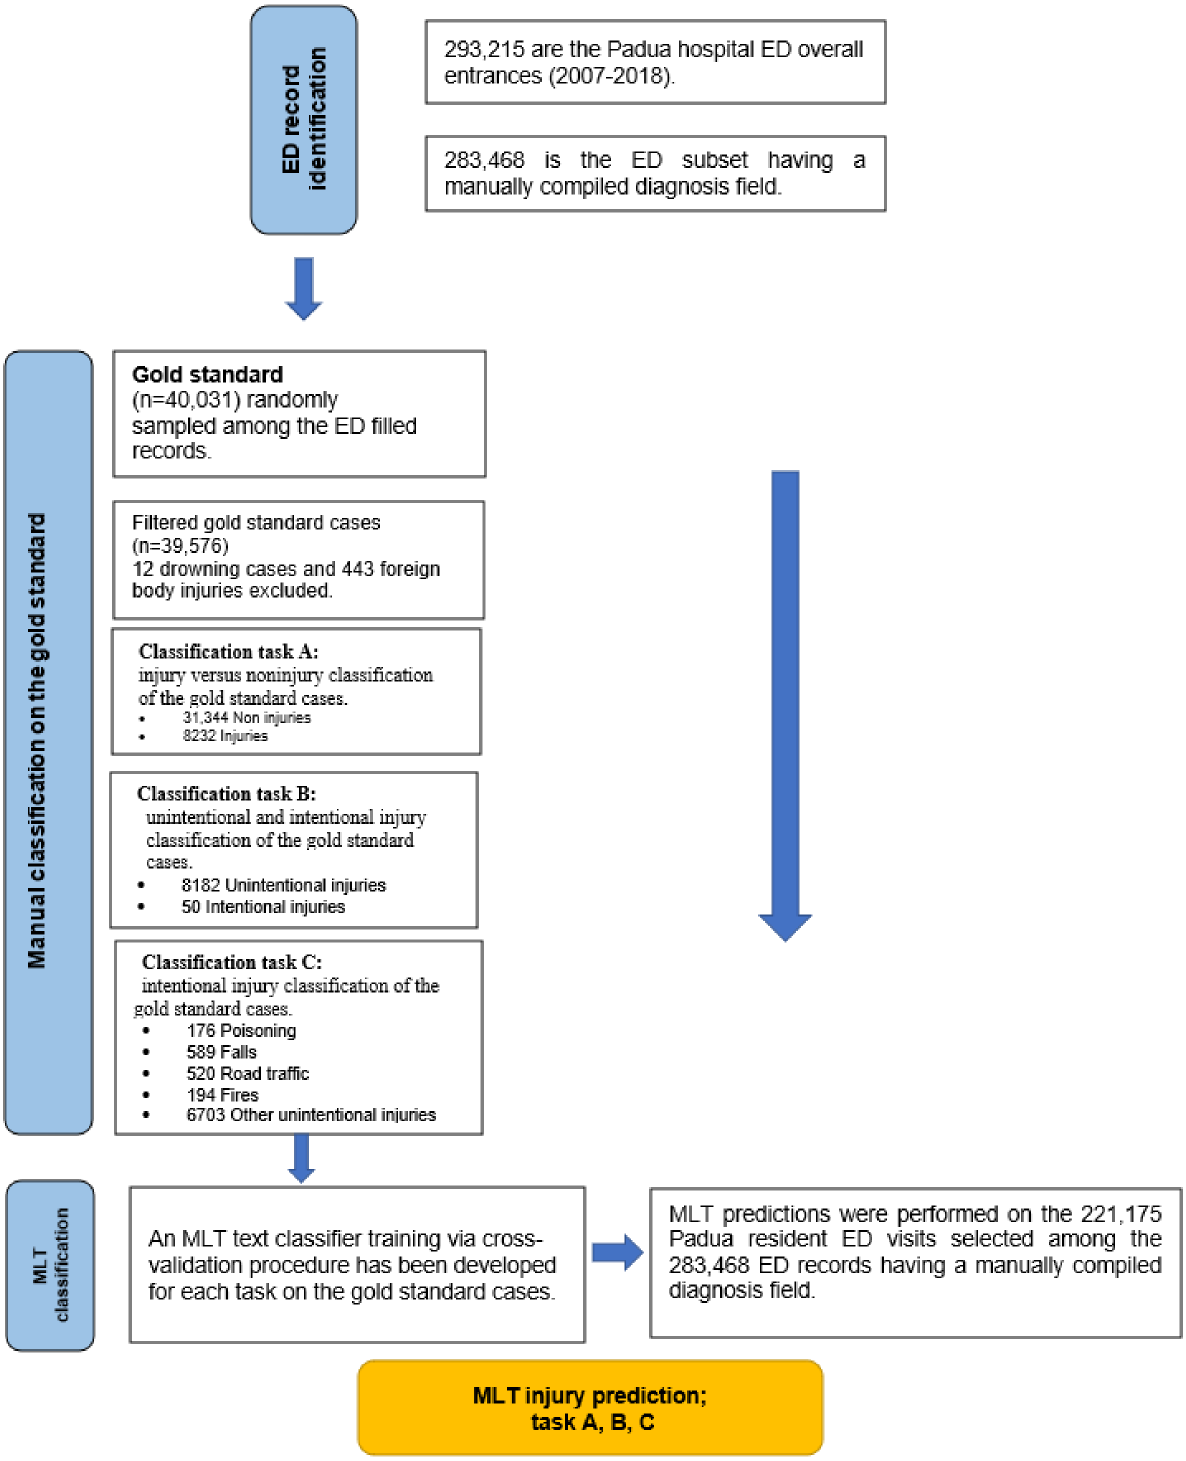
Methods

Data Selection

The study included 283,468 pediatric ED records with a filled discharge diagnosis field among 293,215 records [16] from the local electronic medical record system of Padova University Hospital in Northeast Italy between 2007 and 2018 (Figure 1).

The average ED annual workload is approximately 25,000 visits. The upper age limit to access the pediatric ED is 15 years. A higher and more variable age limit applies to children followed by the Department of Pediatrics for chronic illnesses. The Padova Hospital Pediatrics ED is characterized by high patient turnover with an average hospitalization time of 4-5 days. The number of admissions after ED access is approximately 850 per year.

Figure 1. Study flowchart—emergency department (ED) selection and gold standard identification together with manual injury classification procedure. Machine learning technique (MLT) cross-validation and prediction procedures for tasks A, B, and C are represented by the dark grey box.



Ethics Approval

The study was conducted according to the guidelines of the Declaration of Helsinki and approved by the Ethics Committee of Azienda Ospedaliera of Padova (Hospital Ethics Committee; 0022925) on April 8, 2021. The analysis is carried out on observational data of a secondary nature; however, patients signed a consent form to allow the data to be used for scientific purposes at the time of collection. The records of each patient are kept anonymous with an appropriate identification key excluding personal information. No Compensation has been provided for subjects involved in the research.

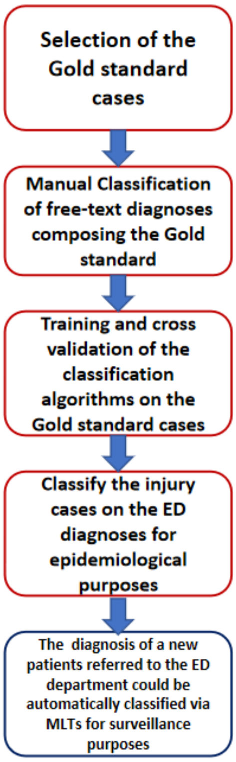
Learning Algorithm for Epidemiological Surveillance

The definition of the free-text classification algorithm and its use for epidemiological surveillance purposes consisted of several phases, as reported in Figure 2. These phases are the following:

1. A training set was defined as a gold standard and was composed of a random sample of ED diagnoses.

2. The gold standard diagnoses were manually classified by an expert physician into injury versus noninjury (task A), intentional versus unintentional injury (task B), and type of unintentional injury (task C), according to the World Health Organization (WHO) classification of injuries.
3. The preprocessed and manually classified gold standard cases were used to train the MLTs algorithms in classifying the diagnoses according to tasks A, B, and C. Several algorithms were considered to define the MLT tools; the most performing algorithms would be considered for the predictive tool definition.
4. The trained tool served to automatically classify the remaining ED diagnoses by providing a proof of concept of the injury epidemiology in the geographical area referring to the Padua ED center.
5. Once optimal algorithms were defined, they could be used to classify diagnoses on a new ED referral pediatric patient by defining an automated epidemiological surveillance system.

Figure 2. Flowchart of learning algorithm development for injury epidemiological surveillance. ED: emergency department; MLT: machine learning technique.



Gold Standard Definition

A randomly extracted subset of 40,031 ED records was manually classified (Figure 1) by a clinician for the following 3 classification tasks:

1. Injury or noninjury events, characterized as classification task A.
2. Intentional or unintentional injury events as classification task B (performed on diagnoses classified as injury in classification task A).
3. Unintentional injury category as classification task C (performed on records classified as unintentional injury in classification task B).

In this study, unintentional injury ED records were classified based on the WHO [17] classification of 5 types of unintentional injuries: road traffic injuries, poisoning, falls, fires, and drowning. We added a sixth category of unintentional injury exclusive of the WHO categories called “other unintentional injury.” In addition, the WHO classes represented by fewer than 15 records were not considered for cross-validation of the automatic MLT classifier.

Foreign body or choking injury events were also excluded because they constitute a separate epidemiological category conducive to purpose-specific studies [18].

Data Preprocessing

Free-text diagnoses were preprocessed by removing punctuation, as reported in the literature [19], stop words, white spaces, and numbers, leaving only word stems. All words were converted to the lowercase font.

After cleaning the text corpus, the free-text data were represented via a document-term matrix (DTM) that represented the diagnostic text data in the form of a matrix. The rows of the matrix reported the sentence for the single diagnosis, and the columns of the matrix represented the single word that composed the sentence. The DTM was filled by weighting each word term with the inverse of its frequency.

The most frequent words in the ED free-text records were also reported considering the unprocessed DTM in manually classified gold standard cases.

Different MLT algorithms were trained and tuned to classify injury diagnoses, as follows:

- The decision tree (DT), random forest (RF), and gradient boosting method (GBM) tree-based models.
- The support vector machine (SVM) method served as a comparison tool against the tree-based models.

MLT Classifier Cross-Validation

The filtered manual classification of 39,576 cases (Figure 1) served as the gold standard for training and cross-validating (4-fold) the MLT tool. In the literature, it is documented that 4- or 5-fold cross-validation is appropriate to minimize the SD accuracy estimate of a tuned model [20].

Tree-Based Methods and the Comparator

Decision Trees (DTs)

DTs are classification or regression models based on a top-down methodology in which, starting from the root node, binary splits of data are generated until a certain criterion is satisfied. The classification error rate has been considered as the fraction of training observations in a particular tree partition that doesn’t belong to the most widely occurring class [21].

The DT is a classification method that in several cases suffers from overfitting; for this reason, ensemble methods are provided in the literature. For example, bagging or bootstrap aggregation is a technique for reducing the variance of an estimated prediction function. Bagging seems to work especially well with high variance and low-bias procedures, such as trees [22].

Random Forest (RF)

Rf is a modification of the bagging method that constructs a large collection of poorly correlated trees and then calculates the average. In many problems, the performance of RF is high; RFs are also easy to train and regularize. As a result, they have become quite popular [23]. The RF tree-based algorithm involves the computation of hundreds to thousands of DTs and merges them to increase the generalizability of the model. The DT combination essentially takes the form of an ensemble method. Weak learner (or single DT) pooling is used as a strategy to obtain more powerful learners [22].

Gradient Boosting Method (GBM)

The GBM is based on sequential boosting improvements of weak classifiers (high bias and low variance). The GBM sequentially adds one classifier at a time so that the next classifier is trained to improve the previously trained DT. In contrast, the RF algorithm trains each classifier independently of the others [22].

Support Vector Machine (SVM) as the Comparator

The main objective of the SVM algorithm is to find an optimal hyperplane of a feature space of N dimensions (where N is the number of features) that distinctly classifies the data points into a binary partition [24]. Several hyperplanes may separate the resulting classes of data points. The SVM algorithm considers the hyperplanes that maximize the margin (the distance between the data points of the classes). The SVM algorithm was selected as a comparator for tree-based algorithms. The kernel hyperplane approach has been considered for the computation.

Classification Tasks

Three classification tasks were considered for the analysis, as follows:

- Classification of injury versus noninjury events (task A)
- Classification of intentional versus unintentional injury events (task B)
- Classification of unintentional injuries (task C) based on the WHO categorization (poisoning, road traffic, falls, fires and burns, drowning, and other unintentional injuries) [5].

Performance Evaluation

The performance of the MLT classifiers was evaluated using cross-validated accuracy and Kappa agreement values compared to the gold standard. In particular, the training set represented by the gold standard is one of the largest such sets produced to classify injuries.

For classification scenarios that involved severe class imbalance (where the minority class is represented by less than 15% of the cases), balanced accuracy was reported.

The mean and maximum accuracies computed for all classes that included unintentional injuries in the gold standard records were also calculated. Other performance measures were reported concerning positive and negative predictive values, sensitivity, and specificity.

MLT Predictions

MLT predictions for classification tasks A, B, and C were calculated for admissions to the ED of children residing in Padua (221,175 records; Figure 1). Subsequently, Poisson 95% CIs for injury incidence rates over the Padova province resident child (aged 0-18 years) population were computed to compare the predictions of the different MLT methods. The person-time was identified in the period of 2007-2018 by considering the official Italian statistic data source ISTAT [25]. The number of cases in the period was estimated using the RF, GBM, DT, and SVM algorithms.

Synthesis of Data

Summary statistics of the gold-standard case data were reported as follows: continuous data were summarized as first quartile, median, and third quartile; categorical data were reported as percentages and absolute frequencies. Wilcoxon-type tests were performed for continuous variables, and Pearson chi-square test or Fisher exact test, as appropriate, were performed for categorical variables.

The computations were performed using R 3.4.2 (R Foundation for Statistical Computing) [26] with the caret package [27] as a machine learning R interface and the rms package [28] for descriptive and standard statistical analyses.

Results

Gold Standard Description

The gold standard set used to train the MLT classifiers (39,576 cases) was composed of 19,659 female and 19,917 male individual admissions (Table 1). The sample was mainly composed of Italians, and 33,474 (85%) gold standard cases were aged between 1 month and 15 years (Table 1).

Injury events were mainly represented by Italian male children between 6 and 15 years of age (Table 1). Among the 8232 injuries in Table 1, only 50 (0.6%) cases were intentional injuries.

Manually classified WHO unintentional injury drowning cases were not considered in the analyses because there were only 12 such cases (Figure 1). Falls and road traffic injuries were the main types of unintentional cases in the gold standard set (Table 1).

Table 1. Characteristics of the gold standard cases. Continuous data are reported as medians (first and third quartiles); categorical data are reported as percentages and absolute frequencies. Wilcoxon-type tests were performed for continuous variables; Pearson chi-square test or Fisher exact test, as appropriate, were performed for categorical variables.

Characteristics	Noninjury (N=31,344), n (%)	Injury (N=8232), n (%)	Overall (N=39,576), n (%)	*P* value

Free-Text Diagnosis Description

The free-text diagnosis field of the gold standard cases was preprocessed, and the DTM was synthesized based on word occurrence. A manual frequency evaluation of noninjury diagnoses found the most frequent words were "high," "respiratory," "tract," "inflammatory," and "fever," whereas the most frequent words in injury diagnoses were "skull," "trauma," "wound," "fracture," and "hand" (Figure S1 in Multimedia Appendix 1).

Regarding the unintentional injury classes (Figure S2 in Multimedia Appendix 1), "trauma" was the most frequent word found in falls, road traffic, and other unintentional injury diagnoses.

Burn events were mainly described with hand-related attributes such as "right" and "left." No drowning events were reported.

The words “ingestion” and “suspected” were mainly associated with poisoning diagnoses.

MLT Classifier Performance

Classification Task A: Injury Versus Noninjury

The average cross-validated accuracy reported as percentages for the different MLT classifiers was greater than 85% in every case and was very similar for the SVM, GBM, and RF models (Table 2).

A high level of agreement among the methods can be found using the kappa measure, which was greater than 79% in every case with the exception of DT (Table 2). In addition, the kappa performance of the RF and SVM methods was very similar.

Most disagreement cases stemmed from a mismatch with the gold standard, and the methods exhibited a high level of consistency in this regard. For example, the percentage of correctly evaluated injuries was very similar for the SVM and RF disagreement cases (Table S1 in Multimedia Appendix 1).

Table 2. Injury versus noninjury classification task comparative cross-validated accuracies and kappa scores of the machine learning technique (MLT) classifiers.

Feature	Random forest	Decision tree	Gradient boosting method	Support vector machine
Overall accuracy (%)	94.09	88.38	94.1	94.14
Overall kappa (%)	81.76	58.66	81.63	81.77
Sensitivity	0.980475	0.993396	0.985065	0.983218
Specificity	0.795633	0.381413	0.7518	0.790492
Positive predictive value	0.945387	0.852819	0.934727	0.944237
Negative predictive value	0.918657	0.941199	0.933117	0.928852

Classification Task B: Intentional Versus Unintentional Injury

The balanced accuracy performance was greater than 70% for RF, GBM, DT, and SVM (Table 3).

Considering the other metrics (ie, sensitivity, specificity, negative predictive values, and positive predictive values), the algorithms were able to classify unintentional cases, as the negative predicted values were greater than 99% in every unintentional case. Intentional injuries, in contrast, were misclassified in several cases, and the positive predictive values were less than 2% in every case (Table 3).

Table 3. Intentional versus unintentional injury classification task comparative cross-validated performance measures of the machine learning technique (MLT) classifiers.

Feature	Random forest	Decision tree	Gradient boosting method	Support vector machine
Balanced accuracy (%)	71.33	75.63	76.65	70.86
Sensitivity	0.6867	0.7	0.7644	0.64
Specificity	0.7401	0.7787	0.7563	0.7631
Positive predictive value	0.0151	0.018	0.0178	0.0154
Negative predictive value	0.9976	0.9978	0.9982	0.9973

Classification Task C: Unintentional Injury Category

The algorithms were trained and tuned on different subclasses of unintentional injuries, and the scores of a balanced accuracy measure were found to be relatively greater and similar for RF, SVM, and GBM, and smaller for DT (Table 4).

For the other metrics, all the algorithms correctly identified poisoning and other unspecified injuries. For these classes, the classification positive predictive values were greater than 60% in every case for the different MLT methods (Table S2 in Multimedia Appendix 1). The metrics reported in Table S2 (Multimedia Appendix 1) also revealed decreased performance for the identification of trauma-related injuries, such as “burns,” “falls,” and “road traffic,” where the sensitivity was less than 15%.

Table 4. Unintentional injury classification task (in every case, maximum accuracy is achieved for the poisoning class).

Feature	Random forest	Decision tree	Gradient boosting method	Support vector machine
Maximum balanced accuracy (%)	91.42	81.09	91.63	91.62
Mean balanced accuracy (%)	64.59	59.26	65.07	64.95

Predicted MLT Injury Incidence Rates

For the 221,175 ED visits studied (Table S3 in Multimedia Appendix 1), the median age was 4 years, and the majority of the children were of Italian nationality (172,577, 78%). The estimated number of injury cases was similar for RF, GBM, and SVM but relatively lower for DT (Table S4 in Multimedia Appendix 1).

The estimated incidence rates of ED entrance for Padova residents (2007-2018) were very similar across the GBM, RF, and SVM methods and slightly lower for DT (Figure S3 in Multimedia Appendix 1).

Discussion

Principal Findings

In Italy, unintentional injuries in children have been scarcely investigated. Padova Hospital is an important health center in Northeast Italy, characterized by a high number of daily ED visits due to unintentional injuries. Analysis of the Padova Hospital ED database represents a suitable starting point for the development of a reliable and generalizable epidemiological injury surveillance system.

The free-text classification may improve the epidemiologic surveillance of pediatric ED injuries. However, the manual classification of free-text diagnoses is often time-consuming and requires highly trained clinicians [29]. On the contrary, automated text classification approaches require relatively fixed data sources and can improve the efficiency and timeliness of ED surveillance systems [29].

Several MLT methods are currently used to perform automatic text classification. The methodological comparison of different MLTs is useful to achieve a valid and accurate text classification [30]. This study demonstrates that ensemble tree-based resampling methods (RF and GBM) and SVMs are consistent with each other [31], reporting good classification accuracy [11] over different classification tasks, as corroborated in the literature [12]. DT is known to have a high variance when using training or test sets different from the same data set because it is prone to overfitting. Moreover, the optimal choice of an MLT classifier should be integrated and tailored to gold-standard data characteristics, such as the number of classes, class imbalance, and the correlation structure of predictors. In the literature, ensemble methods (ie, RF and GBM) have been shown to be more robust in relation to these previously mentioned issues [32].

Cross-validation is a useful method that limits overfitting and allows tuning of DT parameters to optimize model accuracy [33]. The best classifier performance in this study was achieved on the task of identifying injury versus noninjury cases in ED visits (task A).

Regarding surveillance, the implications of our results are clear; current injury surveillance systems are largely based on mortality or hospital discharge data [13]. However, thousands of pediatric patients are treated in the EDs and subsequently discharged [13]. In Italy and other European and newly developed countries, ED data often contain narratives and free text to describe patient diagnoses [11]. Thus, an automated ED surveillance system, not requiring additional physician work, would be a suitable tool for comprehensive surveillance of childhood injuries. A negative predictive value of at least 99% was found to identify unintentional injuries; this indicates that there is a high probability that the cases identified as unintentional by this algorithm were unintentional. MLTs are capable of correctly classifying unintentional cases, which are highly prevalent injury events. In the literature [34], unintentional injury ED visits were found nearly 20 times more than intentional injury ED visits in the United States, and the pattern is similar in European countries [35].

The algorithms in this study performed poorly on the identification of intentional events. The reason for this poor performance was due to a lack of intentional injury cases (n=50, 0.6%) in the data [19]. Other methods are needed to develop a more accurate free-text classifier for intentional injury events. Poor performance was also evident in the distinction of trauma-related injuries (eg, falls and road traffic injuries).

MLTs (especially ensemble algorithms) have shown good classification performance in poisoning events. From an epidemiological perspective, poisoning events remain the third most common cause of unintentional injuries in Italy and Europe [4].

Large EDs are important sources of surveillance for pediatric diseases, especially for trauma and injury-related issues, given that most of such events refer to these departments [13]. However, the staff employed in such facilities often work in stressful situations, and the time and human resources to devote to data collection and accurate diagnosis coding may be very limited. In this general framework, our proposed MLT-based tool could facilitate the automatic classification of events for surveillance purposes. Once implemented, this algorithm could be easily improved by accumulating more data on less prevalent injury categories. It is hereby possible to obtain a general overview of the phenomenon on the territory by monitoring its epidemiological evolution over time. This system could facilitate the timely activation of intervention policies, regardless of the alarming concentrations of injury events.

Moreover, it is also important to improve surveillance systems using classified ED data integrated with hospital discharge or mortality records to design effective injury prevention programs and interventions. In this general context, the proposed ML-based injury classification tool could be a first step toward addressing the burden of pediatric injuries from a new holistic perspective [36].

Limitations

One first limitation of this study is that the data used for injury classification provide little information on what happens between ED admission and the final diagnosis. Moreover, as the triage service is extremely operator dependent, human factors represent an important confounding aspect of injury classification.

Another possible limitation is the small prevalence of certain types of injury, such as intentional injuries and drowning (among unintentional ones); this issue makes the algorithm's performance on these types of events lacking. The injury and unintentional injury classifications constitute the leading classification task for this research; however, further research developments are needed to enrich the diagnosis data on these types of injuries and train the classification machine for a more refined surveillance tool. Moreover, the poorly represented classes of unintentional injuries constitute an issue to be deepened from a technical standpoint. Within this framework, further research is needed to develop algorithms tailored to handle severe class imbalance.

Another point to explore is the generalization of the algorithm; the MLT performance may be influenced by a training process performed on diagnoses data retrieved from the same center, where the referring physicians could maintain the same writing style across the data set. For this reason, data from other centers would be needed to generalize the validity of the epidemiological tool. Despite this limitation, this tool constitutes a proof of concept of an epidemiological surveillance attempt performed using a machine trained on data from a large pediatric ED referral center in Northeast Italy.

Conclusions

This research paper reports an MLT-based free-text classification application conducted for the epidemiological surveillance of pediatric injuries. The algorithms have been trained considering the free-text diagnoses data of the Padova University Hospital ED unit, a large referral center in Northeast Italy.

The results of this study, for the injury classification task, showed that MLTs are a promising tool for improving epidemiological surveillance, allowing for the characterization of pediatric injuries in the ED by considering the free-text diagnoses as data sources.

The reported classification performance is satisfactory, especially for general injuries and intentional injury classification. These research results could facilitate the surveillance of a phenomenon that is often not easy to identify. Moreover, the approach could save time for health professionals working in the ED in manually classifying diagnoses for research purposes.

Data Availability

The database is provided from an administrative data source of the University Hospital of Padua. They could be made available upon motivated request to the authors.

Authors' Contributions

DA, DG, and SB prepared the original draft. DA, GAB, GL, CL, FS, AF, and PB wrote, reviewed, and edited the manuscript. Formal analysis was conducted by DA. The methodology was designed by DA and DG. The study was supervised by DG and LDD.

Abstract

Background: The COVID-19 outbreak has revealed a high demand for timely surveillance of pandemic developments. Google Trends (GT), which provides freely available search volume data, has been proven to be a reliable forecast and nowcast measure for public health issues. Previous studies have tended to use relative search volumes from GT directly to analyze associations and predict the progression of pandemic. However, GT's normalization of the search volumes data and data retrieval restrictions affect the data resolution in reflecting the actual search behaviors, thus limiting the potential for using GT data to predict disease outbreaks.

Objective: This study aimed to introduce a merged algorithm that helps recover the resolution and accuracy of the search volume data extracted from GT over long observation periods. In addition, this study also aimed to demonstrate the extended application of merged search volumes (MSVs) in combination of network analysis, via tracking the COVID-19 pandemic risk.

Methods: We collected relative search volumes from GT and transformed them into MSVs using our proposed merged algorithm. The MSVs of the selected coronavirus-related keywords were compiled using the rolling window method. The correlations between the MSVs were calculated to form a dynamic network. The network statistics, including network density and the global clustering coefficients between the MSVs, were also calculated.

Results: Our research findings suggested that although GT restricts the search data retrieval into weekly data points over a long period, our proposed approach could recover the daily search volume over the same investigation period to facilitate subsequent research analyses. In addition, the dynamic time warping diagrams show that the dynamic networks were capable of predicting the COVID-19 pandemic trends, in terms of the number of COVID-19 confirmed cases and severity risk scores.

Conclusions: The innovative method for handling GT search data and the application of MSVs and network analysis to broaden the potential for GT data are useful for predicting the pandemic risk. Further investigation of the GT dynamic network can focus on noncommunicable diseases, health-related behaviors, and misinformation on the internet.

Introduction

Background

Since the discovery of the first case of COVID-19 in December 2019, the pandemic has continued to develop and spread globally for >3 years. With the new wave of COVID-19 that began in early 2022 owing to the Omicron variant [1], confirmed cases rose to 540 million and deaths rose to 6.3 million by the end of June 2022 [2]. To deal with such serious disease outbreaks, real-time disease surveillance plays a crucial role for policy makers in their efforts to effectively implement timely health measures and allocate resources. However, disease surveillance generally relies on laboratory testing results [3], which are limited by testing time and capacity [4]. Relevant clinical data, such as data for mortality, morbidity, and utility rate of the health system, are regarded as another layer of reliable population-scale indicators for tracking the spread of a pandemic [5]. Unfortunately, these official statistics usually lag behind the infection situation [4,6]. As a result, there is a need to explore other possible population-scale data as complementary sources for tracking pandemic risk in real time without the limitations of the traditional surveillance methods.

Internet use is a common human behavior worldwide, as reflected in the rapidly growing number of internet users and social media users globally [7]. In particular, the internet has become an important source of health care information [8]. Therefore, internet search data are now a valuable population-level resource for tracking disease development, complementing the traditional surveillance methods [9]. Consequently, an increasing number of infodemiological studies have sought to address the need for public health enhancement by applying internet user–contributed, health-related content. Investigations of infoveillance, an emerging type of public health syndromic surveillance that is based on information from the web [10], have been proposed for tracking various health issues [11-13].

Google Trends (GT) is a Google website that analyzes the popularity of search queries and thus provides a platform for the public's use in retrieving the real-time search patterns of internet users worldwide [14]. As an official Google service, the aggregate GT data range from multiple sources of Google search engines, including web searches, image searches, news searches, Google shopping, and YouTube searches. There has been an upward trend in public health and epidemiological research on the use of GT in the last decade [15], and GT data have been proven to be reliable forecast and nowcast measures for official statistics and social topics, such as unemployment [16] and waves of pathogenic infections [17,18]. As the data in the repository are freely available and updated in real time, GT is considered to be a timely infoveillance tool that can complement the traditional surveillance methods well [9,19]. In particular, because the impact of an infectious disease will likely attract the public's attention, many previous studies have attempted to investigate the associations between search volumes of internet queries and disease outbreak trends, such as with the outbreaks of Ebola [20] and Middle East respiratory syndrome coronavirus [21]. A methodology framework was also developed for working with GT data in infodemiology and infoveillance [22]. However, although web-based data are a good indicator for predicting changes in human behaviors [23], the application of GT data to health care research is relatively novel and has been evolving quickly only recently [24,25].

Although access to GT data is free, there are several limitations in retrieving the data. GT does not provide the actual number of searches for a particular topic of interest at a particular time and in a particular geographic region. Instead, it only shows "interest over time" by providing relative search volume (RSV) time series data, normalized to a time and geographic region, using a scale from 0 to 100. A value of 100 represents the peak popularity of a particular search interest at a particular time and location, and a value of 30 indicates that a particular search interest was 30% as popular as that of the peak search activity. Therefore, GT data over long time horizons will result in heavily normalized data with reduced resolution [18], thus rendering the gathered data noisy and limiting the predictive power of the data. The normalization of the GT data does offer convenience in comparison, but it also poses limitations in tracking search behaviors longitudinally with a high frequency, such as daily updating of search volumes. Early research on GT data also indicated that it is a nontrivial endeavor to aggregate information on GT data from multiple keywords. Therefore, there is a need to search for an effective method of retrieving GT data that increases the resolution of RSV to reflect a trend of interest and that integrates search data from multiple keywords.

Previous studies have tended to use the retrieved GT data of specified search queries for correlation analyses and modeling [9,11,19,23,26]. Many previous studies have been conducted on COVID-19–related keywords [18,27-30] and have demonstrated the importance of using multiple keywords. Although the inclusion of multiple search queries can help provide valuable information for tracking human behavior and public health issues [11], the linkage among the search queries remains a challenge for empirical studies seeking to analyze the data systematically [31]. Furthermore, we cannot ignore the potential of connectedness among search interests in reflecting the complexity of information searching behaviors among internet users. Understanding the complex search behavior will be crucial when using search data to develop an effective infoveillance system for infection outbreaks.

Objectives

This study sought to extend the application of GT data in predicting disease outbreaks by demonstrating the application of merged internet search volumes and to propose a dynamic network approach to tracking COVID-19 pandemic risk. Specifically, we introduced the construction of GT networks over time, in which the network nodes were represented by different keywords. Our proposed GT network method can help incorporate internet search information from multiple keywords into a network. Using GT network structures and related network statistics, we were able to study the dependence among keywords—for example, COVID-19–related words—and learn topological features of search volumes of different keywords. We also examined the predictive power of the proposed application of our GT network method through trend analysis and dynamic time warping (DTW). In the case of COVID-19, which we studied in this research, we investigated the implications of topological features on the COVID-19 pandemic risk.

Methods

This section describes the methodology used in this study. A set of custom Python scripts was used for data acquisition, cleansing, analysis, and most of the data visualization. *Gephi* 0.9.7 from Gephi Consortium [32] was used to create the base network graphs.

Data Acquisition

In this study, the aggregated data from GT were retrieved for analysis. We used the time series data of “interest over time” as the RSV. The numerical data, ranging between 0 and 100, indicated the “search interest relative to the highest point” for the defined filtering region and the period. However, according to Google’s own definition, the value of “50” means the search term is “half as popular,” whereas “0” means low search volume was recorded for the term (ie, <1% of the searches attributed to the most searched term in the search list) [33]. This reflects that the “interest over time” can be regarded as a latent variable of the actual volume of searching. However, noise may be introduced through rounding and normalization. Although noise is unavoidable, we attempted to alleviate the effects of noise through a shingling technique, as proposed in the *Transforming Multiple RSVs Into a Single MSV* section, and to focus on the analysis of the constructed temporal network.

Discovery of Related Keywords

Many previous studies used “related queries” to widen their scope of keyword coverage. Although this approach increases the number of search terms drastically, we opted to use “related topics” (RTs) because of their unambiguous characteristics and the inclusion of translations of the same concept into other languages.

For example, if a researcher is interested in understanding the search volume for Apple Inc, the computer and smartphone manufacturing company, when one enters only the word “apple,” GT will return the results for that exact word, without much interpretation. Therefore, the resulting data can hypothetically include a news report for the computer company’s latest product and the nutritional information for the fruit. Instead, researchers can search for a “topic” that filters out searches irrelevant to the computer manufacturer by picking “Apple (Technology Company).”

However, to the best of our knowledge, GT does not provide a public repository of the available topics. Yet, when a user enters certain keywords, GT will recommend a list of related queries and topics that can be used as our starting seed topics. On the basis of this method, we entered several queries, namely, “COVID-19” and “coronavirus,” which yields 3 RTs: “Coronavirus disease 2019 (Disease),” “Severe acute respiratory syndrome coronavirus 2 (Virus),” and “Coronavirus (Virus).” We continuously downloaded the RTs of the 3 seed topics we yielded in a 7-day sliding window from January 29, 2020, to March 4, 2022. All the keywords prompted by GT were included in the pool of keywords.

To remove the regional effects from our results, keywords related to specific regions were excluded. We determined that a term was region related if it was categorized by GT as one of the following: “country,” “state,” “province,” “prefecture,” “municipality,” “island,” “region,” “county,” “capital,” “city,” “autonomous community,” and “town.” For example, when we receive an RT “Stay-at-home order (Topic)” (machine tag: “/g/11hf9srvdz”) from GT, we will include it in our network, as it was determined as a “Topic” and is not in our exclusion category list. In contrast, if we receive an RT “Germany (Country in Europe)” (machine tag: “/m/0345h”) from GT, we will discard the topic, as the topic was categorized as “country” by Google, which is included in our exclusion category list.

After filtering, 228 topics were selected for this research, referred to as the topic set (see Textbox 1 for the search terms used).

Textbox 1. Selected keywords related to the COVID-19 pandemic, used in the construction of our temporal network.

Coronavirus, Vaccine, COVID-19 vaccine, COVID-19 testing, Test, Signs and symptoms, Symptom, Symptoms of COVID-19, Strain, Severe acute respiratory syndrome coronavirus 2, Worldometers, Statistics, Variant, AZD1222, AstraZeneca, Nasal congestion, Mutation, Emmanuel Macron, Traffic light, GOV.UK, Bill, Preventive healthcare, Northern Beaches Council, Nueva Cepa, Certificate, Virus, Pfizer, BNT162b2, Side effect, Rapid antigen test, Bell's palsy, Transmission, Isolation, Ivermectin, Food and Drug Administration, mRNA-1273, Centers for Disease Control and Prevention, COVID-19 pandemic in New York City, Polymerase chain reaction, Guideline, British Columbia, CVS Pharmacy, Drive-through, CVS Health, Mink, Regions of Italy, Galicia, TousAntiCovid, contagium, Tier 1 network, Blood type, Tier 2 network, Nasopharyngeal swab, 2020 coronavirus pandemic in Scotland, Incubation period, Case, Donald Trump, 2019–20 coronavirus pandemic related application, NHS COVID-19, National Health Service, Dashboard, Common cold, Silvio Berlusconi, Pandemic, Medical test, Departments of France, Serology, Infection prevention and control, Swine influenza, Herman Cain, Hydroxychloroquine, Provinces of Vietnam, COVID-19 pandemic in Victoria, Sore throat, University of Oxford, COVID-19 party, Jair Bolsonaro, World Health Organization, Airborne transmission, 2020 coronavirus pandemic in Canada, Worldometer COVID-19 Dashboard, County, COVID-19 pandemic in Texas, Asymptomatic, Disease outbreak, Rapid diagnostic test, Johns Hopkins University, Mortality rate, Antibody, Maharashtra Police, DG Police Office Mumbai, COVID-19 pandemic in West Bengal expected, Oise, Lysol, Infection, 2019–20 coronavirus pandemic, Death, Chinese language, Influenza, Pneumonia, China virus, Cruise ship, Cure, 2020 coronavirus pandemic in Singapore, Pangolins, Coronavirus disease 2019, SARS, Antigen, Immunoglobulin G, Variety, Prefectures of Japan, Coronavirus Alpha variant, Immunity, RNA, RNA virus, Peplomer, Roche Holding AG, Severe acute respiratory syndrome coronavirus, Roche, Disease cluster, Genome, Yahoo Japan Corporation, Robert Koch Institute, Medical laboratory, Ebola, Avian influenza, Breaking news, Nucleic acid test, NHK, Municipalities of Japan, Federal Office of Public Health of the Swiss Confederation, Test method, Immune system, Immunoglobulin M, Falling Number, Südwestrundfunk, interactive map, Subsidy, Remdesivir, Microscope, Molecular biology, Study group, Oct-04, Bulletin board system, Typhoon, Host, Lockdown, DNA, Hoax, Risk, Dwayne Johnson, 爆サイ, Assay, Shinzo Abe, South African Revenue Service, PTT Bulletin Board System, Reverse transcription polymerase chain reaction, Severance package, Health facility, Dabie bandavirus, Sequela, Inpatient care, Health professional, Go To Campaign, COVID-19 Contact-Confirming Application, Jul-02, U.S. state, Middle East respiratory syndrome–related coronavirus, Chemical structure, Basic reproduction number, Micrometre, HIV/AIDS, HIV, Accuracy and precision, Potency, Icelandic language, Interactivity, Wind wave, SARS outbreak, Genetics, Infectious disease, Bats, Patent, MERS, Spanish flu, Tasuku Honjo, Robert Koch, Kumiko Okae, Ministry of Health, Labour and Welfare of Japan, Website about COVID-19 pandemic in Vietnam, temporarily closed school, Case fatality rate, Mask, event, biological weapon, Diamond Princess, Vaccination rule, Point-of-care testing, Stay-at-home order ordinance, Incidence, Tagesschau, Districts of Germany, hot spot, Press conference, Podkarpackie Voivodeship, Dashboard, National Institute for Public Health and the Environment, Upper Austria, Child benefit, Demonstration, Travel warning, COVID-19 pandemic in Aichi prefecture, Amitabh Bachchan, Tönnies Holding, Patanjali Ayurved, Mayu Watanabe, Logistics, Public transport, Hygiene, Public health, Emergency medical services, Statistic, Advice, and News ticker

Downloading Search Volume Data From GT

To systematically retrieve data from GT, we used the library *pytrends* [34]. We executed the custom script regularly to collect the RSV data. Each request that was sent gathered a set of 30-day “interest over time” data :

For example, the RSV data gathered for the “Coronavirus (virus)” from January 1, 2020, to January 30, 2020 were:

We then repeated the requests to collect data consecutively. We list all the terms in Textbox 1 (topic set). Our data collection period for this research was from January 1, 2020 (t= 2020-01-30) to January 31, 2022 (t= 2022-01-31).

Merging of Multiple Short Time Series Trends Into a Glandular Time Series Over a Longer Period

Inspired by Park et al [35], we devised a range-based merging algorithm.

Let be an n-day actual search volume time series for a topic on the days lying in the interval , and let $X_{i,t}$ be the actual search volume for a topic i on date t:

Assuming that GT applied the normalization with a common correction factor C_t to the entire actual search volume time series, the RSV returned can be considered as :

For any 2 consecutive GT RSV data sets, and , where $v = u + 1$ and have the same data collection duration of n days, based on our previous assumption, and are normalized with the correction factors C_u and C_v within the interval $[u - (n - 1), u]$ and $[v - (n - 1), v]$, respectively.

Given $X_{(i,v)} = X_{(i,u+1)}$:

where

Through the moment estimator of , we can subsequently obtain the estimate of with respect to the RSV , :

For example, considering the correction factor of the data point for the term “Coronavirus (virus)” on January 31, 2020, from 2 RSV series of n=30 is:

Thus, the adjusted data point for “Coronavirus (virus)” on January 31, 2020, is as follows:

We can thus obtain a 31-day merged search volume (MSV) for “Coronavirus (virus),” as shown in Table 1.

Through multiple iterations of estimations using a total of *p* RSV time series, as shown in Tables 2 and 3, we can finally obtain an MSV time series for the search term from *t* − (*n* − 1) to *t* + (*p* − 1):

Continuing from our previous example, we can eventually obtain the MSV time series for “Coronavirus (virus)” as follows:

In this study, we opted to use RSV time series data with a length of 30 days (n=30), and the RSV time series for January 30, 2020, was used as the baseline against which other subsequent RSV series were calibrated.

Table 1. A sample calculation of the correction factor and adjusted data point of January 31, 2020, using data sets from January 1, 2020, to January 30, 2020, and from January 2, 2020, to January 31, 2020. Data set keyword: “Coronavirus.”

Date	Data downloaded on January 30, 2020	Data downloaded on January 31, 2020	Correction factor for new data point on January 31, 2020	Merged Google Trends time series
January 1, 2020	0	Not available in the sequence	Out of scope	0
January 2, 2020	0	0	0 / 0 = 1.000	0
January 3, 2020	0	0	0 / 0 = 1.000	0
...	...	...	...	...
January 27, 2020	75	78	75 / 78 = 0.962	75
January 28, 2020	90	91	90 / 91 = 0.989	90
January 29, 2020	89	88	89 / 88 = 1.011	89
January 30, 2020	100	100	100 / 100 = 1.000	100
January 31, 2020	Not available in the sequence	100		100 × 1.003 = *100.3*

Table 2. A sample calculation of the correction factor and adjusted data point of February 1, 2020, using data sets from January 2, 2020, to January 31, 2020, and from January 3, 2020, to February 1, 2020. Data set keyword: "Coronavirus."

Date	Data downloaded on January 31, 2020	Data downloaded on February 1, 2020	Correction factor for new data point on February 1, 2020	Merged Google Trends time series
January 2, 2020	0	Not available in the sequence	Out of scope	0
January 3, 2020	0	0	0 / 0 = 1.000	0
...	...	...	...	...
January 27, 2020	78	77	78 / 77 = 1.013	75
January 28, 2020	91	91	91 / 91 = 1.000	90
January 29, 2020	88	89	88 / 89 = 0.989	89
January 30, 2020	100	95	100 / 95 = 1.053	100
January 31, 2020	100	100	100 / 100 = 1.000	100 × 1.003 = 100.3
February 1, 2020	Not available in the sequence	72		72 × 1.008 = *72.60*

Table 3. A sample calculation of the correction factor and adjusted data point of February 1, 2022, using data sets from January 1, 2022, to January 30, 2022, and from January 2, 2022, to January 21, 2022. Data set keyword: "Coronavirus."

Date	Data downloaded on January 30, 2022	Data downloaded on January 31, 2022	Correction factor for new data point on January 31, 2022	Merged Google Trends time series
January 1, 2022	55	Not available in the sequence	Out of scope	76 × 0.3007 = 22.85
January 2, 2022	64	60	24.88 / 60 = 0.4146	90 × 0.2764 = 24.88
...	...	...	...	...
January 26, 2022	94	90	38.17 / 90 = 0.4241	95 × 0.4018 = 38.17
January 27, 2022	89	87	36.14 / 87 = 0.4154	88 × 0.4107 = 36.14
January 28, 2022	86	82	33.87 / 82 = 0.4130	82 × 0.4107 = 36.14
January 29, 2022	83	77	32.08 / 77 = 0.4167	80 × 0.4010 = 33.87
January 30, 2022	79	76	31.77 / 76 = 0.4181	79 × 0.4022 = 31.77
January 31, 2022	Not available in the sequence	78		78 × 0.4149 = *32.36*

Construction of Daily Search Volume Networks Using Merged GT Time Series Data

Let N be the size of the search term set. We considered the temporal network construction in an R-day rolling window. To better focus on the changes of MSVs and to ease the magnitude of differences between MSVs, we followed the studies by Chu et al [36] and So et al [37] to obtain square-rooted-differenced data. Thus, the square-rooted-differenced MSV matrix ($\mathbf{Y}_t$) at time t is as follows:

A covariance matrix (ρ_t) of each search term in the square-rooted-differenced MSV matrix ($\mathbf{Y}_t$) can be determined, where the correlation between the search terms i and j at time t is .

Using the correlation matrix ρ_t, we can then construct an undirected network of search terms with an adjacency matrix $\mathbf{A}_t$ formation at time t as:

In this study, we used a rolling window length (R) of 30 days to construct the network.

Calculation of Network Statistics

Network Density

On the basis of the method proposed by Chu et al [36], we defined the network density (D_t) of a network at time t as follows:

where E_t is the number of edges in the network at time t and C_t is the number of possible connections between all nodes (ie, search terms) at time t. D_t assesses the connectedness of the nodes present at time t. Higher values represent higher connectedness at a given moment.

Global Clustering Coefficient

As defined by So et al [37], the global clustering coefficient (GC_t) was calculated based on the local clustering coefficients $c_{i,t}$ of all nodes in the network at the time (ie,). We first defined the calculation of the local clustering coefficients for the search term i as follows:

where $e_{i,t}$ is the “number of connected pairs among the neighbors of vertex i at time t” and $k_{i,t}$ is the “number of neighbors for each vertex.”

Thus, the global clustering coefficient (GC_t) can be calculated as follows:

GC_t represents the ratio of the number of established connections (edges) to the number of possible connections. The higher the value of the coefficient, the more interconnected the network nodes are.

Calculation of DTW

DTW is an algorithm for measuring the similarity between 2 time series by determining the shortest total distances between the 2 series [38]. It is useful to detect the leader-follower interaction. We used the Python library *dtw-python* (version 1.1.12) to create the DTW-aligned plots [39]. The algorithm in the library associates a node from the query time series (in our case, network statistics, network density, and global clustering coefficients) to a node from the template time series (confirmed COVID-19 cases in and severity risk score [SRS]) with the lowest distances.

Calculation of DTW Metric

To quantify the DTW results, we adopted the DTW-based metric proposed by Laperre et al [40]. The proposed algorithm augments the existing DTW algorithm by including a “forward-looking only” constraint, that is, a latent variable (such as network density and global clustering coefficient) observed at time $t + p$ can only be mapped to a historical or the current observation (such as number of COVID-19 cases or SRSs) from t to $t + p$, where the time shift value . A time shift value of 0 indicates that the latent variable moves in sync with the observation, whereas a value >0 indicates a leading effect of the latent variable on the observation.

Calculation of the SRS

Adopted from the study by So et al [37], the SRS represents the presymptomatic transmission owing to possible interaction between the susceptible population in one country and currently infected cases in another country, before the confirmed cases are identified and force isolated or quarantined. Higher scores indicate stronger signals that the pandemic is uncontrolled, which could be regarded as a systematic risk assessment.

Ethical Considerations

Ethics approval is not required as no individually identifiable information was gathered, processed, or analyzed in this research.

Results

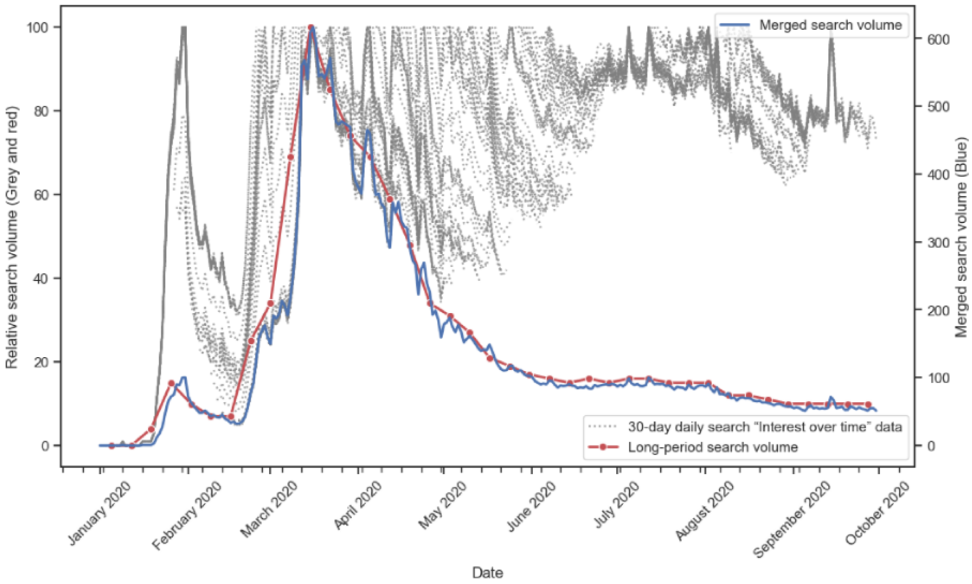
Transforming Multiple RSVs Into a Single MSV

To extract a search volume time series to reflect the trend of a specific search interest, we adopted a data transformation algorithm to construct MSVs using the rolling window approach. The primary idea was to produce a long time series of MSVs that could serve as a proxy for the search volume of keywords. Thus, the MSV series can be used to draw statistical inferences and predictions. MSV was produced by aggregating the RSV data while also exhibiting the trend indicated by the RSVs. With MSV, we were able to extend the investigation horizon beyond 9 months for daily observations and beyond 270 weeks for weekly observations, which was of interest because 9 months and 270 weeks are the longest periods for retrieving daily and weekly RSV data, respectively, from GT. Therefore, MSVs could be very helpful for tracking search interests over a long period in public health studies, such as in following the status of the COVID-19 pandemic, which has now lasted for >2.5 years.

We focused on “interest over time” as the proxy for the actual search volumes in Google. In this study, we did not specify any geographic regions but instead adopted the global web search data to obtain a more generic and globally inclusive searching phenomenon. Using these filter settings, the daily RSV data were extracted from GT for further data transformation, following the calculation procedure shown in Tables 1-3. Using the ratio of the “interest over time” data points for the same date in the 2 consecutive sequences, we calculated the correction factors for each day that existed in both sequences (as tabulated in the fourth column in the tables) to obtain the averages of the factors (as shown in the last cell in the fourth columns). The newly discovered data points (in this example, the data points on January 31, 2020; February 1, 2020; and January 31, 2022, respectively) were multiplied by the appropriate average correction factors (in this example, 1.003, 1.008, and 0.4149, respectively) to obtain the adjusted data point in the merged series. This process was repeated consecutively, as shown in Tables 1-3.

We further visualized and herein presented the process of creating the MSV series in Figure 1. Using the GT RSV data of the COVID-19 pandemic during the first 9 months as a demonstration, the 30-day “interest over time” data set (shown as 245 dotted lines) for the dates between January 1, 2020, and September 30, 2020, was downloaded from GT. We then calculated the next-day interest based on the data from the previous 29-day data and replicated the steps to compile the final MSV series (shown as the blue line in Figure 1) with 274 data points of daily MSV. The daily RSVs shown in the 245 dotted lines produced the relative search interest over a fixed period of 30 days. Extending the investigation period to longer than 30 days could reduce the sensitivity of the daily RSV in reflecting the daily time trend of the search interest. In contrast, the data directly retrieved from GT between January 1, 2020, and September 30, 2020, contained only 39 data points of weekly RSVs (shown by the red line in Figure 1). This reduction of data points implied that we needed to lower the time interval of investigation to 1 week, meaning that we could not study a daily dynamic in the search interest. Owing to the constraints of GT, we could only retrieve weekly RSVs of an interval of at most 270 weeks. Using our proposed MSV approach, we merged the 733 RSV series into one singular, extended MSV time series, aiming to recover the daily trend of the search interest. In fact, the patterns of the MSV (the blue line) and the weekly RSV (the red line) were similar, indicating that the transformation algorithm for constructing the MSV was reasonable in the sense that the trend of the search interest revealed by the MSV was consistent with the trend of the search interest revealed by the weekly RSV provided by GT. This example shows that although GT restricts the search data retrieval into weekly data points over a long period, our proposed approach could recover the daily search volume over the same investigation period to facilitate subsequent research analyses.

Figure 1. An example of the process of creating a merged search volume series (data set keyword: “Coronavirus”; dates: from January 31, 2020, to September 30, 2020). Dotted lines: the 30-day “interest over time” relative search volume (RSV) data set from Google Trends (GT). Red line: the weekly RSV series retrieved from GT. Blue line: the daily merged search volume series using our transformation algorithm to merge RSVs through a rolling window approach.



Selection of Coronavirus-Related Search Keywords

To understand the associations between the search interest and the pandemic spread, we explored a list of coronavirus-related keywords based on the metrics of “related topic” provided by GT. We searched the related keywords for 3 seed topics: “Coronavirus disease 2019,” “Severe acute respiratory syndrome coronavirus 2,” and “Coronavirus,” with a 7-day sliding window.

By combining the shorter lists of keywords returned by GT when searching for the 3 seed terms in each 7-day period over 108 weeks (from January 1, 2020, to January 31, 2022), we obtained a raw list of keywords. Then, we filtered out the duplicates and irrelevant keywords and eventually settled on a keyword set of 228 elements (search topics), which are listed in Textbox 1. Using the transformation algorithm proposed in the *Transforming Multiple RSVs Into a Single MSV* section, the MSV of each keyword was calculated for dynamic network analysis, which involved compiling network statistics using related keywords as network nodes for a pandemic risk assessment.

MSVs and COVID-19 Waves

To understand the relationship between internet search interest and pandemic development, the MSV trends of several selected keywords were compared in parallel with the newly confirmed COVID-19 cases (Figures 2 and 3). Owing to the severity of the COVID-19 pandemic in the United States compared with other countries, we evaluated the MSV data against the new COVID-19 cases in the United States in Figure 2, in addition to the global cases, as shown in Figure 3. We noticed a similar pattern between MSV data and the number of COVID-19 cases in the United States and globally. Therefore, we used the situation with COVID-19 in the United States as a basis for further discussion, and the peaks of the 5 waves of COVID-19 in the United States were highlighted in different colors as a reference to illustrate the different stages in the development of the pandemic. Diverse associations with the waves can be observed in the trend comparisons. For example, drastic reactions in MSVs can be observed for the keywords "Coronavirus," "Symptom," "Airborne transmission," "Travel warning," "Hygiene," and "Emergency medical service" in Figures 2A-2D, 2F, and 2H before the number of COVID-19 cases reached the first wave peak (highlighted in light blue) in early April 2020. These abrupt increases in the search interest of the general pandemic-related keywords provide evidence of the capabilities of MSVs in the early detection of outbreak risks.

In contrast, the MSV trends for "Vaccine" and "Rapid diagnostic test" in Figures 2G and 2I show different variations during the latter waves of the COVID-19 pandemic. Although vaccination and efficient diagnostic tests are typically developed in the later phase of an emerging infectious disease, the corresponding MSV trends still aligned with symbolic milestones in COVID-19 control efforts. This occurred when effective rapid diagnostic tests and vaccines for COVID-19 became available in the United States, during and after the third pandemic waves, respectively. These diverse associations between the search interest of keywords and pandemic developments also motivated and supported our approach to investigating the dynamic connectedness among the coronavirus-related search keywords through network analysis.

We also compared the MSV trends of the selected keywords with the number of confirmed new COVID-19 cases worldwide in Figure 3. In Figure 3, we can draw similar conclusions to Figure 2. We also noted an increase in confirmed cases of COVID-19 globally from April to May 2021, which correlated with the sharp rise in the MSVs of "Airborne transmission" and "Vaccine."

Figure 2. Comparison of US-confirmed new cases (blue line) sourced from the World Health Organization and the merged search volume of selected keywords, including (A) Coronavirus, (B) Symptom, (C) Airborne transmission, (D) Travel warning, (E) Public transport, (F) Hygiene, (G) Vaccine, (H) Emergency medical services, and (I) Rapid diagnostic test (red line), constructed by transforming the relative search volume of Google Trends from January 1, 2020, to February 3, 2022. Highlighted areas: the 5 wave peaks observed in confirmed new cases in the United States.

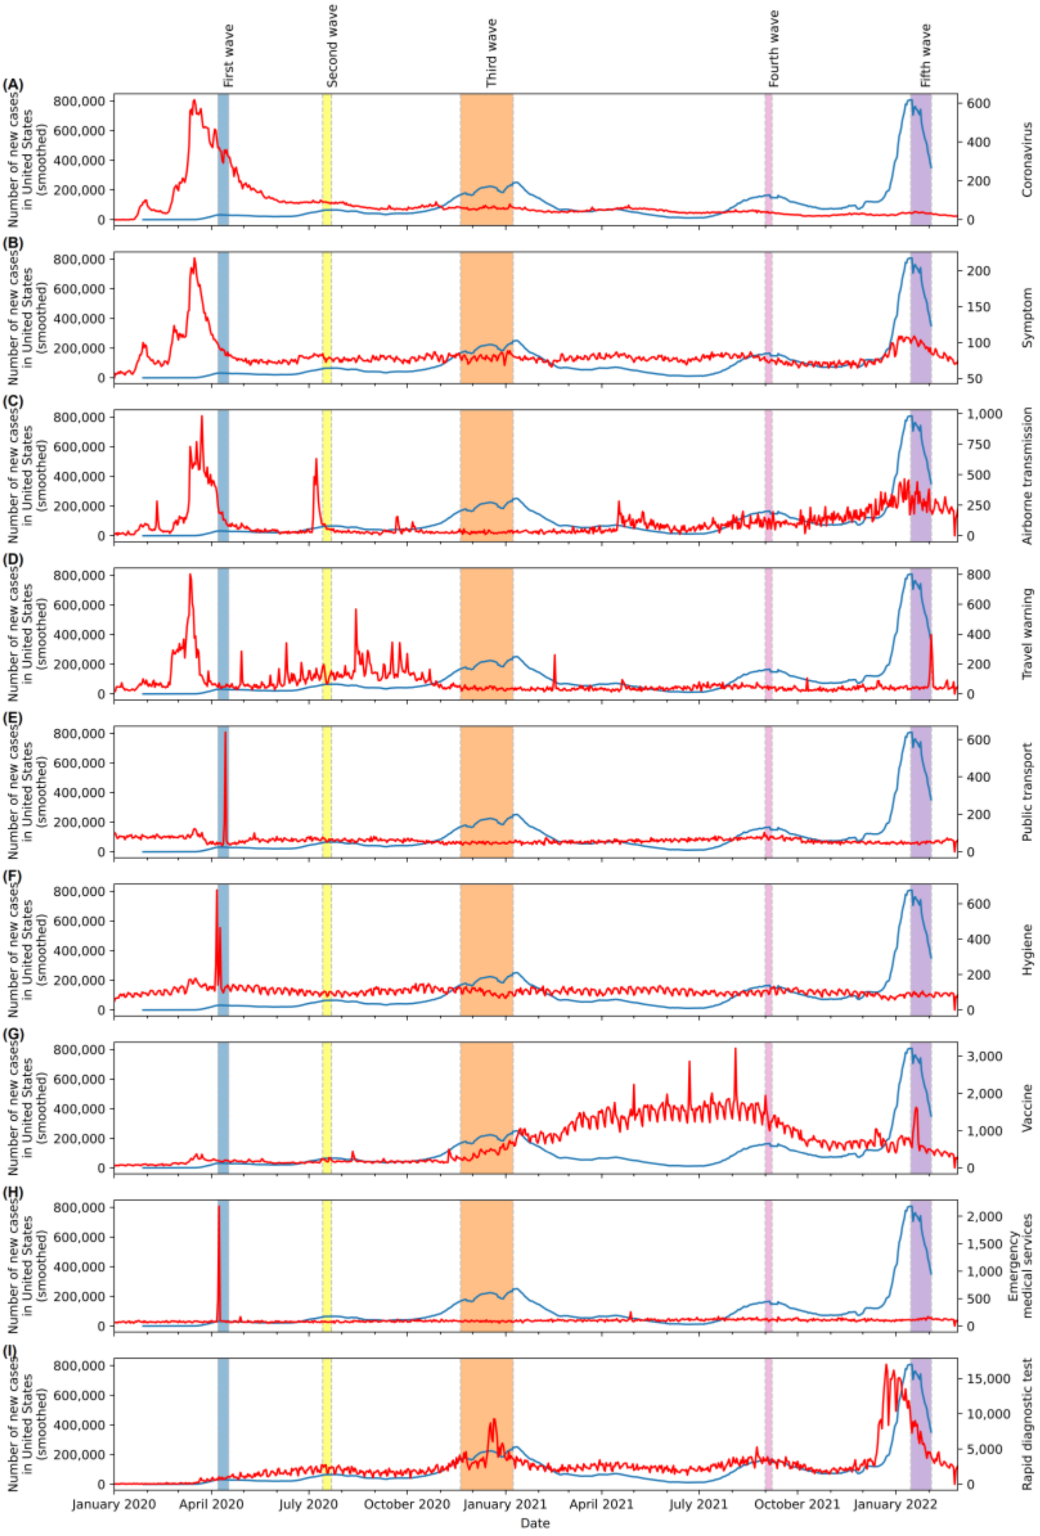


Figure 3. Comparison of worldwide confirmed new cases (cyan line) sourced from the World Health Organization and the merged search volume of selected keywords, including (A) Coronavirus, (B) Symptom, (C) Airborne transmission, (D) Travel warning, (E) Public transport, (F) Hygiene, (G) Vaccine, (H) Emergency medical services, and (I) Rapid diagnostic test (red line), constructed by transforming the relative search volume of Google Trends from January 1, 2020, to February 3, 2022. Highlighted areas: the 5 wave peaks observed in confirmed new cases in the United States.

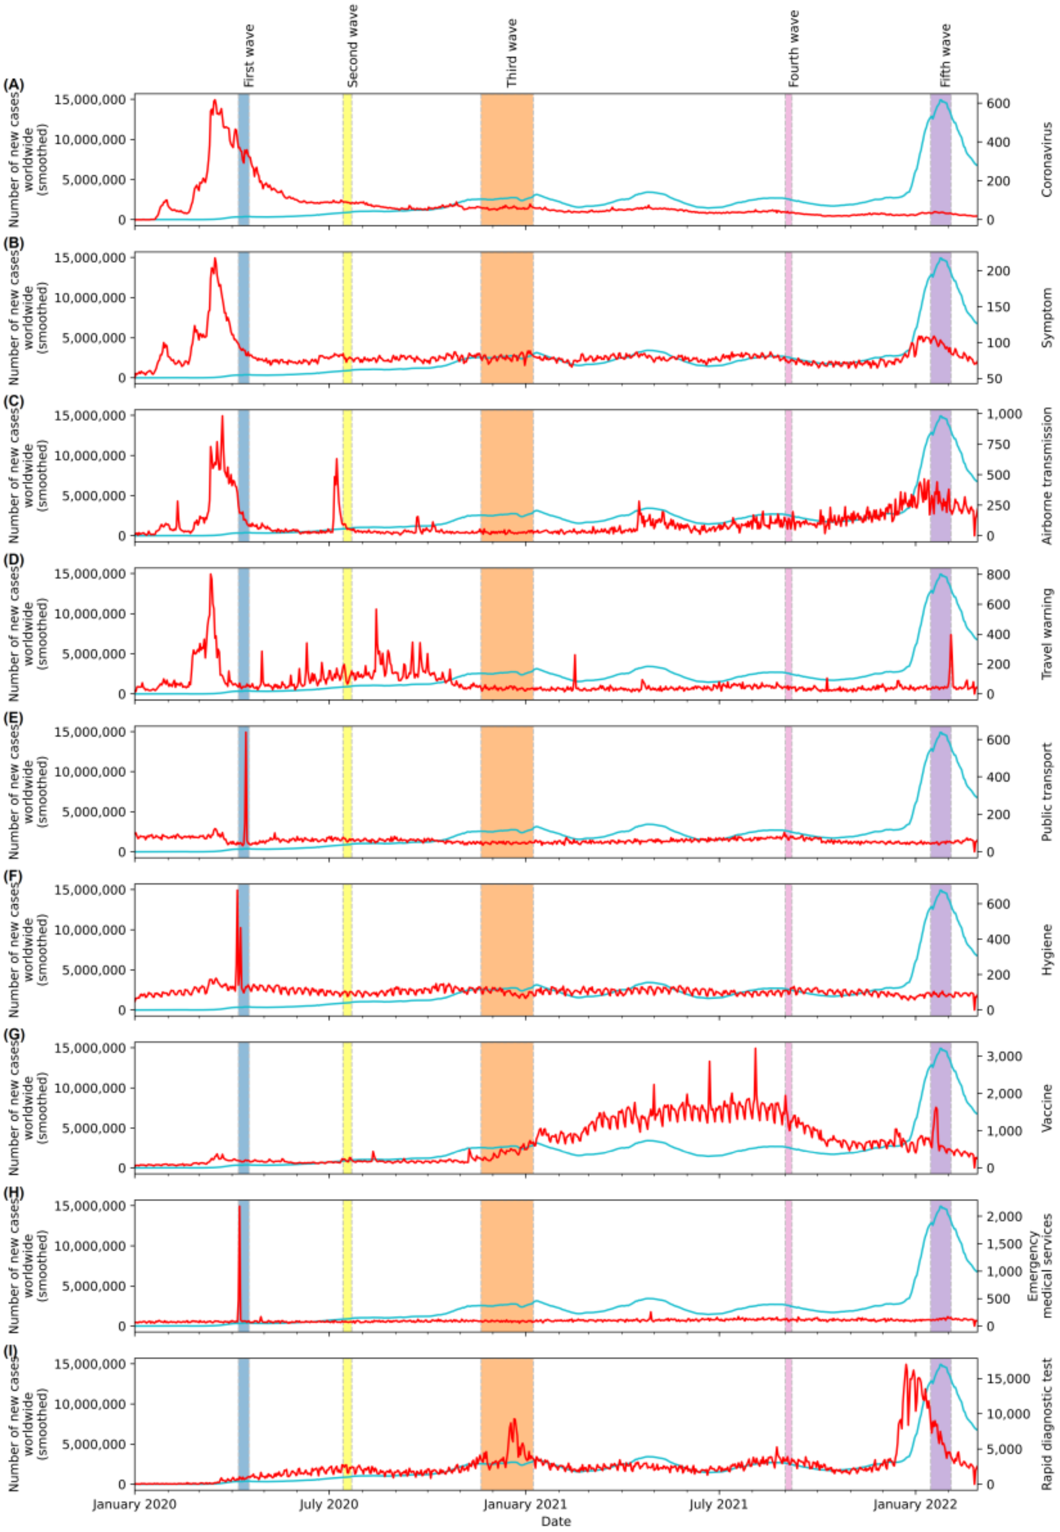

Dynamic GT Network Construction

After computing the MSVs of all the selected keywords, we constructed a dynamic GT network based on the correlations between the search volume data of pairs of selected keywords. In the network analysis terminology, we established an edge (a connection) between 2 keywords (also known as nodes in a network) if the corresponding correlation coefficients were significantly high (when the correlation coefficient is >0.5; the threshold we adopted) [36,37]. This approach allowed us to quantify the connectedness of the relevant search queries using temporal dynamic network statistics.

As the search volume of keywords from a common topic (COVID-19, in our case) represents people's concerns about the topic, we anticipated that any common trend or comovement of the COVID-19–related keywords could indicate people's interest in the pandemic as they looked for relevant helpful information through internet searches. An increase in the MSVs of different keywords simultaneously might indicate an increasing concern about the common topic associated with the keywords.

To incorporate common trends in the search interest of multiple keywords, network analysis is a viable approach [41-45]. A network is a natural configuration that integrates common trends of information about multiple keywords together, from which we can perform a network analysis; for example, based on network statistics, we can understand the general interest in a collection of keywords simultaneously. Through the connectedness of a GT network [43,46-48], we quantified the coherence of changes in search interest for different keywords over time and studied the implications of the pandemic risk in this research. The set of network nodes is represented by the set of keywords, which is constant over time. However, the set of edges changes over time to reflect time-varying patterns of search interests. By construction, the MSV represents a proxy time series of the search volume, and the correlation of changes in the MSVs of 2 keywords exceeding a certain threshold can be interpreted as a strong comovement whose occurrence can be used to define an edge of the 2 keywords. For example, if the correlation between changes in the MSV of "Coronavirus" and "Symptom" at time *t* is >0.5 (the correlation threshold we took in this research), we created an edge between the nodes "Coronavirus" and "Symptom" in the GT network at time *t*. This construction mechanism used the same rationale that was used in the pandemic network constructions in other studies [43,46,49]; however, instead of using the number of confirmed COVID-19 cases in regions, we used the MSVs of keywords.

In addition to using 0.5 as the correlation threshold, we used 2 alternating correlation thresholds—0.4 and 0.6 for sensitivity analysis. A comparison of the network density and the global clustering coefficient constructed by the 3 different correlation thresholds at 0.4, 0.5 (the threshold used in this study), and 0.6 is shown in Figure 4. The pattern of the network density plots with thresholds of 0.4 and 0.6 is very similar to that of the one with a threshold of 0.5. We also observed a similar phenomenon in the global clustering coefficient, with an exception in March 2020, where the coefficient with a threshold of 0.6 showed a marginally narrower peak than those with thresholds of 0.4 and 0.5.

Following the studies by Chu et al [36], So et al [37], and So et al [46], the correlations of changes in MSV at time *t* were calculated using a rolling window approach that was based on the past *R*-day (including time *t*) MSV changes of keywords; therefore, the topology of the edges in the GT network would reflect the search interest characteristics of multiple keywords at time *t*. Ultimately, we had a constellation of dynamic GT networks constructed by correlations of changes in MSVs among keywords. Experience from the early research papers on COVID-19 revealed that the dynamic GT network, which summarized the infodemiology of relevant keywords, could provide an effective visualization of a pandemic situation [46], early warning signals of the pandemic [36], and pandemic risk assessments [37,50].

Figure 5 depicts a snapshot of the dynamic GT networks for 4 significant events: "Public Health Emergency of International Concern" on January 31, 2020, "COVID-19 was declared as a global pandemic by WHO" on March 11, 2020, "the Delta variant was named" on May 21, 2021, and "the Omicron variant was named" on November 26, 2021. Figure 5 also highlights the nodes with the top 5 most frequently appearing topic types: diseases (blue nodes), viruses (orange), vaccines (green), government agencies (red), and pharmaceutical companies (purple). It is obvious that the nodes related to diseases (blue nodes) occurred in the central cluster in all 4 snapshots. Several virus-related nodes (orange nodes), such as another official name for COVID-19 ("severe acute respiratory syndrome coronavirus 2" or "SARS-CoV-2"), were also included in the central clusters in most of the 4 time points we studied. These 2 observations matched our intuition that the general public seeks unknown information about COVID-19 through the search engine.

It was found that the vaccine-related nodes (green nodes) had a high degree of connectedness on all sampling days, even before any COVID-19 vaccine was approved for administration. In Figures 5C and 5D, disease-related and virus-related nodes drifted away from the cluster center, whereas nodes related to vaccines and pharmaceutical industry companies moved toward the center of the cluster.

To study the network macroscopically, we computed 2 network statistics over time—the network density and the global clustering coefficient—by using a 30-day rolling window. The network density is a measure of the node connectedness of a network, whereas the global clustering coefficient represents the ratio of the number of established connections (edges) to the number of possible connections. The higher their values, the more interconnected the network nodes are. Figure 6 presents a time series of the GT network density (blue line) and a time series of the GT network clustering coefficient (green line). In Figure 6, we also mark the 4 time points from Figure 5 to assess the relationships among the 2 network statistics, network density and global clustering coefficient, and the propagation of COVID-19. In the very early stage of COVID-19, on January 31, 2020, both the network density and global clustering coefficient were in the middle level of approximately 0.2 for the network density and 0.12 for the global clustering coefficient (the maximum value is 1.0). Probably because of the warnings of an emerging public health concern and because some keywords are not directly related to the pandemic, the search interest intensity was already quite high in January 2020. Both network statistics climbed to a peak of approximately 0.35, which alerted people to the severity of the disease's spread, thus inducing more search interest for the keywords at the same time. Subsequently, the network density remained at a relatively low level of approximately 0.15, even when the Delta variant was named on May 31, 2021. This reflects a relatively lower attention to the pandemic among the general public owing to people's adaptation to and fatigue from the long-term antipandemic living environment. What is particularly alarming is the occurrence of another peak in the 2 network statistics during October to early November 2021, before the Omicron variant was named. The GT network density and global clustering coefficients show a substantial increase in the public's interest in searching for keywords, probably indicating growing public awareness about and panic toward the next phase of the pandemic. Not long after that, in early 2022, the Omicron variant had a great impact on many countries.

Figure 4. A comparison of network density and clustering coefficient constructed by 3 different correlation thresholds at 0.4, 0.5 (the threshold used in the study) and 0.6.

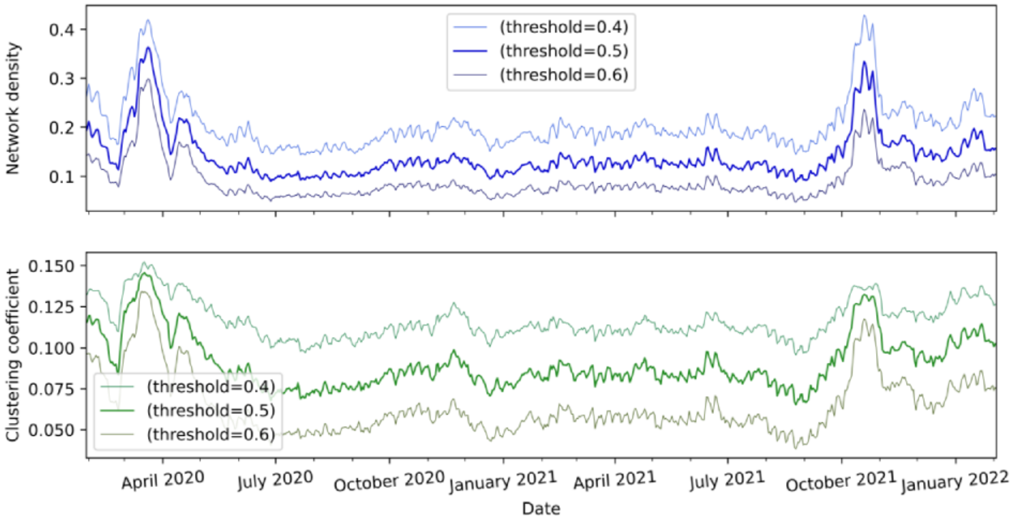

Figure 5. Snapshots of the dynamic Google Trends network. Snapshots were taken of the network on (A) January 31, 2020, (B) March 11, 2020, (C) April 31, 2021, and (D) November 26, 2021. Nodes are highlighted with different colors to represent the top 5 categories: diseases (blue), viruses (orange), vaccines (green), government agencies (red), and pharmaceutical companies (purple).

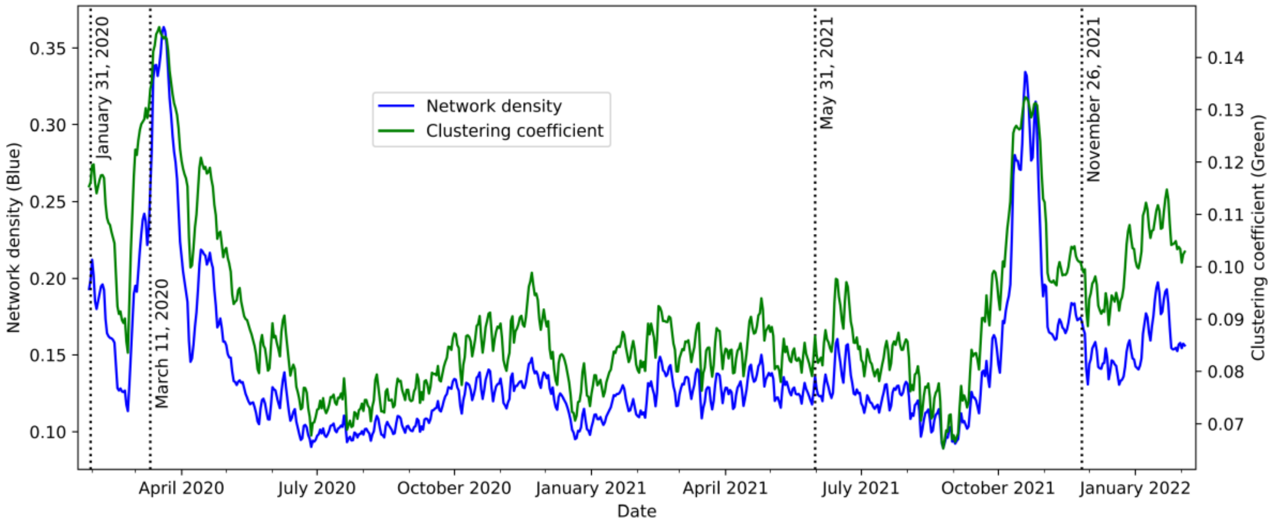
(C) May 31, 2021 **(D)** November 26, 2021

Figure 6. Network density and global clustering coefficients of the merged Google Trends network over time. The occurrences of significant events are marked with dotted lines. The 4 significant events marked are as follows: (1) COVID-19 was declared a “Public Health Emergency of International Concern” (on January 31, 2020), (2) COVID-19 was declared a pandemic (on March 11, 2020), (3) the Delta variant was named (on April 31, 2021), and (4) the Omicron variant was named (on November 26, 2021).



Comparing Network Statistics and SRSs Using DTW

Figures 7 and 8 illustrate the association between network statistics and the COVID-19 pandemic propagation in multiple directions. As mentioned in the *MSVs and COVID-19 Waves* section, the waves of COVID-19 cases represent the progression of the pandemic. As Figure 7 shows, there was an upward trend and peak in the dynamic network before every peak of the COVID-19 pandemic wave (highlighted in yellow). This shows that the dynamic networks of related keywords were capable of providing an early signal of not only the first outbreak but all 5 outbreaks throughout the COVID-19 pandemic (as shown in Figures 7A and 7B).

We further examined the predictive power of the dynamic network for the coronavirus-related keywords using the DTW algorithm [38,39]. By evaluating the similarity between the network and the newly confirmed cases in the United States, the resulting paths (the dotted lines) connect the 2 series of data and show an asymmetric step pattern. The consistently backslashed direction of the dotted lines suggests the lag-lead relationship between the dynamic network and the variation in the daily confirmed cases.

To evaluate the pandemic predictive capability of the dynamic network among the selected keywords in multiple layers, we also computed the DTW scores between the network and SRSs). The SRS, adopted from the studies by So et al [37,50], is regarded as a systematic measure that assesses the risk of the COVID-19 outbreak worldwide. A higher SRS represents a stronger signal, indicating that the global pandemic is uncontrolled. The DTW diagram in Figure 8 shows the lead-lag relationship of the SRSs throughout the entire observation period of the COVID-19 pandemic. These findings indicate that the dynamic network of related search keywords can predict the severity of the global risks of a pandemic. If regional search data are used, the predictability of the regional pandemic risk is also possible.

Figure 7. The 2-way dynamic time warping diagrams of the confirmed new COVID-19 cases in the United States (blue line) and the network statistics (black line) of the selected keywords in Google Trends: (A) network density trend versus confirmed new cases in the United States and (B) trend of the global clustering coefficient versus confirmed new cases in the United States. Yellow highlighted areas mark the 5 wave peaks observed in confirmed new cases in the United States.

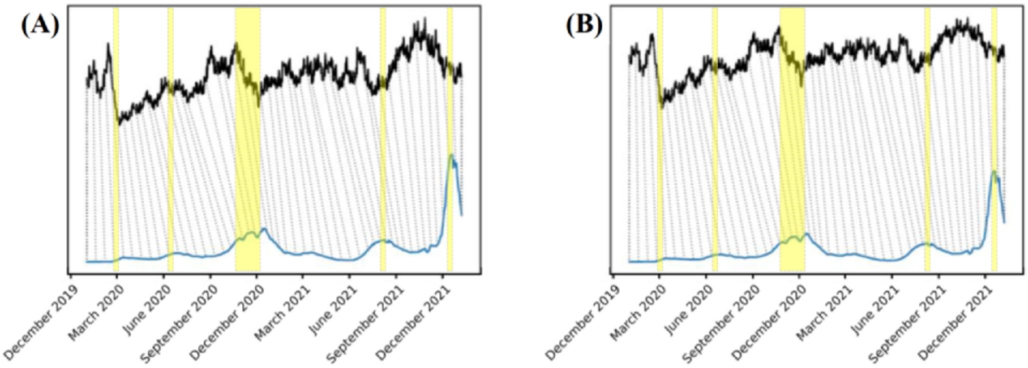


Figure 8. An illustrative evaluation of dynamic time warping (DTW) connections of the severity risk scores (SRSs) of the COVID-19 pandemic in the United States and the network statistics. Top: the 2-way DTW diagrams of the SRSs of the COVID-19 pandemic in the United States (blue line) and the network statistics (black line) of the selected keywords in Google Trends: (A) network density trend versus SRSs and (B) trend of global clustering coefficients versus SRSs. Bottom: (C) The summary plot of the time shifts (p) in each connection in (A), drawn with orange line, and (B), drawn with blue line. The data points at time shift $p = 0$ are muted in the plot.

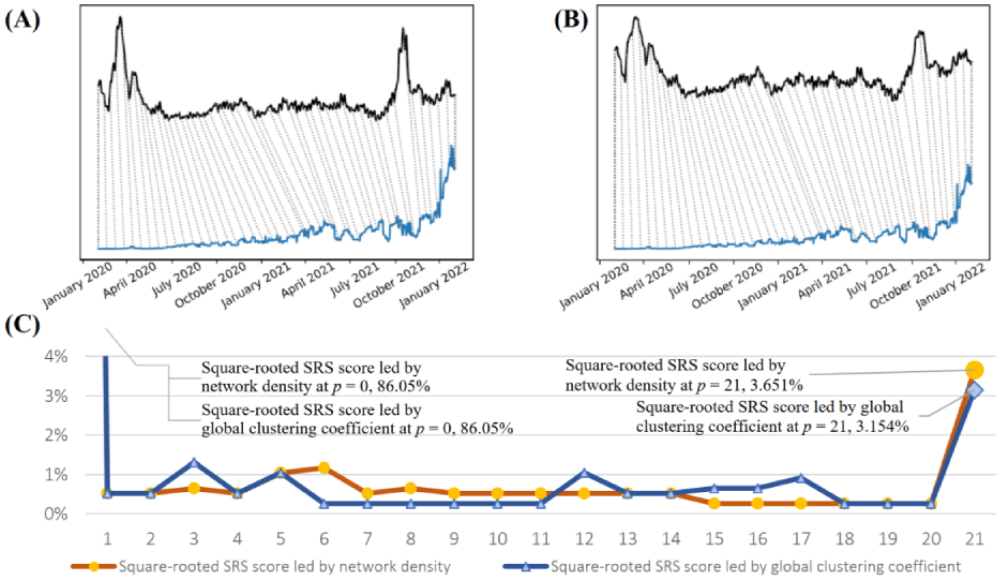

Quantify the Asynchronous Movement of Statistics

We further quantify our observations in the 2-way DTW plots in Figures 8A and 8B by tabulating the portion of different time shift values, which shows the equivalently compelling result. As shown in Figure 8C, most of the connections between the SRS series and the network statistics series were on days 0 and 21.

We are not particularly interested in non–time-shifted DTW connections. Owing to the design of the DTW algorithm, the start and end of the pair of latent variables and observations will often warp to each other one-on-one, without any time shift, resulting in a nontrivial portion of the connections between any 2 time series defaults to $P= 0$ (ie, no time shift). Thus, we can safely assume that there is an insignificant amount of information in these connections, and we also masked the corresponding points in Figure 8C.

In contrast, the substantial portion of 21-day-forward-shifted connections offers an interesting insight. As many of the DTW connections detected have some form of forward time shift, the connections indicate that the movement of summary network statistics has a certain leading effect on the COVID-19 observed statistics. On the basis of our visual inspection and the DTW metric, the potential of summary network statistics in predicting real-life COVID-19 events is quite evident.

Dynamic Property of the MSV Network in the Pandemic Progression

In addition to the magnitude of the dynamic network, we explored the pattern alterations during the progression of the pandemic. In Figure 9, the construction of the networks on March 11, 2020, and October 23, 2021, are depicted, where the MSV network peaks are observable before the first and the fifth COVID-19 outbreaks, respectively. In addition to network density, the global clustering coefficients for these 2 dates also form peaks, indicating high clustering coefficients in the network of the selected coronavirus-related keywords during those periods.

On March 11, 2020, the dense network was represented by noticeable clusters in Figure 9A, although a small separation was found between the 2 clusters. Although the nodes of search queries “Travel warning,” “Airborne transmission,” and “Vaccine” are connected within the cluster, the nodes for “rapid diagnostic test” are located farther away from it.

Comparatively, we observe a single large cluster in Figure 9B, which shows a generally high connectedness among the coronavirus-related keywords. Moreover, the indicated node “rapid diagnostic test” has shifted into the main cluster with another node, “vaccine.” This may reflect the increasing importance and availability of effective rapid diagnostic tests for COVID-19 worldwide in the latter phase of the pandemic’s progression. Conversely, the nodes “Travel warning” and “Airborne transmission” are located outside the main cluster, as shown in Figure 9B. This change in their position may imply a reduced focus in the community owing to a relatively sufficient understanding of COVID-19 transmission and control. This finding suggests that the proposed approach to a dynamic MSV network is a possible infoveillance application that would allow nonstationary patterns of search interests during the progression of a pandemic.

We also included the square root of the SRS [37,50] in Figure 10 for comparison. The pandemic network statistics showed an upward trend that aligned with the variations in SRSs. The GT network statistics even provided a sensible signal in late 2021, alerting to the latter peak of SRS, which probably reflected the notable impact of the Omicron variant worldwide.

Figure 9. Visualization of the network construction using selected dates: (A) snapshot on March 11, 2020, and (B) snapshot on October 23, 2021. Highlighted nodes: search queries “rapid diagnostic test,” “vaccine,” “airborne transmission,” and “travel warning.” Large red and blue circles: observable clusters.

Discussion

Principal Findings

This study introduced an innovative method for handling GT search data in research analysis, including an algorithm for constructing an MSV series and a dynamic GT network.

The original data extracted from GT have several limitations that affected the analysis in this study. First, the search volume data available in GT are normalized to the specified time and region [33]. The time series data of "interest over time" of a particular keyword only indicate the search interest relative to the highest point for a defined region and period. The resulting search data were also rescaled as integers ranging from 0 to 100 [33]. The normalization and rounding processes may lead to data inaccuracy in representing the search interest. In addition, GT restricts the availability of data over a long period. When one requests search data over a long duration, only weekly or monthly data will be returned, rather than daily data [25]. This restriction greatly reduces the resolution of the search data and affects further investigation [31,51]. Therefore, this study introduced a merged algorithm that helps recover the resolution and accuracy of the search volume data extracted from GT over long observation periods. The suggested MSVs can broaden the potential value of GT data in long-term surveillance of health phenomena.

Strengths and Limitations

Using our novel merged algorithm, we observed similar phenomena in search volumes, which have been suggested in previous work, such as certain search terms correlated with COVID-19–confirmed cases [9], and there were increasing or decreasing searches for some keywords before major COVID-19 events [51]. However, unlike other previous infoveillance studies using GT [9,15-21,23-31,52-54], which often have to either sacrifice data resolution or data time horizon, we are able to use higher-resolution data with shorter delays for prolonged periods.

In addition to the merged algorithm, we demonstrated the potential of network analysis as a useful tool for infodemiology and infoveillance. Network analysis offers not only an integrated perspective of multiple time series but also cross-sectional visualization. In this study, we illustrated the cross-sectional network constructions at different timestamps in Figure 5 to investigate the clustering effect and associations of various keywords at different moments. We further presented an overall view of a temporal network via 2 summary statistics, namely, network density and global clustering coefficient, and revealed the lead-lag relationships between the official COVID-19 statistics and the summary statistics. The promising findings suggest that network analysis could be an important component for developing new predictive models.

Interestingly, the vaccine-related nodes (green nodes) in Figure 5 had a high degree of connectedness on all sampling days, even before any COVID-19 vaccine was approved for administration. It may be inferred that before the start of the pandemic, the public, health experts, and researchers searched for information about the coronavirus and its vaccines, resulting in a high number of correlations at the early stage, as shown in Figure 5A. Later, as the pandemic hit harder and the public began to understand more about COVID-19, people sought information more targeted at recovering from the COVID-19 pandemic, such as information on vaccinations and medications, as demonstrated in Figures 5C and 5D. In Figures 5C and 5D, disease-related and virus-related nodes drifted away from the cluster center, whereas nodes related to vaccines and pharmaceutical industry companies moved toward the center of the cluster.

Organizations such as government agencies and pharmaceutical companies were also on the radar of public awareness. At the beginning of the COVID-19 pandemic, members of the public understandably sought information on preventive measures and guidance from their government. As the pandemic continued, the public became familiar with social distancing and testing measures, and their attention shifted to vaccinations. As a result, the vaccines and the manufacturers of COVID-19 vaccines thus became part of the focal points, as illustrated in Figures 5C and 5D, where vaccine-related nodes (green) and nodes of pharmaceutical companies (purple) move toward the center of the cluster.

Our findings also revealed the capability of MSVs for the early detection of outbreak risk of emerging infectious diseases. Early signals are critical in controlling an emerging infection outbreak, as they allow policy makers and governments to impose rapid measures to curb the propagation of the disease. On the basis of our study findings, the MSVs of the generic keywords, such as the name of the infectious disease, symptoms, and transmission method, can provide an early signal of the risk of a potentially serious outbreak. This early detection may be related to self-diagnosis or information-seeking behaviors conducted via the internet, similar to the findings by Mangono et al [51]. Previous studies have raised the issue that a growing number of people will search the internet for health information about emerging diseases and their bodily changes and will make self-diagnoses [53] and seek preventive measures [23]. This causes the popularity of the related keywords to increase rapidly before an actual outbreak. In contrast, public transportation is considered as a factor in the spread of infectious diseases during the early stage of a pandemic. Therefore, the related keywords (eg, “travel warning” and “public transport” in Figures 2D and 2E) could be an indicator of citizens’ mobility intentions and provide useful information for predicting the spread of a pandemic.

In addition to discovering the early detection capability, we also revealed that different related keywords could have increased in popularity in search engines based on their roles at different stages of pandemic development. In the 5 observable waves of the COVID-19 pandemic in the United States since January 2020, each wave consisted of unique epidemiologic characteristics and caused the US government to take diverse actions to respond to the outbreaks [55,56]. Unlike other chronic diseases, the continual evolution of a pandemic and policy making may drastically vary the association between the public’s search interests and the progression of a disease of concern. Lu and Reis [19] also elaborated that the association between some search keywords and a disease’s progression may not be stable and persistent in the later waves of an outbreak because of increased public education about the particular disease.

By aligning the trends of MSVs with the COVID-19 pandemic waves, we discovered the dynamic property of multiple search queries when associated with the pandemic’s progression. This dynamic search pattern may be related to a shift in the public’s search interests regarding the same aspect of the pandemic. For example, personal hygiene was a crucial precautionary measure promoted during the first wave of the COVID-19 outbreak [54]. With appropriate health education and promotion, the public then developed a fundamental understanding of the measures, such as handwashing and mask wearing. With the 3 waves of COVID-19, people raised the demand for vaccines as an effective precaution against the disease [52]. As can be seen in our findings (Figures 2F and 2G), there was a shift of public search interests in precautionary measures from “hygiene” to “vaccine” after the third wave. Similarly, people with COVID-19 symptoms apparently considered “emergency medical service” during the early phases of the pandemic [57], but with the available “rapid diagnostic test” in 2021, those with symptoms tended to conduct the rapid tests before seeking medical services [58]. This yielded an observable shift in public search interests in diagnostic procedures from “emergency medical service” to “rapid diagnostic test” during the third wave. The shifting search interest may have been owing to changes in information-seeking behaviors before public policy implementation [51].

As the dynamic relationship between the internet data and the pandemic trends in the long run limited the potential of the conventional predictive models using search volumes as predictors [31], we mitigated this problem by considering the connectedness of the keywords, which could reflect the actual linkages of public concerns and human information-seeking behaviors. In this study, we provided an innovative application of network statistics that quantified the connectedness of MSV data in processing the prediction. Although multiple COVID-19 variants occurred that varied the pandemic’s development and the corresponding implementation of health measures [54], the resulting network trends could still be longitudinally associated with the 5 COVID-19 waves in the United States. By using DTW, the dynamic network of the MSVs was further justified as a leader of the trend of US-confirmed cases and of the severity of the global pandemic risk. Although previous studies revealed that linkages and patterns existed among the search queries specific to the pandemic [19,51], our proposed method took the nonstationary pattern among the relevant search queries into account during pandemic predictions. The method was able to demonstrate that the network of the merged GT volumes can be considered as a new form of official web-based data, not only associated with the pandemic but also capable of predicting its development.

This study’s approach using network analysis is innovative in the field of health and epidemiology research. Our early ground research provided a comprehensive empirical foundation for applying network statistics to investigate diverse pandemic-related issues, including infection topology [37], travel restrictions [43,47,49], and financial impacts [36,45,48]. In particular, pandemic networks using COVID-19 confirmed cases have proved their capability in tracking and providing early warnings of infection outbreaks [44,46]. We adapted the construction of a pandemic network to an infodemiological setting by investigating the dynamic GT network. In Figure 10, we compare our GT network statistics with the corresponding pandemic network statistics proposed in multiple relevant studies [36,37,44,46,47,49]. The pandemic network density and global clustering coefficients were shown to provide early warning signals of the COVID-19 pandemic [36,37,43]. Interestingly, both the GT network density and global clustering coefficients behaved similarly with the pandemic network statistics at the early stage of COVID-19 progression. On the basis of this comparison, we anticipate that both sets of network statistics can convey and deliver useful measures for pandemic risk and progression. As search data are considered to be complementary infoveillance measures, our proposed methodology of GT network analysis provides an important scientific discovery of the potential usefulness of search volume data in infodemiological research.

In addition to data analysis, the importance of keyword selection in infodemiology research has also been emphasized in the literature [59]. The procedure of excluding noisy queries is known to be important in ensuring the validity of research findings. However, there is a lack of a suitable framework for research on internet searching patterns during a pandemic. To prevent a stringent keyword selection by excluding potential keywords, we adopted a novel keyword selection approach based on relatively explicit data for “related topics” in GT. Although this approach helped us discover the keywords relevant to the pandemic and facilitated our interpretation of the findings, future studies in infodemiology could also adopt this approach to strengthen their selection of search queries.

We realize that our network consisted of regional topics associated with countries that have significantly higher than average internet coverage, such as Switzerland (internet penetration rate [IPR]: 98%), the United Kingdom (IPR: 98%), Japan (IPR: 94%), and the United States (IPR: 92%) [7]. Furthermore, IPR is skewed by the level of development of a country. However, because the proportion of those topics is as large as other nonregional terms, it is safe to assume that the network highlighted the interests of internet users in those regions, but the impact of the regional topics was nonsignificant and marginal.

Furthermore, we intentionally included most of the keywords we obtained from GT, as our research focuses on the worldwide public behavioral pattern during the COVID-19 epidemic. Despite the seeming irrelevance of some keywords, all the keywords collectively indicate the information the public received, with various levels of trustworthiness. Although only keywords for GT categories associated with regional effects were excluded in our study, future studies can examine the determined GT categories and exclude the keywords that are pathologically, psychosocially, or epidemiologically unrelated to their specific health concerns. In addition to the time and labor involved, researchers should consider the objectivity and validity of manually including or excluding certain keywords to develop the most rigorous data sets in their research.

Conclusions

As the growth of the epidemic in the United States generally relates to the transmission across multiple countries, our research investigates the linkage between worldwide public behavioral patterns and the COVID-19 pandemic in the United States. Future studies should further investigate the association between regional GT data and noncommunicable diseases.

Although we did not focus on investigating the spread of misinformation during COVID-19, research has shown that receiving accurate and inaccurate information is inversely correlated with individuals’ compliance with COVID-19 health guidelines [60-63]. Our data also show that the public may actively seek information on misinformation, as evidenced by the noninsignificant search interest in the term “hydroxychloroquine” (Textbox 1). Owing to the nature of GT, we cannot confirm whether the users were searching for misinformation out of their beliefs in certain misinformation, the inclusion of users’ interest in the information of different trustworthiness [60-62] and users’ interest in those who propagate said information [40] is critical to a comprehensive infoveillance instrument.

To the best of our knowledge, this study is the first of its kind to use a rolling window ensemble method [45,64] to recover data resolution in GT. This is also the first study to investigate the network statistics of GT data for predicting the development of a pandemic. The results also provide insights for researchers in further investigating the patterns of web-based searching behaviors, which is an important focus in infodemiological research. With the ongoing rapid growth of internet use, people will rely increasingly more on web-based information for decision-making. As the search volume data are freely available on the GT platform, it is expected that GT will become more common as a complementary, free, and timely data resource for traditional surveillance methods of health-related events. Future studies can focus on expanding the dynamic networks of search keywords to investigate noncommunicable diseases, health-related behaviors, and misinformation on the internet.

Abstract

Background: As one of the major constituents of the cannabis sativa plant, cannabidiol (CBD) is approved for use in medical treatment and cosmetics because of its potential health benefits. With the rapid growth of the CBD market, customers purchase these products, and relevant discussions are becoming more active on social media.

Objective: In this study, we aimed to understand the users’ attitudes toward CBD products in various countries by conducting text mining on social media in countries with different substance management policies.

Methods: We collected posts from Reddit and Xiaohongshu, conducted topic mining using the latent Dirichlet allocation model, and analyzed the characteristics of topics on different social media. Subsequently, a co-occurrence network of high-frequency keywords was constructed to explore potential relationships among topics. Moreover, we conducted sentiment analysis on the posts’ comments and compared users’ attitudes toward CBD products on Reddit and Xiaohongshu using chi-square test.

Results: CBD-related posts on social media have been rapidly increasing, especially on Xiaohongshu since 2019. A total of 1790 posts from Reddit and 1951 posts from Xiaohongshu were included in the final analysis. The posts on the 2 social media platforms, Reddit and Xiaohongshu, were categorized into 7 and 8 topics, respectively, by the latent Dirichlet allocation model, and these topics on the 2 social media were grouped into 5 themes. Our study showed that the themes on Reddit were mainly related to the therapeutic effects of CBD, whereas the themes on Xiaohongshu concentrated on cosmetics, such as facial masks. Theme 2 (CBD market information) and theme 3 (attitudes toward CBD) on Reddit had more connections with other themes in the co-occurrence network, and theme 3 and theme 1 (CBD therapeutic effects) had a high co-occurrence frequency (22,803/73,865, 30.87%). Meanwhile, theme 1 (CBD cosmetics) on Xiaohongshu had various connections with others (169,961/384,575, 44.19%), and the co-occurrence frequency of theme 4 (CBD ingredients) and theme 1 was relatively prominent (27,128/49,312, 55.01%). Overall, users’ comments tended to be positive for CBD-related information on both Reddit and Xiaohongshu, but the percentage was higher on Xiaohongshu (82.25% vs 86.18%; $P<.001$), especially in cosmetics and medical health care products.

Conclusions: The CBD market has grown rapidly, and the topics related to CBD on social media have become active. There are apparent differences in users’ attitudes toward CBD in countries with different substance management policies. Targeted CBD management measures should be formulated to suit the prevalence of CBD use of each country.

Introduction

Background

Cannabidiol (CBD) is a nonintoxicating principal constituent of the cannabis sativa plant discovered in 1940 [1]. In recent years, CBD has been widely used in cosmetics, food supplements, beverages, electronic cigarette liquids, and prescription pharmaceuticals. There are dozens of different forms of CBD products on the market, such as oils, capsules, edibles, and so on. Unlike tetrahydrocannabinol (THC), which is the main psychoactive component of cannabis, relevant studies have shown that CBD is a relatively safe and nonaddictive substance [2]. Moreover, there is evidence that CBD has variety of pharmacological effects on the receptor system, producing analgesic, anti-inflammatory, antianxiety, and antipsychotic effects [3]. Relevant clinical studies have also shown that CBD has the potential to treat anxiety disorders, panic disorders, and pain [4-7]. In addition, Tóth et al [8] suggested that CBD may be helpful in treating some skin symptoms, such as dryness and itching. Nevertheless, owing to the lack of large-scale randomized controlled trials, the clinical effectiveness and safety of CBD are uncertain [9,10] and its potential side effects have not yet been confirmed [11].

In the context of the global legalization of cannabis, government policies regarding CBD are inconsistent. In the United States, most states allow CBD for medical use and residents can purchase it from pharmacies or on the web [12]. However, products containing CBD with therapeutic claims are tightly regulated by the Food and Drug Administration, and except Epidiolex, no products have been approved by the Food and Drug Administration [13]. As the second largest CBD market, most European countries have legalized CBD products (THC not exceeding 0.2%), and those products with medical claims must be authorized as medical products [14,15]. Most customers in Europe are still free to purchase CBD products on the web. The acceleration of global cannabis legalization will lead to a further boom in the CBD market in the United States and European countries. In contrast, in countries such as China and Singapore, illicit drugs are strictly regulated by the government, including heroin, cannabis, and its derivatives. The legality of CBD has not been approved, and its use in food, medicine, and cosmetics is prohibited, as well as web-based or offline trade [16,17]. However, because of the fast-growing interest in lifestyle upgrades, customers in these countries have also begun to pay attention to CBD products [18].

With the explosive growth in the popularity of CBD products, related topics on social media are steadily increasing. People, especially adults aged between 18 and 35 years, are keen to share their feelings on social media. Moreover, users can comment on topics that they are interested in to express their thoughts and interact with others. Social media is an essential channel for CBD product marketing. Users often read related promotions when surfing on social media. Approximately 38% of customers discovered CBD through internet searches [19]. Keeping abreast of topics on social media will assist us in understanding the trends in CBD products, which have a substantial impact on people's behavior [20]. Previous studies have demonstrated the potential of social media in perceiving product trends in CBD [21,22]. However, these studies focus on social media data in the United States and European countries, where CBD has been approved for use and sale.

Objectives

Propelled by the spread of information and promotion by celebrities, CBD products are landing on social media in China. As China implements strict drug regulatory policies, the popularity of CBD products on social media in China will bring new challenges to current policies, and there is no relevant research to date. This study aimed to extract and analyze topics on social media in China and other countries to explore users' attitudes toward CBD products and compare the differences with social media users. We hope to provide suggestions to policy makers to cope with the rapid development of the CBD market.

Methods

Data Collection and Preprocessing

First, we chose 2 popular social media platforms, Reddit and Xiaohongshu. Reddit is an English language–centric social community that includes a variety of topics, and its user base is primarily Western countries [23]. A report on the demographics of Reddit users showed that their locations were mainly from the United States, Australia, Brazil, Canada, Denmark, Norway, and other countries, which were also representative countries where CBD products were used. High school and college education accounted for the highest proportions, and the users' age ranged from 18 to 49 years [24,25]. As one of China's fastest growing social media apps, Xiaohongshu has approximately 100 million active users, most of whom are from China [26]. Xiaohongshu encourages its users to post different contents of their lives, and users can interact based on interests, such as fashion, food, and many other aspects. A study emphasized that posts on Xiaohongshu had a substantial influence on the purchasing behavior of Chinese consumers [27]. Considering that marijuana is strictly regulated in China, related posts are not allowed to be published. As Xiaohongshu is a platform connecting domestic and overseas users, CBD-related posts highlighted the current attitude of domestic users. Therefore, these posts on Xiaohongshu, as a representative, were used to analyze attitudes of users in China. We formulated a keyword list to retrieve CBD-related posts from the 2 social media platforms (Figure 1). In the beginning, we randomly searched 100 posts containing *CBD* from the 2 social media platforms and then 2 experts independently reviewed these posts and selected the appropriate keywords. Finally, the Delphi method was used to determine the completed search keyword list (Textbox 1) [28]. We searched all posts and the related comments from social media based on the keyword list we formulated until May 31, 2021. Each post included the serial number that was used to filter duplicates, titles, detailed content, and published dates. The comments on the post were composed of text content and comment date (Multimedia Appendix 1, Figure S1). As unstructured data contained considerable noise, all the original data were further processed to facilitate subsequent analysis. Duplicate posts resulting from different search keywords were removed with their comments based on the serial number. Then, nontext data (eg, video and picture) or blank content in the posts or comments were deleted. Subsequently, unnecessary sentence components (eg, emoji, hyperlink, and punctuations) and meaningless words (common stop words in English and Chinese) in the text were removed. Moreover, regular expressions were used to eliminate nonalphanumeric characters. In addition, we noticed that there were still a few irrelevant posts in the data set. Two researchers independently filtered unrelated posts. If there was a discrepancy, a third researcher determined the final outcome. Finally, for the Chinese posts on Xiaohongshu, we executed a word segment on the sentence using Jieba 0.42. In addition, we performed lemmatization on Reddit posts to extract more textual information using NLTK 3.5. After the above preprocessing, all the remaining data constituted the corpora of Reddit and Xiaohongshu.

Data Analysis

Applying Topic Model

The topic model is a statistical algorithm for discovering the latent semantic structures of large corpora that can offer insights into ways we can better understand the main idea of the text. Latent Dirichlet allocation (LDA) is an unsupervised generative probabilistic method for modeling extensive text, resulting in different topics and document clusters [29]. Before applying LDA to the topic model, the text in the corpora was converted to a vector of term counts using Scikit-learn, a Python library (Figure 1). Perplexity was used as the criterion for evaluating the effectiveness of the LDA model; the lower the perplexity, the better the model predicts [30]. To determine the appropriate number of topics in the corpus of documents, the 5-fold cross-validation was applied in LDA model training. We randomly shuffled the corpus and divided it into 5 groups, 4 of which were training data sets, and the remaining one was a validation data set [31,32]. The candidate number of topics ranged from 2 to 15. We also calculated coherence measures to evaluate the candidate number of topics. Topic coherence measures scored a single topic by measuring the degree of semantic similarity between high-scoring words in the topic. Coherence value (CV) was selected as the metric in this study, and the higher value indicated optimal topic coherence [33,34]. Then, during each training iteration, we calculated and compared the perplexity and coherence scores of different candidate topic numbers in the validation data sets and presented these results in a scatter plot. Therefore, the final number of topics in the corpus was determined using a combination of perplexity and coherence. After the LDA model training was completed, we visualized the generated topics and related keywords. In the visualization layout, topics were represented in the form of bubbles, and each bubble represented one topic. The distance between the bubbles was an approximation of the semantic relationship between the topics. The overlap of bubbles indicated that there were similar parts between the topics. On the basis of the outcomes in the layout and combined with a better expression of the semantics of these topics, we merged similar topics (overlapping and closer in the distance) extracted by the LDA model into new themes.

Construct Co-occurrence Network of High-Frequency Keywords

A co-occurrence network was used to provide an intuitive expression of potential relationships between topics within corpora, and it was the collective interconnection of various high-frequency keywords based on their paired presence within the posts in the corpora. The top 10 high-frequency keywords in each theme were regarded as representative high-frequency keywords. We then formed pairs of these high-frequency keywords (Figure 1). In this study, we defined "co-occurrence" as a pair of keywords appearing in the same post. For example, "cannabidiol" (keyword in theme 1) and "experience" (keyword in theme 3) appeared in the post, so this pair (cannabidiol-experience) was said to "co-occur." Moreover, we counted the frequency of co-occurrence of high-frequency keywords in the corresponding corpora. We then constructed a co-occurrence network diagram of high-frequency keywords, where the nodes with colors represented the keywords of themes and the thickness of the edges indicated the frequency of co-occurrence in the corresponding corpora. In addition, the corresponding heatmaps were created to provide the relationships between various themes intuitively. In the co-occurrence heatmap, the number represented the frequency of co-occurrence between different themes, and the pie chart indicated the proportion of 1 theme in all themes in each row. This work was performed using Gephi 0.9.2 (Gephi Consortium) and Seaborn modules in Python 3.6 (Python Software Foundation).

Sentiment Analysis

Social media is one of the most important ways for people to obtain information, and sentiment analysis can help understand a person's opinion about a particular subject or topic based on the comments on posts [35]. Therefore, we selected posts with comments to form subcorpora and performed sentiment analysis on them (Figure 1). As the comments were feedback on the content of posts, we first paid attention to the content discussed in these posts, and we found that most of them were divided into 3 subjects: cosmetics, food, and medical health care products. We assigned 2 researchers with medical backgrounds to annotate the subject of posts with labels. The 2 researchers were asked to independently classify the posts and reach a consensus on the final label results. If there was an inconsistency, an expert would participate and ensure the final agreement. Next, we arranged for 2 other researchers to independently annotate the comments based on the detailed text to determine sentiment polarity (positive or negative). Positive comments referred to those messages that users liked or accepted in the content of posts, and negative comments were just the opposite. The process of determining positive or negative comments was consistent with the above process. According to the sentiment polarity annotation results on the comments, we set a sentiment classification label for each post. For example, the posts that had more positive comments than negative ones would be classified as positive posts and vice versa. Finally, we drew a scatter plot of sentiment polarity. The horizontal coordinates indicated the subject classification of the post, and the vertical coordinates indicated the number of comments (positive posts used the number of positive comments and negative posts used the number of negative comments). The differences in sentiment distribution between the 2 social media platforms were verified using the chi-square test executed in SPSS (version 22.0; IBM Corp).

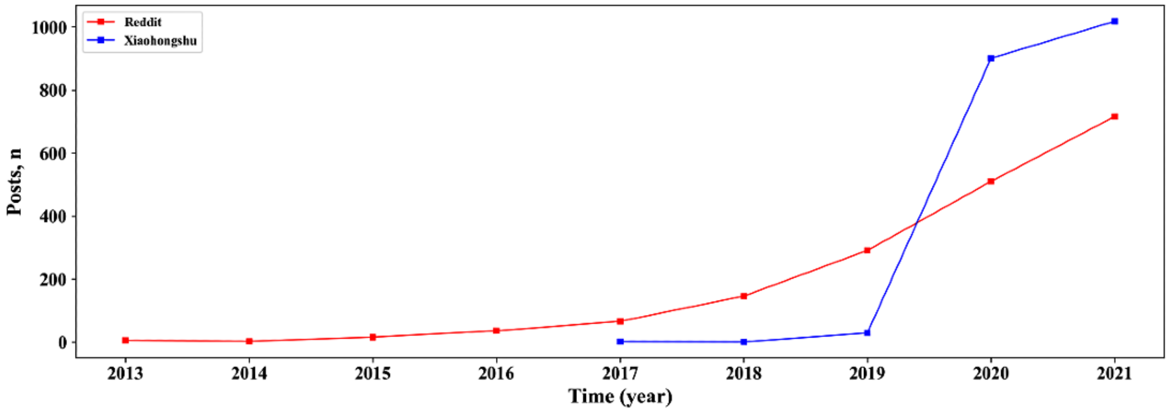
This study was approved by the Peking University Institutional Review Board (IRB00001052-16016).

Results

Basic Statistics Information

By the end of May 31, 2021, 3212 Reddit posts and 2512 Xiaohongshu posts were collected. After preprocessing, 1790 and 1951 posts were included in the statistical analyses. According to the statistics of the number of posts by years, it was apparent that there was a rising trend of CBD-related posts, both on Reddit and Xiaohongshu (Figure 2). In particular, compared with posts on Reddit, the attention paid to CBD on Xiaohongshu was hysteretic, and there had been explosive growth since 2019.

Figure 2. The number of posts on Reddit and Xiaohongshu per year.



Topic Modeling Result

After 5-fold cross-validation, perplexity was the lowest when the topic number was 7 on the Reddit corpus (199.34-201.91). Likewise, the highest CV using CV metric ranged from 0.63 to 0.67 with a topic number of 7. Therefore, 7 topics were identified from the posts on Reddit (Multimedia Appendix 1, Figures S2 and S3). The 7 topics were grouped into 5 themes: CBD product treatment and effect (theme 1, including 2 topics), market information related to CBD products (theme 2, including 2 topics), user attitudes toward CBD products (theme 3, including 1 topic), products and forms related to CBD (theme 4, including 1 topic), and consumer-oriented CBD product format (theme 5, including 1 topic). The keywords for each theme with the percentage of the given documents are summarized in Table 1. It showed that theme 1 was the most popular, accounting for 47.64% (43,197/90,676) of the keywords. Moreover, in theme 3 (17,565/90,676, 19.37%), many users expressed their desire to try CBD products, as advertisements on the CBD were readily available on similar websites. In addition, it was clear that there were various forms of CBD products in the consumer market, which were distinctive from the themes of Xiaohongshu. Perplexity and coherence varied for different values of the number of topics. On the basis of the perplexity and coherence of the Xiaohongshu corpus, we determined 8 as the optimal number of the topics with the minimum perplexity (137.15-140.70) and maximum coherence (0.64-0.68; Multimedia Appendix 1, Figures S4 and S5). We grouped these 8 topics into 5 themes (Table 2). The most obvious characteristic was that Xiaohongshu's themes were concentrated on cosmetics field. Theme 1 (including 3 topics) had the highest percentage (25,750/55,097, 46.74%) and was CBD-related cosmetics categories and functions, such as facial masks, creams, and essences. In addition, the themes on Reddit and Xiaohongshu both involved brands of CBD. However, there were not only domestic brands on Xiaohongshu but also international brands from the United States and Europe (theme 2, including 2 topics; 10,001/55,097, 18.15%). Moreover, theme 3 (including 1 topic) and theme 4 (including 1 topic) introduced the effect evaluation of CBD products and the raw materials of CBD cosmetics, respectively. Theme 5 (including 1 topic) described medical health care products with therapeutic benefits claims, and a similar theme also appeared in Reddit.

Table 1. Topic classification and keywords on Reddit corpora.

Classification and topics	Keywords	Values, %
Theme 1: CBD[a] production treatment and effect		
Topic 1: CBD production treatment	pain, anxiety, body, treatment, patients, use, reduce, sleep, disorders, cancer	25.56
Topic 2: Multiformat CBD products effect	hemp, make, gummies, benefit, plant, oil, cannabidiol, extract, high, health	22.08
Theme 2: Market information related to CBD products		
Topic 3: Company information of CBD	company, products, base, business, market, release, sell, service, live, develop	11.43
Topic 4: Brand and report of CBD	hemp, brand, share, report, sales, industry, grow, research, offer, hold, price	8.61
Theme 3: Attitudes toward for CBD products		
Topic 5: Attitude to use CBD products	like, know, want, feel, work, try, think, start, experience, really, need, good	19.37
Theme 4: Products and forms related to CBD		
Topic 6: Raw materials and other products	cannabis, marijuana, medical, extract, weed, capsule, flower, smoke, food	6.82
Theme 5: Consumer-oriented CBD product format		
Topic 7: Product formats and distribution channels	vape, bottle, liquid, spectrum, cream, free, online, shop, pure, website, order	6.13

[a] CBD: cannabidiol.

Table 2. Topic classification and keywords on Xiaohongshu corpora.

Classification and topics	Keywords	Values, %
Theme 1: CBD[a]-related cosmetics categories and functions		
Topic 1: Skin care cosmetics	skin (皮肤), sensitive (敏感), ingredient (成分), cream (面霜), skin care products (护肤品), lotion (水乳), absorb (吸收), oil skin (油皮), protect (护理)	19.33
Topic 2: Benefits of CBD mask	facial mask (面膜), repair (修护), stay up late (熬夜), hydrating (补水), emollient (舒缓), serum (精华液), fight against acne (消炎), antioxidant (抗氧化), emergency (急救)	15.67
Topic 3: Benefits of other CBD cosmetics	acne prone (痘痘), oil-control (控油), moisturize (保湿), purify (淡化), resurfacing (清爽), nutritious (舒缓), whitening (美白), antiwrinkle (抗皱), active (活化)	11.74
Theme 2: CBD-related cosmetics brands and research		
Topic 4: Study on the effectiveness of CBD	function (作用), efficacy (功效), research (研究), cell (细胞), health (健康), control (抑制), discovery (发现), stimulate (刺激), balance (平衡)	9.32
Topic 5: CBD-related cosmetics brands	products (产品), brand (品牌), industry (工业), extract (提取物), western (欧美), formulation (配方), America (美国), price (价格), domestic (国产)	8.83
Theme 3: Effect evaluation of CBD products		
Topic 6: Cosmetics effect evaluation	feel (感觉), really (真的), particular (特别), smell (味道), comfy (舒服), recommend (推荐), good (不错), try (试试), share (分享)	12.11
Theme 4: Main ingredients of CBD cosmetics		
Topic 7: Ingredient introduction	Cannabis (大麻), ingredient (成分), essence (精华), vitamin (维生素), essential oil (精油), extract (提取), add (添加), plant (植物), natural (天然)	11.98
Theme 5: Declared disease treatment effect		
Topic 8: CBD treatment of diseases	sleep (睡眠), anxiety (焦虑), relieve (缓解), insomnia (失眠), stress (压力), emotion (情绪), pain (疼痛), adjustment (调节), improve (改善)	11.02

[a] CBD: cannabidiol.

Co-occurrence Network of High-Frequency Keywords

For the themes on Reddit, there were wide connections between the different themes. Obviously, theme 2 had the most connections with other themes, which was 24.48% (83,733/342,066) followed by theme 3 that accounted for 21.59% (73,865/342,066; Figure 3A). The heatmap of high-frequency keywords showed that theme 3 and theme 1 had a high co-occurrence frequency (22,803/73,865, 30.87%); that is, users were interested in the therapeutic effects of CBD and expressed their thoughts on trying and some even used this type of product for the first time (Figure 4A). This study also showed that there were various forms of CBD products for users to try and choose, which was why the co-occurrence frequency of theme 5 and theme 3 was relatively high (6419/28,364, 22.63%). In contrast, as users in Xiaohongshu shared all kinds of posts about cosmetics, the themes of CBD-related cosmetics (theme 1) categories had various connections with others (169,961/384,575, 44.19%; Figure 3B). Furthermore, unlike the themes of Reddit mentioned above, the themes in Xiaohongshu that claimed the therapeutic effects (theme 5) were simply associated with cosmetics and derivatives of CBD ingredients (theme 4), which was only 6.89% (1758/25,503). Xiaohongshu users were more willing to spend time introducing ingredients in cosmetics, especially those related to CBD. Therefore, the co-occurrence frequency of theme 4 and theme 1 was relatively prominent (27,128/49,312, 55.01%; Figure 4B).

Figure 3. Co-occurrence network of high-frequency keywords on Reddit and Xiaohongshu. (A) The nodes represent the keywords of the themes on Reddit. The edge between two nodes (source node and target node) indicates that two keywords appear in the same post, and the thickness of the edges indicates the frequency of co-occurrence in the posts. The color of the edge is consistent with that of the source node. Theme 1: CBD production treatment and effects. Theme 2: market information related to CBD products. Theme 3: attitudes toward CBD products. Theme 4: products and forms related to CBD. Theme 5: consumer-oriented CBD product format. (B) The nodes represent keywords of the themes on Xiaohongshu. The edge between two nodes (source node and target node) indicates that two keywords appear in the same post, and the thickness of the edges indicates the frequency of co-occurrence in the posts. The color of the edge is consistent with that of the source node. Theme 1: CBD-related cosmetic categories and functions. Theme 2: CBD-related cosmetic brands and research. Theme 3: effect evaluation of CBD products. Theme 4: main ingredients of CBD cosmetics. Theme 5: declared disease treatment effect. CBD: cannabidiol.

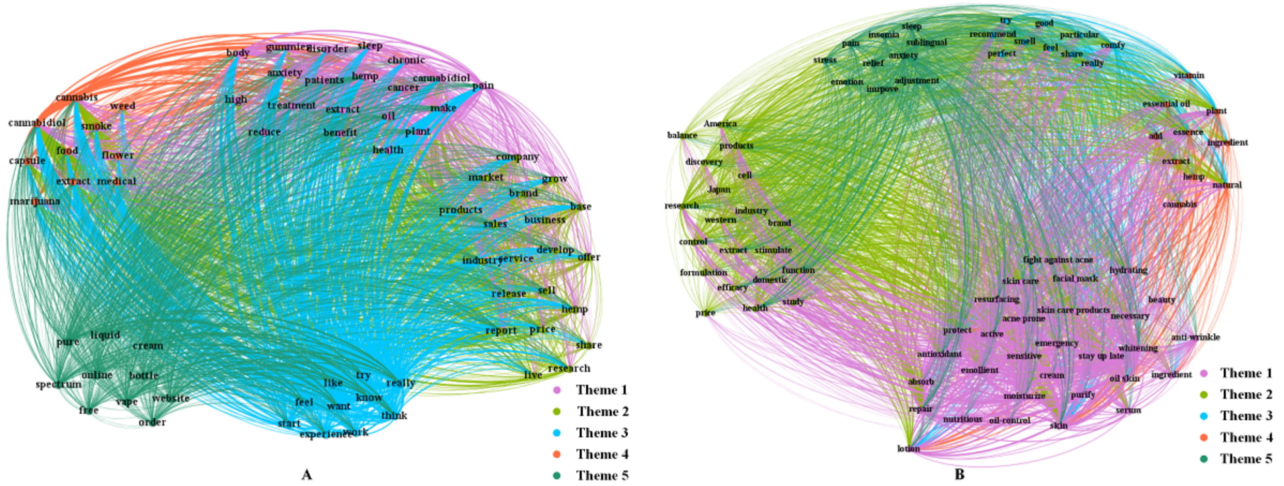


Figure 4. Co-occurrence heatmap of high-frequency keywords on Reddit and Xiaohongshu. The number is the frequency of co-occurrence between different themes, and the pie chart (blue part) indicates the proportion of one theme in all themes in each row. (A) The themes on Reddit—theme 1: CBD production treatment and effect, theme 2: market information related to CBD products, theme 3: attitudes toward CBD products, theme 4: products and forms related to CBD, and theme 5: consumer-oriented CBD product format. (B) The themes on Xiaohongshu—theme 1: CBD-related cosmetics categories and functions, theme 2: CBD-related cosmetic brands and research, theme 3: effect evaluation of CBD products, theme 4: main ingredients of CBD cosmetics, and theme 5: declared disease treatment effect. CBD: cannabidiol.

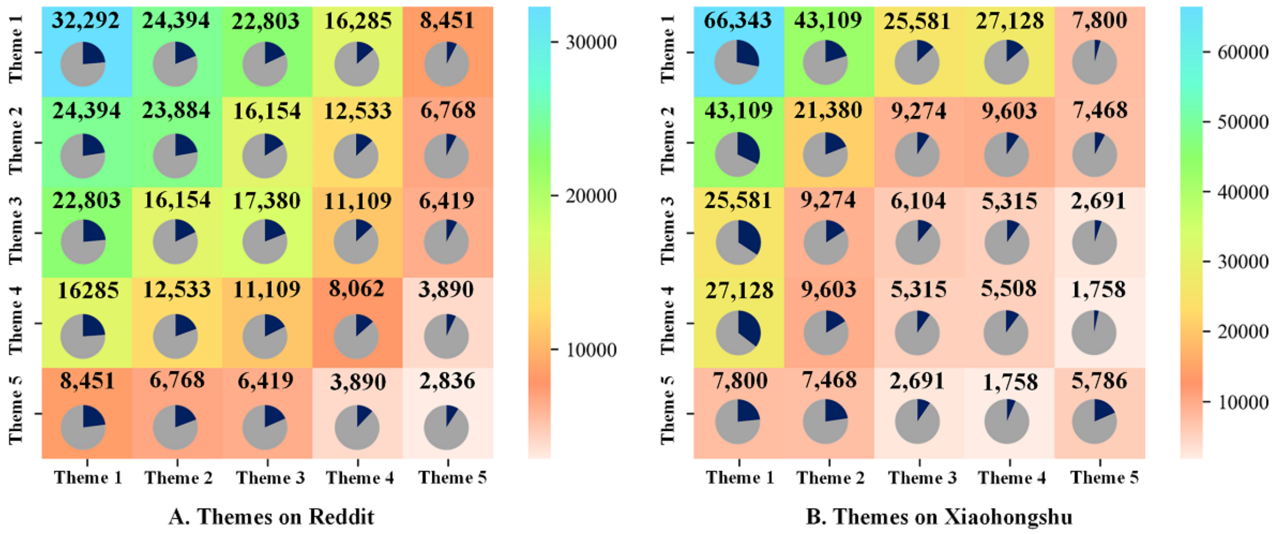

Distribution of Sentiment Polarity

After processing, there were 693 and 767 posts with comments on Reddit and Xiaohongshu, respectively (Figure 1). From the perspective of the classification subject of the posts, it was evident that the posts on Reddit were more focused on medical health care products (571/693, 82.4%), whereas the posts on Xiaohongshu had the highest proportion of posts on cosmetics (605/767, 78.88%; Figure 5). On Xiaohongshu, information about food containing CBD ingredients did not attract much attention (22/767, 2.87%), and discussions about cosmetics in Reddit were also less common (47/693, 6.78%). However, we noted that approximately 2.6% (18/693) of posts on Reddit reported using CBD products as alternative medicines, such as recreational cannabis and painkillers.

Overall, regardless of Reddit or Xiaohongshu, users' comments tended to be positive for CBD-related information, but the percentage was higher on Xiaohongshu (Reddit vs Xiaohongshu: 82.25% vs 86.18%; *P*<.001). Compared with Reddit, Xiaohongshu also had a higher percentage of positive comments on the subject of cosmetic and medical health care products (74.47% vs 91.57% in cosmetics and 82.84% vs 86.43% in medical health care products; *P*=.02). There was no significant difference in the proportion of posts with positive or negative emotions on the food subject between the 2 social media platforms (Table 3).

Figure 5. Sentiment distribution of posts on Reddit and Xiaohongshu. The horizontal coordinates indicate the subject classification of the post, and the vertical coordinates indicate the number of comments (positive posts used the number of positive comments, and negative posts used the number of negative comments).

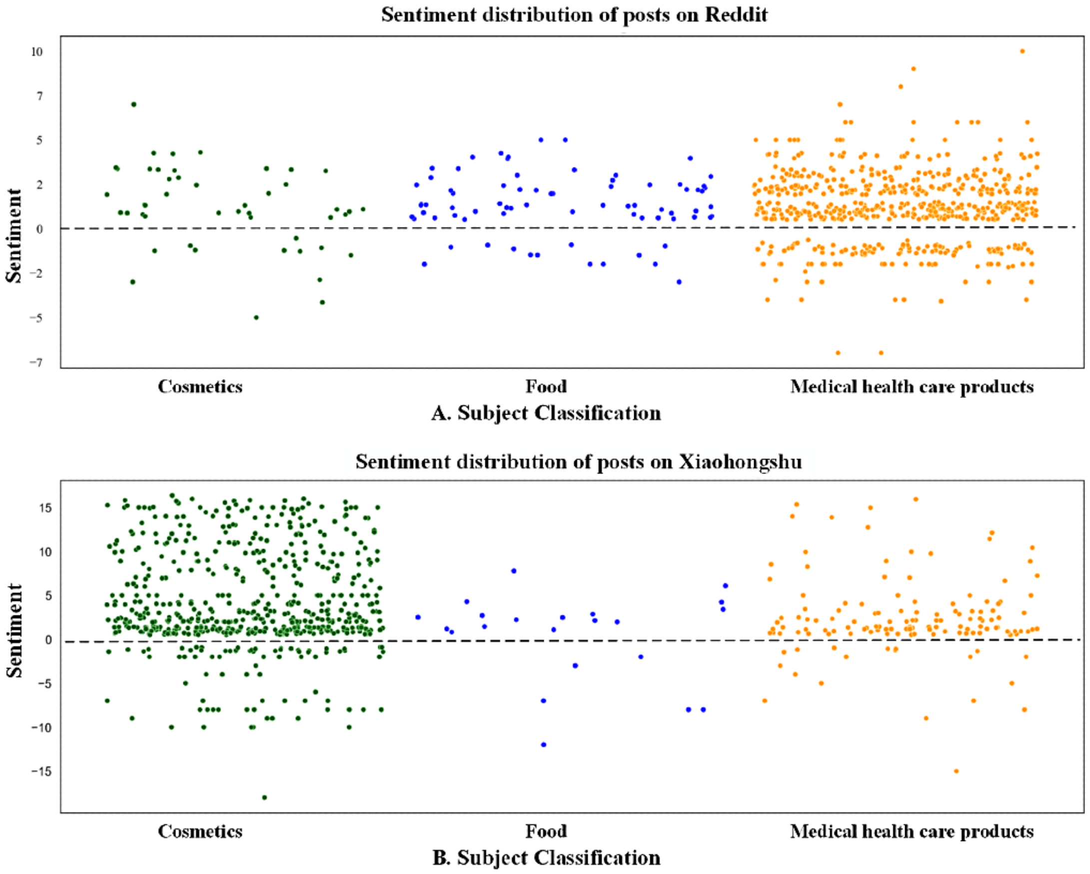

Table 3. The distribution of sentiment polarity on Reddit and Xiaohongshu.

	Overall			Cosmetics			Food			Medical health care products		
	Value, n (%)	Value, N	*P* value	Value, n (%)	Value, N	*P* value	Value, n (%)	Value, N	*P* value	Value, n (%)	Value, N	*P* value
Comments			<.001			.02			.30			.02
Reddit												
Positive	540 (82.25)	693		35 (74.47)	47		62 (82.67)	75		443 (82.84)	571	
Negative	153 (17.75)	693		12 (25.53)	47		13 (17.33)	75		128 (17.16)	571	
Xiaohongshu												
Positive	661 (86.18)	767		524 (91.57)	605		16 (72.73)	22		121 (86.43)	140	
Negative	106 (13.82)	767		81 (8.43)	605		6 (27.27)	22		19 (13.57)	140	

Discussion

Principal Findings

This novel study analyzed the posts related to CBD products on social media and compared users' attitudes toward CBD in countries with different substance management policies. The number of cannabis-related topics on social media was massive, and CBD was one of the emerging topics that attracted more and more attention. Benefiting from the formulated search keywords, the corpus in this study filtered out many data with high-noise levels, which also made the corpus relatively small. Therefore, we could build a more effective topic model to mine users' attitudes toward CBD products. The results showed that there were differences in the themes that users discussed on social media and their attitudes toward CBD had their own characteristics. Obviously, compared with some Western countries, there was a "vacuum period" when the relevant theme was first available on Xiaohongshu in China. Although China adheres to the strict drug control policy (including cannabis and its derivatives), with the popularity of legalization of medical and recreational cannabis, related themes have become increasingly active on social media in China [36,37]. The text-based topic model analysis in this study provided a reference for cross-cultural research. In traditional cross-cultural studies, qualitative methodologies were prominent and mostly conducted by cultural anthropologists in the form of ethnographies [38]. This required researchers to have a variety of cultural backgrounds, which may otherwise cause research bias. Language independence is commonly presented as one of the advantages of modern machine learning approaches to natural language processing (NLP), and it is an important type of scalability [39]. NLP technology can help us achieve cross-cultural quantitative analysis. In this study, we established an automated topic analysis process. A sequence of NLP functions was used to mine and extract topics from social media texts, and these topics were compared in different cultural contexts.

Social media serves as the vital source of information, as people are willing to share information on social media, and we can mine topic information from user-generated content on social media [40]. Although China is the largest producer of industrial hemp, its strict policy supervision has restricted the application of CBD. Cosmetics with CBD ingredients have attracted consumers, and it has been booming on social media. Even the international brands from the United States and Japan are also sold in the domestic market through e-commerce platforms (eg, Taobao and JD). Not only cosmetics but also some medical health care products that claimed to relieve anxiety or body pain have also appeared on social media in China. As more countries approved CBD for medical purposes, previous studies reported similar trends on other social media in Western countries [22]. Currently, there is a lack of scientific evidence for its effectiveness in treatment, and policy makers should pay attention to this phenomenon. Although the sale of cannabis and its derivatives is banned in China, CBD products for medical use have bypassed the legal supervision under the cover of cosmetics. In addition, many users claimed that taking CBD was good for health and even advocated anticancer effects, which may cause patients to eschew proven treatments and increase the disease burden [15]. Although CBD is touted for its therapeutic properties by consumers, public health professionals should be cautious when recommending CBD products and should ensure that regional and local laws are followed. Health care providers should clearly inform patients of the potential risks, especially in vulnerable groups such as children, older adults, and patients who are chronically ill. Moreover, our study found that users' attention to the 2 social media platforms was significantly different. Regarding CBD products, Xiaohongshu users posted more frequently about CBD in skin care, whereas Reddit users posted more frequently about the potential medicinal value of CBD products. Therefore, the government needs to strengthen the surveillance of the market and guide consumers to correctly understand CBD to avoid unnecessary risks owing to false propaganda.

There are various novel CBD product forms (eg, vaping and gummies) on Reddit, which are popular among teenagers. We noticed a close connection between this theme (theme 5) and the theme of therapeutic effects (theme 1) on Reddit. When teenagers are exposed to such information on social media, curiosity may drive them to try these CBD products, such as e-cigarettes, to relieve anxiety and further use CBD with high THC levels or even cannabis [41]. Although there were few related themes on Xiaohongshu, China would face the same situation with the rapid growth of the e-cigarette market. Therefore, it is urgent to conduct education and intervention in schools or entertainment venues. In addition, it is necessary to improve the detection of THC in CBD products. A previous study reported several CBD products with excessive THC in the European market [15]. The customs department should strengthen its supervision of the imported e-liquid. On Xiaohongshu, internet celebrities often introduced the main ingredient CBD and its relationship with cannabis when they shared the experience of using cosmetics. However, some of the contents lacked scientific evidence or were fake news. These kinds of fake news on social media mislead people and put public health at risk [42]. Therefore, social media should exercise professional responsibility to ensure that accurate information is published and disseminated. Policy makers need to penalize false or unsubstantiated CBD advertisement claims, especially for CBD foods with unclear efficacy. Any products making claims for therapeutic or medical use must be approved by regulatory authorities upon submission of data. In addition, regulators should strengthen the training of health care providers to ensure the safety and effectiveness of the prescriptions.

Finally, the sentiment polarity of comments on the 2 social media platforms reflected that users' attitudes toward CBD products differed. The almost overwhelmingly positive comments on cosmetics showed the popularity of CBD cosmetics among Chinese consumers. Most of the comments on Reddit focused on CBD health care products, but the proportion of negative comments was higher than that on Xiaohongshu. In contrast to China's drug policy, people in the West (ie, the United States and European countries) are free to buy and use medical CBD products. However, the therapeutic efficacy with actual experience may be lower than the advertised therapeutic efficacy, leading to more negative comments on social media. For example, 1 user said that the use of CBD oil did not alleviate body pain at all, and that the illness was finally cured by routine clinical treatment. In addition, the discussion on the legal status of CBD revolves around the question of whether it is a drug or food supplement. Many products were labeled as food to avoid regulation, but current data show that consumers, both in China and the West, are not particularly concerned about it. Overall, users were more positive about CBD products on social media in China, even though CBD is still illegal. As an emerging trend, domestic consumers know little about CBD and do not know enough about its management requirements and use risks, so the government should focus on publicizing CBD-related scientific evidence and management measures. Public health communities need to keep abreast of the latest research and implement evidence-based practice standards and guidelines to reduce the risk of potential misuse of CBD products.

Limitations

This study has several limitations. Our data were collected from social media, which are mostly used by internet-savvy young people. Therefore, there may be a lack of input from older adults who rarely use social media. However, considering that the primary consumers of CBD products are young people, our study represented most of the target population. In addition, the user demographics of Reddit and Xiaohongshu are not representative of all Western and Chinese populations. It is necessary to investigate more users beyond social media platforms to evaluate actual consumer attitudes. The NLP analysis is correlated with the amount of data, and the relatively precise search strategy used in this study may limit the size of the corpus. We will expand our corpus from other platforms to train a more comprehensive topic model. Also, as a formative study, more traditional measures of consumers' behavior are needed in addition to study on other social media platforms. Therefore, future research should consider analyzing more data on other social media platforms to explore users' attitudes toward CBD more comprehensively.

Conclusions

We collected posts related to CBD products from Reddit and Xiaohongshu and conducted theme mining using the LDA model. We analyzed the characteristics of the themes on social media and performed sentiment polarity on posts' comments to compare users' attitudes toward CBD products from different countries. The results showed that consumers in countries with different substance management policies had significantly different attitudes toward CBD. Therefore, more targeted CBD management measures should be formulated to suit each country's national conditions. In addition, we hope that this study can provide a reference for other countries where CBD has not been approved for use in medicines, cosmetics, and food.

Abstract

Background: The rising number of migrants worldwide, including in China given its recent rapid economic development, poses a challenge for the public health system to prevent infectious diseases, including sexually transmitted infections (STIs) caused by risky sexual behaviors.

Objective: The aim of this study was to explore the risky sexual behaviors of international immigrants living in China to provide evidence for establishment of a localized public health service system.

Methods: Risky sexual behaviors were divided into multiple sexual partners and unprotected sexual behaviors. Basic characteristics, sexual knowledge, and behaviors of international immigrants were summarized with descriptive statistics. Multivariate logistic regression analyses were used to identify factors associated with risky sexual behaviors, and the associations of demographic characteristics and risk behaviors with HIV testing and intention to test for HIV.

Results: In total, 1433 international immigrants were included in the study, 61.76% (n=885) of whom had never heard of STIs, and the mean HIV knowledge score was 5.42 (SD 2.138). Overall, 8.23% (118/1433) of the participants had been diagnosed with an STI. Among the 1433 international immigrants, 292 indicated that they never use a condom for homosexual sex, followed by sex with a stable partner (n=252), commercial sex (n=236), group sex (n=175), and casual sex (n=137). In addition, 119 of the international immigrants had more than three sex partners. Individuals aged 31-40 years were more likely to have multiple sexual partners (adjusted odds ratio [AOR] 2.364, 95% CI 1.149-4.862). Married participants were more likely to have unprotected sexual behaviors (AOR 3.096, 95% CI –1.705 to 5.620), whereas Asians were less likely to have multiple sexual partners (AOR 0.446, 95% CI 0.328-0.607) and unprotected sexual behaviors (AOR 0.328, 95% CI 0.219-0.492). Women were more likely to have taken an HIV test than men (AOR 1.413, 95% CI 1.085-1.841). Those who were married (AOR 0.577, 95% CI 0.372-0.894), with an annual disposable income >150,000 yuan (~US $22,000; AOR 0.661, 95% CI 0.439-0.995), considered it impossible to become infected with HIV (AOR 0.564, 95% CI 0.327-0.972), and of Asian ethnicity (AOR 0.330, 95% CI 0.261-0.417) were less likely to have an HIV test. People who had multiple sexual partners were more likely to have taken an HIV test (AOR 2.041, 95% CI 1.442-2.890) and had greater intention to test for HIV (AOR 1.651, 95% CI 1.208-2.258).

Conclusions: International immigrants in China exhibit risky sexual behaviors, especially those aged over 30 years. In addition, the level of HIV-related knowledge is generally low. Therefore, health interventions such as targeted, tailored programming including education and testing are urgently needed to prevent new HIV infections and transmission among international immigrants and the local population.

(JMIR Public Health Surveill 2023;9:e35713) doi:10.2196/35713

KEYWORDS

international immigrants; HIV; risky sexual behavior; China

Introduction

Under globalization, the number of international travelers has increased significantly worldwide during the past decade, from 2433 million in 2008 to 3188 million in 2019 [1,2]. Owing to its rapid economic development, China has become a popular country and attracted numerous international immigrants. For example, the National Bureau of Statistics showed that approximately 845,697 international immigrants lived in China in 2020, increasing by 251,865 compared to that recorded in 2010 [3,4]. Thus, an increasing number of international immigrants settled in China with different ethnic backgrounds and cultures, and this significant number of immigrants can inevitably cause some public health problems [5]. The health challenges posed by migration, not only for the immigrants themselves but also for residents, have become an important global health issue. For example, migration has proven to be a risk factor for sexually transmitted infections (STIs), especially with respect to the spread of HIV to residents of the destination country during unprotected sexual encounters [6]. Risky sexual behaviors might increase upon immigration given the removal of factors that might inhibit sexual freedom in the home country, including physical separation of partners or social networks, escaping from the pressure of home community or social culture, and especially an increase in casual sex [7].

The total number of people living with HIV/AIDS worldwide increased from 31.1 million in 2010 to 37.7 million in 2020 [8]. However, new HIV infections have declined by 31%, from 2.1 million in 2010 to 1.5 million in 2020 [8]. Migration has become one of the key issues related to HIV prevention and control in recent years considering the increasing number of HIV infections among migrants [9]. Indeed, since the beginning of the HIV epidemic, governments have been worried that migrants may be largely responsible for spreading HIV [10,11]. However, specific public health responses have not yet been established to monitor HIV among migrants, especially international immigrants, in most countries. Considering that the majority of international immigrants are sexually active young people and their interaction with local Chinese residents is inevitable, active responses for public health and related research are particularly important.

In China, the number of newly reported HIV-infected international immigrants reached up to 15,319 between 2004 and 2017 [12], although there is currently no mandatory screening for HIV or other STIs for international immigrants in China. Most studies regarding the sexual behaviors of international immigrants have been conducted in high-income countries such as the United States, Canada, and the United Kingdom [13-15]. The status of sexual behaviors among international immigrants living in China is currently unclear. Moreover, considering the differences in cultures and health services, interventions that are employed in high-income countries may not be suitable for international immigrants in China. Therefore, we aimed to explore the risky sexual behaviors of international immigrants living in China to provide evidence for establishment of a localized public health service system to address the significant increase in the number of international immigrants under globalization.

Methods

Participants

We used a cross-sectional web-based study design to collect data from international immigrants living in China by a snowball sampling method. Three to six international immigrants with different occupations, ages, home countries, and genders from Yiwu, Guangzhou, Beijing, and Hangzhou were invited to start the investigation. These immigrants were then asked to invite other international immigrants living in China to participate in the survey to expand the sample. We selected these locations in particular because Yiwu, as one of the largest commodity trading cities, attracts nearly half a million international immigrants every year [16]; Guangzhou is located in the core of the Pearl River Delta [17], and is also an important trading port representing one of the cities receiving a significant number of international immigrants; Beijing is the capital of China, which is bound to attract a substantial number of foreign people as the political center; and Hangzhou is the provincial capital of Zhejiang and located in the eastern coast of China, which has developed rapidly in recent years because of the high-tech service industry, resulting in a large foreign population.

The inclusion criteria of participants were: (1) international immigrants whose homeland was not China but were living in China, (2) above 18 years old, (3) could read English, and (4) willing to participate in the study. The exclusion criteria were: (1) under 18 years old; (2) Chinese nationality; and 3) did not pass the “attention check” in the questionnaire, which was used to identify careless respondents and improve the data quality.

The sample size was calculated based on the 31.14% HIV diagnosis risk among international immigrants according to previous studies [11,18], which required at least 330 participants. We also estimated the sample size based on 5-10 times the number of questions in the questionnaire, which required 650 respondents. To select the maximum representative sample from the population, 1460 participants were recruited and the responses of 1433 international immigrants were incorporated in the final analysis.

Data Collection

Considering the sensitivity of sexual issues and the COVID-19 pandemic, we used an online questionnaire rather than a face-to-face survey, which was conducted between January and September 2021, including sociodemographic information (eg, gender, age, marital status, education level, employment, and annual disposable income), HIV-related knowledge, STIs history (eg, diagnosis of genital herpes, syphilis, and condyloma in the past), HIV testing history (ie, have taken an HIV test in the past), and intention to have an HIV test in the future.

In addition, all participants were invited to recall their related sexual behaviors while living in China in the past year. Sexual behavior–related data included the number of sexual partners; condom use; stable, casual, commercial, homosexual, and group sexual behaviors; as well as illicit drug use. Risky sexual behaviors were classified as having multiple sexual partners and unprotected sexual behaviors. HIV-related knowledge was measured using the 8-item HIV Knowledge Questionnaire (HIV-KQ-8) [19]. If the answer was correct, a score of 1 was assigned, whereas a score of 0 was given if the answer was wrong or “do not know.” HIV/STIs knowledge was finally evaluated by the total scores, with a maximum score of 8 if all answers were correct; thus, a higher score represented a higher level of HIV/STIs knowledge among international immigrants. The questions regarding sexual behaviors were designed based on the guidelines of intervention work for the prevention of HIV/AIDS issued by the China Center for Disease Control and our previous study [20,21]. The reliability and validity of the questionnaires were confirmed using Cronbach α (.996) and the Kaiser-Meyer-Olkin test (0.961).

Ethics Considerations

The study protocol and consent procedure were approved by the Ethics Review Committee, School of Public Health, Zhejiang University (#2019-064). Informed consent information was provided before the questions; participants had the option to exit the survey after reading the informed consent information or to provide consent to continue. The confidentiality of individuals was properly protected in the management of the investigation and the processing of data.

Statistical Analysis

Descriptive statistics were used to analyze the basic characteristics, sexual-related knowledge, and sexual behaviors of international immigrants using frequency and percentage or mean (SD) as appropriate. Univariate and multivariate logistic regression analyses were used to identify the factors associated with risky sexual behaviors among international immigrants and the association with HIV test history and intention to receive an HIV test in the future. SPSS 24.0 statistical software (IBM, Armonk, NY, USA) was used to analyze all data. *P*<.05 was considered to indicate a statistically significant association.

Results

Basic Characteristics of International Immigrants in China

In total, 1433 international immigrants were included in the study, with a predominance of men (Table 1). The average age was approximately 25 years and most of the participants were well-educated with 68.95% (988/1433) reporting more than 11 years of education. The annual disposable income of the majority of the international immigrants was less than 50,000 yuan (~US $7200). The majority of the respondents were unmarried, and the largest proportion of immigrants were from Africa, followed by America, Europe, and Asia (Table 1).

[b] There were 31 responses missing.

Knowledge on HIV Among International Immigrants in China

Among the 1433 international immigrants, 61.76% (885) had never heard of STIs or HIV. Among the immigrants who had heard of HIV/STIs, the mean knowledge score on HIV was 5.42 (SD 2.138). The percentage of respondents with an HIV knowledge score <4, 4-6, and >6 was 6.98% (100/1433), 17.31% (248/1433), and 13.89% (199/1433), respectively.

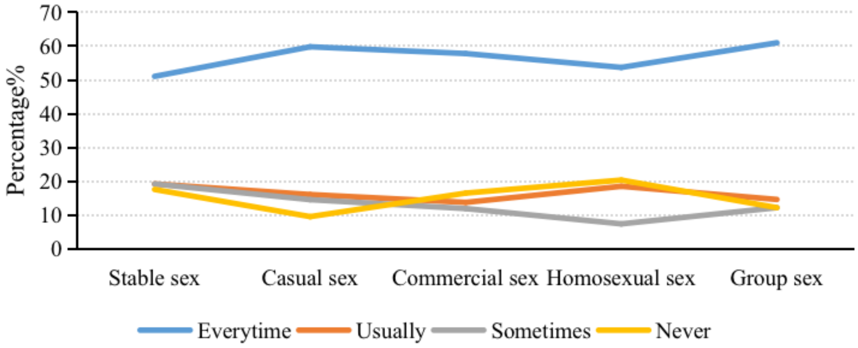
Self-Report of STIs Among International Immigrants

Overall, 91.77% (1315/1433) of international immigrants had not been diagnosed with any STIs, whereas 8.23% (118/1433) of the international immigrants had been diagnosed with at least one STI, including gonorrhea (16/1433, 1.12%), syphilis (12/1433, 0.84%), condyloma acuminatum (1/1433, 0.07%), herpes progenitalis (3/1433, 0.21%), hepatitis B (9/1433, 0.63%), and hepatitis C (2/1433, 0.14%). In addition, 4.82% (69/1433) of the participants had been diagnosed with HIV.

Risky Sexual Behaviors

As shown in Figure 1, more than 50% of international immigrants reported using a condom during sexual behaviors. However, 20.38% (292/1433) of international immigrants engaging in homosexual sex reported never using condoms, followed by 17.59% (252/1433) in stable sexual relationships, 16.47% (236/1433) engaging in commercial sex, 12.21% (175/1433) for group sex, and 9.56% (137/1433) for casual sex. In addition, 8.30% (119/1433) of international immigrants had more than three sexual partners.

Figure 1. Frequency of condom use according to sexual behavior among international immigrants.



Factors Associated With Risky Sexual Behaviors Among International Immigrants

The binary logistic regression model showed the factors affecting whether the respondents had multiple partners or unprotected sex as a risky sexual behavior (see Table S1 in Multimedia Appendix 1). We found that being aged 31-40 years was significantly associated with having multiple partners (adjusted odds ratio [AOR] 2.364, 95% CI 1.149-4.862). Married respondents indicated more unprotected risk behaviors (AOR 3.096, 95% CI –1.705 to 5.620) compared with unmarried respondents. Asians tended to have fewer multiple partners (AOR 0.446, 95% CI 0.328-0.607) and unprotected risk behaviors (AOR 0.328, 95% CI 0.219-0.492) compared with Africans.

Demographic Characteristics, Risk Behaviors, and Their Association With HIV Testing and Intention to Test for HIV

Table S2 in Multimedia Appendix 1 shows the associations of demographic characteristics and risk behaviors with HIV testing. Women had a higher probability of having taken an HIV test in the past than men (AOR 1.413, 95% CI 1.085-1.841). People who were married had less intention to take an HIV test (AOR 0.577, 95% CI 0.372-0.894) compared to unmarried respondents. Those considering it to be impossible to become infected with HIV were less likely to have ever taken an HIV test (AOR 0.523, 95% CI 0.281-0.975) or to intend to take an HIV test (AOR 0.564, 95% CI 0.327-0.972) compared with those who thought it could be possible to become infected. Compared to respondents who did not have multiple sex partners, those who reported having multiple sexual partners were more likely to intend to test for HIV (AOR 1.797, 95% CI 1.324-2.438). Furthermore, Asians were less likely to indicate an intention to be tested for HIV (AOR 0.330, 95% CI 0.261-0.417).

Discussion

Principal Findings

International immigrants in China exhibited risky sexual behaviors, with 22.40% and 13.19% of the respondents reporting having multiple sexual partners and unprotected sexual behaviors, respectively. These trends may be partly related to the differences in the new living environment faced by international immigrants from those of the homeland. For example, the absence of family and peer monitoring, language barriers, cultural barriers, and a sense of anonymity may offer immigrants more sexual freedom [22,23]. In addition, 4.82% of the respondents reported that they have been diagnosed with HIV. Therefore, the risk of HIV transmission and infection among international immigrants exists, and interventions are urgently needed to control the HIV epidemic caused by international migration in China.

HIV knowledge is a significant factor contributing to HIV prevention [14]. Previous studies also showed that enhanced knowledge moderated sexual risk behaviors, and HIV knowledge increased safer-sex intentions, condom use, abstinence, and HIV testing and treatment [24-27]. However, the majority of the international immigrants surveyed in our study had never heard of STIs, and the knowledge scores of the participants who were aware of HIV were also quite low. A study in Canada suggested that those born in sub-Saharan African also scored relatively low on the HIV knowledge questionnaire, which was consistent with our results [14]. Based on our analysis between Chinese nationals and international immigrants, the mean score of HIV-related knowledge of international immigrants who had heard of HIV (5.42, SD 2.14) was lower than that of Chinese nationals (6.68, SD 2.08), and there was a much higher number of international immigrants who had never heard of HIV (61.76%) compared to Chinese nationals (5.48%). These results were consistent with previous research [28]. The reasons may include that immigrants represent a marginalized group, who may not receive any HIV education in either their homeland or destination country. However, there are also discrepancies among studies related to the extent of HIV knowledge among immigrants. For example, a study in Thailand indicated that immigrants exhibited a fairly high standard of knowledge about the risk factors of HIV [5], and this knowledge increased among immigrants who had heard of HIV after they came to Thailand, which also showed that they obtained adequate education from the local government. Another study performed in South Korea also found that immigrant workers exhibited better knowledge of HIV compared with Korean respondents [29]. These differences may be caused by the fact that the participants in our study mostly migrated from low- and middle-income countries, where HIV-related resources are limited.

The age group of 30-60 years was significantly associated with having more risky sexual behaviors among the international immigrants surveyed in our study, which was consistent with the majority of previous related studies. This may be related to the fact that this age corresponds to a more physiologically sexually active group, who may have sex with multiple partners without protection. A previous study published in 2018 also reached a similar conclusion, showing that adults of this age group were more likely to have sex without a condom, new sexual partners, and multiple sexual partners [30]. In addition, consistent with a prior study showing that married people tended to have more high-risk sexual behaviors [31], we found that married individuals tended to have more unprotected sexual behaviors than unmarried individuals. There are several possible reasons for this difference. For example, a traditional culture that does not permit engaging in sexual behaviors before marriage could cause more risky sexual behaviors among married than unmarried individuals. In addition, married people may plan to have a baby, which would be accompanied by unprotected sex [32]. Moreover, some people find it shameful to use condoms once married or are pursuing the physical and psychological satisfaction from unprotected sex [13]. However, in our study, 16.13% of the married respondents indicated engaging in unprotected sexual behaviors not with their stable partners. For instance, a prior study also showed that married immigrant men tended to have affairs [33], and 28.48% of the migrant workers who lived apart from their spouses had extramarital sexual behaviors [34]. People engaging in casual sex, commercial sex, homosexual sex, and group sex are considered to be a high-risk population for STIs, and the frequency of condom use was rather low among international immigrants; therefore, health education is necessary and important for these international immigrants. Moreover, the environment of field testing for HIV typically has poor privacy protection, which may lead those at high risk of worrying about disclosure of personal information, especially for international immigrants who may be more insecure about whether they will be able to settle in the destination country if they are diagnosed with HIV.

With respect to the influence of the origin region of the immigrants, we found that Asians exhibited less risky sexual behaviors but also had reduced intention to be tested for HIV compared with Africans. The possible reasons for these differences may include that polygamy still exists in some areas of Africa, especially in some sub-Saharan African countries [35], and international immigrants from Africa tend to have little knowledge about HIV [36,37]. These factors may influence their sexual behaviors, especially increasing the risk of having multiple sexual partners and unprotected sexual behaviors. In addition, the fact that Africa had the highest number of people living with HIV in 2020, suggesting that Africans are most heavily affected by HIV [38], may cause their higher intention to receive an HIV test in the future compared with Asians. Among international immigrants, homosexuals were less likely to have ever tested for HIV than heterosexuals. Generally, homosexuals are considered to engage in risky sexual behaviors. Without an HIV test, the infection status would be unknown, which would place their partners at greater risk for the transmission of HIV and other STIs. Moreover, the proportion of HIV infections transmitted through homosexual behaviors has increased significantly in recent years [31]; thus, there is an urgent need to promote HIV testing among this high-risk group.

Limitations

This study had some limitations. First, it is possible that the participants were influenced by social and cultural norms to hide their risky sexual behavior, including a history of commercial or casual sexual behaviors, which may affect the research results, although an online survey could avoid the embarrassment caused by a face-to-face survey. Second, although the seed participants were selected to have different occupations, ages, homelands, and genders from different cities, a bias caused by snowball sampling may still exist, which could lead to misinterpretation of the related statistical results. In addition, considering the significant number of international immigrants living in China, our participants were mainly from lower socioeconomic strata with a lower annual disposable income, which represents a narrow band of the socioeconomic system. Therefore, the results may not be generalizable to the whole population. Third, the questionnaire regarding risky sexual behaviors was designed based on previous work and was amended according to our research participants and objectives. Thus, the validity of the questionnaire in the survey should be further tested.

Implications for Health Policy

Globalization leads to an inevitable trend of increased population mobility. Under this situation, it is necessary to take proactive public health approaches to manage the health of international immigrants, especially with respect to infectious diseases. Our study showed that the overall HIV-related knowledge of the international immigrants in China was low along with a low rate of intention to test for HIV. Therefore, HIV-related education is essential, such as by community advocacy and online propaganda delivered in their native languages, to address the gaps in HIV knowledge among international immigrants. More importantly, it is difficult for international immigrants to access HIV-related services because of the lack of specified health care and prevention upon arrival in the new country, which may cause immigrants with an HIV-positive status to remain undiscovered until some typical symptoms appear. To prevent the transmission of HIV, the basic public health care services provided by the Chinese government should be extended to cover international immigrants. Active promotion for antiviral treatment is less available for international immigrants with HIV infection than for local residents in China. Thus, an integrated health system for HIV prevention, monitoring, and treatment for immigrants and local residents will be important to reduce the transmission rate of HIV. Moreover, this is also necessary to reduce the inequities in access to health care and health outcomes for immigrants. It is also important to consider the wider health care and socioeconomic barriers immigrants face to be successful in improving HIV outcomes. In addition, as a convenient and efficient method, HIV self-testing could be promoted among international immigrants, such as setting up rapid detection kit vending machine in immigrant gathering communities [39]. Moreover, online measures, including HIV testing, education, and interventions, could be developed using the internet and big data to solve the privacy issues that are a major concern of international immigrants.

Conclusion

Risky sexual behaviors exist among international immigrants in China, including multiple partners and unprotected sexual behaviors, and the level of cognition of HIV knowledge was quite low, especially for married immigrants and those aged above 30 years. Therefore, there is an urgent need to promote health education and HIV testing specified for international immigrants. In addition, it is also important to develop and improve health care access for international immigrants under the current situation of increasing globalization.

Acknowledgments

We are grateful to all study participants for their valuable participation. Abstract

Background: Mobile voluntary counseling and testing (VCT) for HIV has been carried out to improve the targeting of at-risk populations and HIV case detection for men who have sex with men (MSM). However, the HIV-positive detection rate using this screening strategy has declined in recent years. This may imply unknown changes in risk-taking and protective features jointly influencing the testing results. These changing patterns in this key population remain unexplored.

Objective: The aim of this study was to identify the nuanced group classification of MSM who underwent mobile VCT using latent class analysis (LCA), and to compare the difference in characteristics and testing results between subgroups.

Methods: A cross-sectional research design and purposive sampling were applied between May 21, 2019, and December 31, 2019. Participants were recruited by a well-trained research assistant through social networking platforms, including the most popular instant messenger app Line, geosocial network apps dedicated to MSM, and online communities. Mobile VCT was provided to participants at an assigned time and place. Demographic characteristics and risk-taking and protective features of the MSM were collected via online questionnaires. LCA was used to identify discrete subgroups based on four risk-taking indicators—multiple sexual partners (MSP), unprotected anal intercourse (UAI), recreational drug use within the past 3 months, and history of sexually transmitted diseases—and three protective indicators—experience of postexposure prophylaxis, preexposure prophylaxis use, and regular HIV testing.

Results: Overall, 1018 participants (mean age 30.17, SD 7.29 years) were included. A three-class model provided the best fit. Classes 1, 2, and 3 corresponded to the highest risk (n=175, 17.19%), highest protection (n=121, 11.89%), and low risk and low protection (n=722, 70.92%), respectively. Compared to those of class 3, class 1 participants were more likely to have MSP and UAI within the past 3 months, to be ≥40 years of age (odds ratio [OR] 2.197, 95% CI 1.357-3.558; *P*=.001), to have HIV-positive results (OR 6.47, 95% CI 2.272-18.482; *P*<.001), and a CD4 count ≤349/μL (OR 17.50, 95% CI 1.223-250.357; *P*=.04). Class

2 participants were more likely to adopt biomedical preventions and have marital experience (OR 2.55, 95% CI 1.033-6.277; *P*=.04).

Conclusions: LCA helped derive a classification of risk-taking and protection subgroups among MSM who underwent mobile VCT. These results may inform policies for simplifying the prescreening assessment and more precisely recognizing those who have higher probabilities of risk-taking features but remain undiagnosed targets, including MSM engaging in MSP and UAI within the past 3 months and those ≥40 years old. These results could be applied to tailor HIV prevention and testing programs.

Introduction

Background

Owing to the success of antiretroviral therapy for people infected with HIV, and the promotion of HIV screening and prophylactic medications for at-risk populations [1-3], the annual incidence rate of HIV infections among adults has declined globally by 31% between 2010 and 2021 [4]. In Taiwan, an estimated 90% of people living with HIV (PLWH) know their HIV status and 93% of them have initiated antiretroviral treatment, 95% of whom have achieved viral suppression [5]. To reach the World Health Organization’s goal of eliminating HIV infection by 2030, improving the access of the remaining undiagnosed target groups to screening is a critical strategy in HIV case detection and epidemic control [6].

The remaining undiagnosed PLWH require aggressive testing measures to facilitate an early diagnosis. Mobile voluntary counseling and testing (VCT) for HIV is a novel screening method in Taiwan, carried out by disseminating recruitment messages through social networking platforms to deliver testing services to specific groups at a specific time and location [7]. Compared to an outreach model of screening based at a community station, mobile VCT is more flexible with respect to the time and location of testing; therefore, the targeting of at-risk populations and case discovery are improved in the mobile VCT model [8,9]. However, the number of newly diagnosed HIV infections in Taiwan has been declining annually since 2017 [10] and the number of people that are positive for HIV associated with mobile VCT is also decreasing [7], which implies unknown changes in HIV risk-taking patterns and the influence of protective features in people who are uninfected. A possible inference could be that people who were previously at risk of HIV may have reduced their risk-taking behaviors, including avoiding having multiple sexual partners (MSP) and having unprotected anal intercourse (UAI), and abstaining from recreational drug use; concurrently, they may have adopted higher biomedical protection measures, including regular HIV testing, and when necessary, taking postexposure prophylaxis (PEP) and preexposure prophylaxis (PrEP) [11-14]. To provide HIV testing resources to those with relatively high priority needs in a mobile VCT service, it is necessary to be able to precisely recognize those who encompass a higher probability of risk-taking features and a lower probability of protective features. However, the feature classification of MSM who participate in mobile VCT remains unknown.

Latent class analysis (LCA) is a mixture model that is used to identify latent heterogeneity driven by class membership according to responses to a set of observed variables [15]. The theoretical assumption underlying LCA is that an individual shares both latent and observed categorical variables, and membership in unobserved classes can cause or explain patterns of scores across assessment indicators [16,17]. More specifically, LCA helps to identify similar characteristics among individuals to derive subgroups. LCA has been used to discern patterns of HIV risk based on demographic characteristics [18,19] and behaviors [20,21], helping define and target distinct groups. According to the theoretical basis and hypotheses of LCA, as well as previous research findings, LCA is appropriate for analysis of unidentified patterns in MSM who receive mobile VCT.

Objective

The aim of this study was to identify the nuanced group classification based on the risk and protective profile of MSM who accepted mobile VCT using LCA, and then to compare the characteristics and HIV testing results between subgroups to further determine groups of individuals with different patterns.

Methods

Study Design

A cross-sectional research design and purposive sampling were applied. Participants were recruited via social networking platforms. After completing an online questionnaire, we offered mobile VCT at a designated time and location, according to the participants’ preferences, where they could obtain a rapid HIV test.

Participants

The inclusion criteria were age ≥20 years, being literate, self-identification as an MSM, and self-reported as participating in HIV risk-associated behavior. The exclusion criteria included no self-reported risk factors for HIV infection or being HIV-positive.

Ethical Considerations

This study was approved by the Research Ethics Committee of National Taiwan University (201903ES024), and adhered to the regulations of the Human Subjects Research Act issued by the Ministry of Health and Welfare of Taiwan and the Personal Data Protection Act issued by the National Development

Council in Taiwan. After explaining the study purpose and protocol, the participants were asked to complete an online consent form and questionnaires anonymously through a provided URL; all data were processed anonymously. Participants could withdraw at any time without providing a reason. A mask could be worn during the mobile VCT processes to protect privacy. Each participant was eligible to receive an electronic gift certificate worth US $3.27 after all procedures were completed.

Procedure and Data Collection

The study covered the period from May 21, 2019, to December 31, 2019. Participants were recruited in the same manner as described in a previous study [7]. Social networking platforms were used, including the most popular instant messenger app Line and geosocial network apps dedicated to MSM, such as Grindr, Hornet, Jack'd, Scruff, and Blued. Online communities (such as Facebook fan pages) were used to disseminate the study information and recruit participants. Testing appointments were discussed and booked through one-on-one messaging on each recruiting platform. Mobile VCT was provided by a well-trained research assistant at a designated time and location, such as a convenience store, coffee shop, park, or fast-food restaurant, for participants who live in Taipei City and New Taipei City. Study information was provided to the participants, whose identity was verified through previous messaging records. Prior to the test, participants were asked to fill out an online consent form and questionnaire, which took about 10-15 minutes to complete. Following submission of the questionnaire, the researcher and participant would review and confirm whether there were any missing or questionable answers to ensure completeness of the questionnaire. Pretest counseling was provided and a blood drop was collected via a rapid HIV testing kit. Testing results were available immediately and recorded by the research assistant, and posttest counseling and a referral to the hospital HIV case manager to confirm testing and obtain PEP and PrEP were provided. The whole screening process took approximately 30-40 minutes. The CD4+ T-cell counts of each participant were followed and recorded by the research assistant.

Instruments

Questionnaire

The online questionnaire included 18 closed-ended questions; six were focused on demographic characteristics and 12 were focused on risk-taking and protective features. Demographic characteristics of interest included age, education level, marital experience, monthly income, sexual orientation, and if participants were open about their MSM status. HIV risk-taking features included preferred sexual position; number of sexual partners within the past 3 months; frequency of condom use during the previous 10 occasions of anal intercourse within the past 3 months; experience of recreational drug use within the past 3 months, including the number of types of drugs; and history of sexually transmitted diseases (STDs; including syphilis, gonorrhea, genital herpes, chlamydia, human papillomavirus, pubic lice, and hepatitis A, B, and C). HIV-preventing features included awareness of PEP and PrEP, experience of using PEP and PrEP, experience of HIV testing, and frequency of HIV testing.

Rapid HIV Self-Testing Kits

The Alere Determine HIV-1/2 rapid testing kit was used to test for HIV-1/HIV-2 antibodies in the human serum or plasma. This kit is licensed by the Taiwan Food and Drug Administration, and has specificity and sensitivity values of 99.87% and 99.75%, respectively [22]. Results were obtained within approximately 15 minutes and were managed and recorded by trained staff.

Indicator Selection for LCA

Risk-taking– and protection-related indicators were considered conditionally independent and were defined based on previous studies [11-14] and expert input; risk-taking–related indicators were defined as behaviors that directly lead to HIV infection or the features that significantly increase the risk of HIV infection, and the protection-related indicators were defined as proactive HIV screening or preventive drug administration. Three specialists, including an infectious disease physician, HIV case manager, and HIV public health scientist, provided expert input. Finally, seven indicators were selected. The four risk indicators included MSP, UAI, recreational drug use within the past 3 months, and history of STDs. The three protective indicators included experience of PEP use, experience of PrEP use, and regular HIV testing (at 3-6–month intervals when having unprotected sex). All variables were dichotomized (yes vs no).

Statistical Analyses

All data were confirmed to be complete prior to analysis. LCA was performed using the poLCA package within R software (GitHub, Inc) to identify distinct classes based on model fit. The multiple fit statistics, including log likelihood (LL), likelihood ratio test statistic (G^2), Akaike information criterion (AIC), Bayesian information criterion (BIC), and χ^2 goodness of fit, were applied and considered prior to the decision on the model being made [17]. BIC was identified as the best reliable fit statistic model, which is an intuitive calculation method that is commonly used for model selection in univariate and multivariate logistic regression due to its simplicity, and considers the effect of a large sample size to prevent the model from being too complex as a result of high model accuracy [17,23,24]. In addition, we examined the similarity of item-response probability patterns within classes and the interpretability of class separation. Subgroup membership was assigned based on the class of each participant and the highest probability of belonging. A probability of ≥50% per item indicated that group members were more likely to possess a characteristic of interest [19]. The univariable multinomial logistic regression model was applied to determine differences in class characteristics and testing outcomes.

Results

Study Population

In total, 1023 participants made an appointment for mobile VCT via social networking platforms during the study period. Five (0.49%) participants did not attend the testing appointment and lost contact without a reason. A total of 1018 participants completed the questionnaire and entered the screening process. The participants' characteristics are presented in Table 1. The participants' median age was 30.17 (IQR 25-34) years. Most participants were in the age range of 20-29 years, had college- or university-level education, had never been married, and had a stable monthly income of approximately US $714-$1783. Most participants were MSM, and had had a come-out experience, preferred both top and bottom sex positions, had both casual partners and MSP, and frequently used condoms (7-9 times per 10 sexual encounters). Some participants self-reported using recreational drugs (116/1018, 11.39%) within the past 3 months, with the majority indicating the use of one or two substances. Approximately one-fifth had a history of STDs, including, human papillomavirus (106/222, 47.7%), syphilis (71/222, 31.98%), gonorrhea (50/222, 22.5%), hepatitis B (33/222, 14.9%), pubic lice (31/222, 13.96%), genital herpes (18/222, 8.1%), chlamydia (11/222, 4.95%), hepatitis A (11/222, 4.95%), and hepatitis C (10/222, 4.5%). Most participants were aware of PEP, although few had used it. Most participants were aware of PrEP, although again few had used it. Furthermore, most participants had experience of HIV testing, including testing every 3-6 months. Eighteen participants were newly HIV-positive; 9 of whom had a CD4 count ≥350/μL and nine of whom had a CD4 count ≤349/μL.

[a] MSM: men who have sex with men.

[b] Within the past 3 months.

[c] STD: sexually transmitted disease (including syphilis, gonorrhea, genital herpes, chlamydia, human papillomavirus, pubic lice, and hepatitis A, B, and C).

[d] PEP: postexposure prophylaxis.

[e] PrEP: preexposure prophylaxis.

LCA Results

After entering the seven indicators selected for LCA, the outcomes of 2-6 latent classes were produced and compared. The final model was determined according to the lowest value of BIC and class separation, although the lowest values of LL, AIC, G^2, and χ^2 were inconsistent with those of BIC (Table 2). A three-class model was selected, based on fit statistics and model interpretation. Table 3 presents the probabilities of HIV risk-taking and the protective profile of the three-class model.

Classes 1, 2, and 3 represented the highest risk (n=175, 17.2%), highest protection (n=121, 11.9%), and low risk and low protection (n=722, 70.9%), respectively. Participants in class 1 had the highest risk of having MSP and UAI; they were also more likely to get tested regularly. Participants in class 2 had the highest probabilities of protective features, including experience of PEP and PrEP and regular HIV testing, whereas they had a medium risk of having MSP and UAI. Compared to those of classes 1 and 2, participants in class 3 had a lower risk of having MSP and UAI, and they tended to get regularly tested, which was considered an HIV-protection feature (Table 3).

Table 2. Goodness of fit indices for model selection.

Model	LL[a]	G^{2b}	AIC[c]	BIC[d]	χ^2	*df*	Number of parameters
1-class	–3683.55	471.03	7381.11	7415.59	894.34	120	7

[c] AIC: Akaike information criterion.

[d] BIC: Bayesian information criterion.

[e] The selected class based on the lowest BIC value.

Table 3. Posterior probabilities (%) for the three-class model (N=1018).[a]

Indicators	Class 1, highest risk (n=175, 17.2%)	Class 2, highest protection (n=121, 11.9%)	Class 3, low risk and low protection (n=722, 70.9%)
Risk-taking indicators			
Multiple sexual partners[b]	96.5	66.3	51.1
Unprotected anal intercourse[b,c]	100.0	58.8	52.7
Experience of recreational drug use[b]	23.2	13.4	7.1
Experience of STDs[d]	43.8	24.6	14.0
Protective indicators			
Experience of using PEP[e]	8.4	76.3	2.8
Experience of using PrEP[f]	16.1	67.0	1.3
Regular HIV testing[g]	74.8	94.4	51.7

[a] Probabilities greater than 50% indicate items for which members of a given class were more likely to be classified within that class.

[b] Within the past 3 months.

[c] Not using a condom every time during past 10 encounters of anal intercourse.

[d] STD: sexually transmitted disease (including syphilis, gonorrhea, genital herpes, chlamydia, human papillomavirus, pubic lice, and hepatitis A, B, and C).

[e] PEP: postexposure prophylaxis.

[f] PrEP: preexposure prophylaxis.

[g] Testing frequency between 3 and 6 months in the case of regular unprotected sex.

Univariable Multinomial Logistic Regression Results

Class 3 was used as a reference due to the lower probability of HIV risk and protective features. Compared to those of class 3, class 1 participants were more likely to be ≥40 years old, to have an HIV-positive test result, and a CD4 count ≤349/μL. Class 2 participants were more likely to have been married (Table 4 and Table 5).

Discussion

Principal Results

LCA was used to derive three subgroups, based on best fit statistics and model interpretation, of MSM who underwent mobile VCT via social networking platforms. Two risk-taking indicators (having MSP and UAI) and three protective indicators (experience of PEP, experience of PrEP, and regular HIV testing) had probabilities >50% and were used to determine discrete classes in the final model. The profile of the highest risk group was class 1. The three classes were heterogeneous in age and marital history. These findings may help to identify subgroups suitable for targeted interventions and HIV testing.

MSP and UAI were two risk indicators that exceeded 50% in all three groups. Previous studies have confirmed that having experience of MSP and UAI can be one of the predictive factors for HIV-positivity rates of MSM [25,26]. The results of this study provide additional information; that is, the participants who were >40 years old were more likely to be grouped in class 1 and were at an increased risk of HIV and late diagnosis. Higher probabilities of MSP and UAI and age >40 years concurrently could be the first risk assessment items for setting priorities of those who need to be tested, especially when mobile VCT represents a competitive resource and needs to be applied precisely for those in the highest risk group. This result echoes a previous discussion that, compared to younger-aged MSM, middle-aged (40-50 years) adults are still at high risk for HIV infection [27]. The emergence of dating apps has enabled older MSM to connect with a different generation and to participate in condomless sexual activity [28]. Furthermore, feelings of loneliness and fatigue associated with HIV prevention may increase the risk of unprotected sexual encounters and the number of sexual partners among older MSM, thereby increasing the infection risk [29,30]. Additionally, the signs and symptoms of early HIV infection, including persistent influenza-like symptoms, herpes zoster, a single episode of bacterial pneumonia, thrombocytopenia, and lymphocytopenia, may be attributable to diseases of aging, and these people and their caregivers may neglect their risk for HIV and delay HIV testing; therefore, older adults are at increased risk of late diagnosis [31].

The other two risk indicators, drug use within the past 3 months and lifetime STDs, did not exceed a probability of 50% in the three subgroups. There are several possible reasons to explain this finding. Class 1 participants had a drug use probability of 23.2%, which was higher than those in the other classes and was lower than the probability of 77.3% from a previous report based on an online survey in a single Chinese city [32]. This probability was also lower than that previously reported (30%) in a pen-and-paper investigation, without any intervention, from 13 European cities [33]. This difference may be because the previous two studies investigated the experience of recreational drug use in a lifetime, which is longer than the past 3 months considered in this study. In addition, all participants in this study underwent counseling and testing; thus, the self-reported rate of drug use was likely an underestimate. That is, participants may be less likely to report drug use in face-to-face interactions than in online channels and paper questionnaires for fear of judgment and legal consequences. The probability of lifetime STDs (43.8%) in class 1 was higher than those in the other two classes, was comparable to that (43.3%) previously reported in a cross-sectional survey of American urban MSM undergoing a physical examination and STD testing [34], and was higher than that (13.0%) quoted in a study based on self-reports in a Chinese city [35]. Self-reporting of STDs may be limited by the feelings of shame and recall bias [36,37]. However, in this study, compared to the low-risk group, MSM in the highest risk group were more likely to disclose a history of STDs. These participants may believe that STDs are curable and have expected a medical referral for diagnosis and treatment through this consultation. These results suggest that in addition to MSP and UAI, lifetime STDs, especially a history of human papillomavirus, syphilis, and gonorrhea, and recreational drug use within the past 3 months could be considered as the minor risk-taking assessment items for arranging the priority for HIV testing.

The probabilities of the three protective indicators exceeded 50% in class 2 and were higher than those in the other two groups. It is noteworthy that the highest risk group, class 1, engaged in regular testing as the only protective measure, and the probability of taking PrEP and PEP was lower than that in class 2. Although this study did not investigate the reasons that hinder the use of PEP and PrEP in the highest risk group, previous studies have revealed that barriers include the lack of awareness of HIV risk behaviors, side effects and high cost of PrEP, the compliance difficulties and stigma of using PrEP [38,39], and low access to or tolerability of PEP [40]. Furthermore, age and income may have hindered the uptake of PrEP and PEP in this study. The proportion of participants aged ≥40 years in class 1 was 7.6% higher than that of class 2 and the proportion having a monthly income of ≤US $713 in class 1 was 7.5% higher than that of class 2. Older MSM may have a poorer economic status and were less likely to be aware, or have an inappropriate understanding of, PrEP than MSM ≤30 years old, which made them less likely to use it [41,42]. Improving HIV prevention may involve providing counseling on PEP and PrEP use during HIV testing for high-risk targets, including basic knowledge, side effect management, using reminders to ensure compliance, and providing financial and social support that increases the likelihood of preventive medication use [43].

Compared to those of class 3, class 2 participants were more likely to have been married. Studies have shown that approximately half of Chinese MSM intend to marry women and most of them expect to engage in extramarital homosexual relationships [44]. MSM who had recent UAI with unknown partners declared PrEP acquisition intentions [45]. Our findings still require further analysis to understand whether having experience of marriage could facilitate the adoption of HIV-prevention behaviors by MSM to protect their spouses.

Class 3 was the largest group and had lower risk and lower protective features than the other two classes. Over half of the participants in class 3 perceived themselves at risk of HIV infection and regularly undertook convenient, free, and anonymous HIV screening as a protective measure. Thus, HIV testing seems to be the best way to reach those who meet the characteristics of class 3. Accordingly, screening staff should continually reinforce this group of HIV risk-reducing behaviors and provide more protective options to promote the best preventive effect.

Limitations

This study had some limitations. First, convenient sampling was used and participants were recruited mainly in northern Taiwan, thereby reducing the generalizability of the findings and representativeness of the sample. Second, this research was conducted before the COVID-19 outbreak, and thus our results may not be inferenced and applied to the COVID-19 pandemic, since the pattern of risky and protective behaviors could have changed during that period. Third, self-reported data are likely subject to bias, which may affect the validity of these findings. Fourth, this study was cross-sectional, precluding discussions about causality. Fifth, this research did not consider the factors that may affect the acceptance of mobile VCT of MSM with regard to social and environmental aspects, such as avoidance of screening due to discriminatory attitudes of health care providers. In follow-up research, indicators of more dimensions could be added to promote a more comprehensive analysis.

Conclusions

MSM who underwent mobile VCT via social networking platforms exhibited different risk and protection profiles. LCA helped to derive a classification based on risk-taking and protective indicators. These results may inform policies for simplifying the prescreening assessment and precisely recognizing those who have higher risk-taking features but remain undiagnosed targets, including MSM engaging in MSP and UAI within the past 3 months and those ≥40 years old. Longitudinal studies could be conducted to evaluate the efficacy of this approach.

Acknowledgments

The authors would like to thank the Taiwan Centers for Disease Control (program number JK107053) for providing research funding. The authors thank all participants for undergoing mobile VCT and providing valuable information.

Conflicts of Interest

Abstract

Background: Nearly one-third of new HIV infections occurred among youth in 2019 worldwide. Previous studies suggested that student youths living with HIV and nonstudent youths living with HIV might differ in some risk factors, transmission routes, HIV care, and disease outcomes.

Objective: This study aimed to compare the HIV epidemic, disease outcomes, and access to care among student and nonstudent youths living with HIV aged 16 to 25 years in Guangxi, China.

Methods: We performed a historical cohort study by extracting data on all HIV or AIDS cases aged 16 to 25 years in Guangxi, China, during 1996-2019 from the Chinese Comprehensive Response Information Management System of HIV or AIDS. We conducted analyses to assess possible differences in demographic and behavioral characteristics, HIV care, and disease outcomes between student and nonstudent youths living with HIV. Multivariate Cox regression was used to assess differences in mortality and virologic failure between student and nonstudent cases.

Results: A total of 13,839 youths aged 16 to 25 years were infected with HIV during 1996-2019. Among them, 10,202 cases were infected through sexual contact, most of whom were men (n=5507, 54%); 868 (8.5%) were students, and 9334 (91.5%) were not students. The number of student youths living with HIV was lower before 2006 but gradually increased from 2007 to 2019. In contrast, the nonstudent cases increased rapidly in 2005, then gradually declined after 2012. Student cases were mainly infected through homosexual contact (n=614, 70.7% vs n=1447, 15.5%; *P*<.001), while nonstudent cases were more likely to be infected through heterosexual contact (n=7887, 84.5% vs n=254, 29.3%; *P*<.001). Moreover, nonstudent cases had a significantly lower CD4 count than student cases at the time of HIV diagnosis (332 vs 362 cells/µL; *P*<.001). Nonstudents also had a delayed antiretroviral therapy (ART) initiation compared to students (93 days vs 22 days; *P*<.001). Furthermore, the mortality rate of 0.4 and 1.0 deaths per 100 person-years were recorded for student and nonstudent youths with HIV, respectively. Overall, the mortality risk in nonstudent cases was 2.3 times that of student cases (adjusted hazard ratio [AHR] 2.3, 95% CI 1.2-4.2; *P*=.008). The virologic failure rate was 2.3 and 2.6 per 100 person-years among student and nonstudent youths living with HIV, respectively. Nonstudent cases had double the risk of virologic failure compared to student cases (AHR 1.9, 95% CI 1.3-2.6; *P*<.001).

Conclusions: Nonstudent youths living with HIV might face a low CD4 count at the time of HIV diagnosis, delayed ART initiation, and increased risk of death and virologic failure. Thus, HIV prevention and interventions should target youths who dropped out of school early to encourage safe sex and HIV screening, remove barriers to HIV care, and promote early ART initiation to curb the HIV epidemic among youths.

HIV; student; nonstudent; antiretroviral therapy; mortality; China

Introduction

According to the Joint United Nations Programme on HIV/AIDS, 31% of new HIV infections globally occurred among youths aged 15 to 24 years in 2019 [1]. Sexual transmission, including heterosexual and homosexual transmission, was the primary route of HIV/AIDS transmission among young people [1-4]. In China, the incidence rate of HIV/AIDS increased fivefold from 0.27 cases per 100,000 in 2008 to 1.49 cases per 100,000 in 2017. HIV/AIDS is a major cause of death from infectious diseases in adolescents [5]. The number of youths living with HIV showed this increase in some cities [6]. Furthermore, nonstudents aged 15 to 24 years accounted for 81% of HIV cases compared to 19% of students in 2017 [7]. Students and nonstudents might differ in HIV risk and risk factors [8].

Antiretroviral therapy (ART), introduced globally since 1996, improves immune function by suppressing viral replication and dramatically declines the morbidity and mortality of people living with HIV [9]. ART early initiation—initiating ART as early as the day of HIV diagnosis—has numerous benefits, including reducing the HIV epidemic, improving the health status and quality of life, as well as extending the life expectancy of people living with HIV [10,11]. However, adolescents living with HIV in southern Africa are likely to have less access to HIV care and a hard time adhering to ART compared to adults, which in turn has resulted in negative consequences, such as poorer viral suppression and HIV-related deaths [12-14]. Student youths living with HIV may face more barriers to ART, such as stigma, fear of unintended disclosure of HIV status (due to the information on drug packaging and lack of privacy while taking pills), challenges in drug storage in school, inability to coordinate their studies and clinic-related activities, and lack of structured supporting systems in schools. These barriers may lead to sadness, anger, frustration, and stress among student youths living with HIV [15]. At the same time, the educational level, some demographic and behavioral characteristics, and low perceived risk for HIV are associated with late ART initiation in nonstudent youths living with HIV [6]. Thus, student and nonstudent youths with HIV aged between 16 and 25 years might also show differences in the ART initiation and treatment outcomes.

Currently, there is limited information on the demographic and behavioral characteristics, HIV infection routes, access to HIV care, long-term ART outcome, and mortality rate among student and nonstudent cases in a large population. Therefore, we conducted a historical cohort study from 1990 to 2019 to investigate the HIV epidemic, access to care, and HIV/AIDS disease outcomes among youths aged 16 to 25 years in Guangxi, China, to better understand the disease characteristics among student and nonstudent youths with HIV. The findings of this study will inform the design of AIDS programs, considering the differences in risk factors, transmission routes, the ART initiation rate, and treatment outcomes between students and nonstudents. In addition, the findings will guide more tailored HIV prevention and care strategies to curb the HIV epidemic among adolescents further.

Methods

Study Sites and Population

The study was conducted in Guangxi Zhuang Autonomous Region, southwest China. Guangxi was among the top 3 provinces and autonomous regions with the most HIV/AIDS cases in China from 2004 to 2007. Besides, it had the second highest number of HIV/AIDS cases between 2011 and 2013 [16]. Most HIV cases were infected through sexual contact [17], and youths were very vulnerable to HIV. Therefore, we designed this study to investigate HIV-positive youths aged 16 to 25 years (age at diagnosis) and living in Guangxi (at the time of data exporting, January 2021) between January 1, 1996, and December 31, 2020.

Data Sources

We used data extracted from the Chinese Comprehensive Response Information Management System of HIV/AIDS (CRIMS), which includes the National Case Reporting Database (NCRD) and the National Free Antiretroviral Therapy Database (NFATD). The NCRD contains data on all HIV/AIDS cases from local hospitals, Centers for Disease Control and Prevention (CDC) clinics, and blood banks, including demographic information, the HIV diagnosis date, reporting organization, as well as the first CD4 test reporting date and result. The first CD4 test was conducted after an HIV diagnosis. The NFATD contains information on the ART, such as viral load and time, ART regimens, interregional transfer, comorbid diseases, loss to follow-up, death, and time of death [18]. In our study, time for the initiation of the ART was used as the baseline time point, and then patients were invited to visit the clinic for follow-up at 15 days, 1 and 3 months, and every 3 months; their information about the ART was then updated in the NFATD accordingly. Patients were also recommended to test the viral load and CD4 count once every 12 months. Individual cases in the NFATD were matched to the NCRD database using the case's card numbers [18]. Anonymous and deidentification data were extracted from the NCRD and NFATD by designated staff at CDC offices in Guangxi.

Variables collected in this study are about the patient status at the time of HIV diagnosis and follow-up information, including whether they are a student or nonstudent, age, gender, ethnicity, marital status, education, time and sites of HIV diagnosis, infection route, CD4 count, the ART initiation, HIV viral load, and death. We collected the HIV-positive cases reported from January 1, 1996, to December 31, 2019. However, the viral load and death data were collected until December 31, 2020. This study included all newly diagnosed HIV-positive youths aged 16 to 25 years (age at diagnosis) each year living in Guangxi.

Ethics Approval

This study was approved by the institutional review board of Guangxi (GXIRB2016-0047-3).

Data Analyses

We compared the demographic and behavioral characteristics, HIV care, virological loads, and deaths between students and nonstudents living with HIV. Chi-square tests were used for categorical variables (eg, gender, ethnicity, occupation, marital status, education, infection route, calendar year of HIV diagnosis, health facilities providing HIV diagnosis, and the ART initiation), and *t* tests or nonparametric tests were used for continuous variables (eg, CD4 count at HIV diagnosis and time from HIV diagnosis until the ART initiation). Multivariable Cox regression was conducted to assess if students or nonstudents' status were associated with all-cause death and virologic failure, adjusting for sex, ethnicity, marital status, education, infection route, CD4 count before the ART initiation, and the World Health Organization (WHO) clinical stage before the ART.

Results

Demographic and Behavioral Characteristics Among Youths Living With HIV

A total of 13,839 youths aged 16 to 25 years were diagnosed with HIV or AIDS in Guangxi between 1996 and 2019. Among them, 883 (6.4%) were students, and 12,956 (93.6%) were nonstudents. The number of students living with HIV was low before 2006 but gradually increased from 2007 to 2019. In contrast, the nonstudent cases living with HV increased rapidly in 2005 and gradually declined after 2012. The number of student youths was one-third of the nonstudents youths living with HIV in 2019 (Figure 1). The student cases were predominantly male; the majority of nonstudent youths living with HIV were male except during 2008-2011 (Figure 2). The homosexual transmission was the main infection route among student youths living with HIV in Guangxi. However, among the nonstudent cases, injecting drugs was the main route of infection before 2005, followed by heterosexual transmission during 2006-2019. At the same time, homosexual transmission showed an increasing trend in recent years (Figure 3). The mean CD4 count at the time of diagnosis was slightly higher in student youths living with HIV and showed an increasing trend during 1996-2019 in both student and nonstudent youths living with HIV (Figure 4).

Of the 13,839 youths, 61.8% (n=8551) were male and 38.2% (n=5288) were female. The HIV-positive youths were mostly of Han ethnicity (n=8647, 62.5%), nonfarmer (n=8687, 62.8%), single (n=8768, 63.4%), and with middle school education level or below (n=9211, 66.6%). Homosexual contact was the primary route of transmission for students (n=614, 69.5%), while heterosexual contact was the main transmission route for nonstudents (n=7887, 60.9%; *P*<.001; Table 1).

Demographic and Behavioral Characteristics Among Youths Living With HIV Through Sexual Contact

A total of 10,202 youths aged 16-25 years were infected with HIV through sexual contact between 1996 and 2019 in Guangxi. Among them, 8.5% (868/10,202) were students, and 91.5% (9334/10,202) were nonstudents. Compared with nonstudent cases, student cases were more likely to be male (n=820, 94.5% vs n=4687, 50.2%; *P*<.001), nonfarmer (n=868, 100% vs n=5396, 57.8%; *P*<.001), single (n=862, 99.3% vs n=5555, 59.5%; *P*<.001), with an educational level of college or above (n=656, 75.6% vs n=1066, 11.4%; *P*<.001). Furthermore, student youths living with HIV were more likely to be infected through homosexual contact (n=614, 70.7% vs n=1447, 15.5%; *P*<.001) and diagnosed with HIV between 2013 and 2019 (n=774, 89.2% vs n=4134, 44.3%; *P*<.001; Table 2).

HIV Care Between Student and Nonstudent Youths Living With HIV

Among the HIV/AIDS cases infected through sexual contact reported from 2008 to 2019 in Guangxi, student youths living with HIV were more likely to receive an HIV diagnosis in CDC compared to nonstudent cases (n=458, 59.6% vs n=3099, 44.1%; *P*<.001). In addition, student cases had a higher average CD4 count (median 362 [IQR 262-481] cells/µL) compared to nonstudents (median 332 [IQR 204-459] cells/µL; *P*<.001) at diagnosis. Although most youths were on the ART in both groups, student youths with HIV who were on the ART were significantly higher in number compared to nonstudent youths (n=740, 96.2% vs n=6247, 88.8%; *P*<.001). The median time from HIV diagnosis until the ART initiation was 22 days for student cases and 93 days for nonstudent cases (*P*<.001; Table 3).

Mortality Rate Between Student and Nonstudent Youths Living With HIV

Among the 7803 youths infected through sexual contact and who started the ART from 2008 to 2019, a total of 45,610.4 person-years were observed, and 446 youths died before December 31, 2020. The overall death rate among nonstudent youths living with HIV was 1.0 deaths per 100 person-years, which was higher than that among student youths living with HIV (0.4 deaths per 100 person-years). After adjusting for sex, ethnicity, marital status, education, infection route, CD4 count before the ART initiation, and the WHO clinical stage before the ART, nonstudent youths living with HIV had mortality risk doubled compared to student youths with HIV (adjusted hazard ratio [AHR] 2.3, 95% CI 1.2-4.2; *P*=.008). Youths who had initiated a zidovudine-based regimen had a 30% decreased mortality rate compared to those who took a stavudine-based regimen (AHR 0.7, 95% CI 0.5-0.9; *P*=.002). Youths who initiated a tenofovir disoproxil fumarate–based regimen also had a decreased mortality rate compared to the stavudine-based regimen group (AHR 0.7, 95% CI 0.5-1.0; *P*=.03; Table 4).

Table 4. Mortality rate of youths living with HIV aged 16-25 years by student status in Guangxi, China, from 2008 to 2019.

Virologic Failure Between Student and Nonstudent Youths Living With HIV

We assessed the virologic failure among youths who started ART in 2008 since free and standardized ART programs started from 2008 in China. Of the 4119 youths who started ART during 2008-2019, a total of 24,388.6 person-years were observed, and 632 youths met the clinical criteria of virologic failure during the follow-up period. The virologic failure rate among nonstudent youths with HIV was 2.6 deaths per 100 person-years, which was higher than that of student youths with HIV (2.3 per 100 person-years). After being adjusted for sex, ethnicity, marital status, education, infection route, CD4 count before the ART initiation, and the WHO clinical stage before the ART, the risk of virologic failure among nonstudent youths with HIV had doubled compared to student youths (AHR 1.9, 95% CI 1.3-2.6; *P*<.001). Youths who had initiated the ART during 2013-2019 had a 30.9 times increased risk of virologic failure compared with those who initiated the ART during 2008-2012 (AHR 31.9, 95% CI 18.2-55.9; *P*<.001). Youths who initiated the ART with a zidovudine-based (AHR 1.5, 95% CI 1.2-2.0; *P*=.003) and TDF-based regimen (AHR 1.9, 95% CI 1.4-2.6; *P*<.001) had an increased risk of virologic failure compared to those who took a stavudine-based regimen (Table 5).

Discussion

To our knowledge, this is the first study investigating the characteristics of youths living with HIV in southwest China. Nonstudent youths living with HIV accounted for 93.6% (12956/13839) of the total HIV cases in youths during 1996-2019. This percentage was much higher than that in youths aged 15-24 years in Hangzhou, China, during 2012-2016 (70.4%) [6]. Given the low numbers before 2006, an obvious increasing trend was observed among student youths living with HIV, approximately one-third of nonstudent cases in 2019. Homosexual transmission was the main infection route among student youths living with HIV in Guangxi (n=614, 69.5%), while heterosexual contact was the primary transmission route among nonstudent cases (n=7887, 60.9%), which was different from the primary transmission route in Hangzhou (ie, homosexual transmission) [6]. Heterosexual contact is the primary mode of HIV transmission in China [7,19]. Although the mean CD4 count at the time of diagnosis was slightly higher in student cases and consistently increased from 1996 to 2019 among student and nonstudent youths living with HIV, there is still a need to promote frequent HIV testing for early HIV diagnosis in youths in the future.

Among youths who were infected with HIV through sexual contact, the 2 groups showed differences: student youths with HIV were mainly male (n=820, 94.5% vs n=4687, 50.2%) and unmarried (n=862, 99.3%), and homosexual contact was the primary transmission route (n=614, 70.7%). In general, youths were considered sexually active and less likely to use a condom [20]. Unprotected sexual activity raises the risk of HIV transmission among youths [21]. Moreover, our study demonstrated that most nonstudent youths living with HIV had an educational level of middle school or below (n=6558, 70.3%). Limited access to sexual education, leading to the lack of HIV awareness, could be a possible reason of high-risk sexual behaviors. Thus, these findings could be applied in tailored HIV prevention programs with the goal of reducing the HIV epidemic among youths. In addition, more attention should be given to homosexual student and nonstudent youths who dropped out before high school.

Furthermore, student youths living with HIV had declined CD4 levels at the time of HIV diagnosis, and the CD4 level for nonstudent cases was even lower. This might be a result of delayed HIV testing. Besides, more than half of the nonstudents with HIV (n=3710, 52.7%) received an HIV diagnosis in hospitals instead of CDCs, implying low awareness of HIV testing, as CDCs have voluntary counseling and testing, but clinics and hospitals usually conduct HIV tests as part of physical examination. Moreover, student youths with HIV (n=740, 96.2%) had a slightly higher rate of the ART compared to nonstudent cases. At the same time, nonstudents had a longer median time for the ART initiation (93 days) compared to students (22 days). Stigma and lack of knowledge are major factors leading to delayed ART [6]. Therefore, future programs should promote early diagnosis and treatment to enhance the treatment efficacy and improve outcomes [11], and consequently, reduce morbidity and mortality [22].

Nonstudnet youths living with HIV had a higher risk of experiencing virologic failure and death compared with student cases after the ART initiation. More attention should be given to nonstudents for preventing virologic failure and death. It could be explained by the findings of this study that nonstudent youths with HIV in Guangxi were less likely to adopt the ART, had a lower CD4 count at the time of HIV diagnosis, and a delayed ART initiation. Early ART initiation could lead to improved clinical outcomes [23]. Therefore, future programs should work on eliminating barriers to HIV care and promoting early ART initiation among youths, especially among nonstudents. In this study, 70.9% (n=9189) of nonstudents youths with HIV in Guangxi had an educational level of middle school or below, and only 8.3% (n=1078) obtained university or higher education. Previous studies found that low level of education is associated with delayed HIV care [24], and school-based interventions could increase HIV knowledge and awareness among students [25,26], which in turn could probably reduce their risk behaviors and promote benefit behaviors. In addition to the school-based interventions, various interventions targeting out-of-school youths should be promoted to increase ART awareness and reduce risky sexual behaviors among the youths.

Based on the findings of this study, tailored HIV programs could be more effective in HIV prevention among the youths. For nonstudents aged 16-25 years, who accounted for the majority of HIV cases, social media–oriented HIV education using platforms like Douyin and WeChat has a great potential to deliver future HIV programs due to their wide coverage and accessibility. For students, more attention could be given to the high-risk groups, such as homosexual men. At the same time, sex education and safe sex should be strengthened in middle school, high school, and college. Given the high mortality rate as well as high risk of virologic failure and delayed ART among nonstudent youths with HIV, increased health protection awareness is crucial to encourage early diagnosis and early ART initiation [27]. Moreover, peer counseling and group therapy might be good ways to address psychological barriers to HIV testing and care, including stigma and lack of support [28,29]. Furthermore, HIV prevention campaigns could also create more awareness among the general public and clinic doctors, reduce stigma, and create a safe environment for youths to discuss their behaviors [30].

However, this study had some limitations. First, the study used historical cohort study data extracted from existing public health databases, and some information that might be useful were not available, such as the details on ART adherence and its side effects. Second, we investigated all-cause mortality instead of AIDS-related mortality, which might give different results. Third, students and nonstudents were generalized, disregarding their level of education; for example, middle and high school students might have different behaviors in HIV care and treatment outcomes from college students. For nonstudents, different levels of education may result in different perceptions and concerns about health. Thus, we adjusted for the educational background in the multivariate analysis to correct these discrepancies. Despite these limitations, this study provides valuable information on HIV risk behaviors, HIV care, and treatment outcomes for both student and nonstudent youths living with HIV. Overall, these findings will guide future HIV prevention and intervention programming in youths.

Abstract

Background: The sexual health of transmasculine (TM) people—those who identify as male, men, or nonbinary and were assigned a female sex at birth—is understudied. One barrier to conducting HIV- and sexually transmitted infection (STI)–related research with this population is how to best capture sexual risk data in an acceptable, gender-affirming, and accurate manner.

Objective: This study aimed to report on the community-based process of developing, piloting, and refining a digitally deployed measure to assess self-reported sexual behaviors associated with HIV and STI transmission for research with TM adults.

Methods: A multicomponent process was used to develop a digital-assisted self-interview to assess HIV and STI risk in TM people: gathering input from a Community Task Force; working with an interdisciplinary team of content experts in transgender medicine, epidemiology, and infectious diseases; conducting web-based focus groups; and iteratively refining the measure. We field-tested the measure with 141 TM people in the greater Boston, Massachusetts area to assess HIV and STI risk. Descriptive statistics characterized the distribution of sexual behaviors and HIV and STI transmission risk by the gender identity of sexual partners.

Results: The Transmasculine Sexual Health Assessment (TM-SHA) measures the broad range of potential sexual behaviors TM people may engage in, including those which may confer risk for STIs and not just for HIV infection (ie, oral-genital contact); incorporates gender-affirming language (ie, *genital* or *frontal* vs *vaginal*); and asks sexual partnership characteristics (ie, partner gender). Among 141 individual participants (mean age 27, SD 5 years; range 21-29 years; n=21, 14.9% multiracial), 259 sexual partnerships and 15 sexual risk behaviors were reported. Participants engaged in a wide range of sexual behaviors, including fingering or fisting (receiving: n=170, 65.6%; performing: n=173, 66.8%), oral-genital sex (receiving: n=182, 70.3%; performing: n=216, 83.4%), anal-genital sex (receptive: n=31, 11.9%; insertive: n=9, 3.5%), frontal-genital sex (receptive: n=105, 40.5%; insertive: n=46, 17.8%), and sharing toys or prosthetics during insertive sex (n=62, 23.9%). Overall barrier use for each sexual behavior ranged from 10.9% (20/182) to 81% (25/31). Frontal receptive sex with genitals and no protective barrier was the highest

(21/42, 50%) with cisgender male partners. In total, 14.9% (21/141) of participants reported a lifetime diagnosis of STI. The sexual history tool was highly acceptable to TM participants.

Conclusions: The TM-SHA is one of the first digital sexual health risk measures developed specifically with and exclusively for TM people. TM-SHA successfully integrates gender-affirming language and branching logic to capture a wide array of sexual behaviors. The measure elicits sexual behavior information needed to assess HIV and STI transmission risk behaviors. A strength of the tool is that detailed partner-by-partner data can be used to model partnership-level characteristics, not just individual-level participant data, to inform HIV and STI interventions.

Introduction

Background

Transmasculine (TM) people—those who identify as men, male, transgender men, or a nonbinary gender identity and were assigned female sex at birth [1]—are at risk of HIV and other sexually transmitted infections (STIs), such as gonorrhea, chlamydia, and human papillomavirus (HPV). Historically, research has largely focused on the risk of HIV and STIs in transfeminine populations, that is, those who identify as women, female, transgender women, or a nonbinary gender identity and were assigned male sex at birth [2,3]. Studies on HIV and STI burden in TM people remain scarce [2,4]. Moreover, there is a lack of consistency in the reported rates of STIs in transgender men, with 1 review finding STI ranges of 0% to 4.2% for syphilis, 0% to 10.5% for gonorrhea, and 1.2% to 11.1% for chlamydia [2]. It is important to capture the diverse sexual practices of TM people that may be relevant not only for HIV but also for STIs such as genital or anal HPV, gonorrhea, and chlamydia, as well as for counseling on family planning and contraception needs. Failure to collect complete detail regarding sexual behaviors and the timing and recency of those behaviors may result in misclassification of sexual risk exposures, especially given the heterogeneity of sexual behaviors, gender identities, and the bodies of TM people and their sexual partners.

TM people hold a wide range of sexual identities and engage in a variety of sexual behaviors based on their own and their partner's anatomy. Analyzing data from the US National Transgender Discrimination Survey, a sample of 2578 TM respondents identified their sexuality as gay (19%), bisexual (13%), and queer (51%) [5], supporting the need for measures that are able to capture the diversity of sexual partners and behaviors. Statistics show that TM people vary in terms of access to, and desire for, genital surgery. In the 2015 US. Transgender Survey, only 5% of TM respondents had a metoidioplasty (detachment of clitoral ligaments to lengthen an enlarged clitoris to create a neophallus) or phalloplasty (creation of a neophallus using extragenital tissue, typically from the forearm or thigh), but >25% and 19% indicated that they "someday" want a metoidioplasty and phalloplasty, respectively [6,7]. Regardless of anatomy, TM people may or may not engage in sexual behaviors that use their own or their partner's genitals. The wide range of anatomies and sexual identities confers varying sexual behaviors among TM people, which may include higher risk behaviors such as penetrative receptive sex with cisgender gay men that places TM people at risk for the acquisition of HIV and other STIs. Moreover, TM people who experience barriers to surgical access or who do not desire gender-affirming surgery with cervix removal are at risk of cervical cancer caused by high-risk HPV, which can be transmitted or acquired through oral sex, anal sex, and genital-genital contact. Although estimates of HPV are comparable between cisgender women and TM people [8-12], TM people are less likely to receive cervical cancer screenings according to recommended guidelines, underscoring the need for a sexual health measure that allows providers to better understand whether TM patients are at risk of HPV exposure [13]. Other STIs, including gonorrhea, chlamydia, and herpes simplex virus, also warrant attention.

Previous HIV or STI risk surveillance measures, such as the AIDS Risk Behavior Assessment and Risk Assessment Battery, are commonly used and adapted to assess HIV risk [14,15]. However, these measures have limitations. First, these measures use gendered, cisnormative language (eg, assumptions that those who have penises are men and use he or him pronouns), which can be harmful to TM people who are frequently misgendered and systematically misrepresented in data collection [16]. Lack of acceptability of measures in TM populations may lead to nonresponse bias and unwillingness to participate in research or share their sexual history honestly with providers. Furthermore, cisnormative language generates validity concerns when TM people are not able to answer questions accurately according to their or their partners' anatomies. Second, the measures often do not consider sexual practices that may be more common among TM people, such as the use of prosthetics or toys during sex. These sexual practices are common in TM communities and carry the risk of HPV, gonorrhea, chlamydia, and herpes simplex virus transmission or acquisition but are not assessed by traditional measures. Transgender and gender-diverse activists continue to call for inclusive HIV or STI research measures, notably stating, "A lack of research does not mean we are not at risk" [17,18]. Traditional measures may, therefore, underestimate HIV or STI risk in this population by failing to assess common sexual practices. Third, many measures fail to distinguish between insertive and receptive sexual practices, which have different implications for HIV or STI risk and the probability of transmission or acquisition [19]. To our knowledge, only 1 inclusive sexual health and reproductive health inventory has been published for transgender and nonbinary people, which captures sexual behavior, gender affirmation, pregnancy, abortion, and contraception and is of great use for research but may be too lengthy for providers in clinics to accurately and quickly assess HIV or STI risk in only TM people [20]. A study by Bauer et al [21] exploring the sexual health of TM people who have sex with men indicated that they developed and used measures that include a wide range of sexual behaviors, but they did not provide structure or enough details to accurately recreate those measures.

There is limited knowledge and lack of consensus about how best to capture sexual risk data in the TM population, both in terms of accurately characterizing sexual behaviors that confer specific risks for HIV and STI transmission and ensuring that the measure is gender affirming and acceptable for TM respondents. Digital-assisted self-interviewing uses computer- or technology-deployed methods (eg, laptops, electronic tablets, and smartphones) to collect survey data, wherein the respondent completes the assessment via self-reporting without an interviewer administering it. The capacity for programmed branch logic and the highly sensitive nature of sexual risk behavior questions makes this a method well suited for confidential data collection of self-reported HIV- and STI-related risks for TM adults [22,23].

Objectives

This study aimed to develop and test a robust and inclusive sexual health and risk assessment designed *with* and specifically *for* TM people. The aims were twofold: (1) to report on the community-based process of developing and refining a digital-assisted self-interview measure designed to assess self-reported sexual behaviors associated with HIV and STI transmission for research in TM adults, known as the Transmasculine Sexual Health Assessment (TM-SHA), and (2) to field and digitally implement the TM-SHA and characterize the sexual histories, sexual partnership, and sexual practices in a sample of TM adults.

Methods

Overview

This research was undertaken from March 2015 to September 2016 as part of a biobehavioral study to evaluate screening methods for the detection of high-risk HPV in TM adults (ClinicalTrials.gov NCT02401867) [24]. The main outcomes and broader study details have been reported elsewhere [8]. This secondary analysis focuses on the development, implementation, and refinement of the HIV and STI sexual risk measure, including reporting on HIV and STI transmission risk by the gender of sexual partners.

Ethics Approval

All study activities were approved by the Fenway Health Institutional Review Board (FWA00000145).

Consent to Participate

Informed consent procedures ensured that the people understood what was involved in participating in the study, what the risks and benefits were of participation, and voluntarily agreed to participate. The original informed consent also applied to this secondary analysis, for which all study data were anonymized and deidentified. Participants were compensated US $100 for study participation in the form of a prepaid American Express gift card.

Community-Scientific Partnership

A multicomponent community-based process was used to develop and refine a questionnaire to assess HIV and STI risk in TM people using digital-assisted self-interviewing technology. The process used community-based participatory research principles to work *with* not *on* TM communities and to cocreate and refine the sexual behavior assessment. The development process was guided by a 15-member research team that included multiple TM adults who worked closely with a 5-member Community Task Force of TM people and a 5-member multidisciplinary Scientific Advisory Board that comprised content experts in transgender medicine, clinical epidemiology, and infectious diseases research. This was a dynamic process involving community and scientific engagement. At the core of the enterprise was the following tenet: to prioritize being gender affirming and respectful, while collecting accurate data in a patient-centered manner to understand and address sexual health needs of TM people.

Development, Modification, and Refinement of the Measure

The TM-SHA was developed to assess sexual behaviors, partnerships, and protective barrier use that confer transmission risk of HIV and other STIs. The primary purpose was to measure the broad range of sexual behaviors engaged in by TM adults, including those that may confer risk for HIV, HPV, and other STIs, in a gender-affirming, sensitive, and accurate manner.

The basic TM-SHA assessment structure was modeled on an HIV risk assessment originally adapted from the AIDS Risk Behavior Assessment [14] by the LifeSkills trial, a multisite study testing the efficacy of an HIV behavioral intervention to reduce HIV transmission risk for young transgender women aged 16-29 years [20]. The measure was subsequently adapted with young adult transgender men who have sex with men aged 18-29 years in LifeSkills for Men [25]. These HIV risk measures specifically focused on sexual and other behaviors that confer risk for HIV infection, such as genital and anal intercourse and needle sharing in the context of injection drug use or hormone therapy. This study expanded on this to include a broader range of behaviors.

The development of the TM-SHA involved active collaboration between the research team, Task Force, and Scientific Advisory Board to ensure the creation of a gender-affirming assessment that reflected the sexual lives and experiences of TM adults. Among these groups, we discussed the topics of language and terminology, usability, question clarity and specificity, response options, and acceptability. A preliminary version of the TM-SHA was then pilot-tested with members of the Task Force and the research team, who provided feedback regarding the instrument’s functionality and design. After addressing feedback from the pilot test, we field-tested the TM-SHA in a sample of 141 TM adults, all of whom had cervixes and reported at least 1 sexual partner in the past 12 months (see *Field Test of the Assessment* section).

When reviewing the preliminary version of the measure, the following ideas emerged about the components of the ideal assessment: asking about an array of sexual behaviors, including those that are not typically associated with HIV risk; adding an introduction about the complexity of terminology; asking participants' surgical status and programming skip patterns to assess sexual risk accordingly; asking participants what language they use to describe their body parts and then having that populate subsequent questions about sexual behaviors and risks; and assessing sexual partner and partnership characteristics.

On the basis of these ideas, the following changes and refinements to the instrument were made: adding questions to assess the broad range of potential sexual behaviors TM people may engage in, including those which may confer risk for HPV and other STIs, not only for HIV infection; incorporating gender-affirming language to make questions and response options less gendered and binary sex specific (ie, using more generic terms like *genital* vs *vaginal*); and asking sexual partner and partnership characteristics to understand interpersonal context.

TM-SHA Measure

The TM-SHA measure is summarized in Table 1, and Table 2 presents the grid of sexual behaviors and frequency of barrier use (the full TM-SHA measurement and survey logic guidelines can be obtained by contacting the corresponding author). The TM-SHA assessed individual- and partnership-level risks. At the individual level, participants were asked to provide information about their sexual orientation and the total number of sexual partners in the past 36 months.

Participants were then asked to provide demographic and sexual risk–related data for up to 3 sexual partnerships from the past 12 months. These partnership-level data included the gender identity of the sexual partner, configuration of the sexual partnership, behaviors engaged in during sex, frequency of protective barrier use by sexual behavior, and whether the sexual partner had ever been diagnosed with an STI.

Sexual behavior data collected through the TM-SHA consisted of the following 15 sexual behaviors: (1) performing frontal (ie, vaginal) and/or anal penetration with a finger or fist, (2) receiving frontal and/or anal penetration with a finger or fist, (3) performing oral-genital sex, (4) receiving oral-genital sex, (5) performing oral-anal sex, (6) receiving oral-anal sex, (7) frontal insertive sex with genitals, (8) frontal receptive sex with genitals, (9) frontal insertive sex with a toy or prosthetic, (10) frontal receptive sex with a toy or prosthetic, (11) anal insertive sex with genitals, (12) anal receptive sex with genitals, (13) anal insertive sex with a toy or prosthetic, (14) anal receptive sex with a toy or prosthetic, and (15) insertive sex in which a toy or prosthetic was shared.

The use of a protective barrier can be operationalized from the measure as using a condom, internal condom, dental dam, or gloves during sexual activity. The frequency of protective barrier use can be coded as either engaged in sexual behavior with no use of a protective barrier or engaged in sexual behavior and used a protective barrier on at least 1 occasion.

Table 1. Overview of the Transmasculine Sexual Health Assessment.

Section, section #, and item		Type
Introduction		
1	This part of the survey will ask you about sex. Sex is a personal issue that can sometimes be sensitive or difficult to talk about, especially for those who are transgender or gender nonconforming because bodies do not always reflect identity. We will be asking you about different forms of sexual activity including the following: penetrative sex with fingers (“fingering”) or fists (“fisting”), oral-genital sex (putting your mouth on someone’s genitals or someone putting their mouth on your genitals), oral-anal sex (“rimming”), receptive and insertive frontal sex, receptive and insertive anal sex, and use of prosthetics/toys. By “receptive sex” we mean when a person inserts their genitals or a toy into your frontal opening or anus. By “insertive sex” we mean when your genitals are inserted into a frontal opening or anus without the assistance of a prosthetic/dildo/toy/etc. We will also be asking you about your use of barriers during sexual activity. Barriers differ depending on the sexual activity. Barrier methods include condoms, internal condoms, dental dams, and gloves. Except where indicated, all questions about sex refer to consensual sex or sex you experienced because you wanted to participate and not because you were forced, coerced, or otherwise made to have sex. Remember your answers to these questions will be kept completely private. Please try your best to answer each question.	Prompt
Demographics		
1	Please answer the following questions about your sexual identity, attractions, and recent sexual activity.	Prompt
2	Which of the following best describes your sexual identity or orientation today? Choose one... (1) gay/homosexual/same-gender attraction; (2) straight/heterosexual; (3) bisexual; (4) queer; (5) pansexual; (6) questioning; (7) asexual; (8) unsure; (9) I do not label my sexual orientation; (97) Other, please specify; and (99) I prefer not to answer.	Multiple choice
Sexual contact (last 36 months)		
1	Please think about the people you have had sexual contact with in the last 36 months (3 years).	Prompt
2	How many individuals have you had any form of sexual contact with in the last 36 months (3 years)? Sexual contact includes penetrative sex using fingers or fists, oral-genital sex, oral-anal sex, receptive and/or insertive frontal sex, receptive and/or insertive anal sex, and use of prosthetics/toys. If you would prefer not to answer, please enter “99,999.”	Open response
3	Please specify the gender(s) of the partner(s) you have had sexual contact with in the last 36 months (3 years) and the number of partner(s) of each gender. The total must be equal to the number you specified in the previous question. If you did not have sexual contact with a person of a specified gender, please enter 0. If you would prefer not to answer, please enter “99,999”; in each field that you do not wish to answer ... (1) cisgender/nontransgender man, (2) cisgender/nontransgender woman, (3) transgender man (FTM[a]), (4) transgender woman (MTF[b]), (5) male-assigned gender nonconforming/nonbinary person, and (6) female-assigned gender nonconforming/nonbinary person.	Multiple choice
4	Of the partners that you had sexual contact with in the last 36 months (3 years), how many did you have unprotected frontal and/or anal sex with (ie, without a condom or other barrier)? This includes penetrative sex using fingers or fists, oral-genital sex, oral-anal sex, receptive and/or insertive frontal sex, receptive and/or insertive anal sex, and use of prosthetics/toys. If you would prefer not to answer, please enter “99,999.”	Open response
Sexual contact (last 12 months)		
1	Please think about the people you have had sexual contact with in the last 12 months (1 year).	Prompt
2	How many individuals have you had any form of sexual contact with in the last 12 months (1 year)? Sexual contact includes penetrative sex using fingers or fists, oral-genital sex, oral-anal sex, receptive and/or insertive frontal sex, receptive and/or insertive anal sex, and use of prosthetics/toys. If you would prefer not to answer, please enter “99,999.”	Open response
3	Please specify the gender(s) of the partner(s) you have had sexual contact with in the last 12 months (1 year) and the number of partner(s) of each gender. The total must be equal to the number you specified in the previous question. If you did not have sexual contact with a person of a specified gender, please enter 0. If you would prefer not to answer, please enter “99,999”; in each field that you do not wish to answer... (1) cisgender/nontransgender man, (2) cisgender/nontransgender woman, (3) transgender man (FTM), (4) transgender woman (MTF), (5) male-assigned gender nonconforming/nonbinary person, and (6) female-assigned gender nonconforming/nonbinary person.	Multiple choice
4	Of the partners that you had sexual contact with in the last 12 months (1 year), how many did you have unprotected frontal and/or anal sex with (ie, without a condom or other barrier)? This includes penetrative sex using fingers or fists, oral-genital sex, oral-anal sex, receptive and/or insertive frontal sex, receptive and/or insertive anal sex, and use of prosthetics/toys. If you would prefer not to answer, please enter “99,999.”	Open response
Identifying number of sexual partners (last 12 months)		
1	We will now ask you about your 3 most recent sexual partners in the last 12 months (1 year).	Prompt

Section, section #, and item		Type
2	Thinking about the people that you have had sexual contact with in the last 12 months, please enter the initials of your most recent sexual partner. If you do not know the person's initials or do not feel comfortable providing that information, please create your own way of identifying this partner. [c]Note: if you have had sex with >1 partner at the same time, please choose only 1 partner for this question, and use the next question(s) to identify the other, concurrent partner(s).	Open response
3	Thinking about the people that you have had sexual contact with in the last 12 months, did you have another partner in addition to (partner 1 initials)? ... (1) yes, (2) no, and (99) I prefer not to answer.	Multiple choice
4	(If yes) Please enter the initials of this sexual partner. If you do not know the person's initials or do not feel comfortable providing that information, please create your own way of identifying this partner.	Open response
5	(If sex partners last 12 months >2) Thinking about the people that you have had sexual contact with in the last 12 months, did you have another partner in addition to (partner 1 initials) and (partner 2 initials)? ... (1) yes, (2) no, and (99) I prefer not to answer.	Multiple choice
6	(If yes) Please enter the initials of this sexual partner. If you do not know the person's initials or do not feel comfortable providing that information, please create your own way of identifying this partner.	Open response
Sexual partner one		
1	Please answer the following questions about your interactions with (partner 1 initials).	Prompt
2	What was (partner 1 initials)'s gender? ... (1) cisgender/nontransgender man, (2) cisgender/nontransgender woman, (3) transgender man (FTM), (4) transgender woman (MTF), (5) male-assigned gender nonconforming/nonbinary person; (6) female-assigned gender nonconforming/nonbinary person, and (99) I prefer not to answer.	Multiple choice
3	How would you describe your relationship with (partner 1 initials)? If >1 description applies, please select "Other" and describe... (1) married or in a civil partnership; (2) serious relationship (boyfriend/girlfriend/partner), someone you dated for a while and feel very close to; (3) casually dating but not serious; (4) poly (polyamorous); (5) open relationship/nonmonogamous; (6) sleeping with this person ("fuck buddy" or "booty call") but not dating; (7) dom/sub (dominant/submissive); (8) fluid bonded; (9) one night stand; (10) stranger or anonymous person; (11) exchange partner/sex work client; (97) other, please specify; and (99) I prefer not to answer.	Multiple choice
4	For the following questions, please identify whether or not you engaged in any of the following sexual activities in the last 12 months with this partner (partner 1 initials). If you respond "Yes," please specify how often a barrier was used. If you respond "No," please select "I did not engage in this activity" under barrier use. [c]Note: as a reminder, by "barrier" we mean condoms, internal condoms, dental dams, and gloves.	Prompt
5	Sexual behaviors and frequency of protective barrier use grid[d]	Multiple choice
6	STI[e] history[d]: Has this partner ever been diagnosed (by a physician, nurse, or other medical provider) with any of the following STIs?: (1) HIV, (2) HPV[f], or (3) HSV[g] type 1 or 2 (response options: yes, no, I do not know, and I prefer not to answer).	Multiple choice

[a] FTM: female-to-male.

[b] MTF: male-to-female.

[c] The text following "Note" was presented as clarification for participants completing the survey.

[d] See Table 2 for the grid of sexual behaviors and protective barrier use.

[e] STI: sexually transmitted infection.

[f] HPV: human papillomavirus.

[g] HSV: herpes simplex virus.

Table 2. Transmasculine Sexual Health Assessment: grid of sexual behaviors and frequency of protective barrier use.

	Activity performed with (initials of sexual partner)[a] in the last 12 months?			While engaged in this activity, how often was a barrier used?						
	Yes	No	I prefer not to answer	I did not engage in this activity	Never	Less than half the time	About half the time	More than half the time	Always	I prefer not to answer
Frontal and/or anal penetration with a finger (“fingering”) or fist (“fisting”) - performed										
Frontal and/or anal penetration with a finger (“fingering”) or fist (“fisting”) -received										
Oral-genital – performed										
Oral-genital – received										
Oral-anal (“rimming”) - performed										
Oral-anal (“rimming”) - received										
Frontal receptive - with genitals										
Frontal receptive - with toy or prosthetic										
Frontal insertive - with genitals										
Frontal insertive - with toy or prosthetic										
Anal receptive - with genitals										
Anal receptive - with toy or prosthetic										
Anal insertive - with genitals										
Anal insertive - with toy or prosthetic										
Insertive sex toys or prosthetics shared										

[a] Participants were asked to list the initials for each of their most 3 recent sexual partners in the last 12 months (Table 2). The initials for each sexual partners were prepopulated into the assessment grid for sexual behaviors.

Field Test of the Measure

The TM-SHA was subsequently deployed via a digital tablet in a sample of 141 TM people aged 21 to 50 years in the greater Boston, Massachusetts, area. Participants were recruited via convenience sampling methods (eg, flyers and word-of-mouth referral) and through medical providers. Study visits were held at a community health center that specialized in gender-affirming transgender care in Boston, Massachusetts [26], and lasted for approximately 3 hours. During the study visit, the participants completed a 45-minute cross-sectional survey in which the TM-SHA was embedded. The details of the study protocol have been described elsewhere [24]. After the completion of the TM-SHA measure, the participants were asked to provide optional qualitative, open-ended feedback about their experience with the assessment. The TM-SHA required 20 minutes to complete.

Data Analysis

Descriptive analyses characterized the distribution of TM adults’ sexual behaviors and HIV and STI transmission risk by the gender identity of sexual partners. The gender identity of sexual partners was coded into the following 4 groups: TM (combining transgender man and assigned female gender nonconforming or nonbinary person), transfeminine (combining transgender woman and assigned male gender nonconforming or nonbinary person), cisgender man, and cisgender woman. Descriptive statistics for the sample were calculated using TM adults as individual participants (N=141). This participant-level data set was then transposed from *short* to *long* formatting to reorient the sexual partnership data (n=259 partnerships). As participants provided data for up to 3 sexual partnerships within the past 12 months, the long-formatted data set allowed us to descriptively analyze protective barrier use within the sexual partnership data. Protective barrier use was operationalized as using a condom, internal condom, dental dam, or gloves during sexual activity versus not using the aforementioned protective barriers. Statistical analyses were conducted using SAS (version 9.4; SAS Institute). Themes from the open-ended feedback from the participants on the TM-SHA were summarized qualitatively in Excel (Microsoft Corporation).

Data Exclusion

In total, 9 participants were excluded from the data analysis because they did not report any partnership-level data.

Results

Sample Characteristics

The characteristics of participants (N=141) are presented in Table 3. The majority were aged between 21 and 29 years (102/141, 72.3%), with a mean age of 27 years. Approximately 75.2% (106/141) and 14.9% (21/141) of the participants were White and multiracial, respectively. Among all the participants, approximately 14.9% (21/141) reported a personal history of STI diagnosis.

Table 3. Demographic characteristics of transmasculine adults in field-testing sample (N=141).[a]

Characteristics	Values[b]
Age (years), n (%)	
21-24	45 (31.9)
25-29	57 (40.4)
30-34	25 (17.7)
≥35	14 (9.9)

[a] Includes agender, bigender, and write-in gender identities distinguishable from the categories provided.

[b] Percentages may not sum to 100% owing to rounding.

[c] STI: sexually transmitted infection.

[d] Includes any lifetime diagnosis of HIV, chlamydia, trichomoniasis, syphilis, gonorrhea, genital herpes, hepatitis B, hepatitis C, or another STI.

Sexual Partnership Characteristics

In Table 4, descriptive statistics of sexual partnerships (n=259) and practices (15 sexual risk behaviors) are shown, along with the frequency of protective barrier use by sexual behaviors. The participants engaged in a wide range of sexual behaviors, including fingering or fisting (receiving: 170/259, 65.6% and performing: 173/259, 66.8%), oral-genital sex (receiving: 182/259, 70.3% and performing: 216/259, 83.4%), anal-genital sex (receptive: 31/259, 11.9% and insertive: 9/259, 3.5%), frontal-genital sex (receptive: 105/259, 40.5% and insertive: 46/259, 17.8%), and sharing toys or prosthetics during insertive sex (62/259, 23.9%). The overall barrier use for each sexual behavior varied greatly, ranging from 10.9% (20/182) to 81% (25/31).

The prevalence of protective barrier use was heterogeneous across different partnerships and sexual behaviors. For example, frontal receptive sex with genitals with no protective barrier ranged from 2% (1/42; with a transfeminine person) to 50% (21/42; with a cisgender man). In our field test of TM-SHA, we found that 40% (42/105) of participants engaged in frontal receptive sex with genitals without the use of a protective barrier. Of those, more than half (22/42, 52%) engaged in this behavior with a transfeminine person or a cisgender man, which may confer risk for HPV and other STIs. One-third (14/42, 33%) of TM participants reported engaging in frontal receptive sex with genitals and no protective barrier with a cisgender woman partner, which is notable given that HPV is also spread by people without a penis. Notably, TM people engaged in insertive frontal and insertive anal sex, in which an enlarged clitoris (often achieved through hormone use) is inserted into a partner's frontal or anal cavity.

Table 4. Characterizing the sexual partners, sexual behaviors, and protective barrier use of transmasculine adults (n=259 partnerships) by gender identity of sexual partners and protective barrier use across varied sexual behaviors.

[d] The denominator for percentages in the column is the N for barrier use or no barrier use.

[e] Includes transgender women and gender nonbinary assigned-male-at-birth partners.

Lessons Learned From Participants' Open-ended Feedback

Through open-ended feedback in the development and field-testing of TM-SHA, the team learned many lessons for measuring TM people's sexual risk (Textbox 1). The TM-SHA had high levels of acceptability among TM participants. No length-related concerns or participant burden concerns were reported for the measure. Skip logic ensured that participants circumvented any questions that were not relevant to them. Themes that emerged in the open-ended feedback after the completion of the TM-SHA included appreciation expressed by multiple participants for the measure's gender-affirming language and for the comprehensiveness of the assessment and how it asked about diverse behaviors and partnerships. Two participants noted confusion surrounding the terms "receptive" and "insertive" for describing some of the sexual behaviors and suggested further clarification in the future.

Textbox 1. Lessons learned in measuring sexual risk in transmasculine (TM) adults.

- Partner and work with TM community members to ensure gender-affirming, cultural competency, and responsiveness of measures.
- Use introductory language at the beginning to acknowledge, validate, and affirm differences in identity and language use for TM people. Specify terms to be used throughout the survey for body parts, sexual acts, etc, for example, the use of *frontal* sex instead of *vaginal* sex.
- Use simple concrete language, which can be challenging with jargon and sexual health terminology. For TM people, carefully select words and phrases to ensure item clarity, similar interpretation of the item across respondents, response options, and choices (eg, check all, mutually exclusive, and open ended).
- Consider the potential emotional impact that terminology and language may evoke and acknowledge sensitivity and constant evolution of language in TM communities.
- Capture the heterogeneity of sexual identities in TM people, diversity of sexual partnership types and behaviors, and interpersonal contexts.
- Validate all sexual practices TM people engage in, regardless of whether they confer high probability of HIV or sexually transmitted infection transmission risk, by asking about high-, low-, and varying-risk activities.
- Do not assume that TM people are limited to certain types of sex based on their gender identity or based on their anatomy (eg, questions should ask about insertive and receptive sex). For example, given the diversity of bodies, it was important to specify whether a sexual act was performed with or without a prosthetic or toy. Gender of one's sexual partner may not always correspond with their genitals.
- Provide space for open-ended feedback about the assessment and experience of completing the survey. For example, ask participants: Is there anything else you feel to be important that we did not address?

Discussion

Principal Findings

The TM-SHA is one of the first digital sexual health risk measures developed specifically with and exclusively for TM people. It successfully integrated gender-affirming language and branching logic that captures the wide array of sexual behaviors and partnerships in TM people. The TM-SHA was highly acceptable to TM adults, with no participant concerns regarding burdensomeness or length of the measure, and it was found to elicit the sexual behavior information needed to assess HIV or STI transmission risk behaviors. For the parent study's outcome of high-risk HPV, the measure included questions to better assess potential sexual exposures for other STIs besides HIV infection, given that multiple behaviors confer risk for high-risk HPV.

In collaboration with a Task Force and community input, the TM-SHA was adapted with gender-affirming language to measure the sexual behavior and protective barrier use of participants. The use of gender-affirming language may have 2 advantages for measuring the sexual risk behavior of TM people. First, gender-affirming language may improve the validity of the TM-SHA by providing a description of sexual behaviors and genitals in a way that better reflects some of the perspectives of TM people (eg, using *frontal* receptive sex instead of *vaginal* receptive sex) [27]. Second, the gender identity options listed on the TM-SHA reflect those commonly held by TM people and their sexual partners; the instrument served to further acknowledge and validate these gender identities.

The sexual health of TM people remains understudied [2,4], and a barrier to conducting HIV- and STI-related research with this study population is the lack of consensus on how to best capture sexual risk data in a standardized manner that is gender affirming, culturally responsive, and accurate. In the context of widespread stigma facing TM people, there is a need for high-quality measures that are cocreated with communities to maximize acceptability, for example, by avoiding stigmatizing language that may trigger medical and research mistrust and by cueing participants that researchers are knowledgeable and transcompetent in asking sensitive questions. Thus, this study fills an important gap for both researchers and clinicians aiming to capture the wide variety of sexual behaviors of TM people.

The TM-SHA provides a high level of specificity about sexual practices, some of which may confer greater risk for HIV and STIs than others. Additional research is warranted on how to optimize use and interpret the measure. For example, it may be helpful to develop a *scoring* schema to categorize someone for research as *low, moderate, or high* risk based on their reported protection of sexual behaviors or for clinical settings to appropriately counsel a patient on their STI risk or need for Papanicolaou testing. The growing functionality of electronic health records (EHRs) and patient portals offers an opportunity to integrate the TM-SHA and similar tools into clinical care provision. Patients could be asked to complete the TM-SHA before their visit via the patient portal, and the information elicited could be linked to the EHR and integrated into clinical care delivery.

Limitations and Future Directions

With regard to limitations, the current TM-SHA does not consider HIV prevention methods such as pre-exposure prophylaxis (PrEP) or postexposure prophylaxis to prevent HIV acquisition used by participants or their partners. TM people engage in sexual behaviors conferring eligibility for PrEP but have a low uptake of PrEP [28]. Future iterations of the measure may consider adding questions and skip patterns to assess current PrEP and postexposure prophylaxis use for both TM people and their partners. In addition, the current TM-SHA assumes that the participant had a cervix per eligibility criteria for the parent study. Future versions of the measure may consider adding questions and logic to assess gender-affirming surgeries, which may result in different anatomy and, therefore, sexual risks in participants. According to participant feedback, future versions of the measure would benefit from clarifying insertive and receptive sex. For example, in reporting on frontal receptive sex with genitals with a cisgender woman partner, it will be important to learn how people understand or interpret the terms *receptive* and *with genitals*. Cognitive interviewing methods may assist with this process and strengthen the evidence of validity.

The length of the survey and advanced skipped patterns used in the survey, which may be difficult for beginners to code, are best suited for preprogrammed electronic surveys. This may pose a challenge for those with low literacy rates and for medical providers hoping to use this measure in clinic [22]. An audio, digital-assisted self-interview or interviewer-administered assessment may be used to address the low literacy levels of respondents. Researchers and clinical providers may also adapt and shorten the TM-SHA for their research, clinical practice, and patient needs. For example, if HIV risk is the parameter of interest, the assessment could be shortened to only those sexual behaviors that confer a high HIV risk. Future research is needed to reduce the scope of the tool, ensure its accuracy, and externally validate the measure for clinical robustness. Such research could examine clinical outcomes (eg, laboratory or clinically confirmed STIs) alongside patient-reported outcomes and/or gather and compare patient-reported and provider-documented sexual behavior data for accuracy.

Finally, despite efforts to capture all types of sexual behaviors and partnerships, it is possible that not all behaviors were captured by the measure, as currently designed. Thus, open-ended questions at the end of the measure were added. This allows participants the space to disclose any other relevant information, including the behaviors they may want to report, which may be used in data analysis or to improve the measure for future use. A strength of the TM-SHA is that it is inclusive of polyamorous relationships in that for each partnership they report on, participants are asked to describe the type of partnership (eg, casual or polyamorous). In addition, although participants were not asked directly about multipartner sex (eg, group sex), the assessment asked about sexual behaviors with multiple partners. Asking explicitly about multipartner sex is recommended in the future.

Conclusions

This study offers a digital measure designed with and specifically for TM people for future use in TM sexual health research and clinical care. The tool garnered high levels of acceptability from TM participants, was feasible to implement in field-testing, and reported no concerns about participant burden or length in completing the assessment. A strength of this measure is that detailed partner-by-partner data can be used to model partnership-level characteristics in addition to individual-level participant data. Additional psychometric evaluation of the measure is necessary, including longitudinal data, to assess the performance of the TM-SHA over time for research purposes. Clinically, the TM-SHA provides a standardized sexual history measure for TM people, which may help clinicians enhance trust with their patients and more effectively identify sexual behaviors that warrant HIV or STI screening in clinical care. Integration of the measure into clinical research and care via patient portals linked to EHR may facilitate the delivery of culturally responsive and gender-affirming sexual health care.

Acknowledgments

This study was funded by the Patient-Centered Outcomes Research Institute (PCORI; contract CER-1403-12625). All methods were reviewed by the PCORI Scientific Committee and found to be in accordance with their methodology standards. PCORI was not involved in the collection, analysis, or interpretation of study data. The funders had no role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript. The authors would like to thank the Community Task Force, Scientific Advisory Board, and the research team who came together and collaborated on this study to ensure transmasculine people's engagement and participation. The authors also thank the transmasculine people who field-tested the measure and provided input.

Data Availability

The data sets analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

SLR, MBD, SMP, JMWH, and JP conceptualized the study. SLR, DRP, JMWH, and SMP curated data. SLR and DRP conducted the formal analysis. SLR, MBD, SMP, and JP participated in acquiring funding. SLR, MBD, JMWH, SMP, and JP were study investigators. SLR, MBD, JMWH, SMP, and JP contributed to the study methodology. SLR and DJP conducted project administration. SLR and DJP participated in managing resources. SLR and DRP obtained software. SLR, MBD, DJP, and JP provided supervision for the study. SLR, JMWH, and JP validated study findings. SLR and DRP conducted data visualization. SLR, DRP, DJP, and MQ wrote the initial draft manuscript. SLR, DRP, DJP, MBD, JMWH, SMP, MQ, and JP reviewed, edited, and provided critical feedback on the final manuscript.

Abstract

Background: Community-based organizations deliver peer-led support services to people living with HIV. Systematic reviews have found that peer-led community-based support services can improve HIV treatment outcomes; however, few studies have been implemented to evaluate its impact on mortality using long-term follow-up data.

Objective: We aimed to evaluate the associations between the receipt of peer-led community-based support services and HIV treatment outcomes and survival among people living with HIV in Wuxi, China.

Methods: We performed a propensity score–matched retrospective cohort study using data collected from the Chinese National HIV/AIDS Comprehensive Information Management System for people living with HIV in Wuxi, China, between 2006 and 2021. People living with HIV who received adjunctive peer-led community-based support for at least 6 months from a local community-based organization (exposure group) were matched to people living with HIV who only received routine clinic-based HIV care (control group). We compared the differences in HIV treatment outcomes and survival between these 2 groups using Kaplan-Meier curves. We used competing risk and Cox proportional hazards models to assess correlates of AIDS-related mortality (ARM) and all-cause mortality. We reported adjusted subdistribution hazard ratio and adjusted hazard ratio with 95% CIs.

Results: A total of 860 people living with HIV were included (430 in the exposure group and 430 in the control group). The exposure group was more likely to adhere to antiretroviral therapy (ART; 396/430, 92.1% vs 360/430, 83.7%; *P*<.001), remain retained in care 12 months after ART initiation (402/430, 93.5% vs 327/430, 76.1%; *P*<.001), and achieve viral suppression 9 to 24 months after ART initiation (357/381, 93.7% vs 217/243, 89.3%; *P*=.048) than the control group. The exposure group had significantly lower ARM (1.8 vs 7.0 per 1000 person-years; *P*=.01) and all-cause mortality (2.3 vs 9.3 per 1000 person-years; *P*=.002) and significantly higher cumulative survival rates (*P*=.003). The exposure group had a 72% reduction in ARM (adjusted subdistribution hazard ratio 0.28, 95% CI 0.09-0.95) and a 70% reduction in all-cause mortality (adjusted hazard ratio 0.30, 95% CI 0.11-0.82). The nonrandomized retrospective nature of our analysis prevents us from determining whether peer-led community-based support caused the observed differences in HIV treatment outcomes and survival between the exposure and control groups.

Conclusions: The receipt of peer-led community-based support services correlated with significantly improved HIV treatment outcomes and survival among people living with HIV in a middle-income country in Asia. The 15-year follow-up period in this study allowed us to identify associations with survival not previously reported in the literature. Future interventional trials are needed to confirm these findings.

Introduction

Survival Improved Among People Living With HIV

According to the 2020 global AIDS report, 38 million people are living with HIV globally, of whom 25.4 million are receiving antiretroviral therapy (ART) [1]. If the *95-95-95* targets updated by the Joint United Nations Program on HIV/AIDS in December 2020 are to be achieved by 2025 [2], nearly 86% of all people living with HIV worldwide will need to be initiated on ART and achieve viral suppression. China has achieved considerable success in optimizing the HIV care continuum in recent decades. Currently, an estimated 83.4% of all people living with HIV in China are receiving ART, of whom 94.2% have achieved viral suppression [3].

The overall life expectancy of people living with HIV with good adherence to ART is approaching that of the general population in many high-income countries [4,5]; however, significant differences in survival persist in resource-limited settings [6]. The use of ART to improve survival among people living with HIV depends on early initiation of treatment, adherence to ART, and retention in care [7-9]. AIDS-related mortality (ARM) remains high in certain contexts, particularly because of advanced immunosuppression at the time of ART initiation [10,11]. In addition, an increasing proportion of deaths among people living with HIV are attributed to non-ARM (NARM) [12]. A recent global systematic review showed many people living with HIV died of cardiovascular disease, non-AIDS malignancies, and liver disease [13]. To improve health outcomes among people living with HIV, effective interventions are needed to reduce both ARM and NARM.

Community Health Workers Promote the Quality of HIV Care Among People Living With HIV

Task shifting involves the rational redistribution of tasks from the professional health workforce to community-based organizations (CBOs) and community health workers (CHWs) and is recognized by the World Health Organization (WHO) as an important strategy to optimize HIV care [14]. CHWs can play a valuable role in engaging and retaining people living with HIV in care [15,16]. CHWs strengthen the quality of HIV services as well as promote dignity and improve the quality of life for people living with HIV enrolled in those services [14]. Trials in several low-resource settings found CHWs can reduce the rates of virologic failure on ART and loss to follow-up [16-18]. A cluster randomized controlled trial in Zimbabwe found using CHWs to implement a community-based differentiated service delivery model that adapted HIV services to the preferences and expectations of adolescents significantly improved HIV viral suppression [19]. The WHO recommends community-based interventions to support ART adherence and retention in care while acknowledging that the evidence to support this recommendation is weak. Most previous evaluations of peer-led community-based interventions for people living with HIV have been conducted in high-income countries or sub-Saharan Africa, and few have reported survival as an outcome.

CBOs and CHWs have played a critical role in optimizing the HIV care continuum in China, especially in efforts to increase access to ART and improve retention in care [20]. The Chinese government has implemented a nationwide task-shifting strategy for HIV services, supporting the scale-up of CHWs through the China AIDS Fund for CBOs. Few previous studies have evaluated the effect of peer support delivered by CHWs on HIV treatment outcomes in China. We performed a propensity score–matched analysis of longitudinal data extracted from a database of HIV treatment outcomes in China to evaluate the impact of a multicomponent peer support model on ART adherence, viral suppression, and survival among people living with HIV in Wuxi, China.

Methods

Study Design

Using routine surveillance records on people living with HIV, we conducted a propensity score–matched cohort study of individuals who were served by local CBOs on HIV care. Convenient sampling method was used to enroll people living with HIV who had received peer-led community-based support services from local CBOs in the exposure group. In the meantime, we used propensity score matching (PSM) to enroll a comparable control group from other people living with HIV who had never received such a service.

Study Setting

Wuxi is a city of 8.5 million people in China’s Jiangsu Province. As of December 2021, a total of 4111 people living with HIV were registered as living in Wuxi. Rainbow Family is currently the only CBO registered with the local government to provide services for people living with HIV in Wuxi. This CBO has been providing support services to people living with HIV since June 2006.

Standard of Care for People Living With HIV in China

In 2003, China implemented free ART for people living with HIV [21]. Under this policy, all people living with HIV in China can obtain free HIV care and ART from health care providers at infectious diseases hospitals or clinics affiliated with local centers for disease control and prevention (CDCs). National guidelines suggest routine follow-up services should be delivered at 0.5, 1, 2, 3, 6, 9, and 12 months after ART initiation to monitor for adverse drug effects and adjust ART as necessary.

At 13 months after ART initiation, follow-up visits are recommended every 3 months, with CD4 and viral load testing performed at least every 12 months [22].

Peer-Led Community-Based Support Services Provided by Rainbow Family

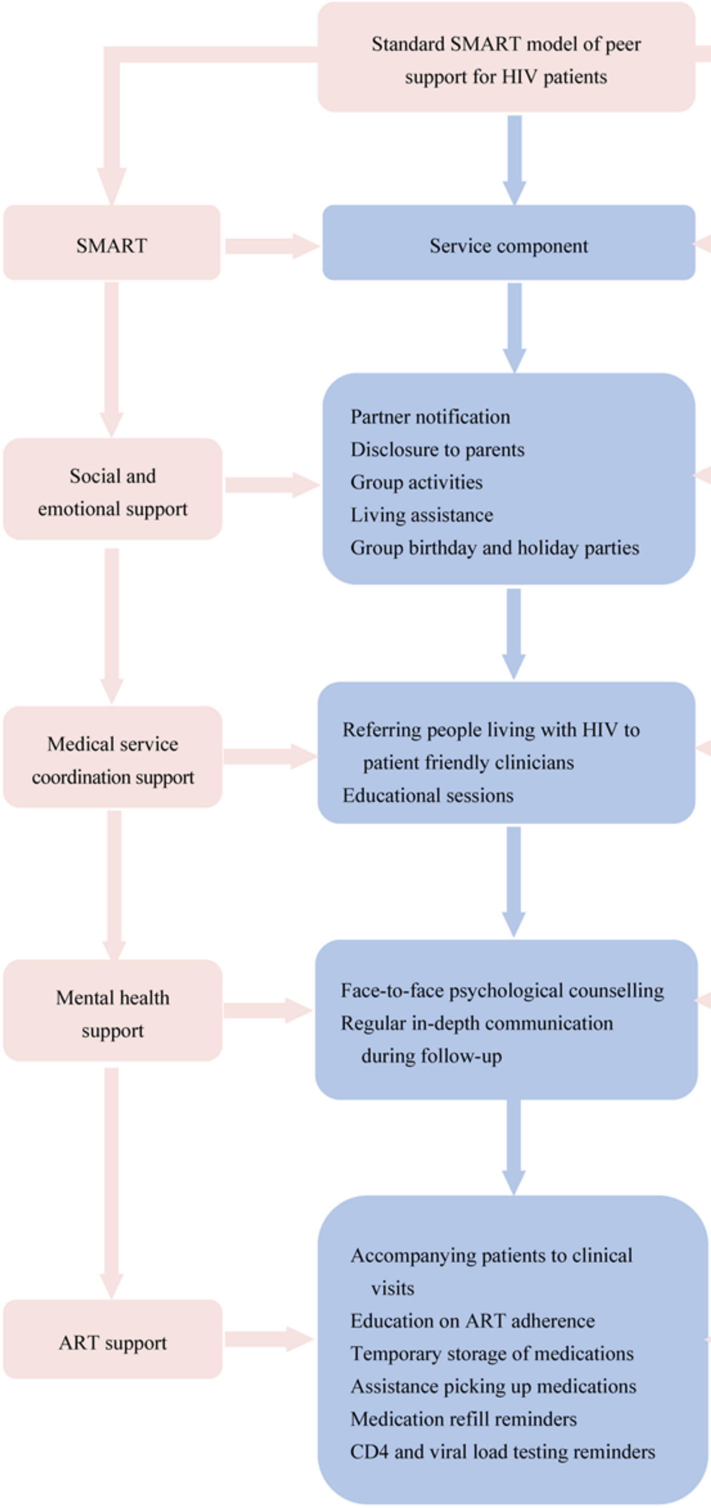
In Wuxi, all newly diagnosed people living with HIV are informed of their diagnosis and receive their initial HIV care visit at a local CDC clinic or infectious diseases hospital. At this initial visit, health care providers will introduce people living with HIV to the peer-led community-based support services offered at Rainbow Family and provide a referral if desired. A CHW from Rainbow Family will be assigned to any referred person living with HIV in Wuxi. Not all newly diagnosed people living with HIV opt to use the peer support services provided by CBOs. Factors influencing decision-making include, but are not limited to, self-acceptance of HIV status, willingness to expose their sexual orientation to others in the CBOs, and willingness to be followed up by peer CHWs in daily life.

CHWs at Rainbow Family are people living with HIV themselves and recruited as volunteers working for CBOs in their spare time who have documented adherence to ART for at least 12 months and demonstrated strong interpersonal and communication skills. Before providing services to clients, CHWs at Rainbow Family receive education on HIV pathogenesis, prevention, and treatment, as well as training on how to provide psychological support and referrals to other medical services. CHW trainings are led by professional health care workers, including public health practitioners from the Wuxi municipal CDC, HIV doctors and nurses, mental health counselors, and experienced peer educators. After passing the professional training, the CHWs will be assigned clients who are people living with HIV and initiate the peer-led community-based support according to guidelines.

The peer-led community-based support model provided by Rainbow Family was designed as a patient-centered peer support model. CHWs build trust and rapport with people living with HIV through regular face-to-face communication, contact through WeChat (an instant messaging software widely used in China), telephone calls, home visits, and group activities. These regular interactions allow CHWs to provide health care services and support to people living with HIV that are tailored to the individual needs of clients.

A social, medical, and mental ART support (SMART) model is used as a conceptual framework to guide this service (Figure 1). This model emphasizes four forms of support: (1) social and emotional support to navigate relationships with sex partners, spouses, family members, and friends, particularly assisting people living with HIV in coping with the emotional stress associated with partner notification and disclosure of HIV status; (2) medical service coordination support to overcome HIV-related stigma and discrimination from health care providers by referring people living with HIV to clinicians with experience providing nondiscriminatory care; (3) mental health support to connect people living with HIV with in-person psychological counseling to address concurrent anxiety, depression, or other mental health disorders; and (4) ART support to provide people living with HIV with additional education emphasizing the importance of ART adherence, accompanying patients to clinic visits to help them navigate ART initiation and maintenance, and providing reminders regarding medication refills and laboratory testing to overcome treatment fatigue.

Figure 1. The social, medical, and mental antiretroviral therapy (SMART) model of community-based peer-led support for people living with HIV in Wuxi, China. ART: antiretroviral therapy.



Data Collection

In accordance with national HIV treatment guidelines, HIV diagnoses are reported via the Chinese National HIV/AIDS Comprehensive Information Management System (CNHCIMS) within 24 hours. Information on sociodemographic characteristics, risk behaviors, CD4 count, HIV viral load, and mortality is recorded in the CNHCIMS. We extracted case report data from the CNHCIMS on sociodemographic characteristics and risk factors for HIV transmission for all people living with HIV in Wuxi between January 1, 2006, and December 31, 2019. We also extracted follow-up data detailing care retention, ART adherence, CD4 and viral load monitoring, mortality, and the cause of death for the same people living with HIV between January 1, 2006, and December 31, 2021.

Exposure Group

Rainbow Family collects and records the name and government-issued ID card number of all people living with HIV who have been assigned a CHW and received peer-led community-based support services. We obtained a list of people living with HIV who ever received peer-led community-based support from Rainbow Family, and persons on this list were linked to the CNHCIMS data by their unique government-issued ID card number. People living with HIV were assigned to the exposure group if they met the following inclusion criteria: (1) age ≥18 years at HIV diagnosis; (2) initiated ART on and before December 31, 2019; and (3) received peer-led community-based support from Rainbow Family for at least 6 months.

Control Group

People living with HIV in Wuxi identified in the CNHCIMS who had not received peer-led community-based support from Rainbow Family were eligible to be assigned to the control group in our analysis. To adjust for potential confounders, PSM was used to match people living with HIV in the exposure group with controls. Sex, age at diagnosis, ethnicity, education, marital status, occupation, the route of HIV infection, and baseline CD4 count are factors found to be significantly associated with survival among people living with HIV in previous studies and therefore were included in our PSM model [12,23,24]. In addition, before June 2016, people living with HIV in China were only eligible to initiate ART if their CD4 count was <500 cells/μL; therefore, the year of HIV diagnosis was also included in our PSM model.

When implementing PSM, propensity scores were generated using logistic regression, with the receipt versus nonreceipt of peer-led community-based support as the dependent variable. Propensity scores were generated for each of the imputed data sets, and an average propensity score for each observation was calculated across data sets. Each patient who received peer-led community-based support services (exposure group) was matched 1:1 with a patient who received routine support (control group) according to their propensity scores, using the nearest neighbor matching method without replacement.

Study Variables

Two sets of variables were extracted from the CNHCIMS. The first set was variables in HIV case report data set evaluated at diagnosis, which involved sex (male and female), age at diagnosis (continuous), ethnicity (Han and others), education (primary or less, secondary, and tertiary), marital status (unmarried, married, and divorced or widowed), occupation (student and others), the route of HIV infection (men who have sex with men and others including heterosexual behavior, drug use, and blood donation), the date of HIV diagnosis, and baseline CD4 count (cells/μL). All these variables were categorized into 2 or 3 subgroups where necessary and applicable. The other set was variables in the follow-up data set recorded after HIV diagnosis, in which drug collection, ART interruption, and scheduled follow-up visit were used to measure adherence to ART, and CD4 and viral load were used to measure retention in care.

Outcomes

All data on study outcomes were extracted from the CNHCIMS, and all outcomes were assessed using these extracted data. Adherence to ART was defined as never having a documented period of ART interruption and never having a period when a scheduled follow-up clinic visit was missed >3 months. Retention in care was defined as having received either CD4 or viral load monitoring on at least 1 occasion ≥12 months after ART initiation. People living with HIV who were on ART for at least 6 months and had a documented HIV viral load ≤1000 copies per mL were considered to be virally suppressed [25].

Information on the cause of death was obtained from diagnosis codes in the CNHCIMS. Causes of death were classified into categories of ARM, NARM, and all-cause mortality according to the coding causes of death in HIV Project protocol [26]. A death was classified as AIDS-related if the cause of death was an AIDS-defining condition. All other deaths were classified as non–AIDS-related. Non–AIDS-related deaths were grouped into several subcategories based on diagnosis codes: non–AIDS-related infections, malignancy, liver disease, cardiovascular disease, respiratory disease, accident and suicide and overdose, and other. ARM, NARM, and all-cause mortality were calculated using the number of AIDS-related, non–AIDS-related, and all deaths and the corresponding duration of follow-up, respectively.

Statistical Analysis

Descriptive statistics were used to summarize baseline demographic characteristics and HIV treatment outcomes for both the exposure and control groups. Differences between groups were compared using the Pearson chi-square test. Person-years (PY) was used to estimate ARM, NARM, and all-cause mortality. The Kaplan-Meier method was used to generate survival curves, and the log rank test was conducted to assess differences in survival time between the exposure and control groups. Competing risk models were used to identify factors potentially associated with ARM. Subdistribution hazard ratios were reported with corresponding 95% CIs. Cox proportional hazards models were used to assess correlates of all-cause mortality with reporting hazard ratios and its 95% CIs. Sex, age at diagnosis, ethnicity, marital status, education, occupation, the mode of transmission, the date of HIV diagnosis, baseline CD4 count, the receipt of peer-led community-based support, adherence to ART, and retention in care were included in the adjusted analysis for correlates of mortality and mortality, in which variables with a *P* value <.05 were retained in the final model. Statistical analyses were carried out using Stata (version 15.0; Stata Corp), and survival curves were completed using R software (version 3.6.0; R Core Team).

Ethics Approval

This study was approved by the Ethics Review Committee of Wuxi Municipal Centre for Disease Control and Prevention (WXCDC2022014). A unique ID number was used to protect each participant's privacy.

Results

Participant Characteristics

Data describing a total of 2794 people living with HIV were retrieved from the CNHCIMS between 2006 and 2019, among whom 430 met the criteria to be assigned to the exposure group. There were significant differences in baseline characteristics, including sex (*P*=.005), age at diagnosis (*P*<.001), education (*P*<.001), marital status (*P*<.001), occupation (*P*<.001), and baseline CD4 count (*P*=.001), comparing the 430 and 2364 people living with HIV who did and did not meet the inclusion criteria to be assigned to the exposure group, respectively. Using PSM, 430 people living with HIV were assigned to the control group. After PSM, people living with HIV in the exposure and control groups were comparable in all recorded baseline characteristics (Table 1).

[a] MSM: men who have sex with men.

[b] Since June 2016, all people living with HIV in China have been encouraged to initiate antiretroviral therapy regardless of CD4 cell count.

Among all 860 people living with HIV included in our analysis, 733 (85.2%) were men, 394 (45.8%) were diagnosed with HIV aged <30 years, 851 (99%) were of Han ethnicity, 373 (43.4%) had completed high school or had a higher level of educational achievement, and 83 (9.7%) were current students. More than half were unmarried (438/860, 50.9%) and were men who have sex with men (523/860, 60.8%). More than one-third (317/860, 36.9%) were diagnosed after June 2016, and just under one-third (248/860, 28.8%) had a CD4 count <200 cells/µL at the time of HIV diagnosis.

ART Adherence and Retention in Care

Compared with the control group, people living with HIV in the exposure group were more likely to adhere to ART (396/430, 92.1% vs 360/430, 83.7%; χ_1^2=14.2; *P*<.001) and remain retained in care (402/430, 93.5% vs 327/430, 76.1%; χ_1^2=50.7; *P*<.001) 12 months after ART initiation (Table 2). The proportion of people living with HIV who received viral load monitoring increased over time for both the exposure group (from 88/430, 20.5% at 9-12 months after HIV diagnosis to 381/430, 88.6% at 9-24 months after HIV diagnosis; χ_4^2=501.5; trend: *P*<.001) and control group (from 59/430, 13.7% to 243/430, 56.5%; χ_4^2=211.4; trend: *P*<.001; Table 3). Rates of viral load monitoring in the exposure group were significantly higher than the rates in the control group from 9 to 24 months after HIV diagnosis (all *P* values <.05). Rates of viral load suppression were significantly higher in the exposure group than the control group from 9 to 24 months after HIV diagnosis (357/381, 93.7% vs 217/243, 89.3%; χ_1^2=3.9; *P*=.048).

Table 2. Antiretroviral therapy (ART) adherence and retention in HIV care between the exposure and control groups (n=860).

ARM and All-Cause Mortality

During the study period, 25 individuals died within 4316.8 PY of follow-up. Among the 25 people living with HIV who died, 19 (76%) and 6 (24%) were attributed to ARM and NARM, respectively. Reasons for ARM were AIDS-related opportunistic infections (9/19, 47%), AIDS-related malignancies (6/19, 31%), and HIV wasting syndrome (4/19, 21%). Compared with the control group, the exposure group had lower rates of ARM (1.8 vs 7.0 per 1000 PY; rate difference −5.2; *P*=.01) and all-cause mortality (2.3 vs 9.3 per 1000 PY; rate difference −7.0; *P*=.002). There was no statistically significant difference in NARM (0.5

vs 2.3 per 1000 PY; rate difference −1.9; *P*=.12) comparing the 2 groups.

Survival analysis showed that people living with HIV in the exposure group had higher cumulative survival rates (χ_1^2=9.1; *P*=.003) compared with controls (Figure 2). After adjusting for other factors, multivariate analysis showed that the receipt of peer-led community-based support was associated with a 72% (adjusted subdistribution hazard ratio 0.28, 95% CI 0.09-0.95) reduction in ARM and a 70% (adjusted hazard ratio 0.30, 95% CI 0.11-0.82) reduction in all-cause mortality. Other factors associated with ARM and all-cause mortality are presented in Table 4.

Figure 2. All-cause mortality between the exposure and control groups.

Discussion

Principal Findings

In this propensity score–matched analysis of HIV treatment outcomes and mortality among people living with HIV in Wuxi between 2006 and 2021, we found that people living with HIV who received peer-led community-based support had better ART adherence, higher rates of retention in care, and improved survival rates than people living with HIV who had not received these services. Rates of viral suppression and compliance to viral load monitoring guidelines were high in the exposure group, with >90% of people living with HIV who had participated in the multicomponent support services program achieving viral suppression 9 to 24 months after HIV diagnosis. Most previous studies evaluating the relationship between peer-led support and HIV treatment outcomes were implemented in low- to middle-income countries (LMICs) in Africa or high-income countries, with few previous studies having been conducted in Asia [27,28]. Previous evaluations of similar interventions also reported improvements in ART adherence, viral suppression, and retention in care, although few have evaluated associations with ARM or all-cause mortality, given the limited follow-up periods [15,29]. Our study adds to the existing literature through demonstrating associations between peer-led community-based support services and improved HIV treatment outcomes, including lower ARM and all-cause mortality, over 15 years of follow-up in a middle-income country in Asia.

The Impact of Peer Support on Improving ART Adherence, Retention in Care, and Viral Suppression

People living with HIV in China who received at least 6 months of adjunctive peer-led community-based support had better ART adherence, viral suppression, and retention in HIV care than those in matched controls who only received standard clinic-based HIV care. Differences in retention in care were particularly pronounced, with >93% and only 76% of people living with HIV in the exposure and control groups retained in HIV care for ≥12 months after ART initiation, respectively. Our findings are similar to previous observational and experimental evaluations of support programs delivered by CHWs to people living with HIV in LMICs [15]. A prospective observational cohort study in Rwanda found that 85% of people living with HIV who received supplementary community-based support services remained retained in care and virally suppressed 1 year after ART initiation, which was a significantly higher proportion than people living with HIV who only received standard clinic-based HIV care (79%) [17]. Several meta-analyses have shown that community-based HIV initiatives and peer support are superior to standard clinic-based care to improve retention in care, ART adherence, and viral suppression [30,31]. There are many possible explanations as to why the receipt of peer-led community-based support was associated with improved HIV treatment outcomes in our analysis. The fear of unintended disclosure of HIV status, stigma, and discrimination have been identified as negatively influencing ART adherence and retention in care [32,33]. The SMART support framework used by CHWs at Rainbow Family explicitly addresses these potential barriers. It includes social and emotional support to help people living with HIV cope with stresses associated with partner notification and the disclosure of HIV status, as well as assistance navigating stigma and discrimination from health care providers. Previous studies have also found anxiety, depression, and treatment fatigue as negatively impacting ART adherence and retention in care [34,35]. The psychological support provided by CHWs in this study included specific strategies to address concurrent anxiety and depression among people living with HIV. CHWs at Rainbow Family also provided reminders regarding medication refills and laboratory testing in efforts to mitigate treatment fatigue, which may have improved rates of ART adherence and viral load monitoring among people living with HIV in the exposure group.

The Impact of Peer Support on Reductions of ARM and All-Cause Mortality

Compared with matched controls, the receipt of peer-led community-based support services was associated with 72% and 70% reductions in ARM and all-cause mortality, respectively, among people living with HIV in China. These findings are consistent with previous studies conducted in Rwanda [17] and South Africa [36] where support services delivered by CHWs in community settings were associated with lower mortality among people living with HIV after ART initiation. The improved HIV treatment outcomes observed among people living with HIV who received supportive services from Rainbow Family were likely a major contributing factor to the higher cumulative survival in the exposure group. Decades of research have shown that retention in care and ART adherence are essential to achieving and maintaining viral suppression, improving immune function, and thereby reducing ARM among people living with HIV [37-42]. Our results suggest that the observed reductions in all-cause mortality between the exposure and control groups were primarily driven by reductions in ARM as NARM did not significantly differ between the 2 groups. Although CHWs at Rainbow Family did provide general education on healthy lifestyle choices beyond HIV care, including the importance of physical activity, balanced diet, and smoking cessation, these were secondary considerations and were not explicitly emphasized by any particular component of the SMART support framework. As the proportion of deaths attributable to NARM among people living with HIV continues to grow worldwide, the scope of CHW support for people living with HIV may need to be expanded to address causes of mortality beyond opportunistic infections and HIV- or AIDS-associated malignancies, such as cardiovascular disease, substance use disorder, renal disease, and liver disease [13].

Differences in Various Peer-Led Community-Based Support Models

The peer-led community-based support services provided by Rainbow Family adopted a multicomponent SMART framework that attempted to provide broad support for HIV care across multiple domains, including HIV education and counseling, ART adherence and laboratory monitoring reminders, social and emotional support for interpersonal relationships and disclosure of HIV status, and mental health counseling. Although the WHO guidelines encourage task shifting of HIV services to CHWs in resource-limited settings, little guidance is available as to which types of support services or delivery models should be prioritized in task-shifting efforts to optimize health outcomes among people living with HIV [14]. Systemic reviews of CHWs interventions for people living with HIV in LMICs have found that support services vary considerably. Many CHW-based or peer-led interventions described in the literature include regular phone calls, SMS text messages, or home visits to answer HIV care questions and reminders to obtain ART refills and laboratory monitoring [31]. Other components that have been inconsistently incorporated into CHW-based or peer-led interventions for people living with HIV include directly observed therapy, referrals to other medical or social work services, harm reduction and substance use management, and various forms of psychosocial support [31]. The wide variety of intervention models as well as substantial differences in study design, setting, and measured outcomes complicate efforts to perform comparative analyses to determine which forms of peer-led community-based support are the most important to improve HIV treatment outcomes among people living with HIV [27]. Future qualitative and implementation science work may be particularly helpful in identifying core components of peer-led community-based support services for people living with HIV and optimizing service delivery across different settings in LMICs.

Engaging CBOs in HIV Care in China

Although the Chinese government has established the China AIDS Fund to support the development of grassroots organizations including CBOs providing service to people living with HIV, there are only a small number of people living with HIV who are served by peer CHWs. As CBOs in China are required to register as an official nongovernmental organization in a local Civil Affairs Bureau and most of them do not have sufficient personnel and funding to support themselves to achieve this, they have to apply for governmental funding on HIV as grassroots organizations through cooperation with local CDCs or specialized infectious disease hospital, which limits their development and growth owing to lacking endorsement from the government [43,44]. Our study showed that providing peer-led community-based differentiated support through peer CHWs in CBOs were likely to significantly improve the survival of people living with HIV. Accordingly, we strongly suggest that the central government and local governments at all levels should formulate more supportive policies and invest more to engage CBOs in HIV care. Because people living with HIV in China are generally experiencing a high degree of stigma owing to the conservative social environment [45], many infected persons are not willing to join CBOs to work as a peer CHW. Consequently, multilateral and multilevel efforts are urgently needed to overcome stigma and discrimination against people living with HIV to encourage them to engage in providing peer-led community-based differentiated support services.

Comparison With Prior Work

To the best of our knowledge, this is the first study to evaluate associations between the receipt of a multicomponent peer-led support service and survival among people living with HIV over a 15-year follow-up period and in a country in Asia based on a propensity score–matched analysis.

Limitations

Our study has several important limitations. The nonrandomized retrospective nature of our analysis prevents us from determining whether peer-led community-based support caused the observed differences in HIV treatment outcomes and survival between the exposure and control groups. Confounding factors may be responsible for some or all of our observed associations. For example, it is possible people living with HIV who were experiencing a mental health crisis or socioeconomic instability were both systematically more likely to have poor HIV treatment outcomes and less likely to remain connected to support services at Rainbow Family for at least 6 months. We used PSM to match individuals in the exposure and control groups to control for many common confounders that are known to influence HIV treatment outcomes; however, the possibility of unmeasured confounders influencing our results remains. Of note, by limiting our analytical sample to the 430 people living with HIV who received peer-led community-based support and 430 of matched controls, the representativeness of our sample may have been impacted, and people living with HIV included in this analysis may not be representative of people living with HIV in China more broadly. Therefore, the generalizability of our results must be interpreted with caution. In addition, although Rainbow Family was the only CBO registered with the local government to provide community-based support services to people living with HIV in Wuxi between 2006 and 2021, it is possible that other local CBOs or nongovernmental organizations were providing support services to some of the persons included in our analysis that were unknown to the local government or these authors, resulting in misclassification bias.

Conclusions

This study adds additional evidence supporting the use of peer-led community-based HIV initiatives and peer support interventions in LMICs, demonstrating that these programs are likely impactful in resource-limited settings beyond sub-Saharan Africa. The SMART framework used to guide the multicomponent HIV support services provided by Rainbow Family may be a model for similar services in other LMICs, particularly in other parts of China and East Asia where comprehensive peer-led support for people living with HIV remains less common. Further studies conducted across diverse settings are needed to confirm the effect and cost-effectiveness of such interventions.

Abstract

Background: China implemented a nationwide lockdown to contain COVID-19 from an early stage. Previous studies of the impact of COVID-19 on sexually transmitted diseases (STDs) and diseases caused by blood-borne viruses (BBVs) in China have yielded widely disparate results, and studies on deaths attributable to STDs and BBVs are scarce.

Objective: We aimed to elucidate the impact of COVID-19 lockdown on cases, deaths, and case-fatality ratios of STDs and BBVs.

Methods: We extracted monthly data on cases and deaths for AIDS, gonorrhea, syphilis, hepatitis B, and hepatitis C between January 2015 and December 2021 from the notifiable disease reporting database on the official website of the National Health Commission of China. We used descriptive statistics to summarize the number of cases and deaths and calculated incidence and case-fatality ratios before and after the implementation of a nationwide lockdown (in January 2020). We used negative binominal segmented regression models to estimate the immediate and long-term impacts of lockdown on cases, deaths, and case-fatality ratios in January 2020 and December 2021, respectively.

Results: A total of 14,800,330 cases of and 127,030 deaths from AIDS, gonorrhea, syphilis, hepatitis B, and hepatitis C were reported from January 2015 to December 2021, with an incidence of 149.11/100,000 before lockdown and 151.41/100,000 after lockdown and a case-fatality ratio of 8.21/1000 before lockdown and 9.50/1000 after lockdown. The negative binominal model showed significant decreases in January 2020 in AIDS cases (–23.4%; incidence rate ratio [IRR] 0.766, 95% CI 0.626-0.939) and deaths (–23.9%; IRR 0.761, 95% CI 0.647-0.896), gonorrhea cases (–34.3%; IRR 0.657, 95% CI 0.524-0.823), syphilis cases (–15.4%; IRR 0.846, 95% CI 0.763-0.937), hepatitis B cases (–17.5%; IRR 0.825, 95% CI 0.726-0.937), and hepatitis C cases (–19.6%; IRR 0.804, 95% CI 0.693-0.933). Gonorrhea, syphilis, and hepatitis C showed small increases in the number of deaths and case-fatality ratios in January 2020. By December 2021, the cases, deaths, and case-fatality ratios for each disease had either reached or remained below expected levels.

Conclusions: COVID-19 lockdown may have contributed to fewer reported cases of AIDS, gonorrhea, syphilis, hepatitis B, and hepatitis C and more reported deaths and case-fatality ratios of gonorrhea, syphilis, and hepatitis C in China.

KEYWORDS

COVID-19; AIDS; gonorrhea; syphilis; hepatitis B; hepatitis C; China; nonpharmaceutical; intervention; STD; disease; virus; cases; deaths; fatality; data

Introduction

China implemented stringent nonpharmaceutical interventions (NPIs), including city lockdowns and traffic restrictions, social distancing, and school closures in the early stages of the outbreak of COVID-19 to contain its spread [1-7]. These NPIs contributed to low morbidity and mortality of COVID-19 in the country [8-10]. However, it is necessary to keep a constant focus on other important infectious diseases. The numbers of documented influenza and pneumonia deaths in the United States in 2020 were reported to increase by 7.5% compared to 2019 [11], and modeling predicted that HIV deaths in African countries would increase [12,13].

As humans migrate and communicate, sexually transmitted diseases (STDs) and diseases caused by blood-borne viruses (BBVs) are a serious global burden [14-16]. Although China has established a national STD surveillance sentinel system, increased publicity and education, and improved treatment guidelines, STDs and BBVs are still on the rise. HIV/AIDS morbidity, mortality, and new HIV infections (defined as newly acquired blood HIV antibodies, as shown by positive results in ELISA and Western blotting and a large viral load in PCR testing) continually increased each year in China from 2004 to 2016 (from 0.235/100,000, 0.057/100, and 1.020/100,000 in 2004, respectively, to 3.990/100,000, 1.034/100, and 6.442/100,000, respectively, in 2016) [17]. Surveillance data from 2004 to 2013 in China showed that the incidence of hepatitis C, HIV infection, and syphilis increased by 19.2% (95% CI 15.9%-22.6%) annually [18].

Understanding changes in AIDS, gonorrhea, syphilis, hepatitis B, and hepatitis C over time is vital to contain the disease burdens of STDs and BBVs. Many studies have mainly focused on changes in respiratory infectious diseases during COVID-19 [19-21]. There is limited and conflicting evidence on changes in STDs and BBVs during the pandemic. A large tertiary care hospital in Chicago [22] reported the rate of presumed active infection with syphilis increased from 1.2% (prepandemic; June 2019-March 2020) to 1.8% (during the pandemic; April 2020-June 2020). Two referral centers in Greece [23] recorded 10% and 36.9% decreases in syphilis and gonorrhea cases, respectively, in 2020. A study of the STD and BBV service of an Italian clinic [24] did not find statistically significant differences compared with the previous 4 years. In addition, previous studies of the impact of COVID-19 on STDs and BBVs in China have yielded widely disparate results [25,26], and data on deaths attributable to STDs and BBVs are scarce. We aimed to elucidate the impact of COVID-19 lockdown on cases, deaths, and case-fatality ratios for AIDS, gonorrhea, syphilis, hepatitis B, and hepatitis C in China using interrupted time series analysis. This may provide evidence of the impact of COVID-19 lockdown on STDs and BBVs at the national level and inform planning for efficient control strategies in the postpandemic era.

Methods

Study Design

China launched a national online routine reporting system for selected infectious diseases in 2003 that covers all 31 provinces in mainland China. Health facilities at various levels are required to report cases through standard case report forms within 2 to 24 hours of the detection of a notifiable infectious disease.

We extracted national data on monthly reported cases and deaths for AIDS, gonorrhea, syphilis, hepatitis B, and hepatitis C, which are mainly or can be sexually transmitted, from January 2015 to December 2021 from the official website of the China Health and Wellness Commission [27]. The lockdown period was considered to start in January 2020 with the Wuhan city lockdown (on January 23, 2020) and massive restrictions implemented nationwide. Although some regions had eased restrictions before April 8 (when Wuhan lifted its restrictions), they tended to take stronger NPI measures to deal with the possible importation of COVID-19 cases from Wuhan. Based on these considerations, we defined the lockdown period as ending in April 2020. AIDS cases are defined as a diagnosis of AIDS. Syphilis cases include both primary and secondary syphilis. Cases that were reported as cases of notifiable infectious disease and died as a result of that infectious disease are reported as deaths, excluding deaths due to accidents or noninfectious diseases.

Statistical Analysis

The primary outcome was the number of cases and deaths reported by month for AIDS, gonorrhea, syphilis, hepatitis B, and hepatitis C before and after lockdown implementation. The secondary outcomes were the incidence and case-fatality ratios. We defined the incidence (per 100,000 population) as the mean value of annual new reported cases divided by the population size and the case-fatality ratio (per 1000 population) as the mean value of annual reported deaths divided by annual new reported cases.

We first summarized monthly reported data on cases and deaths for the 5 STDs and BBVs as the median (IQR) before, during, and after lockdown and calculated the incidence and case-fatality ratios before and after lockdown. The Kruskal-Wallis test was used to compare secondary outcomes before and after lockdown. Since overdispersion occurred in almost all outcomes (Multimedia Appendix 1, Table S1), we conducted an interrupted time series analysis by fitting a negative binominal segmented regression model to estimate the immediate effects of lockdown on cases, deaths, and case-fatality ratios, as well as trends after lockdown [28]. The negative binominal model included (1) a time variable, (2) a dummy variable representing the pre- and postlockdown periods, and (3) an interaction term between time and the dummy variables (Multimedia Appendix 1).

We adjusted for seasonality and long-term trends to control their effects and allow the direct study of changes in public health issues (ie, testing and transmission), as follows: (1) the reporting of STD and BBV data is influenced by individual and clinical activity, so we adjusted for seasonal variation by including a Fourier term consisting of 2 sine-cosine pairs in the model [29]; (2) the reporting of STD and BBV data has long-term trends, so we adjusted for long-term trends by using the prelockdown model to predict the expected outcomes after lockdown (ie, a counterfactual scenario). We analyzed the annual trends of the models for the 5 diseases to determine their seasonality.

The incidence rate ratio (IRR) was calculated by comparing the fitted numbers from the model with the expected numbers from the contemporaneous counterfactual. By subtracting a period from the time variable, we were able to center time in January 2020 and December 2021 to estimate the impact on different timepoints [30]. To calculate the trend after lockdown, we added the coefficients associated with time and the time-dummy interaction. We adjusted the standard errors of the model parameters using the Newey-West method to calculate a 95% CI for the IRR in both January 2020 and December 2021, with lag taking the optimal value calculated [31].

We conducted a sensitivity analysis of the number of pairs of Fourier terms (1, 3, and 5 pairs). All statistical tests were 2-sided, and *P*<.05 was considered statistically significant. We performed all analyses in R (version 4.0.4; R Foundation for Statistical Computing; Multimedia Appendix 1).

Ethical Considerations

This study was a secondary analysis of online reported data with no identifying information available to the researchers. Therefore, ethical review was not applicable.

Results

Overview of Study

From January 2015 to December 2021, 14,800,330 cases of AIDS, gonorrhea, syphilis, hepatitis B, and hepatitis C were reported in China, with a notified incidence of 149.11/100,000 before lockdown and 151.41/100,000 after lockdown. The incidence (mean value of annual incidence) change in these 5 infectious diseases before and after lockdown is shown in Table 1. There were slight but not significant (*P*>.05) changes in the incidence of the 5 diseases after lockdown. The median number of monthly reported cases was 177,556 (IQR 164,546-187,722) during the 60 months before lockdown, 155,491 (IQR 121,585-157,244) during the first 3 months of nationwide lockdown (January 2020 to March 2020), and 184,401 (IQR 180,396-190,466) during the 21 months after lockdown eased (April 2020 to December 2021). Figure 1 shows the annual seasonal pattern in the case counts of the 5 diseases. AIDS peaked in May and October to November, gonorrhea in July and November, syphilis in May to June, and hepatitis B and C in May.

In total, 127,030 deaths were reported during the study period, with the case-fatality ratio changing from 8.15/1000 before lockdown to 9.50/1000 after lockdown. The change in case-fatality ratios (ie, the mean value of annual case-fatality ratios) for the 5 infectious diseases before and after lockdown is shown in Table 2. There was a significant (*P*=.03) increase in the gonorrhea case-fatality ratio after lockdown (from 0.01/1000 to 0.04/1000). The median number of monthly deaths due to the five STDs and BBVs was 1360 (IQR 1208-1692) before lockdown, 1078 (IQR 1054-1270) during lockdown, and 1761 (IQR 1602-1942) after lockdown eased.

Table 1. Case numbers and incidence rates for AIDS, gonorrhea, syphilis, hepatitis B, and hepatitis C in China from January 2015 to December 2021. Incidence was calculated as the mean number of annual new cases divided by the population size (per 100,000).

	Cases[a], n	Incidence before lockdown[b,c]	Incidence after lockdown[b,d]	*P* value	Cases before lockdown[c,e], median (IQR)	Cases during lockdown[e,f], median (IQR)	Cases after lockdown eased[e,g], median (IQR)

Cases and Deaths

AIDS

In the first month of lockdown, there was a 23.4% (IRR 0.766, 95% CI 0.626-0.939; Figure 2A and Table 3) decrease in the number of reported AIDS cases; after lockdown, the monthly number remained unchanged (IRR 1.005, 95% CI 0.990-1.020); by December 2021, AIDS cases were still below the expected level (IRR 0.715, 95% CI 0.586-0.874).

In the first month of lockdown, the number of reported AIDS deaths showed a 23.9% decline (IRR 0.761, 95% CI 0.647-0.896); after lockdown, the number showed an increasing trend of 1.1% (IRR 1.011, 95% CI 1.000-1.021) per month; by December 2021, the number of AIDS deaths remained below the expected level (IRR 0.754, 95% CI 0.654-0.869). In the first month of lockdown, there was no significant change in the AIDS case-fatality ratio (IRR 1.004, 95% CI 0.895-1.125); after lockdown, the monthly number remained unchanged (IRR 1.006, 95% CI 0.997-1.016); by December 2021, the AIDS case-fatality ratio remained in line with the expected level (IRR 1.075, 95% CI 0.924-1.252).

Figure 2. Monthly numbers, trends, and fitted negative binominal segmented regression models for 5 sexually transmitted diseases and diseases caused by blood-borne viruses in China from January 2015 to December 2021: AIDS (A), gonorrhea (B), syphilis (C), hepatitis B (D), and hepatitis C (E). The light blue shaded areas indicate the period during the lockdown, from January 2020 to March 2020, and the dark blue shaded areas indicate the period after lockdown eased, from April 2020 to December 2021. Case-fatality ratios represent the number of deaths divided by the number of new cases (per 1000). NPI: nonpharmaceutical intervention.

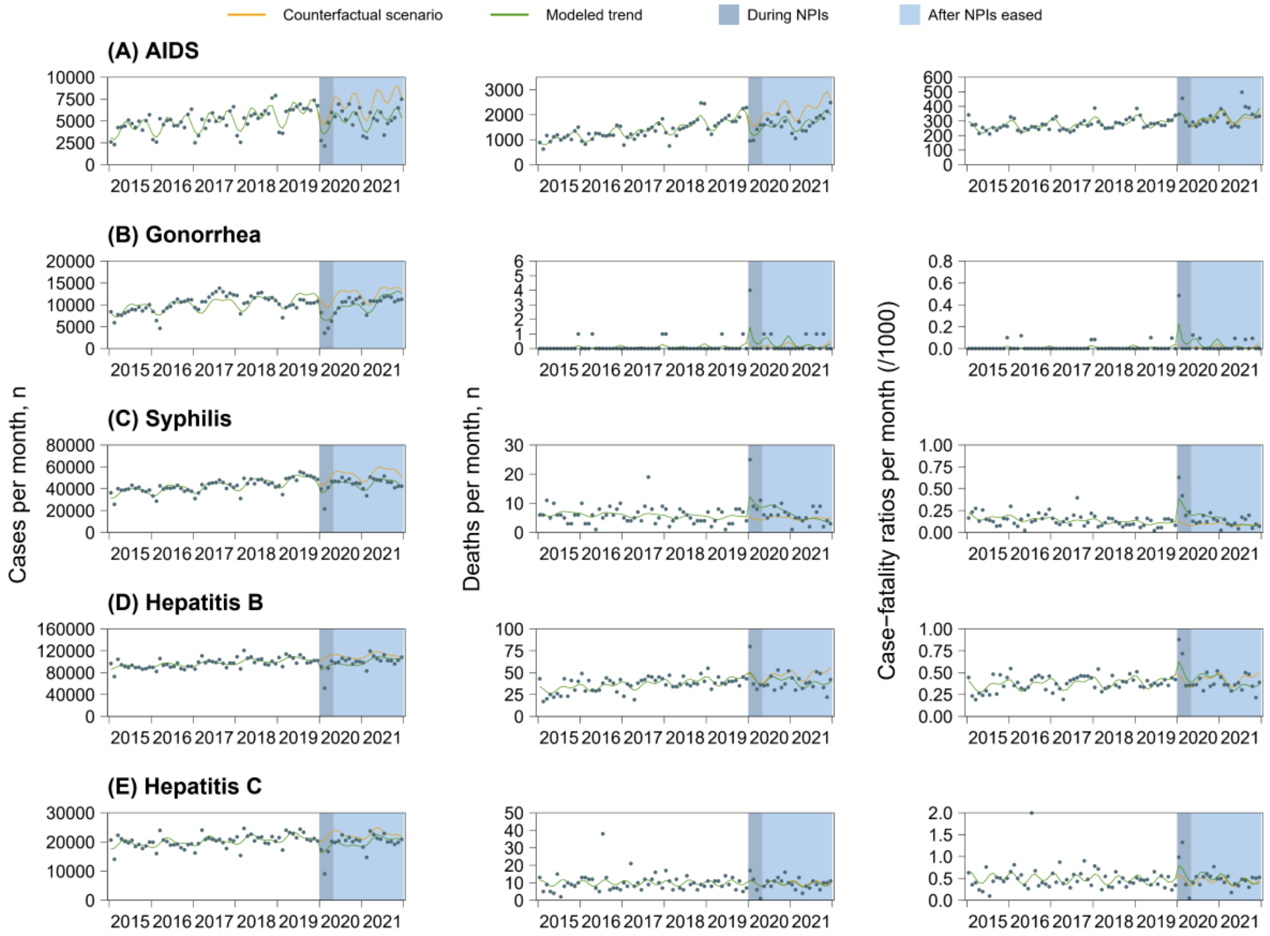

Table 3. Negative binominal segmented regression models of the impact of COVID-19 lockdown on AIDS, gonorrhea, syphilis, hepatitis B, and hepatitis C in China from January 2015 to December 2021. Trend represents the slope change per month. Case-fatality ratio represents the number of deaths divided by the number of new cases. Autocorrelation was addressed for all diseases using Newey-West standard errors to calculate CIs, with lag taking the optimal value calculated.

[a] IRR: incidence rate ratio.

[b] January 2020.

[c] December 2021.

[d] From January 2015 to December 2019.

[e] From January 2020 to December 2021.

Gonorrhea

In the first month of lockdown, there was a 34.3% decline (IRR 0.657, 95% CI 0.524-0.823; Figure 2B and Table 3) in the number of reported gonorrhea cases; after lockdown, there was a 2.1% (IRR 1.021, 95% CI 1.007-1.035) monthly increasing trend; by December 2021, the number of gonorrhea cases had returned to the expected level (IRR 0.952, 95% CI 0.722-1.257).

In the first month of lockdown, the number of reported gonorrhea deaths showed an increase of 490.2% (IRR 5.902, 95% CI 1.090-31.959); after lockdown, the number remained largely unchanged (IRR 0.916, 95% CI 0.804-1.043); by December 2021, the number of gonorrhea deaths had returned to below the expected level (IRR 0.558, 95% CI 0.038-8.266). In the first month of lockdown, there was an 867.6% increase (IRR 9.676, 95% CI 1.764-53.089) in the gonorrhea case-fatality ratio; after lockdown, the number remained unchanged (IRR 0.880, 95% CI 0.766-1.012); by August 2021, the gonorrhea case-fatality ratio had returned to below the expected level (IRR 0.398, 95% CI 0.018-8.890).

Syphilis

In the first month of lockdown, the number of reported syphilis cases showed a 15.4% decrease (IRR 0.846, 95% CI 0.763-0.937; Figure 2C and Table 3); after lockdown, the monthly number per month was unchanged (IRR 1.004, 95% CI 0.998-1.010); by December 2021, the number of syphilis cases was still below the expected level (IRR 0.818, 95% CI 0.751-0.892).

In the first month of lockdown, the number of reported syphilis deaths showed an increase of 138% (IRR 2.380, 95% CI 1.455-3.893); after lockdown, the number per month showed a decreasing trend of 5.4% (IRR 0.946, 95% CI 0.913-0.980); by December 2021, the number of syphilis deaths had returned to below the expected level (IRR 0.735, 95% CI 0.421-1.284). In the first month of lockdown, the syphilis case-fatality ratio showed an increase of 217.3% (IRR 3.173, 95% CI

1.877-5.365); after lockdown, the number per month showed a decreasing trend of 6.7% (IRR 0.933, 95% CI 0.897-0.971); by December 2021, the syphilis case-fatality ratio had returned to the expected level (IRR 0.810, 95% CI 0.442-1.484).

Hepatitis B

In the first month of lockdown, there was a 17.5% (IRR 0.825, 95% CI 0.726-0.937; Figure 2D and Table 3) decrease in the number of reported hepatitis B cases; after lockdown, there was an increasing trend of 1% (IRR 1.010, 95% CI 1.002-1.018) per month; by December 2021, the number of hepatitis B cases had returned to the expected level (IRR 0.968, 95% CI 0.896-1.045).

In the first month of lockdown, there was no significant change in the number of reported hepatitis B deaths (IRR 1.038, 95% CI 0.854-1.261); after lockdown, the number showed a decreasing trend of 1.1% (IRR 0.989, 95% CI 0.979-0.999) per month; by December 2021, the number of hepatitis B deaths was significantly lower than the expected level (IRR 0.704, 95% CI 0.590-0.842). In the first month of lockdown, there was no significant change in the hepatitis B case-fatality ratio (IRR 1.312, 95% CI 0.997-1.726); after lockdown, it showed a decreasing trend of 2.4% (IRR 0.976, 95% CI 0.958-0.995); by December 2021, the hepatitis B case-fatality ratio was significantly lower than the expected level (IRR 0.709, 95% CI 0.556-0.902).

Hepatitis C

In the first month of lockdown, there was a 19.6% (IRR 0.804, 95% CI 0.693-0.933; Figure 2E and Table 3) decrease in the number of reported hepatitis C cases; after lockdown, there was a 1% increasing trend (IRR 1.010, 95% CI 1.001-1.019) per month; by December 2021, the number of hepatitis C cases had returned to the expected level (IRR 0.950, 95% CI 0.854-1.057).

In the first month of lockdown, there was no significant change in the number of reported hepatitis C deaths (IRR 1.006, 95% CI 0.781-1.296); after lockdown, the monthly number remained unchanged (IRR 0.996, 95% CI 0.982-1.011); by December 2021, the number of hepatitis C deaths was not significantly different from the expected level (IRR 0.926, 95% CI 0.672-1.275). In the first month of lockdown, there was a 39.4% increase (IRR 1.394, 95% CI 1.080-1.800) in the hepatitis C case-fatality ratio; after lockdown, it showed a decreasing trend of 2.1% (IRR 0.979, 95% CI 0.966-0.992) per month; by December 2021, the hepatitis C case-fatality ratio was not significantly different from the expected level (IRR 0.906, 95% CI 0.653-1.258).

Sensitivity Analysis

Sensitivity analysis showed that the number of pairs of the Fourier term had little effect on the results (Multimedia Appendix 1, Tables S2, S3, and S4).

Discussion

Principal Findings

This study found that COVID-19 lockdown had a significant impact on the number of reported cases and deaths and case-fatality ratios for AIDS, gonorrhea, syphilis, hepatitis B, and hepatitis C in China. In the first month of lockdown, significant decreases were seen in reported AIDS cases (–23.4%) and deaths (–23.9%), reported gonorrhea cases (–34.3%), reported syphilis cases (–15.4%), reported hepatitis B cases (–17.5%), and reported hepatitis C cases (–19.6%). Gonorrhea, syphilis, and hepatitis C showed small increases in the number of reported deaths and case-fatality ratios in January 2020. By December 2021, nearly two years after the lockdown, the reported cases, deaths, and case-fatality ratios for each disease either reached or remained below expected levels.

Our study found that monthly reported cases of each disease showed an alarming upward trend before the COVID-19 pandemic, which was consistent with the overall trend worldwide. Since the 1980s, the number of new reported cases of STDs and BBVs has declined significantly with comprehensive prevention efforts around the world [32-34]. However, over the past decade, several countries and regions have reported an increasing trend in reported cases of STDs and BBVs. From 2009 to 2019, reported syphilis cases in Sri Lanka and reported gonorrhea and syphilis cases in Thailand showed an increasing trend [35]. A similar trend has been observed in several European countries [36]. With the widespread global epidemic of HIV, STDs and BBVs have become an increasingly serious public health problem.

In addition, the seasonality of reported cases of STDs and BBVs shown in this study is consistent with existing research. A study from Melbourne, Australia [37] found that urethral gonorrhea diagnoses among men who have sex with men (odds ratio [OR] 1.23, 95% CI 1.04-1.46) and nongonococcal urethritis diagnoses among men who have sex with women (OR 1.11, 95% CI 1.03-1.20) were higher in summer compared with winter. This may be due to increased chances of infection due to increased biological sexual desire, number of sexual partners, and sexual activity during the hot summer months [38,39], as well as increased willingness to test for STDs and BBVs in the population due to World AIDS Day (December 1). In addition, the annual seasonal pattern of monthly reported cases of the 5 infectious diseases was largely due to the annual activities of clinics and health facilities. Every year around April, health facilities in different regions in China receive their annual assignments, so most peaks in disease reporting are in the last 3 quarters. In the first quarter, there is a major holiday in China (Chinese New Year), leading to a low disease reporting level. Similar trends were observed in our study, suggesting that our data source and analytic tools were robust.

Decreases in reported AIDS, gonorrhea, syphilis, hepatitis B, and hepatitis C cases during the COVID-19 lockdown have also been observed in other countries. A national study in the United States [40] found that the numbers of weekly reported cases of chlamydia (–49.8%), gonorrhea (–71.2%), and syphilis (–63.7%) were much lower in 2020 than in week 15 of 2019. A study in Catalonia, Spain [41] found that there were 51% fewer reported cases of STDs and BBVs than expected since the beginning of the COVID-19 pandemic, reaching an average of 56% during the lockdown, with the greatest decrease of 72% for chlamydia and the least, of 22%, for syphilis. Difficulties and unwillingness to seek medical care and possible underreporting were considered as reasons for the decrease in the 5 diseases. According to a study on health service use during COVID-19 in China, all-cause visits showed a decrease of 47.6% (ranging from 24.8% in township health centers to 70% in primary care clinics) and inpatient volume showed a decrease of 47.7% (ranging from 26.8% in other health facilities to 57.8% in first-level hospitals) in February 2020 [42]. Another study, in Hong Kong, found that emergency department visits decreased by 27.4%, from 1,426,259 in 2019 to 1,035,562 in 2020 [43]. Several studies have reported that patients have delayed or avoided seeking care for fear of being infected with COVID-19 [44,45].

The decrease in the number of reported cases may also be due to NPIs such as mobility restrictions and social distancing measures affecting people's sexual activity. A study of 967 Chinese youth [46] found that 22% of participants reported decreased sexual desire, 41% decreased frequency of sexual intercourse, 30% increased frequency of masturbation, 20% decreased alcohol consumption before or during sexual activity, and 31% deterioration in partner relationships during the pandemic and related containment measures. An online survey conducted in China [47] showed that 44% of people reported a decrease in sexual partners during COVID-19. In addition, frequent long-term lockdowns reduce interpersonal contact and public gatherings, which may also reduce the risk of transmission of STDs and BBVs in the population.

The immediate decrease in reported AIDS deaths in the first month of lockdown may be due to COVID-19 deaths among people living with AIDS being attributed to COVID-19 rather than AIDS. According to the National Health Commission of China, the cumulative number of deaths nationwide reached 4636 by the end of 2021 [48]. However, we are concerned that incorrect death certificates might obscure the truth about the deaths of HIV patients, especially during the COVID-19 pandemic, when a high work burden might have resulted in incorrect findings and documentation within hospitals and clinics. In the future, it would be valuable to elucidate the reasons behind changes in the number of deaths if more data become available. In addition, AIDS deaths were lower than the expected level 24 months after lockdown, which may be explained by the effectiveness of measures taken in China to prevent antiretroviral therapy (ART) interruption. NPIs adopted by countries or regions around the world during the COVID-19 pandemic were thought to affect the HIV care continuum for people living with HIV/AIDS [12,30,49,50]. The Chinese Center for AIDS/STD Control and Prevention released a nationwide directive on January 26, 2020, under which people living with HIV/AIDS could obtain 1 month of ART from any local HIV care clinic or hospital [51]. Designated hospitals and clinics across the country also contributed to the maintenance of ART. Hospitals in Shenzhen increased the supply of medications for a single ART collection and adopted courier delivery to ensure uninterrupted treatment for people living with HIV/AIDS during the outbreak [52]. Together, these efforts mitigated the disruption of ART to the greatest extent possible.

The increase in reported deaths or case-fatality ratios for gonorrhea, syphilis, and hepatitis C may be associated with shifts in medical resources and services to COVID-19 patients. China heavily focused the use of medical supplies, human resources, and health resources during the pandemic to respond to the explosive increase in confirmed COVID-19 cases, with some hospitals shutting down due to the risk of COVID-19 infection and some admitting only severe and critically ill COVID-19 cases [53]. Reduced willingness to seek medical care and access to care may have contributed to the disruption of treatment and the increase in deaths. However, it is important to note that the absolute numbers of deaths from gonorrhea, syphilis, and hepatitis C were very small and should not be overinterpreted.

The implementation of massive lockdowns did not change the increasing trend of reported cases of gonorrhea, hepatitis B, and hepatitis C. These short-term trends may not necessarily be stable due to the immediate impact of lockdown on STDs and BBVs in January 2020 and will need to be observed over a longer period. As China rapidly brought the domestic COVID-19 pandemic under control, the health system was able to shift resources and human resources to address other infectious diseases. Concerns about seeking health care were alleviated, with health facility visits and inpatient volume showing continued statistically significant increases after March 2020, reaching 89% and 91% of expected levels, respectively, in June 2020 [42]. Meanwhile, frequent and persistent NPIs in China such as social distancing continued to affect sexual activity and limit the spread of STDs and BBVs after the Wuhan lockdown was lifted (on April 7, 2020). By December 2021, reported cases, deaths, and case-fatality ratios for AIDS, gonorrhea, syphilis, hepatitis B, and hepatitis C either reached or remained below expected levels.

Our study used 7 years of nationwide data to estimate the impact of COVID-19 on AIDS, gonorrhea, syphilis, hepatitis B, and hepatitis C in China using 4 indicators adjusted for long-term trends and seasonality. To our knowledge, this is the first study to use interrupted time series analyses to elucidate the number of reported STD and BBV cases and deaths in China during the COVID-19 pandemic. However, our study has several limitations. First, it is an ecological study and cannot demonstrate a causal relationship between COVID-19 lockdowns and changes in trends related to AIDS, gonorrhea, syphilis, hepatitis B, and hepatitis C in China. Second, our study was based on publicly available data, which limited what kinds of data we could obtain. Due to a lack of data reported on a weekly basis, we could only define the time point for lockdown as January 2020, which may be inaccurate. Due to a lack of provincial data, we were unable to provide results for different provinces or regions in this study. Potentially, deaths due to COVID-19 and incorrect death certificates in hospitals and clinics during the COVID-19 pandemic could have affected the accuracy of this study's results. The lack of prevalence data is also a limitation, given that the prevalence of many infectious diseases is unknown. Although the case-fatality ratio cannot be interpreted as the overall risk of death from an infection, it is the most commonly used metric because most countries collect this information [18,54,55]. As prevalence is unknown, the case-fatality ratio not only provides a crude estimate of the risk of death (such as in the COVID-19 outbreak [56]), but also allows for cross-sectional comparisons. Finally, this study was a secondary analysis of online reported data with no identifying information available to the researchers, which limits our consideration of disease intersections in the analysis. The subjects of our study should be interpreted as reported cases of a single disease rather than as individuals.

Conclusion

In summary, these findings suggest that AIDS, gonorrhea, syphilis, hepatitis B, and hepatitis C in China were transiently affected by COVID-19 lockdown. Our findings may promote the development of STD and BBV policies and control measures in the context of the COVID-19 pandemic and the persistence of lockdowns. More long-term observations are needed to investigate trends in STDs and BBVs over time.

Acknowledgments

This study was supported by the Natural Science Foundation of China Excellent Young Scientists Fund (82022064), the Special Support Plan for High-Level Talents of Guangdong Province (2019TQ05Y230), the High Level Project of Medicine in Longhua, Shenzhen (HLPM201907020105), the Sanming Project of Medicine in Shenzhen (SZSM201811071), the Shenzhen Nanshan District San-Ming Project (SZSM202103008), and the "Pearl River Talent Plan" Innovation and Entrepreneurship Team Project of Guangdong Province (2021ZT09Y544). No funding parties had any role in the design of the study or in the explanation of the data. The corresponding author had full access to all the data in the study and had final responsibility for the decision to submit it for publication.

Data Availability

The data sets generated during and/or analyzed during the current study are available in the public, open-access China Health and Wellness Commission repository [27].

Authors' Contributions

HZ, CY, XW, XZ, and YC conceived and designed the study in consultation with the other authors. YC contributed to data collection. XZ reviewed scientific literature. XW contributed to data analysis and presentation. All authors contributed to the interpretation of the study findings. XW drafted the report with all authors critically reviewing the paper. All authors saw and approved the final report. HZ and CY contributed equally to this work. XW, XZ and YC contributed equally to this work.

Conflicts of Interest

None declared.
