Abstract

Background: Undiagnosed tuberculosis (TB) cases are the major challenge to TB control in Nigeria. An early warning outbreak recognition system (EWORS) is a system that is primarily used to detect infectious disease outbreaks; this system can be used as a case-based geospatial tool for the real-time identification of hot spot areas with clusters of TB patients. TB screening targeted at such hot spots should yield more TB cases than screening targeted at non–hot spots.

Objective: We aimed to demonstrate the effectiveness of an EWORS for TB hot spot mapping as a tool for detecting areas with increased TB case yields in high TB-burden states of Nigeria.

Methods: KNCV Tuberculosis Foundation Nigeria deployed an EWORS to 14 high-burden states in Nigeria. The system used an advanced surveillance mechanism to identify TB patients' residences in clusters, enabling it to predict areas with elevated disease spread (ie, hot spots) at the ward level. TB screening outreach using the World Health Organization 4-symptom screening method was conducted in 121 hot spot wards and 213 non–hot spot wards selected from the same communities. Presumptive cases identified were evaluated for TB using the GeneXpert instrument or chest X-ray. Confirmed TB cases from both areas were linked to treatment. Data from the hot spot and non–hot spot wards were analyzed retrospectively for this study.

Results: During the 16-month intervention, a total of 1,962,042 persons (n=734,384, 37.4% male, n=1,227,658, 62.6% female) and 2,025,286 persons (n=701,103, 34.6% male, n=1,324,183, 65.4% female) participated in the community TB screening outreaches in the hot spot and non–hot spot areas, respectively. Presumptive cases among all patients screened were 268,264

(N=3,987,328, 6.7%) and confirmed TB cases were 22,618 (N=222,270, 10.1%). The number needed to screen to diagnose a TB case in the hot spot and non–hot spot areas was 146 and 193 per 10,000 people, respectively.

Conclusions: Active TB case finding in EWORS-mapped hot spot areas yielded higher TB cases than the non–hot spot areas in the 14 high-burden states of Nigeria. With the application of EWORS, the precision of diagnosing TB among presumptive cases increased from 0.077 to 0.103, and the number of presumptive cases needed to diagnose a TB case decreased from 14.047 to 10.255 per 10,000 people.

Introduction

Tuberculosis (TB) continues to be a global health concern, which explains why ending the disease epidemic by 2030 is a target of sustainable development goals [1]. Regarding the burden of TB at the country level, Nigeria is sixth globally and the first in Africa [2]; therefore, controlling this chronic infectious disease is a top priority for the national TB program [3]. Globally, the number of annual case notifications is usually far below the estimated incident cases. Unfortunately, this gap (ie, missing TB cases), which had consistently narrowed over the years, widened in 2020 due to a large drop in the number of newly diagnosed TB cases due to the impact of the COVID-19 pandemic [2,4]. In 2020, there were about 9.9 million estimated incident TB cases worldwide, but only 5.8 million were notified, leaving a large gap of about 4.1 million missing cases; notably, Nigeria contributed significantly to this global gap, ranking first in Africa [2].

These missing TB cases could either be due to underreporting or underdiagnosis. In Nigeria, however, underdiagnosis contributes to most missing cases; this calls on the country to strengthen access to high-quality screening, diagnostic, and treatment services [5]. The KNCV Tuberculosis Foundation Nigeria (KNCV Nigeria) continues to assist the Nigerian TB control program in this regard through several projects, including the successful demonstration of the excellent capacity of TB loop-mediated isothermal amplification technology for TB diagnosis among adults in Nigeria [6], as well as the need for X-ray–based mass TB screening in Nigerian prisons [7].

Because undiagnosed TB cases are the major challenge to TB control in Nigeria, any strategy that will identify ongoing TB transmission hot spots in the community is crucial for finding and treating missing TB cases. Electronic recording and reporting of TB are becoming adopted widely by the national TB control programs [8]. The electronic data can be imported into a geographic information system (GIS) for mapping and spatial analysis; thus, the data can be used to identify TB transmission hot spots in the community [8]. Such an electronic GIS strategy has been used in early warning systems (EWSs) for infectious disease surveillance [9], such as the China Infectious Disease Automated Alert and Response System (CIDARS) [10] and an early warning outbreak recognition system (EWORS) implemented by the Indonesian Ministry of Health [11]. Both systems serve as complementary country-wide disease surveillance tools; however, while the CIDARS is a case-based EWS, the EWORS in Indonesia is a syndromic surveillance-based EWS [9]. In Nigeria, an EWORS is operational at the subnational level for routine electronic disease surveillance—the system automatically sends elevated disease activity messages to appropriate disease surveillance officers, which triggers the investigation of the affected areas to prevent outbreaks [12].

Though the EWORS is an early-warning system for infectious diseases to detect outbreaks and guide control practice, it can also predict TB hot spots at the community level by identifying TB patients’ residences in clusters. Because TB is infectious, it is expected that community-based active case finding (ACF) in such EWORS-identified hot spot areas will yield more TB cases when compared to non–hot spot areas. To demonstrate this expectation, KNCV Nigeria applied an EWORS as a geospatial tool for real-time identification of hot spot areas with high TB prevalence for targeted community-based ACF interventions. This innovative project aimed to demonstrate the effectiveness of EWORS TB hot spot mapping for increased TB case yield in 14 states of Nigeria with a high TB burden.

Methods

Overview

This is a retrospective review of data from community-based active TB screening interventions by KNCV Nigeria in EWORS-identified TB hot spot areas in 14 states of Nigeria with a high TB burden. This public health intervention was part of the US Agency for International Development–funded TB Local Organization Network Regions 1 and 2 Project. The 14 states involved include 8 northern Nigerian states (Bauchi, Benue, Kaduna, Katsina, Kano, Nasarawa, Plateau, and Taraba) and 6 southern Nigerian states (Anambra, Akwa Ibom, Cross River, Delta, Imo, and Rivers). The 16-month intervention lasted from October 2020 to January 2022.

KNCV Nigeria instituted TB hot spot analysis using InStrat Global Health Solutions’ EWORS to inform community mass TB screening interventions in the identified communities in the 14 project states. The EWORS used an advanced surveillance mechanism to identify TB patients’ residences in clusters, enabling it to predict hot spots at the ward and community level. The EWORS hot spot analytic dashboard portal was developed per state. State hot spot data visualization included heat maps that allowed users to drill down to the ward or community level to pinpoint locations of active cases. Every day, EWORS pulled real-time data from a Commcare-based mobile app—an open-source data capture tool running on Android smartphones that records routine TB surveillance data at health facilities providing TB services in the project states. The Commcare cloud server sent data to the EWORS via a custom data transfer application programming interface. Information was synchronized that predicted the likelihood of the occurrence of disease clusters at the ward or community level and included patient-level clinical data (ie, TB symptoms, TB investigations, TB diagnoses, and treatment status) and nonclinical data (ie, state of residence, local government area [LGA], and ward).

The EWORS triggered an alarm when a hot spot was identified. For the project, a hot spot was identified when any ward or community had a confirmed TB case count of 5 or more, and the presumptive to confirmed case count was less than 10. Similar alarm thresholds were set for individual states. The thresholds that drove the state algorithms were informed by the historical state-level TB notification and epidemiological data. The EWORS applied the incoming ward level data against these thresholds to determine wards and communities that met the thresholds and automatically generated alarms for affected communities. The algorithms analyzed data on a rolling 7-day basis, and alarm notification emails were sent to field officers to institute community outreach activities. Following the notification, the state and local teams would review the alarms in concert with the heat maps, then mobilize and conduct mass TB screening outreach activities at the affected alarm locations. We identified 121 hot spot areas—an average of 10 (range 6-25) hot spots per state. Field officers used the World Health Organization (WHO) 4-symptom screen (W4SS) to offer TB screening to consenting individuals during community outreach activities. Symptomatic outreach participants (presumptive TB patients) were further evaluated for TB using the GeneXpert instrument or chest X-rays (for patients that could not produce sputum). Confirmed TB cases were linked to treatment and to the national TB program.

To demonstrate the effectiveness of the EWORS analytic system in identifying missing TB cases, this study compared the TB case yield from the hot spot wards and areas with the yield obtained from data from health outreach activities in 213 non–hot spot wards and areas in the same 14 project states. The non–hot spot areas were selected purposely from all the LGAs where one or more community hot spot areas were identified. The methods of TB screening, evaluation, notification, and treatment for consenting patients in the non–hot spot areas were the same as described for the hot spot areas.

Deidentified project data relevant for this report from the hot spots and non–hot spots were retrieved from the Commcare-based mobile app and analyzed retrospectively using SPSS (IBM Corp). The data included the participants' age, sex, TB case yield, and the number needed to screen (NNS) for each location area (hot spot and non–hot spot). Proportions were compared with the chi-square test, and a *P* value of less than .05 was considered significant. TB case yield was operationally defined as TB cases detected directly through the mass TB screening activities, calculated as a percentage of persons screened versus presumptive TB cases within the defined geographical area.

To assess the effectiveness of EWORS, this study used hot spot analyses to verify whether there were statistically significant spatial clusters of confirmed TB cases. Getis-Ord Gi* and optimized hot spot analyses were conducted to reveal the spatial heterogeneity of hot spots and non–hot spots [13]. Additionally, we examined spatial-stratified heterogeneity, which indicated the spatial differences between multiple layers or domains [14]. Ignoring the characteristics of spatial-stratified heterogeneity in the analysis could have led to model misspecification and estimation errors [15]. In this study, we used the Q statistic to measure the degree of stratified heterogeneity for hot spot analysis. The Q statistic is a value of the intensity of spatially stratified heterogeneity. It ranges between 0 and 1 and is calculated by comparing the stratified heterogeneities within the attribute and those between the strata. The higher the Q value, the stronger the stratification heterogeneity effect [14]. The Q statistic values from the Getis-Ord Gi* and optimized hot spot analyses were compared to each other to select the best hot spot model, which was then used to estimate the effectiveness of the EWORS. The Q statistic was calculated using the R package *geodetector*.

Ethical Considerations

The study was determined to be a nonresearch program evaluation. It required no direct contact with human subjects (ie, there were no interviews and no sample collection). Also, only deidentified, pooled program data that formed part of the standard of care were used; thus, informed consent was not required.

Results

To identify TB hot spots in the 14 study states, we first mapped them based on the number of diagnosed TB cases per 10,000 people. The result is shown in Figure 1. As shown on the map, Plateau, Nasarawa, and Akwa Ibom states had the highest numbers of confirmed cases. On the other hand, the states of Imo, Kaduna, and Anambra showed relatively low numbers.

Table 1 shows the estimated numbers of cases, TB tests, and treatments in the 14 states based on the numbers of diagnosed TB cases per 10,000 people. These results confirmed that to accurately identify hot spots and ultimately evaluate the effectiveness of the EWORS, it would be necessary to consider various factors, such as the number of presumptive TB cases and disease density, as well as the number of TB diagnoses in each state.

TB is a representative infectious disease, so to find precise hot spots, we considered the number of occurrences and the density of diagnosed cases. Therefore, we performed a kernel density analysis based on the location where TB was diagnosed. This analysis differentiated between regions with a high number of diagnosed TB cases but low disease density and areas with a low number of diagnosed cases but high disease density. Using a threshold for kernel density of 46,242.3 meters, we applied planar kernel density estimation for mapping. In planar kernel density estimation, an area is characterized as a 2D, uniform

Euclidean space, and its density is estimated at many regularly spaced positions [16,17]. Figure 2 shows the results of the kernel density analysis. The density of TB was relatively high in the northern and southern regions but with different characteristics. The northern region showed a very high density only in a specific area centered on Kano state. On the other hand, TB cases were widely distributed in the southern regions with a relatively low density. We defined TB hot spots by considering the number and density of hot spots using the optimal hot spot analysis technique with LGAs as units.

The Moran I test revealed a statistically significant level of spatial autocorrelation among confirmed tuberculosis cases (Moran I=0.773, *z* score=31.54), which confirms the validity of the hot spot analysis. Table 2 shows the results of the Getis-Ord Gi* and optimized hot spot analyses, indicating that the Getis-Ord Gi* method had a higher spatial stratified heterogeneity measured by the Q statistic than the optimized method. Therefore, in this study, the effectiveness of the EWORS was estimated using the Getis-Ord Gi* method.

Table 1. Ranking of the 14 study states for number of screened tuberculosis cases. All values represent cases per 10,000 people.

	State	Screened, n	Presumptive, n	Tested, n	Diagnosed, n	Treated, n
1	Plateau	957.29	50.16	38.71	4.25	4.08
2	Taraba	696.20	55.08	41.38	5.23	4.62
3	Bauchi	667.17	38.10	25.90	3.91	3.86
4	Nasarawa	598.21	44.80	34.50	3.47	3.31
5	Delta	585.78	34.05	28.40	2.63	2.34
6	Katsina	487.82	29.69	26.68	2.36	2.15
7	Cross River	460.68	32.18	25.52	2.25	2.06
8	Kano	442.55	33.01	27.61	3.01	2.90
9	Akwa Ibom	394.03	27.07	22.32	3.96	3.42
10	Anambra	360.45	38.01	30.04	1.61	1.52
11	Rivers	347.40	25.67	22.17	2.16	1.90
12	Kaduna	343.31	21.20	15.97	1.56	1.52
13	Imo	325.84	19.89	15.15	1.48	1.43
14	Benue	315.41	22.31	17.33	1.57	1.46

Figure 2. Kernel density based on number of diagnosed tuberculosis cases. Darker shades of purple indicate a higher density of occurrences. Created using ArcGIS® software by Esri and are used under license. Copyright © Esri.

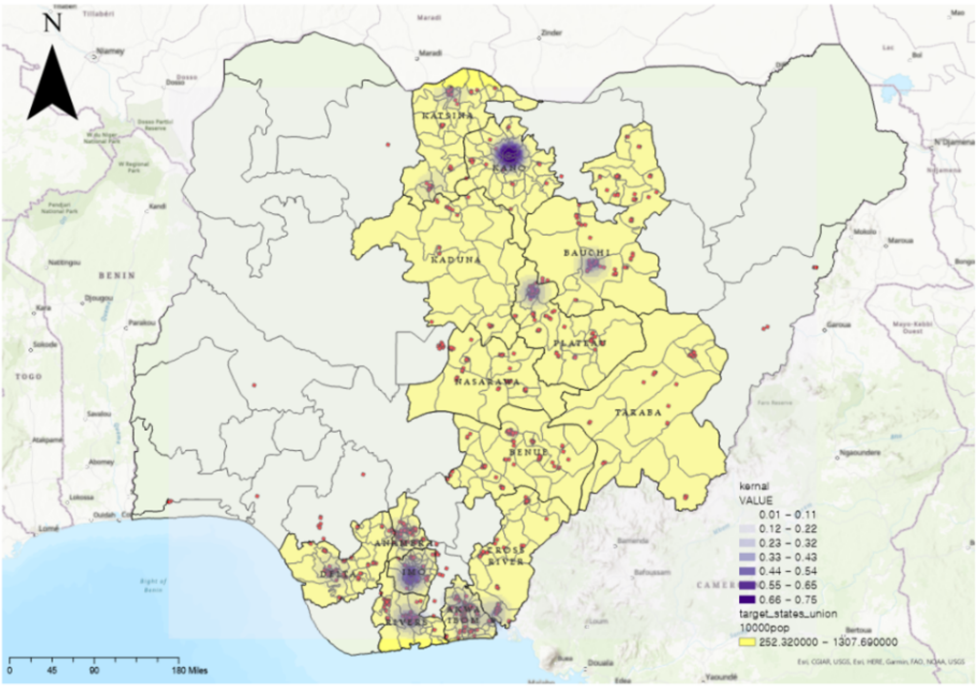

Table 2. Results for the Q statistic.

Hot spot model	Value	*P* value
Optimized method		
F	404.88	<.001
Q statistic	0.603	<.001
Getis-Ord Gi* method		
F	251.61	<.001
Q statistic	0.709	<.001

Figure 3 shows the hot spot identification results. The hot spot areas had a higher TB incidence with a higher density than the surrounding area. On the other hand, the cold spots were areas with a lower occurrence frequency and density than the surrounding area. The unmarked areas indicate that there might have been confirmed cases, but the hot spot clustering was not statistically significant.

With the EWORS, we were able to identify 121 hot spots in LGAs, 113 cold spots, and 100 other regions, but cold spots and other areas were combined as "non–hot spot" areas for analysis in this study. Therefore, we identified 121 hot spot regions and 213 non–hot spot regions to confirm the effectiveness of the EWORS. We first examined the characteristics of the TB outbreaks in hot spots and non–hot spots. The results are shown in Table 3. In the TB case-finding intervention, 1,962,042 persons (n=734,384, 37.4% male, n=1,227,658, 62.6% female) versus 2,025,286 persons (n=701,103, 34.6% male, n=1,324,183, 65.4% female) participated in the community TB screening outreaches in the hot spot and non–hot spot areas, respectively. The participants' most and least common age groups for both areas were 25 to 34 years (hot spots: 447,911/1,962,042, 22.8%; non–hot spots: 506,913/2,025,286, 25%) and 65 years or older (hot spots: 117,212/1,962,042, 6%; non–hot spots: 133,360/2,025,286, 6.6%). Only 127,733 of 1,962,042 (6.5%) patients in the hot spot areas were presumptive TB cases, against 140,531 of 2,025,286 (6.9%) patients in the non–hot spot areas. Details of the distribution of participants in both hot spot and non–hot spot regions according to sex, age group, and number of presumptive TB cases identified and evaluated for TB are shown in Table 3.

As shown in Table 4, of the 3,987,328 patients screened, 222,270 (ie, 5.5% of all patients screened during the project) were further evaluated for TB in the hot spot and non–hot spot areas. The patients were predominantly female (n=2,551,841, 64%) and the modal age group for presumptive TB cases tested was 25 to 34 years (n=954,824, 23.9%). A total of 22,618 patients were confirmed TB cases, giving a TB yield of 10.2% (n=222,270) among presumptive TB cases evaluated and a yield of 0.6% (3,987,328) among all patients screened for TB. Among the TB cases, males predominated (n=13,607, 60.2%) while the main age group was 25 to 34 years (n=5,325, 23.5%). Out of all TB cases diagnosed, 21,071 (93.1%) were placed on treatment.

Figure 3. Hot spot analysis of diagnosed tuberculosis cases per 10,000 people. Red areas on the map indicate hot spots discovered through the early warning outbreak recognition system and blue areas indicate cold spots. Created using ArcGIS® software by Esri and are used under license. Copyright © Esri.

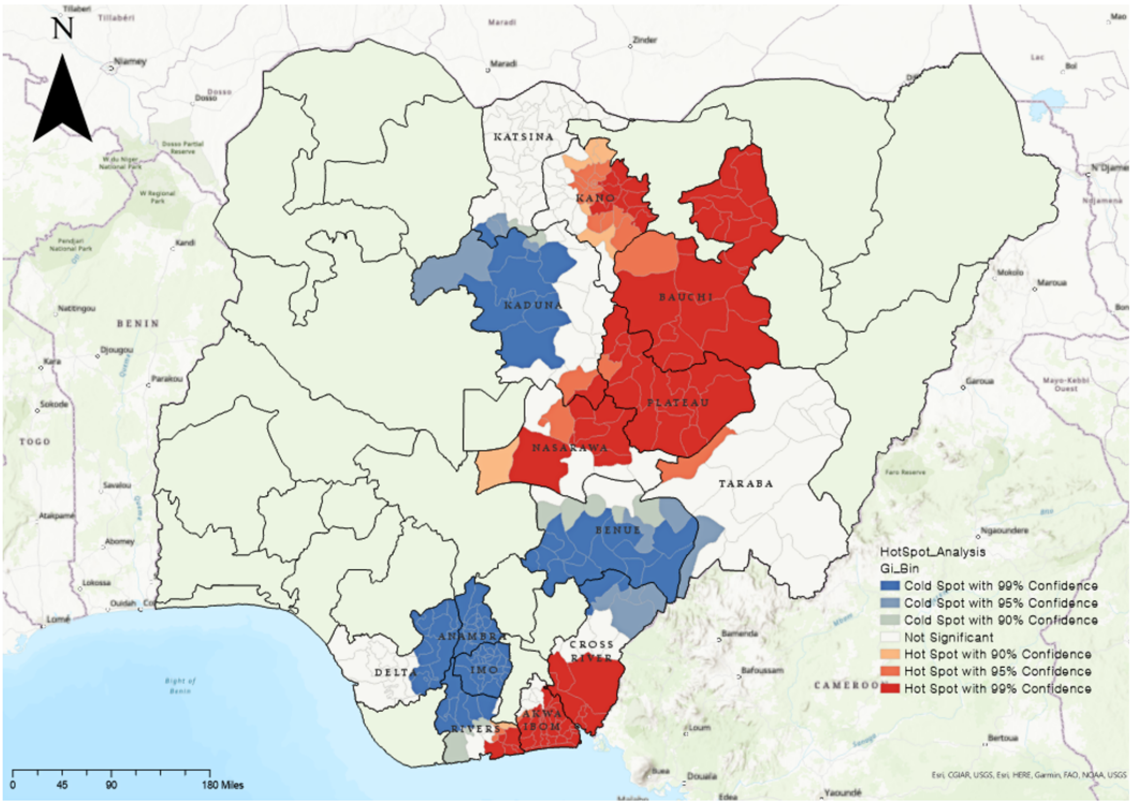

Table 3. Distribution of participants by sex, age group, and number of presumptive tuberculosis cases in hot spot and non–hot spot areas.

Characteristics	Hot spot area patients (n=1,962,042)	Non–hot spot area patients (n=2,025,286)
Sex, n (%)		
Male	734,384 (37.4)	701,103 (34.6)
Female	1,227,658 (62.6)	1,324,183 (65.4)
Age group (years), n (%)		
0-4	211,792 (10.8)	258,942 (12.8)
5-14	169,125 (8.6)	130,761 (6.5)

[a] TB: tuberculosis.

Table 5 compares the TB diagnostic outcomes per 10,000 people between the hot spot and non–hot spot areas based on the EWORS. We used precision, number needed to screen (NNS), and number needed to test (NNT) to examine the effectiveness of TB diagnosis in the EWORS hot spot and non–hot spot areas. Precision is the ratio of true diagnosed cases to total presumptive cases; the higher the value, the higher the diagnostic accuracy. On the other hand, NNS and NNT refer to the ratios required for screening and testing for accurate diagnoses. Therefore, the lower the value, the lower the social cost. The prevalence of TB among all patients in the hot spot areas (3.76 per 10,000) was significantly higher than that in non–hot spot areas (2.14 per 10,000, $P<.001$; 95% CI 0.96-2.45). The precision was 10.5% for hot spots and 7.5% for the non–hot spots. The NNS for the hot spot areas was lower than the non–hot spot areas (146.22 versus 193.44). The NNT required fewer cases in hot spots, with an NNT in hot spots and non–hot spots of 9.51 and 13.43, respectively.

We thus confirmed that the EWORS could effectively identify TB hot spots and cold spots. According to the EWORS, the number of confirmed cases of TB per 10,000 people was higher in hot spot areas. Higher accuracy and a lower NNS and NNT were needed for hot spot areas with a higher risk of TB transmission. Based on these results, we compared the changes before and after application of the EWORS to measure its effectiveness, with particular attention to its effectiveness based on an analysis of the changes in precision and NNT before and after EWORS was applied in 14 major states. A 1-tailed, paired *t* test was used as an analysis method. Figure 4 shows the precision before and after EWORS application. According to the map results, before EWORS was applied, the average precision was 7.7% and was less than 10% in all regions. On the other hand, the precision after applying EWORS increased to an average of 10.3%. In other words, in the region where EWORS was applied, the precision to identify actual TB cases increased significantly.

Table 5. Comparison of tuberculosis diagnostic outcomes between the hot spot and non–hot spot areas.

	Hot spot area	Non–hot spot area	*P* value
Patients screened per local government area (per 10,000 people), n	549.80	413.97	N/A[a]
Presumptive cases evaluated for tuberculosis (per 10,000 people), n	35.79	28.75	N/A
All tuberculosis cases diagnosed (per 10,000 people), n	3.76	2.14 (95% CI 0.96-2.45)	<.001
Precision	0.105	0.075	N/A
Number needed to screen (per 10,000 people), n	146.22	193.44	N/A
Number needed to test (per 10,000 people), n	9.51	13.43	N/A

[a] N/A: not applicable.

Figure 4. Comparison of diagnostic precision before and after application of an early warning outbreak recognition system. Light blue indicates precision less than 10%, and dark blue indicates precision higher than 10%. A: Before the system was applied (average precision: 7.7%); B: after the system was applied (average precision: 10.3%). Created using ArcGIS® software by Esri and are used under license. Copyright © Esri.

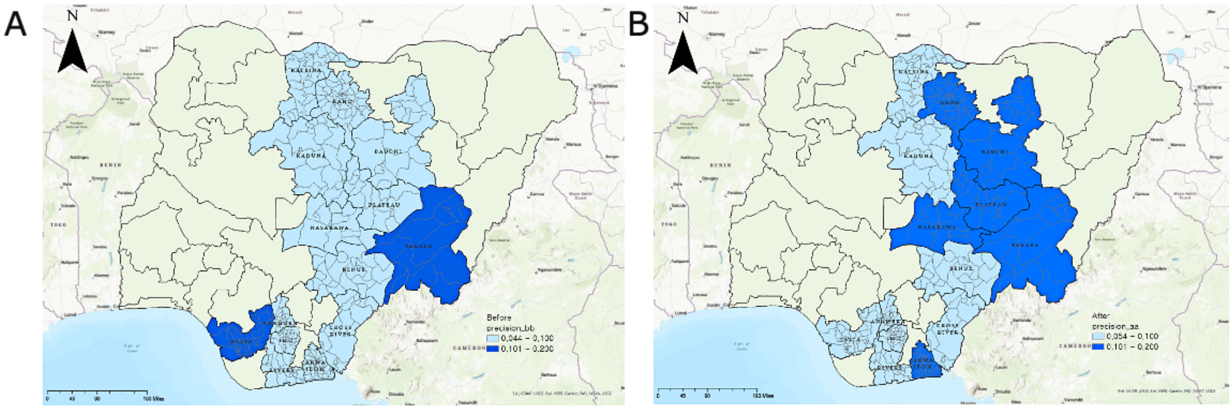

Table 6 shows the paired *t* test results for changes in precision before and after the EWORS was applied. Comparing the overall scores shows that the precision before the EWORS was applied was 7.7%. However, after applying the EWORS, the precision was 10.3%. This was a statistically significant improvement of about 2.7%. We also compared the precision changes by dividing the hot spot and non–hot spot regions. Prior to the application of the EWORS, the precision of the hot spot areas was 6.4%. However, after applying the system, the accuracy of the actual TB diagnoses increased to 11.9%. Similarly, in non–hot spot regions, the precision increased to 9.2% after the EWORS was applied. In other words, it was possible to improve the precision of diagnosing cases of TB among presumptive cases with the EWORS.

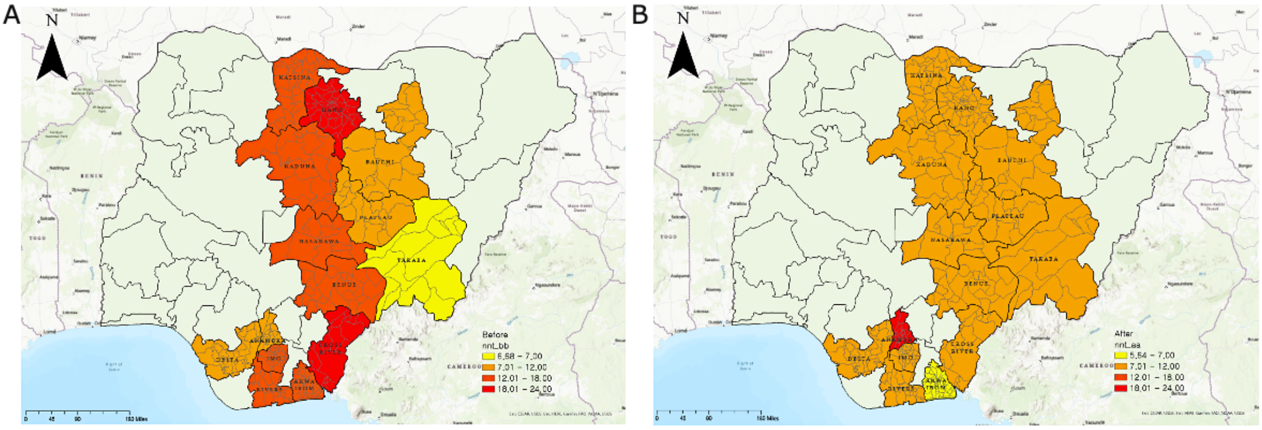
Next, we compared the NNT for diagnosing TB among presumptive cases before and after the EWORS was applied. Figure 5 shows the NNT before and after the EWORS was applied. According to the figure, a high NNT was required in most states before the EWORS was applied. However, after the EWORS was applied, a very low NNT was needed in all but one state. In other words, NNT, representing the social cost of diagnosed cases, was found to be substantially reduced after the implementation of EWORS.

Table 6. The results of the paired *t* test for precision. Precision is defined as true positive cases / (correct presumptive cases + incorrect presumptive cases).

	Before the EWORS[a]	After the EWORS	Difference	$t_{(668)}$	*P* value
Total precision (SE)	7.7% (0.12%)	10.3% (0.15%)	2.7% (0.19%)	13.764	<.001
Hot spot precision (SE)	6.4% (0.14%)	11.9% (0.26%)	5.5% (0.29%)	18.613	<.001
Non–hot spot precision (SE)	8.6% (0.15%)	9.2% (0.11%)	0.5% (0.19%)	2.747	.003

[a] EWORS: early warning outbreak recognition system.

Figure 5. Comparison of numbers needed to test for tuberculosis diagnosis before and after the early warning outbreak recognition system was applied. Deeper shades of red indicate a higher number. A: Before the system was applied (average number needed to test: 14.047); B: after the system was applied (average number needed to test: 10.255). Created using ArcGIS® software by Esri and are used under license. Copyright © Esri.



Finally, we statistically compared the change in NNT before and after the EWORS was applied. The results are shown in Table 7. NNT before the EWORS was applied was 14.047 and decreased to 10.255 after it was applied, a statistically significant difference. Also, when the hot spot regions were classified, the NNT in the hot spot regions before the EWORS was applied was very high, at 16.788. However, after the system was applied, the NNT in the hot spot areas decreased to 8.829. Similarly, NNT was significantly reduced after using the EWORS in the non–hot spot regions. In other words, by applying the EWORS, NNT in the high-risk hot spot areas, as well as the entire area, was statistically significantly reduced.

Table 7. The results of paired *t* tests for the number needed to test to diagnose cases of tuberculosis among presumptive cases.

	Before the EWORS[a]	After the EWORS	Difference	$t_{(668)}$	*P* value
Total number needed to test (SE)	14.047 (0.2229)	10.255 (0.1457)	3.792 (0.2663)	14.237	<.001
Hot spot number needed to test (SE)	16.788 (0.3756)	8.829 (0.1522)	7.958 (0.4053)	19.633	<.001
Non–hot spot number needed to test (SE)	12.006 (0.1498)	11.316 (0.1953)	0.690 (0.2462)	2.802	.004

[a] EWORS: early warning outbreak recognition system.

Discussion

KNCV Nigeria proposed that an EWORS, which is primarily used to detect and control infectious-disease outbreaks, could predict TB hot spots at the ward and community levels by identifying TB patients' residences in clusters. This project made innovative use of an EWORS for identifying TB hot spot areas in 14 states of Nigeria and found that the TB case yield in hot spot areas was significantly higher than in non–hot spot areas. Such large-scale, community-based ACF was necessary to counter the negative effect of the COVID-19 pandemic on TB notification and care at both the global and local levels [2,4]. Despite the predominance of female patients during outreach, there was a higher predominance of males among the TB cases, as expected because of the known epidemiology of TB in Nigeria [18-20]. The predominant age group also agreed with the reported pattern in the Nigerian population [7,18,21].

The WHO recommends systematic screening for TB among the general population in areas with an estimated TB prevalence of 0.5% or higher [22]; therefore, with an average TB case yield per LGA of 3.8% in the hot spot areas and 2.14% in the non–hot spot areas, the ACF interventions were justified in all areas of the project states. Moreover, this project demonstrated that because the EWORS tracked clusters of households with TB cases, it offered the added advantage of predicting communities with higher than usual TB prevalence (ie, hot spot areas), which will help prioritize community TB screening activities in underresourced settings like Nigeria. Despite the relatively lower efficiency of the W4SS TB screening method in the general population, it was suitable for this large-scale project because it is easy to implement, cheap, highly acceptable to patients, and accurate [22]. However, with a sensitivity of about 71%, a few false-negative TB cases were likely missed [20]. The same algorithm was used for both hot spot and non-spot areas, so the effect of this limitation on the study's estimates would have been nondirectional. Nevertheless, with a reported sensitivity of 85% to 94%, mobile chest X-rays for community ACF, where affordable, would have reduced the missed cases and increased the TB yield for both areas [22].

The average precision and diagnostic accuracy for identifying a patient as a TB case following W4SS TB screening and further testing with GeneXpert instrument/chest X-ray in the EWORS-identified hot spot areas was about twice that of the non–hot spot areas in this project (Table 5). This finding suggests that the EWORS can be used to enhance the identification of missed TB cases in Nigerian communities. Most importantly, in underresourced settings such as Nigeria, it can be used to prioritize the siting of community health outreaches for TB to save cost. The EWORS was designed as an early warning system to detect infectious disease outbreaks and guide control practices, so its adaptation in this project as a warning system for areas or wards with a high cluster of TB cases, marking them for follow-up with community ACF, was innovative and novel. The possible effect of the W4SS TB screening regarding missed cases discussed above was a limitation. Also, the project did not evaluate patients without TB symptoms for TB preventive treatment eligibility.

The analysis showed that the EWORS effectively identified tuberculosis-risk hot spots in the 14 Nigerian states. In particular, it offered high precision, a low NNS, and a low NNT for hot spot areas. We also measured the effectiveness of applying the EWORS and found that the precision increased significantly after it was applied. In particular, the precision of hot spots was dramatically improved, and the number of presumptive cases required for a diagnosis of TB saw a statistically significant decrease after the EWORS was applied. Taken together, the EWORS not only effectively identified hot spots but also improved precision after it was applied. Prior to the introduction of the EWORS, the TB surveillance process to identify hot spots in Nigeria involved the manual collation of TB notification data by a designated local government TB and leprosy supervisor (LGTBLS) at the LGA level. Each LGTBLS collated data from each health facility within the LGA on case findings at the end of the quarter and submitted the data to the state TB program; thereafter, the data were reviewed to determine areas of high or low TB notification [23].

The EWORS applies a syndromic surveillance-based EWS and uses kernel density estimation to create a smooth, continuous surface for the density of observations. The application of Bayesian techniques in EWORS hot spot identification helps to reduce the rates of false-negative and false-positive hot spots in comparison to classical methods of hot spot identification, such as confidence intervals [24]. This is in line with other recent tools, such as Gettis-Ord Gi*, StatsCan, and Local Indicators of Spatial Association (LISA), which are used to improve the identification of hot spots through the "mining" of spatial patterns and applying hot-spot related factors, which can help distinguish between hot spots and normal areas [25]. However, while the Gettis-Ord Gi* and StatsCan add definition to maps by estimating the density distribution of events at the local level, which allows assessment of the spatial association of a particular observation or in a study area and identifies statistically significant hot spots and cold spots, the LISA technique measures the extent to which points that are close to a given point have similar values based on a measure of contiguity among these units within a specified radius, and thus is useful for identifying local spatial autocorrelation [26]. These methods serve as complementary techniques to address the limitations of mapping methods that use geographic boundary areas, such as uniform grid cells (or quadrants) or census blocks as the unit of spatial analysis (eg, thematic maps) to depict patterns of spatial clustering [24].

However, our approach has some limitations. First, we used planar kernel density estimation to show the density of tuberculosis outbreaks by region. Since the planar method assumes spatial homogeneity, it is impossible to confirm the movement of patients with confirmed tuberculosis over time [16]. Also, we used the optimal threshold for kernel density mapping, but there may be differences in the density map depending on the choice of reference point. In addition, we analyzed hot spots by LGA unit, but aggregated them at the state level when comparing efficiencies. This approach may find hot spots more accurately by considering internal deviations within each state, but the efficiency comparison is restricted to only the state level. Additionally, our hot spot analysis results cannot be used to determine causation [17].

We conclude that active TB case finding in EWORS-mapped hot spot areas yielded a higher number of TB cases than in the non–hot spot areas in 14 high-burden states of Nigeria. As the national TB program scales up active TB case finding in Nigeria, the EWORS should be used to identify and prioritize wards or communities for TB screening health outreach to optimize the use of available resources.

Acknowledgments

We acknowledge the important contributions of Nigerian community leaders in supporting local mobilization and awareness efforts. We thank the national and state tuberculosis and leprosy control programs and the United State Agency for International Development for their support. We extend our warm gratitude to all the study participants and the staff of KNCV Nigeria for their excellent work on this study.

Authors' Contributions

BO, CO, SU, OC, N Nkiru, and OO planned the EWORS intervention. CA, BO, SO, TO, DN, MG, OO, and OC-A conducted advocacy and engagement of strategic partners. OC, CO, US, N Nkiru, and BO supervised field engagement, screening, and testing. BO, SU, N Nkiru, OC, CO, OO, DN, and RE contributed to intervention design, algorithms, and field manuals. CO, SG, OC-A, OO, and N Nihalani designed the monitoring and evaluation system and field manuals. OO, CO, DJ, CM, DK, and FN harmonized data sets, DJ and CO conducted data analyses, and CD and OC wrote the draft manuscript. OO, DJ, CM, DK, FN, and GM contributed to data interpretation and writing. All authors read and approved the final manuscript.

Abstract

Background: Regular chlamydia and gonorrhea testing are essential for key populations, such as female sex workers (FSWs). However, testing cost, stigma, and lack of access prevent FSWs in low- and middle-income countries from receiving chlamydia and gonorrhea testing. A social innovation to address these problems is “pay it forward,” where an individual receives a gift (free testing) and then asks whether they would like to give a gift to another person in the community.

Objective: This cluster randomized controlled trial examined the effectiveness and cost of the pay-it-forward strategy in increasing access to chlamydia and gonorrhea testing among FSWs in China.

Methods: This trial integrated a pay-it-forward approach into a community-based HIV outreach service. FSWs (aged 18 years or older) were invited by an outreach team from 4 Chinese cities (clusters) to receive free HIV testing. The 4 clusters were randomized into 2 study arms in a 1:1 ratio: a pay-it-forward arm (offered chlamydia and gonorrhea testing as a gift) and a standard-of-care arm (out-of-pocket cost for testing: US $11). The primary outcome was chlamydia and gonorrhea test uptake, as ascertained by administrative records. We conducted an economic evaluation using a microcosting approach from a health provider perspective, reporting our results in US dollars (at 2021 exchange rates).

Results: Overall, 480 FSWs were recruited from 4 cities (120 per city). Most FSWs were aged ≥30 years (313/480, 65.2%), were married (283/480, 59%), had an annual income <US $9000 (301/480, 62.7%), and had never been tested for chlamydia (401/480, 83.5%) or gonorrhea (397/480, 82.7%). Chlamydia and gonorrhea test uptake in the pay-it-forward and standard-of-care arms were 82% (197/240) and 4% (10/240), respectively, with an adjusted proportion difference of 76.7% (lower bound 95% CI 70.8%). All those who tested positive were referred to and received treatment at local sexually transmitted infection clinics. This finding was consistent when adjusting for marital status, income, inconsistent condom use during commercial sex in the last 3 months, and HIV testing history. Among 197 women who received tests in the pay-it-forward arm, 99 (50.3%) donated money, with a median donation of US $1.54 (IQR 0.77-1.54). The economic cost per person tested was US $568.71 for standard of care and US $43.20 for pay it forward.

Conclusions: The pay-it-forward strategy has the potential to enhance chlamydia and gonorrhea testing for Chinese FSWs and may be useful for scaling up preventive services. Further implementation research is needed to inform the transition of pay-it-forward research into practice.

Introduction

Chlamydia and gonorrhea are two of the most common bacterial sexually transmitted infections (STIs). Each year, there are an estimated 129 million new cases of chlamydia and 82 million new cases of gonorrhea globally, and the majority are asymptomatic [1]. Female sex workers (FSWs) face a high burden of chlamydia and gonorrhea, with an estimated prevalence of 4% to 15% and 1% to 11%, respectively, while FSWs in low- and middle-income countries (LMICs) have a higher prevalence of chlamydia and gonorrhea [2-6].

Testing, especially for high-risk women, is essential for chlamydia and gonorrhea control and the reduction of adverse sexual and reproductive complications [1,7]. The World Health Organization guidelines recommend regular chlamydia and gonorrhea molecular assay testing for sex workers in LMICs [8]. However, despite a high disease burden, few FSWs receive chlamydia and gonorrhea testing in LMICs. For example, less than one-tenth of Chinese FSWs have ever received chlamydia and gonorrhea testing [9]. First, although chlamydia and gonorrhea testing are available in many Chinese hospitals, the out-of-pocket cost for testing is relatively high (US $11) and not covered by most public or private health insurance programs [10]. Given that more than half of Chinese FSWs have an average monthly income of less than US $1000 [11], financial limitations may remain a significant barrier preventing FSWs from accessing chlamydia and gonorrhea testing. Second, current STI prevention services in many LMICs, including China, mainly focus on HIV and syphilis [1]. These well-established HIV and syphilis testing systems do not typically integrate other STI testing [12]. China does not have a screening strategy for chlamydia or gonorrhea for high-risk and other vulnerable populations, nor does it have widespread programs supporting chlamydia and gonorrhea testing. Third, peer factors relating to mistrust in services may decrease interest in routine service delivery [13]. This mistrust in STD services might dramatically reduce access to STD care services, including chlamydia and gonorrhea testing in clinical settings [14]. A lack of community engagement might be an essential reason for mistrust [15].

A pay-it-forward health approach may help promote test uptake among FSWs. In a pay-it-forward approach, one person receives a gift (eg, a free STI test, alongside community-engaged messages) and then is asked whether they would like to donate money to another person [16]. This social innovation has the potential of not only reducing financial barriers but also increasing trust and community engagement in health services by increasing community ownership. Two studies among Chinese men who have sex with men (MSM) found that the pay-it-forward approach could substantially increase chlamydia and gonorrhea testing uptake [10,17]. However, these studies only focused on MSM in 2 cities, limiting the generalizability of the findings.

This multisite cluster randomized controlled trial (RCT) aimed to evaluate the effectiveness and cost of a pay-it-forward strategy in increasing dual chlamydia and gonorrhea testing among FSWs in 4 cities of Guangdong Province, China, compared with a standard fee-based system.

Methods

Study Design

This study was a superiority cluster RCT to test whether the pay-it-forward intervention was superior to the standard of care in increasing chlamydia and gonorrhea testing. The study was conducted in 4 cities (Maoming, Yunfu, Yangjiang, and Yingde), with 1 cluster per city, in Guangdong Province, China. These cities were chosen based on local capacity and the availability of ongoing public health community-based outreach programs for FSWs. The reason for choosing a cluster RCT design was that many FSWs in the same city would be recruited from the same venues, and an individual RCT design may have caused contamination between different arms.

The local Centre for Disease Control and Prevention outreach team included a nurse, an STI physician from a local STI clinic, and a public health practitioner (as a health educator). The outreach team routinely provided venue-based sexual health care services to local FSWs. These outreach teams have long-standing relations with FSWs and provide comprehensive health services, including condom promotion, reproductive health services, STI counseling, symptomatic STI treatment, and on-site HIV testing.

We estimated we needed 480 participants from the 4 clusters (120 from each city). Participants were recruited after randomization of the selected cluster. Our previous studies among MSM indicated that the pay-it-forward approach is superior to the standard of care by a 20% margin. We kept the same margin for this superiority trial. The sample size was determined using the following assumptions: the testing rate of the null hypothesis for the pay-it-forward group was set at 30% (the null hypothesis was that the pay-it-forward group would increase the testing rate by at least 10%), the testing rate of the alternative hypothesis was set at 50%, and the testing rate of the null hypothesis for the standard of care group was set at 20%, with an interclass correlation of 0.1.

Ethical Considerations

Study approval was gained from the ethics review committees of the Southern Medical University Dermatology Hospital (#2020018). The CONSORT (Consolidated Standards Of Reporting Trials) cluster-extension guidelines were used to report the findings from this study (Multimedia Appendix 1). This study was registered at the Chinese Clinical Trial Registry (ChiCTR2000037653). All the participants who participated in the survey signed an informed consent form. The informed consent form included a statement that study data were anonymous or would be deidentified.

Participants

Many sex workers in China do not routinely seek clinic-based services, so we integrated this study within an ongoing HIV- and syphilis-testing outreach program. The study participants were recruited by having the outreach team, including a study staff member, go to their workplaces during working hours (usually in the evening). Before this study, the local outreach team mapped sex-work venues in each study site according to geographic area and type of venue. Convenience sampling was used to enroll FSWs at venues in each city. We categorized the sex work venues into high and low tiers based on the clients' socioeconomic status and the cost for clients of commercial sex at these venues [18]. Low-tier venues included foot-bath shops, hair salons, massage parlors, roadside restaurants, roadside shops, guesthouses, streets, and public outdoor places. High-tier venues included karaoke bars, hotels, saunas, and nightclubs.

The inclusion criteria were as follows: sex at birth was female, age was 18 years or older, the participant self-reported as having engaged in transactional sex to obtain money or property in the past month in the sampling city, the participant had not previously participated in a research project related to gonorrhea or chlamydia testing, and the participant had not been tested for gonorrhea or chlamydia in the past 12 months.

The study was anonymous, but the eligible participants had to provide a cell-phone number for testing results notification. The phone number was also used for deduplication. If the participants had positive test results for as either chlamydia or gonorrhea, they were provided free treatment at a local STI clinic, regardless of whether they had symptoms.

Randomization and Masking

Before participant recruitment, the 4 clusters were randomized into the 2 study arms in a 1:1 ratio. Participants recruited from Yunfu and Yingde cities were randomized into the pay-it-forward intervention group, and participants recruited from Maoming and Yangjiang cities were randomized into the control group. The reason for adopting a cluster randomized allocation method was the strong correlation between FSW test uptake in local areas of a city [19]. In addition, many of the FSWs were recruited from the same study sites. Individual-level randomization would have induced strong contamination between the study groups. We did not randomize the participants based on venue, as many street-based FSWs work alone.

Procedures

The intervention was adapted from our previous trials, and a pilot intervention was implemented among 40 FSWs in Guangzhou, China, before the study was carried out.

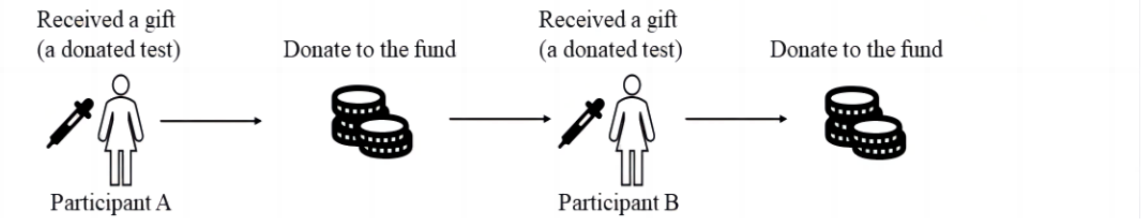
The pay-it-forward strategy was implemented in the intervention group. The study staff visited FSW workplaces in the selected cities in the pay-it-forward arm. First, after providing HIV and syphilis testing services, the study staff briefly introduced the reasons for chlamydia and gonorrhea testing, explained the pay-it-forward strategy, informed the participants of the market price of chlamydia and gonorrhea testing (approximately US $11 for both the intervention and control groups), and communicated that the testing cost had been covered by donations from other FSWs who care about their health. Therefore, each FSW could decide whether to receive donated chlamydia and gonorrhea testing services. If they chose to receive the test, they self-collected urine samples in a private room at their workplace. After that, they were asked whether they would voluntarily donate any amount to other FSWs for testing. A combination of study funds and donations from previous participants covered all testing costs for the intervention group. The donations were voluntary and were given after the testing. The key concepts of the pay-it-forward model are depicted in Figure 1.

The researchers also introduced chlamydia and gonorrhea testing to the standard-of-care arm without mentioning the pay-it-forward intervention. Participants who wished to be tested for chlamydia and gonorrhea in the standard-of-care arm self-collected their samples for testing in outreach settings. They were only required to pay a reduced price for their testing (approximately US $11). The participants in both arms were offered an incentive of US $7.50 for their participation and time spent in the research.

Participants in each group were invited to complete a short baseline questionnaire to collect information on their sexual history, testing history, attitudes toward the test, and the psychosocial environment in which they lived. We asked participants whether they used a condom during their last commercial sex act and whether they consistently used a condom during commercial sex in the previous months (consistent use meant using a condom every time).

All samples were transported to the laboratory at the Dermatology Hospital of Southern Medical University in Guangzhou for nucleic acid amplification testing (Cobas 4800 CT/NG Test Kits; Roche Molecular Systems).

Figure 1. The pay-it-forward approach.



Outcomes

The primary outcome was the uptake of dual chlamydia and gonorrhea testing immediately after the intervention, measured during the study visit. The secondary outcome was the cost per person tested and the incremental cost-effectiveness ratio (ICER) between the 2 study arms. We calculated the financial and economic costs from a health care provider perspective, including direct medical expenses related to testing and personnel time. Costs are presented in US dollars (at 2021 exchange rates). We calculated the cost per person tested by dividing each arm's total cost by the number of FSWs tested. The ICER was also calculated as the incremental cost of the intervention arm compared to the control arm divided by the incremental effectiveness (per person tested).

Statistical Analysis

All statistical analyses were conducted at the cluster level. We first compared the sociodemographic characteristics of the participants in the 2 study arms. The generalized estimating equations (GEEs) with a binomial distribution and an identity link function were used to compare the proportion of chlamydia and gonorrhea tests in the different arms, reported as the crude probability difference. The equal correlation structure was specified as the correlation structure within groupings. Additionally, due to the small number of clusters in this study, the Mancl and DeRouen bias-corrected covariance estimator was applied to our generalized estimating equations to minimize the risk of a type I error [20,21]. A sensitivity analysis was also conducted, exploring the effects when considering FSW workplaces as clusters in the GEE model corrected by the Kauermann-Carroll method (Multimedia Appendix 2, Table S1) [21,22]. In the adjusted model, we further adjusted for the following variables: marital status and past experience of testing for HIV, chlamydia, or gonorrhea. These covariates were considered potential confounders, and some were not balanced between the 2 study groups because of the small cluster size. As this study used a superiority trial design, only one side of the CI is reported [17].

A subgroup analysis was performed to investigate the probability difference categorized by age, consistent condom use during commercial sex in the past 3 months, history of ever having been tested for HIV, and whether the participant worked in a high-tier workplace. These analyses were conducted with Stata (version 16; Stata Corp). The economic evaluation was performed using TreeAge Pro 2021 (TreeAge Software Inc).

Results

Study Participants

This study was implemented from August 12, 2020, to November 15, 2020. We screened 530 female sex workers and recruited 480 who met the screening criteria. Fifty women were excluded from the study (2 were younger than 18 years, and 48 self-reported not engaging in commercial sex; Figure 2); 240 participants from 2 clusters were included in each study group. All enrolled women had data on the primary outcome.

Table 1 shows the participants' sociodemographic characteristics, sexual behavior, and past STI testing history. Most women were aged 30 years or older (313/480, 65.2%), were married (283/480, 59%), and had a middle-school or lower education level (395/480, 82.3%). The majority worked at high-tier venues (311/480, 64.8%) and had an annual income of less than US $9000 (301/480, 63.6%). Nearly half of the women (235/480, 49%) had worked for longer than one year at their workplace. Around one-third of the participants (179/480, 37.3%) had used a condom consistently during commercial sex in the past 3 months. Many (290/480, 60.4%) women had never been tested for HIV, and the majority had never been tested for gonorrhea (397/480, 82.7%) or chlamydia (401/480, 83.5%).

[a] High-tier venues included karaoke bars, hotels, saunas, and night clubs.

[b] Low-tier venues included foot-bath shops, hair salons or barbershops, massage parlors, roadside restaurants, guesthouses, streets, and public outdoor places.

[c] N/A: not applicable.

[d] For these values, n=203, n=197, and n=10 for the total, pay-it-forward, and standard-of-care groups, respectively.

Testing Uptake

Overall, 197 of 240 (82.1%) women in the pay-it-forward arm and 10 of 240 (4.2%) women in the standard-of-care arm received dual chlamydia and gonorrhea testing (Table 2). In the pay-it-forward arm, 34 of 197 (17.3%) women were diagnosed with chlamydia, and 3 of 197 (1.5%) were diagnosed with gonorrhea. No chlamydia or gonorrhea was detected among women who received a standard-of-care test. All women who received a test were informed of the test results via text message (for women who tested negative) or phone call (for women who tested positive for a chlamydia or gonorrhea infection). Test-positive women were referred to local STI clinics for free treatment. The reasons for testing or not testing in the pay-it-forward arm and the program's perceived benefits are summarized in Multimedia Appendix 3, Table S4.

The GEE model showed that the pay-it-forward intervention was associated with a 77.9% (lower-bound 95% CI 70.3%) increase in test uptake probability compared to the standard-of-care arm. After adjusting for marital status and past testing experience for HIV, chlamydia, and gonorrhea, the outputs were consistent with the crude results (adjusted probability difference 76.7%, lower-bound 95% CI 70.8%; Table 2).

Table 3 shows findings from prespecified subgroup analyses. The difference between the control and pay-it-forward arms was most significant among FSWs who had used condoms consistently during commercial sex in the previous 3 months (86%, 95% CI 78.6%-93.5%) and women older than 30 years (82%, 95% CI 75.7%-88.2%). The difference between the control and pay-it-forward arms was 4% (95% CI –8.6% to 16.6%) for a past history of HIV testing (no vs yes) and –5.1% (95% CI –16.3% to 6%) for workplace tier.

Table 2. The proportion of participating female sex workers tested for chlamydia and gonorrhea in Guangdong, China, in 2020 (N=480). The model was adjusted for marital status and past testing experience for HIV, chlamydia, and gonorrhea.

	Subjects, n (%)	Probability difference[a]	One-sided 95% CI[b]	Intraclass correlation	Adjusted probability difference[a]	One-sided 95% CI[b]

[f] High tier vs low tier.

Economic Evaluation

Among 197 women who received chlamydia and gonorrhea tests in the pay-it-forward arm, 99 (50.3%) donated to the pooled funds. The total donation amount was US $326, and the median donation amount per donor was US $1.54 (IQR 0.77-1.54). The largest donation was US $119.54, and the lowest was US $0.15. Complete cost and cost-effectiveness analyses are provided in Multimedia Appendix 4, Tables S2 to S3 and Figures S1 to S3. The economic cost per person tested was US $42.24 for the standard-of-care arm and US $41.80 for the pay-it-forward arm. The ICER for the pay-it-forward arm compared to standard of care was minus US $2.79 per additional person tested.

Discussion

Principal Findings

Upstream reciprocity theory suggests that people who are cared for by someone are more likely to help others. Our study confirmed this theory by promoting chlamydia and gonorrhea testing among FSWs in China through a pay-it-forward approach. Our study extends the existing literature by testing the effectiveness of the pay-it-forward approach in increasing STI testing uptake among FSWs, conducting the study in an outreach setting outside of a formal clinic, and integrating the approach with HIV services. As a social innovation approach, we found that the pay-it-forward intervention dramatically increased STI testing uptake among Chinese FSWs and that the participants covered a substantial portion of the costs associated with testing.

Women in the pay-it-forward arm had higher chlamydia and gonorrhea testing uptake than women in the standard-of-care arm. This finding is consistent with previous studies among Chinese MSM, which suggest that the pay-it-forward approach can motivate more people to use STI testing services [10,17]. In addition, the pay-it-forward strategy is more effective than other STI testing–uptake intervention approaches, such as social marketing [23], digital health [24], and point of care [25]. Several factors may have led to the strong testing uptake among individuals in the pay-it-forward arm. The first was generosity and trust. Due to stigma and other barriers, few Chinese FSWs are willing to undergo or pay for chlamydia and gonorrhea testing [26]. The low testing rates in our standard-of-care arm demonstrate this. Our pay-it-forward strategy revealed substantial generosity and promoted responsibility among the FSWs to change their testing behaviors. Second, free testing may have driven the increased test uptake rates because of the zero-price effect [27]. Our previous studies indicate that generosity (ie, voluntary donations) integrated with free testing strongly motivates behavior change [10,17].

Lack of community engagement and low social trust are 2 critical barriers to STI testing uptake among FSWs [28]. In our study, about half of the FSWs who were tested in the pay-it-forward arm donated some money for future testing. Although the donation rate in our study was lower than in our previous studies among MSM in China [10,17], around half of the FSWs chose to contribute. This is remarkable given the low socioeconomic status of FSWs and the lack of a culture of donating in China. Pay-it-forward approaches may increase community ownership and social trust, supporting STI testing [16,29]. Two systematic reviews further support this explanation, reporting that being kind is associated with well-being, especially psychological functioning [30] and subjective well-being [31]. Qualitative studies that aim to further confirm these psychological impulses are needed.

Our findings indicate that the pay-it-forward strategy increased STI testing uptake and reduced barriers to sustaining STI testing. STI testing among FSWs reduces STI transmission and adverse sexual and reproductive health consequences. The pay-it-forward approach provides an alternative to using limited public funding to maintain or expand testing. Our findings need to be extended beyond this initial research study, as they have several public health implications. First, a pay-it-forward strategy could reduce costs for STI testing for funding bodies and dramatically remove the financial barrier to STI testing among participants. Second, unlike the free-testing approach, the pay-it-forward method could generate strong community ownership and trust. Third, as an approach to increase testing uptake and the regularity of testing, the pay-it-forward intervention has a robust public health benefit. Improving testing coverage and the regularity of testing could reduce the high chlamydia and gonorrhea prevalence among Chinese FSWs (17.3% for chlamydia in our study) by identifying and treating asymptomatic infections earlier, thus reducing morbidity and onward transmission to the clients of FSWs and their other sexual partners [32].

Limitations and Implications

Our study has several limitations. First, although this was a cluster RCT, the number of clusters in our study was relatively small. Therefore, the characteristics of the participants in the 2 study arms were not completely balanced, which may have resulted in a selection bias. However, our main findings were robust when we adjusted for marital status, condom use during the last commercial sex act, and past HIV testing experience. In addition, the data were analyzed with GEE models for a small number of clusters. At the same time, a sensitivity analysis was also conducted by treating FSWs recruited from the same venue as a cluster. Second, the test uptake rate in the standard-of-care arm was low, further complicating data analysis. However, FSW test uptake rates are generally low in China [11] and many other LMICs [33]. Third, the level of community engagement in our study was suboptimal. Unlike our previous studies evaluating the pay-it-forward strategy in improving STI care, the FSWs in this study did not engage in community activities, such as passing postcards or messages to other FSWs in their social network; this needs to be improved in future studies.

Our study has several implications. First, qualitative research is needed to evaluate how and why generosity works among FSWs in promoting STI testing. Second, this study did not collect data on implementing the evidence-based pay-it-forward intervention and scaling it up. Additional implementation-science research is needed to expand the pay-it-forward intervention into other settings, including integrating it with other STI services. Third, strategies to increase demand and the informational messages on the need for chlamydia and gonorrhea screening (ie, the introduction to chlamydia and gonorrhea and the pay-it-forward intervention model) were not developed together with the FSWs; the study was carried out solely by study staff from public health authorities. Future research could examine how the engagement of local FSWs at the formative research stage could further improve testing uptake and program sustainability. Fourth, this study was implemented during the period from August to November 2020, a time when the COVID-19 pandemic may have impacted the implementation of the study itself and reduced the responsiveness of the FSWs, as many FSWs had temporarily ceased working during the pandemic period. We anticipated that more low-income FSWs would continue their work even while high-tier venues were shut down due to COVID-19 measures.

Conclusion

Innovative and effective intervention strategies are urgently needed to fill the gap between the high global burden of chlamydia and gonorrhea disease and suboptimal STI testing services. A pay-it-forward approach has the potential to enhance chlamydia and gonorrhea testing uptake among Chinese FSWs. It may be a valuable tool for scaling up STI services. Further implementation research is needed to inform the transition of pay-it-forward research into practice.

Acknowledgments

We are grateful to all participants in this study, without whom this study could not have been completed. We thank the study implementation team at the Dermatology Hospital Guangzhou site for all their dedication and efforts, which made this research possible. We appreciate the collaborating chronic-disease control centers in Maoming, Yunfu, Yangjiang, and Yingde for their help in facilitating and coordinating this study. Funding for this study came from the National Natural Science Foundation of China (grant 81903371) and the National Institutes of Health (grants NIAID K24AI143471 and R34MH119963).

Data Availability

The deidentified data have been uploaded as supplemental data.

Authors' Contributions

WT and CW conceived the study. YX and MX led the piloting and implementation of the study. MX, CW, and BY assisted with recruitment. YX cleaned and analyzed the data and generated figures and tables to present the paper’s findings. JJO advised on modeling approaches. WT, YX, and CW wrote the initial draft of the paper. DW, JJO, TEW, and JDT provided constructive comments and edited the manuscript. All authors read and authorized the final version.

Abstract

Background: Health research using commercial data is increasing. The evidence on public acceptability and sociodemographic characteristics of individuals willing to share commercial data for health research is scarce.

Objective: This survey study investigates the willingness to share commercial data for health research in the United Kingdom with 3 different organizations (government, private, and academic institutions), 5 different data types (internet, shopping, wearable devices, smartphones, and social media), and 10 different invitation methods to recruit participants for research studies with a focus on sociodemographic characteristics and psychological predictors.

Methods: We conducted a web-based survey using quota sampling based on age distribution in the United Kingdom in July 2020 (N=1534). Chi-squared tests tested differences by sociodemographic characteristics, and adjusted ordered logistic regressions tested associations with trust, perceived importance of privacy, worry about data misuse and perceived risks, and perceived benefits of data sharing. The results are shown as percentages, adjusted odds ratios, and 95% CIs.

Results: Overall, 61.1% (937/1534) of participants were willing to share their data with the government and 61% (936/1534) of participants were willing to share their data with academic research institutions compared with 43.1% (661/1534) who were willing to share their data with private organizations. The willingness to share varied between specific types of data—51.8% (794/1534) for loyalty cards, 35.2% (540/1534) for internet search history, 32% (491/1534) for smartphone data, 31.8% (488/1534) for wearable device data, and 30.4% (467/1534) for social media data. Increasing age was consistently and negatively associated with all the outcomes. Trust was positively associated with willingness to share commercial data, whereas worry about data misuse and the perceived importance of privacy were negatively associated with willingness to share commercial data. The perceived risk of sharing data was positively associated with willingness to share when the participants considered all the specific data types but not with the organizations. The participants favored postal research invitations over digital research invitations.

Conclusions: This UK-based survey study shows that willingness to share commercial data for health research varies; however, researchers should focus on effectively communicating their data practices to minimize concerns about data misuse and improve public trust in data science. The results of this study can be further used as a guide to consider methods to improve recruitment strategies in health-related research and to improve response rates and participant retention.

KEYWORDS

commercial data; data sharing; participant recruitment; loyalty cards; sociodemographic factors; data donation; data; health; public; acceptability; digital; mobile phone

Introduction

Health researchers are increasingly aiming to include accurate personal information collected outside of health care settings, including commercial data collected or processed for businesses relating to their customers (eg, internet searches, social media, loyalty cards, wearable devices, and mobile phone apps), to enhance our understanding of individuals' health-related behaviors and health outcomes. With the rise of different data sources to track, monitor, and forecast disease and health outcomes, interest in carrying out research using individual commercial data has grown substantially [1-3]. However, much of this valuable research is often criticized for its representativeness and the low participation rates associated with public attitudes toward data sharing.

Evidence on the public acceptability of sharing health-related data is vast and suggests that improving the transparency of data collection and processing practices across institutions, creating trustworthy data ecosystems, and providing agency and data stewardship for data participants can improve the willingness to take part in research and share data [4-12]. The evidence for willingness to share data across different contexts varies depending on the type, purpose, and use of data. These often show that the public has some understanding of how data are being used and equally suggest that raising awareness about data practices does not increase willingness to share data [9]. A recent report highlights that further research is needed to improve public trust in light of the Cambridge Analytica scandal and other reported data misuse incidences [12].

Furthermore, with the implementation of the General Data Protection Regulation (GDPR) in 2018 [13], all individuals were given the right to carry out a subject access request from any organization that holds any information about them, thus allowing researchers to start analyzing new types of data sets with individual consent to understand behaviors such as diet [14], self-medication [15], and cancer risk [16] using purchase history recorded on loyalty cards; that is, an identity card issued by retailers to its customers to collect information on buyer behavior and generate reward schemes. However, a common limitation is the small sample size and biased population of individuals who are more willing to share their data [17]. A number of qualitative studies investigated willingness to share commercial data, specifically loyalty cards for health research, echoing the principal evidence shared across disciplines, as discussed earlier [15,18,19]. In contrast, for mobile and biosensor data sharing, there is a growing body of literature on the importance of understanding nonparticipation and willingness to share mobile phone apps and biosensor data [20-24]. A study that took place in England before the GDPR highlighted that, in the context of mobile data sharing, user behavior is also associated with willingness to share passive or actively collected mobile data [21]. Further experimental studies have highlighted the behavior of sharing mobile data, which requires capabilities from the users to fulfill the task and the characteristics of the individuals, framing of the request, emphasis on control over data, and assurances of privacy and confidentiality [22]. The implications of the willingness to share smartphone and sensor data with researchers are further understood in studies where the response rate for data sharing is less than 15%, and the representativeness of the population that shares the data is less than optimal [23]. This highlights the importance of understanding the characteristics of the population who are willing to share commercial data sets before data collection so that strategies can be developed to improve response rates and minimize bias.

Therefore, this study aims to investigate GDPR awareness and sociodemographic and psychological factors associated with the willingness to share commercial data for health research purposes after the implementation of the GDPR in the United Kingdom. Furthermore, it aimed to provide a summary of the public's awareness of GDPR in 2020, 2 years after the GDPR and Data Protection Act 2018 were enacted in the United Kingdom. The GDPR has been kept in UK law as the UK GDPR [24]. For epidemiological research to advance using commercial data sets and effectively recruit participants, it is important to investigate the factors associated with the willingness to share commercial data for health research.

Methods

Setting and Design

A 10-minute web-based survey was conducted in the United Kingdom in August 2020 via Survey Monkey using Dynata International Limited. Nonprobability quota sampling was used for an adequate representation of different age groups in the United Kingdom, with the aim of recruiting 1500 participants to achieve a 1:10 participant-to-item ratio [25]. The distribution of the sample, respectively, based on age and sex distribution in the UK population was 18 to 29 years (20%), 30 to 39 years (17%), 40 to 49 years (18.5%), 50 to 59 years (15.5%), 60 to 69 years (14%), >70 years (15%), male (49.4%), and female (50.6%) [26].

Ethics Approval

The project was reviewed by the University of College London Research Ethics Committee and received a favorable opinion (ref: 18095/001) and reported using the Strengthening the Reporting of Observational Studies in Epidemiology guidelines for cross-sectional research [27]. Information regarding ethics approval can be obtained directly from the University of College London Research Ethics Committee. The survey study only included anonymized data from the participants; therefore, the research team had no contact with the participants following their participation in the study. If individuals dropped out of the survey before its completion, this was considered a withdrawal from the study, and no data were included. Participants were paid a small monetary incentive through Dynata International Limited in line with their participant payment policies.

Survey Measures

All measures with their item heritage are included in Multimedia Appendix 1. There were 3 primary outcome measures. These were the willingness to share commercial data for health research with different institutions (government, private, and academic), the willingness to share different types of commercial data (internet searches, social media, shopping data on loyalty cards, wearable devices, and mobile phone apps) with academic institutions, and the willingness to participate in health research based on different invitation sources. The rationale for these outcomes is as follows. In comparison to government and private organizations, which are often the primary data controllers for health, administrative, and commercial data, researchers at academic institutions often need to request access to data collected and controlled by government and private organizations. The differences between institutions were considered to understand the potential baseline response rate for potential research projects that aim to use commercial data in health research at academic institutions. The second primary outcome was then focused on willingness by data type and the extent to which this differentiates from the baseline willingness to share commercial data with academic institutions. The last outcome is included to consider how much willingness varied depending on the source of the invite to better understand the best ways to recruit participants who are more willing to share their data. All these outcomes were used to inform the communication strategies of a much larger academic project that aimed to recruit individual participants with informed consent requesting access to their commercial data, specifically loyalty card data from 2 UK-based high-street retailers, investigating self-care behaviors before ovarian cancer diagnosis [16].

The independent variables were included under four sections: (1) sociodemographic factors, including age, sex, marital status, education, ethnicity, and location in the United Kingdom; (2) the participants' GDPR awareness; (3) psychological factors including trust in institutions, trust in data practices in academia, worry about data misuse, perceived risk in data sharing, perceived importance of privacy, and perceived benefit of data sharing; and (4) past experience taking part in health research and past experiences of data misuse.

Statistical Analysis

We reported all measures and exclusions in this study and used complete case analysis without imputing missing data, as all questions were mandatory.

Factor analyses using principal component analysis (PCA) and reliability tests were carried out to ensure that the items included in various other studies measured the intended outcomes. Once the factors were identified, the scales were computed using total scores. A Cronbach alpha coefficient was calculated for each scale for internal consistency, and the interitem and interscale correlations were checked for internal consistency of items and scales. Each computed scale was reported using range, mean, SD, and Cronbach alpha coefficient.

Participant characteristics, self-reported GDPR awareness, and people's awareness of personal data and GDPR law were reported using descriptive statistics. Some categorical items were recoded for ease of presentation and understanding of the differences in each category. Responses to items including "prefer not to say" and "other" were coded as missing because of the low cell count (<5 observations in each category) in sociodemographic items which would not have been coded negatively and subsequently excluded from the main analyses (40/1594, 2.5%). Primary outcome variables were recoded into "definitely yes" or "probably yes"=1 and "probably no" or "definitely no"=0 to compare 2 distinct intentions to share data for the comparison between sociodemographic characteristics of the participants [28]. Differences in the proportions of willingness to share commercial data were tested using chi-square statistics and reported in percentages. Ordered logistic regression was used to test for psychological factors associated with willingness to share commercial data for health research with different organizations and different types of data adjusted for the sociodemographic characteristics of the participants, previous research participation, and GDPR awareness. The variance explained by each model is included in Multimedia Appendix 1. Further ordered regression analyses were carried out for the different types of research invitations to identify whether there were sociodemographic factors associated with willingness to participate in health research (Multimedia Appendix 1). All results reported using adjusted odds ratios (aORs) and 95% CIs were reported using a P value of <.05.

Results

Factor Analysis Results

The 32 items measured in this study were subjected to PCA using SPSS (version 27; IBM Corp). Before performing PCA, the suitability for performing PCA was assessed. Inspection of the correlation matrix revealed the presence of many coefficients >0.3. The Kaiser-Meyer-Olkin value was 0.93, above the recommended value of 0.6, and the Bartlett Test of Sphericity reached statistical significance, supporting the factorability of the correlation matrix. The PCA revealed the presence of 5 components with eigenvalues exceeding 1, explaining 28.6%, 19.7%, 7.5%, 6.9%, and 5.3% variance (Multimedia Appendix 1). A total of 8 items were recoded, and 2 items were deleted, as they measured trust in 2 different organizations. On the basis of these results, 5 scales were computed. These are, namely, perceived importance of privacy (mean 8.46, SD 1.38; range 2-10; Cronbach α=.65), worry about data misuse (6 items; mean 21.28, SD 5.69; range 5-30; Cronbach α=.95), trust in data practices in academic institutions (9 items; mean 31.96, SD 7.14; range 5-45; Cronbach α=.95), perceived risk of data sharing for health research (3 items; mean 9.40, SD 2.73; range 3-15; Cronbach α=.88) and perceived benefits of data sharing (5 items; mean 17.76, SD 4.31; range 5-25; Cronbach α=.93). Factor correlations as separate scales suggest that the scales have weak to moderate correlations, indicating that they measure separate scales (Multimedia Appendix 1).

Participant Characteristics

Out of the 1897 responses, 1534 participants gave their consent and completed the survey (Table 1). Approximately 49.1% (753/1534) of participants were male, 50.7% (777/1534) were female, and 0.2% (4/1534) indicated other. The age distribution of participants was consistent with the quota sample for the distribution of age in England. Most respondents self-identified with a White ethnic background (1325/1534, 86.4%), compared with only 12.9% (198/1534) who identified themselves with other ethnicities. Approximately 53.1% (814/1534) of the participants were married or had a legal partnership. Approximately 45.6% (699/1534) of participants had higher education (degree and above) qualifications, almost half of them (765/1534, 49.9%) had less than higher education qualifications, and only 4.5% (69/1534) did not have any educational qualification.

Table 1. Participant characteristics (N=1534).

Characteristics	Values, n (%)	Population composition of England and Wales based on 2011 Census (excludes Scotland and Northern Ireland) [21], %
Sex		
Male	753 (49.1)	49.4
Female	777 (50.7)	50.6

[b] Data are not available for the distribution of the General Data Protection Regulation Awareness and previous health research participation in England.

GDPR and Personal Data Awareness

At the time of the survey, 11.7% (179/1534) of the participants indicated that they were not aware of GDPR, 27.9% (428/1534) had heard of GDPR but did not know much about it, 42.9% (658/1534) had heard and knew a little about GDPR, and 17.5% (269/1534) of respondents had heard and knew a lot about GDPR.

The results of participants' expectations of what is considered personal data under GDPR showed that >80% (1227/1534) of the participants were able to correctly state common information that was classified as personal information, such as name, age, gender, marital status, and home address and email address. Less than 75% (1150/1534) of participants considered sensitive personal information, such as sexual orientation (1121/1534, 73.1%), religion (1067/1534, 69.6%), criminal records (1100/1534, 71.7%), and health or medical records (1136/1534, 74.1%) as personal data.

Less than two-thirds of the participants expected the various types of information collected on the internet to count as personal data. A quarter of the participants incorrectly stated that web-based purchases (383/1534, 25.0%), location data based on General Packet Radio Service recorded on mobile phones (353/1534, 23%), tracking information on websites (cookies; 383/1534, 25%), social media information (424/1534, 27.6%), and device IDs (353/1534, 23%) were not personal data.

More than 80% (1227/1534) of the participants correctly identified what GDPR law should cover most of the rights that protect personal data. Most of the remaining participants stated that they did not know the right answer ranging from 6.6% (101/1534) to 13.4% (205/1534). Approximately 13.4% (205/1534) did not know that they had the right to erase their data, and 12.3% (189/1534) did not know that they had the right to be informed about the use of their data. Additional details are provided in Multimedia Appendix 1.

Willingness to Share Commercial Data With Different Institutions

Descriptive Results

Figure 1 shows that nearly two-thirds of the participants indicated that they would be willing to share their commercial data for health research if their data are shared with a government institution (937/1534, 61.1%) or an academic research institution (936/1534, 61.0%). In contrast, less than half were happy to share their commercial data with private organizations for health research (658/1534, 42.9%). Across all participants, only 4.8% (73/1534) of the participants stated "definitely yes" to share with all types of institutions. In comparison, 7.4% (114/1534) of the participants stated "definitely no" to share commercial data for health research with all institutions.

Figure 1. Willingness to share commercial data with different organizations for health research.

Sociodemographic Factors

In Table 2, the analysis shows significant differences in the willingness to share commercial data with government institutions by age, sex, education, and GDPR awareness. Specifically, less than two-thirds of participants were happy to share their data among those aged 40 to 49 years (841/1534, 54.8%) and 50 to 59 years (871/1534, 56.8%), compared with the 18 to 29 (923/1534, 60.2%), 30 to 39 (1040/1534, 67.8%), 60 to 69 (922/1534, 60.1%), and ≥70 years (1020/1534, 66.5%) groups, respectively (χ^2_5=14.6, *P*=.12). Male participants were more likely to share their commercial data for health research than female participants with the government (994/1534, 64.8% vs 887/1534, 57.8%; χ^2_1=7.9, *P*=.005). There was a 14.4% difference between willingness to share among those who were unaware of GDPR (822/1534, 53.6%) and those who stated that they knew a lot about GDPR (1043/1534, 68.0%; χ^2_3=9.7; *P*=.02). No differences were found in marital status, ethnicity, previous research participation, and personal experience of data misuse in the past.

There were differences in the willingness to share commercial data with private organizations based on most factors, except for education and previous research participation. The largest differences were observed for age between those who were aged 30 to 39 years (147/255, 57.6%), and 60 to 69 years (64/213, 30%), and ≥70 years (80/266, 30.1%), as well as by ethnicity among those identified as Black (28/45, 62.2%) and White (555/1326, 41.9%; χ^2_5=74.1, *P*<.001). Similarly, only one-third of those who reported not being aware of GDPR were willing to share their data (54/179, 30.2%) compared with those who were aware but did not know much (177/428, 41.4%), a little (292/658, 44.4%), and knew a lot about GDPR (138/269, 51.3%; χ^2_3=20.5, *P*<.001). Ever experienced a negative event of data misuse was also positively associated with willingness to share commercial data for health research with private organizations compared with never experiencing a negative event (287/596, 48.2% vs 374/938, 39.9%; χ^2_1=10.1, *P*=.001).

There were no significant differences in the proportion of people who indicated “Definitely and Probably yes” to sharing with academic institutions by marital status, age, sex, ethnicity, and previous experience. However, educational level (above degree: 459/697, 65.9% vs below degree: 474/830, 57.1%; χ^2_1=12.1, *P*<.001), previous participation in health research (yes: 266/402, 66.2% vs no: 670/1132, 59.2%; χ^2_1=6.0, *P*=.01), and greater GDPR awareness (not aware 84/179, 46.9% vs know a lot about it 179/269, 66.5%; χ^2_3=20.8, *P*<.001) were positively associated with sharing data with academic institutions.

Table 2. Willingness to share commercial data with different organizations by sociodemographic factors (N=1534).

Willingness to share	Government organizations	Private organizations	Academic institutions
Marital status			
Single, n (%)	284 (57.7)	230 (46.7)	306 (62.2)

P value	.13	.001	.15

Psychological Predictors

Adjusted ordered regression analyses for willingness to share data with each institution in Table 3 show that greater trust is positively associated with sharing commercial data with government (aOR 2.499, 95% CI 2.228-2.802; *P*<.001), private (aOR 2.513, 95% CI 2.221-2.842; *P*<.001), and academic institutions (aOR 2.283, 95% CI 2.011-2.59; *P*<.001). Greater worry about data misuse was negatively associated with willingness to share with government (aOR 0.94, 95% CI 0.918-0.961; *P*<.001), private (aOR 0.951, 95% CI 0.930-0.973; *P*<.001), and academic institutions (aOR 0.947, 95% CI 0.926-0.969; *P*<.001).

Participants' perceived importance of privacy was negatively associated with willingness to share with the government (aOR 0.909, 95% CI 0.833-0.992; *P*=.03), private institutions (aOR 0.833, 95% CI 0.763-0.909; *P*<.001), and academic institutions (aOR 0.869, 95% CI 0.797-0.948; *P*=.002). Participants' perceived risk of data sharing was not associated with their willingness to share their data with any organization. The perceived benefits of sharing data were positively associated with government institutions (aOR 1.111, 95% CI 1.083-1.14; *P*<.001), private institutions (aOR 1.081, 95% CI 1.054-1.109; *P*<.001), and academic institutions (aOR 1.116, 95% CI 1.087-1.146; *P*<.001).

Table 3. Psychological predictors of willingness to share commercial data for health research with different organizations[a].

	Government institutes, aOR[b] (95% CI)	Private institutes, aOR (95% CI)	Academic institutes, aOR (95% CI)
Trust in organizations	2.499 (2.228-2.802[c])	2.513 (2.221-2.842[c])	2.283 (2.011-2.590[c])
Worry about data misuse	0.940 (0.918-0.961[c])	0.951 (0.930-0.973[c])	0.947 (0.926-0.969[c])
Perceived risk of data sharing	1.041 (0.997-1.086)	1.042 (0.997-1.089)	1.016 (0.974-1.060)
Perceived importance of privacy	0.909 (0.833-0.992[d])	0.833 (0.763-0.909[c])	0.869 (0.797-0.948[c])
Perceived benefits of sharing data and participation	1.111 (1.083-1.140[c])	1.081 (1.054-1.109[c])	1.116 (1.087-1.146[c])

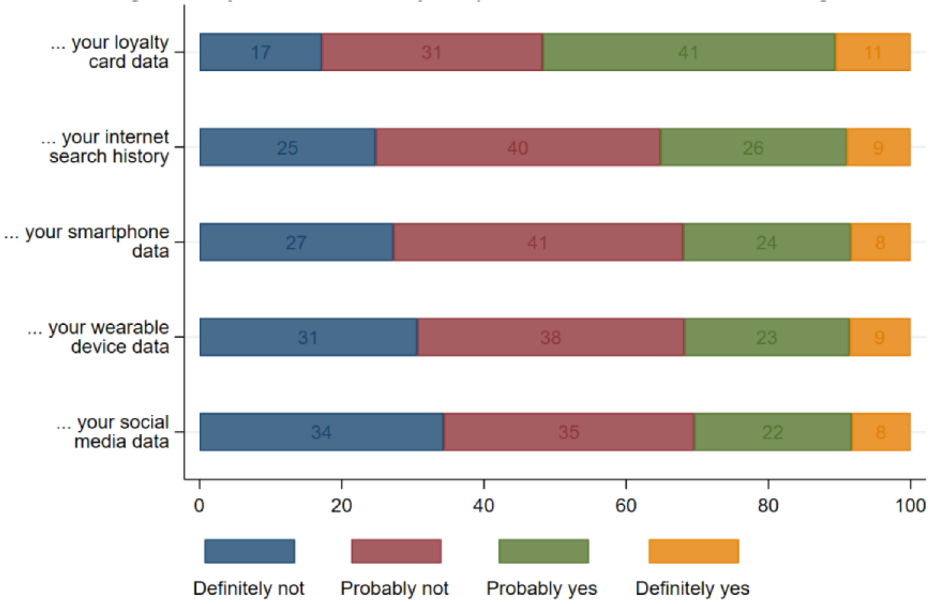
Willingness to Share Different Types of Commercial Data

Descriptive Results

Figure 2 shows that the participants' willingness to share commercial data varied across all data types. The willingness to share loyalty card data had the highest proportion of participants at 51.8% (795/1534) stating that "Definitely or Probably yes." In comparison, the proportion was much lower at 35% (540/1534) for internet search history, 32% (491/1534) for smartphone data, 32% (488/1534) for sharing wearable device data, and 30% (467/1534) for social media data. Across all participants, only about 3.2% (49/1534) of the participants stated "definitely yes" to share all types of commercial data sets. In comparison, 13.3% (204/1534) of the participants stated "definitely no" to share all types of commercial data sets.

Figure 2. Willingness to share different types of commercial data with academic institutions for health research.



Sociodemographic Factors

Table 4 shows the proportion of people who stated “Definitely and Probably yes” for willingness to share different types of commercial data for health research with academic institutions based on the sociodemographic characteristics of the participants. There were significant differences across all types of health research data according to marital status, age, and past experience of data misuse. In contrast, no associations were found between the participants’ educational level and previous participation in the research. Greater GDPR awareness was positively associated with willingness to share all types of data, except for internet searches.

Among these characteristics, notable differences were observed for marital status, where a larger proportion of people who were single reported willingness to share commercial data sets compared with those who were married or in a legal partnership, or widowed, divorced, or separated. Furthermore, an increase in the age of participants was negatively associated with their willingness to share. Less than a fifth of the participants in the 60 to 69 years and above age groups were willing to share smartphone, social media, and wearable device data. Across all types of commercial data, those aged 18 to 29 years had the highest proportion of individuals willing to share at 65.1% (185/284) for loyalty card data, 48.6% (138/284) for smartphone data and wearable devices, 47.2% (134/284) for social media, and 46.8% (133/284) for internet data.

Female participants were less likely to share smartphone data (male: 282/753, 37.5% vs female: 207/777, 26.6%; χ^2_1=20.5 *P*<.001), wearable devices (male: 280/753, 37.2% vs female: 206/777, 26.5%; χ^2_1=20.0 *P*<.001), and social media data (male: 271/753, 36% vs female: 196/777, 25.2%; χ^2_1=20.8 *P*<.001).

In comparison, the differences in proportions were smaller for internet searches (male: 286/753, 38% vs female: 253/777, 32.6%; χ^2_1=4.9, *P*=.03) and loyalty card data (male: 399/753, 53% vs female: 393/777, 50.6%; χ^2_1=0.8, *P*=.35). The proportion of people willing to share loyalty card data did not differ by ethnicity or sex. In contrast, the proportion was lower among those from White ethnic backgrounds for internet searches, social media, wearable devices, and smartphone data compared with those who were identified from Black and Asian ethnic backgrounds.

Those who had ever experienced a data misuse event were more likely to share loyalty card data (ever: 344/596, 57.7% vs never: 450/938, 48%; χ^2_1=13.8, *P*<.001), internet search data (ever: 263/596, 44.1% vs never: 277/938, 29.5%; χ^2_1=34.0, *P*<.001), smartphone (ever: 245/596, 41.1% vs never: 246/938, 26.2%; χ^2_1=37.0, *P*<.001), social media (ever: 240/596, 40.3% vs never: 227/938, 24.2%; χ^2_1=44.4, *P*<.001), and wearable devices (ever: 255/596, 42.8% vs never: 233/938, 24.8%; χ^2_1=54.1, *P*<.001) than those with no previous data misuse experience.

Table 4. Willingness to share different types of commercial data by sociodemographic factors.

Willingness to share	Internet searches	Loyalty card	Smartphone	Social media	Wearable devices
Marital status

Psychological Predictors

The results from the ordered logistic regression analyses adjusted for the sociodemographic characteristics of the participants in Table 5 show that each point increase in trust in data practices in academia, perceived benefits in participation, and perceived risks of data sharing are positively associated with willingness to share all types of commercial data. In contrast, each point increase in the perceived importance of privacy and worry about data misuse was negatively associated with the willingness to share all types of commercial data.

Table 5. Psychological predictors of willingness to share different types of commercial data for health research with academic institutions[a].

	Internet search data, aOR[b] (95% CI)	Loyalty card data, aOR (95% CI)	Smartphone data, aOR (95% CI)	Social media data, aOR (95% CI)	Wearable devices data, aOR (95% CI)
Trust in data practices in academic institutions	1.097 (1.078-1.117[c])	1.103 (1.083-1.123[c])	1.097 (1.077-1.117[c])	1.087 (1.067-1.107[c])	1.075 (1.056-1.095[c])

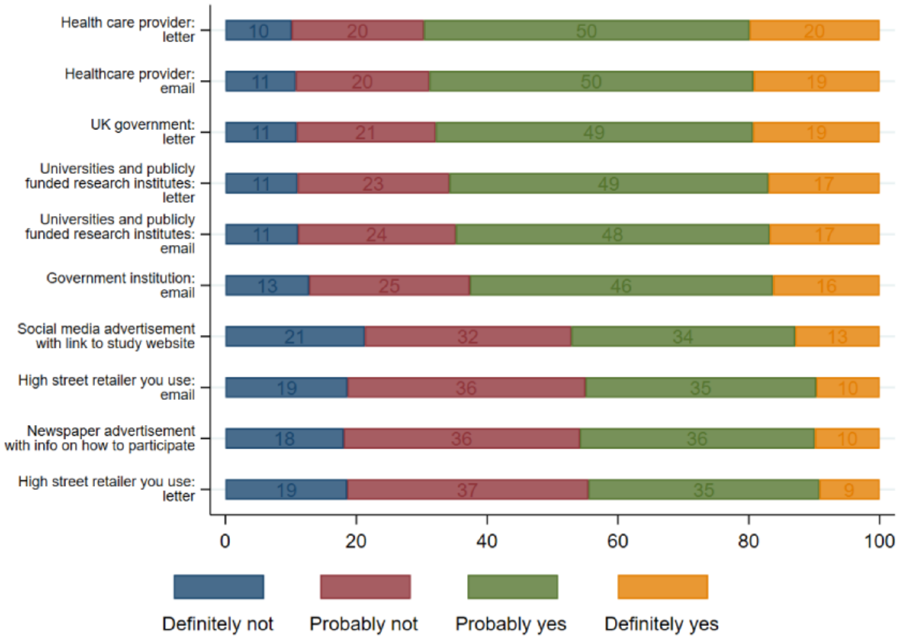
[c] *P*<.001.

[d] *P*<.05.

Willingness to Take Part in Research Based on Invitation Sources

Figure 3 shows that the most preferred ways of being invited to health research using commercial data were receiving a letter (1069/1534, 69.6%) or an email invitation (1056/1534, 68.6%) from the health care provider, followed by a letter invitation from the government (1041/1534, 67.9%) and universities or publicly funded research institutes (1009/1534, 65.8%). Digital invitations had a much lower preference compared with letter-based invitations, except for letter invitations from high-street retailers to participate in the research (683/1534, 44.5%). Research advertisements on social media or newspapers were preferable for less than half of the participants, with 47.1% (723/1534) and 45.8% (703/1534), respectively. The ordered logistic regression analysis in Multimedia Appendix 1 shows that across all invitation types, greater GDPR awareness was the only predictor of invitation source, and there were some nuanced differences in sociodemographic characteristics.

Figure 3. Preferences for the source of research participation invitation.



Discussion

Principal Findings

With an interest to develop a better understanding of psychological factors and sociodemographic characteristics of individuals who would be willing to participate in health research using individual and commercially collected data sets, this study investigates the willingness to share commercial data for health research with different institutions and different types of commercial data in an age-stratified population-based sample in the United Kingdom. Our results showed that two-thirds of the participants were willing to share their commercial data on health research with academic institutions. In contrast, when participants were specifically asked about sharing different types of commercial data for health research with a focus on academic institutions, only about half of them were willing to share their shopping data, and less than one-third were happy to share internet search history, wearable devices, social media, and smartphone apps. Only a small minority of the participants across all outcomes were willing to share their data, highlighting the potential barrier in participant recruitment that needs to be addressed in health research using complex data sets.

Comparison With Prior Work

A key outcome of this study is the validation of the previous evidence that, irrespective of individuals' GDPR awareness and their sociodemographic characteristics, greater trust is consistently associated with greater willingness to share commercial data for health research [12]. This study also adds to the evidence that greater perceived importance of data privacy and greater worry about data misuse are negatively associated with the willingness to share commercial data for health research. Interestingly, the perceived risk of sharing data was not associated with the willingness to share data with institutions, but it played a role in all types of data that they were willing to share. This is in line with the Nissenbaum [29] contextual integrity framework for privacy, suggesting that individuals' information-sharing principles are context dependent and socially constructed. A previous focus group study also found similar results in that participants were more concerned about the use of subjective data sets such as social media posts compared with objective shopping data collected on loyalty cards as more important than the organizations in which they share their data with [15]. Furthermore, we found a positive univariate association between the participants who had ever experienced a negative data-related event, for example, they might have had a data breach and personal information stolen on the internet and used for other people's gain, were more likely to share their data. Although we do not have sufficient information to assess why this may be the case, it could be interpreted that those who have experienced a negative event are more likely to be risk-aware than risk-averse. An interesting explanation for this result could be studied further based on "the privacy paradox," which suggests that intentions to share data may not be directly associated with actual behavior, and other mediators should be better understood [30]. Future experimental studies with a factorial design can further explore how these experiences impact people's perceptions and use of technologies.

We identified various sociodemographic factors associated with all outcome variables with the participants' age particularly being an important factor to be considered for participant recruitment. Our results showed that the participants' willingness reduced with an increase in age, except for sharing data with government institutions where we observed an inverse association. This is an important outcome to consider when implementing pilot health interventions for the general population [17]. The participants who identified themselves as Black consistently had a higher proportion of willingness not just across all institutions but also for all data types. Health researchers should identify resources to improve the visibility of health research opportunities to improve participation and diversity in research. Recruitment through social media advertisements has been shown to be effective in targeting minority populations [31]. However, there is a lack of ethical and methodological guidance for recruitment via paid social media advertisements to be carried out effectively [32].

Limitations

A key limitation of this survey was that participants were not provided with examples of how commercial data could be used for specific health studies, such as facilitating earlier cancer diagnosis, identifying mental health conditions, and not including nonprofit organizations. A previous study showed that people were more willing to donate their data to Cancer Research UK compared with nonspecific health research organizations, which was found to be associated with individuals' level of altruism and prosocial tendencies [33]. Owing to the exploratory nature of this study, a priori hypotheses were not included in the statistical analysis plans, and the following warnings are warranted. Although we adjusted for past health research participation, participants from the recruitment panel were subject to desirability bias. The social desirability bias in perceived privacy, intention to share data, and actual behaviors has previously been demonstrated in the privacy paradox [30]. Future studies arising from this study could investigate mediators between intention and behavior gaps. Similarly, the use of nonprobability sampling of the participants could also lead to greater bias in this study. Although accumulating evidence suggests that the willingness to share commercial data is a complex behavior and cannot be reduced to one-off intention measures, we believe that the outcomes of this study can be used as a guide for identifying populations with the least likelihood of sharing data when recruitment methods for studies requesting data from its participants are operationalized. However, it should be acknowledged that the measures included in this study, as well as sociodemographic characteristics, explain less than 20% of the variance in the willingness to share commercial data (Multimedia Appendix 1). This highlights the complexity of the evidence surrounding data sharing and slow progress in health-related research in relation to building a better understanding of the mechanisms that hinder and facilitate data-sharing principles. Thus, future studies could benefit from the use of a theoretical model, such as the capability, opportunity, motivation, and behavior model [34], to understand how physical and psychological capabilities, such as participants' engagement with existing technologies, could potentially moderate their willingness to share data. Similarly, social opportunities could be an important factor for the willingness to participate in research advertised through social media. Notwithstanding, this survey included a UK age-representative cohort based on the 2011 Census [26], had a larger proportion of individuals from non-White ethnic backgrounds in comparison with other panel-based survey studies with a UK population representative sample [35,36], and also adjusted for the participants' geographic region in the United Kingdom to improve the external validity and generalizability of its outcomes for the wider UK population.

Conclusions

This survey study demonstrated the public acceptability of sharing commercial data for health research in the United Kingdom with an extensive exploration of people's knowledge and understanding of what constitutes personal data and GDPR, their willingness to share with different organizations, their willingness to share various types of commercial data, and their willingness to consent and share data if invited through different methods. The outcomes of this study are of interest to be considered in the guidelines and recommendations for public acceptability of data sharing beyond electronic health records and will be useful for developing data stewardship frameworks and initiatives to improve the use of data in the United Kingdom. Where possible, these outcomes can also be used to develop recruitment strategies for research using stratified sampling techniques where it is expected to have low response rates. Future studies using experimental methods are warranted to identify the effectiveness of behavioral science techniques and communication methods to improve the public acceptability of sharing commercial data for health research.

Acknowledgments

This study was funded by Cancer Research UK Early Detection and Diagnosis project grant (C38463/A26726), with support from the Peter Sowerby Foundation. YH and HRB were funded by Cancer Research UK (C38463/A26726). The authors would like to acknowledge Wenjia Wang, MSc, who worked on this project as part of her MSc Health Psychology dissertation project at University College London.

Data Availability

The anonymized data collected as part of this survey will be made available to researchers upon publication in the Open Science Framework.

Authors' Contributions

YH developed the study concept. YH, LT, and MMR designed and developed the questionnaire. STS and YH performed the data analysis, and YH, LT, MMR, JMF, and HRB informed the interpretation. YH drafted the manuscript, and all authors provided critical revisions. All authors approved the final version of the manuscript for submission.

Conflicts of Interest

None declared.

Multimedia Appendix 1

(1) The results of the factor analysis; (2) a detailed description of the survey measures including the original questionnaire with item heritage; (3) descriptive data tables for the General Data Protection Regulation awareness in the United Kingdom; (4) ordered logistic regression results on willingness to share commercial data based on invitation sources; and (5) full ordered regression model tables for the primary outcomes.

Abstract

Background: Public involvement in research is a growing phenomenon as well as a condition of research funding, and it is often referred to as coproduction. Coproduction involves stakeholder contributions at every stage of research, but different processes exist. However, the impact of coproduction on research is not well understood. Web-based young people's advisory groups (YPAGs) were established as part of the MindKind study at 3 sites (India, South Africa, and the United Kingdom) to coproduce the wider research study. Each group site, led by a professional youth advisor, conducted all youth coproduction activities collaboratively with other research staff.

Objective: This study aimed to evaluate the impact of youth coproduction in the MindKind study.

Methods: To measure the impact of web-based youth coproduction on all stakeholders, the following methods were used: analysis of project documents, capturing the views of stakeholders using the *Most Significant Change* technique, and impact frameworks to assess the impact of youth coproduction on specific stakeholder outcomes. Data were analyzed in collaboration with researchers, advisors, and YPAG members to explore the impact of youth coproduction on research.

Results: The impact was recorded on 5 levels. First, at the paradigmatic level, a novel method of conducting research allowed for a widely diverse group of YPAG representations, influencing study priorities, conceptualization, and design. Second, at the infrastructural level, the YPAG and youth advisors meaningfully contributed to the dissemination of materials; infrastructural constraints of undertaking coproduction were also identified. Third, at the organizational level, coproduction necessitated implementing new communication practices, such as a web-based shared platform. This meant that materials were easily accessible to the whole team and communication streams remained consistent. Fourth, at the group level, authentic relationships developed between the YPAG members, advisors, and the rest of the team, facilitated by regular web-based contact. Finally, at the individual level, participants reported enhanced insights into mental well-being and appreciation for the opportunity to engage in research.

Conclusions: This study revealed several factors that shape the creation of web-based coproduction, with clear positive outcomes for advisors, YPAG members, researchers, and other project staff. However, several challenges of coproduced research were also encountered in multiple contexts and amid pressing timelines. For systematic reporting of the impact of youth coproduction, we propose that monitoring, evaluation, and learning systems be designed and implemented early.

KEYWORDS

web-based youth coproduction; mental health; public involvement; young people; advisory groups

Introduction

Background

Increasingly, participatory and collaborative research methods have been used to reduce the gap between evidence and implementation [1-3]. One way to do this is to involve target groups in research, using coproduction processes, particularly the involvement of youth, to reflect their needs in research [4,5]. Coproduction is “an approach in which researchers, practitioners and the public work together, sharing power and responsibility from the start to the end of the project, including the generation of knowledge” [6]. Coproduction aims to ensure that the knowledge generated is informed by the needs of the target group, is relevant to them, and has greater applicative value in their local setting [7]. This is somewhat different from what Baum et al [8] describe as participatory action research, where participants are involved in a reflective manner, by collecting and analyzing the data and then determining the outcome. Thus, the active involvement of knowledge users (eg, young people with mental health difficulties) in research, who are experts in their experience, aims to enhance the quality and utility of research.

Coproduction in Mental Health Research With Youth

Different forms of mental health researcher and knowledge user partnerships have grown in popularity, primarily in high-income settings, particularly among young people [9]. With most lifelong mental health conditions having an onset by the mid-20s [10], there is a vital focus on better understanding youth mental health needs and curating services tailored to their needs. Several benefits of such youth-researcher collaborations have been identified. For example, coproduction with youth increases the relevance of research aims [11] and facilitation of recruitment [12,13] and helps the production of richer and more reliable data [14]. Researcher-intensive tasks such as data analysis, the presentation of findings, and dissemination also benefit from youth involvement [15]. Coproduction also enables incorporating lived experiences effectively; with regard to user outcomes, coproduction helps young people develop transferable skills [9,16] and research skills [11] and to understand their own mental health better [17].

Complexities and Challenges of Undertaking Coproduction With Young People

Though coproduction of knowledge may seem like an elegant solution to ensure the implementation of evidence-based practices, it is a highly complex, context-specific experimental process that is often time-consuming and resource intensive [18]. Effective coproduction requires collaborative effort at every stage of the research process [19]. The environment is important, as are researcher traits, such as openness, tolerance, and flexibility [20], and organizational qualities, such as building trustworthy relationships and innovative methodologies [21,22].

The complex process of coproduction with youth comes with specific challenges, as complicated power dynamics may need to be identified, acknowledged, and addressed. Researchers may need to address youth-adult hierarchies [23], which may disrupt effective collaborative work. If such traditional patterns are not disrupted, tokenism, difficulties in conflict resolution and shared decision-making between youth and researchers can ensue [24]. Research processes that ensure coproduction with youth require additional time and resources owing to a number of cultural, ethical, and safety considerations, such as assent-consent procedures for legal minors [25] and ensuring safe practices while also recognizing their agency [5].

Measuring the Impact of Coproduction

Understanding and evidencing the impact of coproduction with youth remains an area in need of further development. The current literature on the monitoring and evaluation of young people’s involvement in research is diffuse and dispersed and does not have a standard taxonomy or methodology [26]. Moreover, much of the focus has been on “measurable, economic and quantifiable impacts,” which does not take into account the numerous dynamic processes of coproduction [27]. The diversity of approaches, evaluative frameworks, and depth of discourse have made it difficult to measure the impact of coproduction on research processes and outcomes.

Few studies report the impacts of youth coproduction [28], complex processes of collaboration, and nonlinear impacts for stakeholders [29]. The MindKind study used mixed methods to elicit young people’s views on data governance and to assess the feasibility of setting up a user-controlled global mental health databank [30]. This study was conducted in India, South Africa, and the United Kingdom. Participants aged 18 to 24 years (16 to 24 years in the United Kingdom) were enrolled on a separate website and randomized into 1 of the 4 data governance options [30]. Using an app designed for the study, participants were invited to share data on key active ingredients of mental health, such as sleep, body movement, social connections, and positive experiences over a 12-week period. Study participants in the qualitative arm took part in country-specific and multinational group deliberative democracy sessions [31] focused on building a consensus pertaining to the governance of a future mental health databank. Each arm of the study had a strong focus on coproduction.

Given the gaps that exist in the literature, in this study, we aimed to evaluate the impact of coproduction in the MindKind study, and the processes involved in achieving such an impact. We defined the impact of coproduction as a powerful or major influence on 4 stakeholder groups: youth (professional youth advisors and young people's advisory group [YPAG] members), researchers (staff who contributed to research design, data collection, and analysis), decision makers (principal investigators and funders), and support and administrative staff (broadly defined to include anyone who undertook substantial administrative and support responsibilities as part of their role). We used the impact framework proposed by Beckett et al [27], which applies a multifaceted lens to understand the breadth of coproduction at different levels, the interactions between these levels, and emergent mechanisms. These levels include paradigmatic, structural, organizational, group, and individual levels. Paradigmatic impacts are those impacts of coproduction with the potential to modify ways of understanding and shift frames of reference. Infrastructural impacts include broader social, economic, policy, and political impacts. Organizational impacts include rules, norms (culture), practices, and organizational structures. Group impacts include interpersonal and stakeholder relationships, whereas individual impacts include personal changes such as improved mental or physical health and improved practice and skills. The emphasis within this framework is to "consider longer term developments, wider social changes, any unintended consequences and how coproduced research might affect and be affected by different power dynamics" [27].

We note that the findings discussed in this manuscript do not include any data from the main MindKind study or any of the randomized arms. The objective of this manuscript was to describe the impact of coproduction with youth on different stakeholder groups [32]. Coproduction with youth was designed to influence both the qualitative and quantitative study arms (ie, youth were coresearchers), and we evaluated such impact of youth acting as coresearchers on key stakeholder groups. Advisors in the project did not participate in the qualitative or quantitative study conducted as part of the MindKind study.

Methods

Ethics Approval

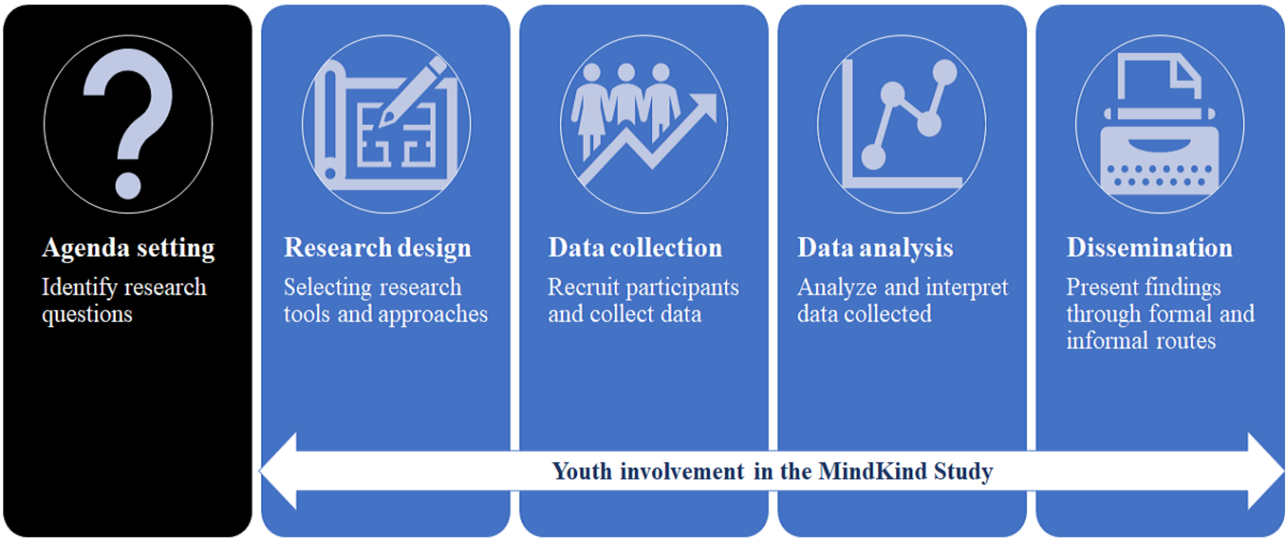
Ethics approval for the MindKind study was obtained from each of the country sites, namely the United States (WIRB #20212067), the United Kingdom (University of Cambridge, Department of Psychology Research Ethics Committee: Ref. PRE.2021.031 and University of Oxford: Ref R73366/RE00), South Africa (Walter Sisulu University #029/2021 and the Department of Higher Education and Training), and India (India Law Society #ILS/242/2021 and Health Ministry Screening Committee).

Overview of Youth Coproduction

Each MindKind study site employed a full-time youth lead or professional youth advisor (youth advisor), to convene and run a YPAG in each country site (India, South Africa, and the United Kingdom) and advise on all aspects of the study. The youth advisor was a young person aged 18-23 years who had lived experience of mental health challenges. The in-country YPAGs in each site comprised of young people with lived experience of mental health challenges aged 18-24 years (16-24 years in the United Kingdom), known as YPAG members. In addition to the in-country YPAGs, around 3 to 4 YPAG members from each site joined an international YPAG to advise on broader study questions.

Each youth advisor had 1 vote on the study's Steering Committee and, therefore, actively participated in study decision-making. Sessions conducted with the in-country and international YPAGs were planned collaboratively by the research teams and led by the respective youth advisors. Sessions were recorded, and feedback shared by the YPAGs was reported by the youth advisors to the research teams via a web-based platform called Airtable. Researchers were then required to respond in Airtable to clarify whether the feedback had been actioned, and if not, why. Youth involvement in MindKind is described in Figure 1.

Figure 1. Youth involvement in the MindKind study.



Data Sources

Coproduction with youth occurred during the study period between September 2020 and July 2022. Data collection to evaluate the impact of coproduction was conducted sequentially in 2 stages with 4 sets of stakeholder groups: youth (advisors and YPAG members), researchers (staff who contributed to research design, data collection, and analysis), decision makers (principal investigators and funders), and support and administrative staff (defined broadly to include anyone who undertook substantial administrative and support responsibilities as part of their role).

First, we collated various project documents generated between September 2020 and January 2022, such as meeting recordings and minutes, project descriptions, and work plans, to determine the coproduction outcomes relevant to all stakeholder groups (youth, researchers, decision makers, and administrative staff). A total of 17 documents were downloaded from the project database for analysis. A summary of these data sources is presented in Textbox 1. The outcomes identified at this stage allowed us to refine subsequent data collection on significant changes for the 4 stakeholder groups.

Second, building on the identified outcomes, we generated data based on the *Most Significant Change* (MSC) technique on the main changes that resulted from coproduction with youth for the 4 stakeholder groups, that is, moving from the outcomes that were intended to take place to the impacts that actually took place [33]. This technique involved gathering stories of the MSCs from stakeholders via open questions to distill key learning about the study and recommendations for the future. In this study, MSC technique meant gathering views from the 4 stakeholder groups on what had changed or had been impacted as a result of youth coproduction. Researchers and youth advisors implemented the MSC technique via web-based in-depth group discussions with in-country and international YPAGs. In these group discussions with YPAG members, the youth advisor in that study site and the lead authors gathered youth views on what impacts they felt had taken place as a result of youth coproduction.

For other stakeholders (ie, researchers, decision makers, and administrative staff), an open-ended web-based questionnaire solicited views on significant changes across 4 to 5 specified outcomes for each stakeholder group. This web-based questionnaire was emailed to all stakeholders in the study and completed by 16 (52%) out of 31 participants. Although the final sample of respondents was not very large, it involved representation from each of the stakeholder groups and therefore, represented a wide cross section of views. All questionnaire responses were deidentified before analysis.

Textbox 1. Summary of documentary data sources.

Initial project discussion notes

- Youth panel decisions between August and November 2020
- Global Mental Health Databank (initial name of MindKind) feedback documents
- Global Mental Health Databank project structure and governance
- Youth panel engagement
- Youth panel objectives

Steering committee notes

- Agenda and meeting minutes
- Presentation on project goals
- Presentation on data usability group feedback and results

Global youth panel meetings

- Meeting notes
- Presentation

Youth advisor onboarding materials

- Project governance plan
- Proposal for youth involvement
- Youth panel concept note

Youth advisory planning spreadsheet

- Youth panel deliverable tracker

Youth advisory planning presentation

- Airtable feedback loop

Funder materials on youth mental health

- Mental health priority log

Data Analysis

The analysis focused on building a picture of key changes that occurred for the 4 stakeholder groups as a result of implementing youth coproduction in the MindKind study and understanding how stakeholders perceived its functioning and progress. We used a qualitative approach to collate and synthesize the collected data. Analysis took place at 2 time points: from December to February 2022 and from March to May 2022.

The first stage consisted of a document analysis performed by on of the lead authors (LN). Outcomes aimed to be achieved due to youth coproduction were derived from study documents. These outcomes were then mapped to the impact framework by Beckett et al [27] (Textbox 2). Following this, inputs were gathered from youth advisors, researchers, and YPAG members in each site, and outcomes were revised as a result of such inputs.

The second stage consisted of analyzing the MSC data to identify the MSCs identified by the 4 stakeholder groups that took place as a result of youth coproduction. This analysis was performed collaboratively by 3 researchers, 3 youth advisors, and 7 YPAG members from the United Kingdom and India, who expressed their interest in being involved in data analysis. Web-based sessions with the YPAGs were transcribed, and open-ended survey responses were summarized. These transcripts and summaries were then scrutinized for impacts on the 4 stakeholder groups, which were categorized under the impact framework [27].

In the final stage of analysis, MSC data were coanalyzed by all analysts using an iterative voting approach to increase the reliability of the findings [33]. This involved all analysts discussing the key impacts, identifying the most impactful quotations shared by participants from each of the 4 stakeholder groups, discussing reasons for their choices, and then voting again. A preliminary version of the findings was developed and revised after discussion with advisors and YPAG members.

Textbox 2. Outcomes of coproduction intended to take place, derived from study documents.

Outcomes at the paradigmatic level

- Better conceptualization of study questions, measures, and design
- Reorientating common research practices and assumptions

Outcomes at the infrastructural level

- Research that values youth voices
- Exploration of youth preferences and attitudes on a range of topics pertinent to data governance and mental health
- Youth-informed dissemination strategies
- Empowerment of young people as data users

Outcomes at the organizational level

- Established communication channels between all stakeholders
- Accountability mechanisms for receipt of feedback
- Increased connection between youth and research institutions
- Differentiated information outputs based on different information needs of stakeholders
- Time and effort invested in team building to fully integrate youth

Outcomes at the group level

- Engaging and authentic relationships between stakeholders, especially between youth and other stakeholders
- Youth-driven rules of engagement for advisors and young people advisory group members

Outcomes at the individual level

- Increased knowledge and capacity of research concepts and processes (for youth) and contexts of youth lives (for other stakeholder groups)
- Adequate compensation for time and effort; networking and skill development opportunities; insights into own mental health experiences; feeling heard (for youth)

Results

Overview

A total of 31 stakeholders working across all MindKind study sites, belonging to the 4 stakeholder groups, participated in group discussions and questionnaires: 11 youths (3 advisors; 7 members across YPAGs in India, South Africa, the United Kingdom and an international YPAG; and 1 lived experience consultant at the funding organization); 11 researchers in India, South Africa, the United Kingdom, and the United States; 6 decision makers (individuals responsible for key study decisions, such as principal investigators and youth); and 3 support and administrative staff. All participants were employed in the MindKind study and had <1 to 25 years of health research experience. Where stakeholders belonged to more than 1 group, the primary group affiliation was used for the analysis (eg, a professional youth advisor could belong to the youth, researcher, and decision maker stakeholder groups). The participants were based in both high- and middle-income settings.

We found that impact occurred at 5 levels detailed in the framework developed by Beckett et al [27], namely, the paradigmatic, infrastructural, organizational, group, and individual levels. Detailed findings are available in Multimedia Appendix 1.

Paradigmatic Impact: Big-Picture Learnings for Coproduction

Paradigmatic impacts are those impacts of coproduction with the potential to modify ways of understanding and shift frames of reference [27]. We identified 2 paradigmatic impacts of coproduction in the MindKind study: first, coproduction enabled new and unexpected ways of conducting research, and second, coproduction modified research priorities and influenced study conceptualization and design, although this was not always successfully implemented.

With regard to the first impact of new ways of conducting research, we observed that youth advisors prompted researchers and decision makers to engage with diverse groups of youth to advise as part of YPAGs and use innovative methods to recruit study participants (eg, using Instagram stories and posts to reach young people). For YPAGs, advisors ensured that recruited members represented diverse backgrounds in research experience, ethnicity, geographic location, gender, or disability status. Previous research shows that YPAG recruitment is limited in diversity and geographic reach (eg, more advisors who are women with prior research experience, based locally) [11]. However, improved digital and technological flexibility in web-based coproduction enabled greater diversity.

Key impacts of youth coproduction were the introduction of Airtable, weekly youth-focused meetings, and relationship building among individual site teams. These immediate impacts then helped improve the process of coproduction by creating separate spaces for youth to share feedback, enabling practices for all stakeholders to engage with one another, and setting up multiple avenues for examining how coproduction goals were being met. Accountability mechanisms are also important for tracking the implementation of generated ideas:

> *We have to create spaces to explicitly solicit young people's feedback; just "having them in the room" may be too overwhelming an environment to engage.* [Researcher]

Second, coproduction with youth transformed research priorities and activities and influenced study conceptualization and design. Through coproduction, we identified points of dissonance between different stakeholder groups and used them to improve study activities, key research decisions, and research knowledge generated to align more with youth priorities, life experiences, and contexts. One example of this was to introduce more capacity building activities for advisors and YPAGs as a priority to effectively advise and participate in research implementation. Without such capacity building activities, youth stakeholders can find it difficult to provide timely and effective advice, and researchers and decision makers find it challenging to incorporate youth perspectives in research. A shared mission and common goals were important for guiding the overall direction of coproduction.

YPAG members and advisors advised on the structure and content of the MindKind app, such as preferred app engagement features, which were a core component of the quantitative study. They also reviewed and shared feedback on questions designed to be used in qualitative group discussions with the study participants. However, some of their feedback on the MindKind app could not be successfully incorporated into the app development process because of the research and funding timelines. Timing was critical, as a number of early decisions had to be made (owing to logistical and funding constraints) before the coproduction systems had been set up. This highlights the importance of timing and early engagement; otherwise, there was a risk of disengagement among youth stakeholders:

> *If one is going to be doing research around youth, then involve youth from the beginning right through to the end. I think MindKind didn't quite do this as we had already developed the App and the areas to focus on before we started the youth advisory groups...we did a bit of "roughshodding" and hoped they would agree with us!* [Decision maker]

Capacity building activities for youth to advise on research implementation and dissemination needed significant additional time and resources, especially from advisors and early career researchers, which were exacerbated by restricted funding timelines. These constraints meant that there were contexts in which coproduction was limited, and the study had to consider meaningful ways of course correction or acknowledge which parts of the study could not be meaningfully coproduced. However, systems for reflection in multiple teams, forums, and different groups were critical in ensuring that meaningful engagement was always possible, and attempted, even if not successful in every instance:

> *Many discussions around involvement have revolved around equality. However, I thought it was important to emphasise equity. This meant taking a unique approach which focused on youth capacity development and ongoing reflexivity rather than assuming involvement just meant a seat at the table.* [Youth stakeholder]

Infrastructural Impact: Constraints and Opportunities in Existing Systems

We describe infrastructural impacts of coproduction on dissemination activities, as well as infrastructural constraints within research, administrative, and funding structures that governed the larger MindKind study.

Coproduction had positive impacts on research dissemination for both formal (the MindKind final report, journal publications, and conference presentations) and informal (blog posts, seminar discussions, and internal presentations) outputs. For example, we coanalyzed and cowrote our youth coproduction publications with advisors and YPAG members, which introduced views and perspectives that might not have otherwise been incorporated. Advisors at each site (India, South Africa, and the United Kingdom) shared their views on the topics to be addressed in publications arising from the study. They also contributed to preparing an outline for each publication, participated in documentary analysis, and shared key learnings from youth involvement via blog posts. Advisors and YPAG members also coanalyzed qualitative data by assisting with theme and subtheme selection, voting on the most important findings to be highlighted, and commenting on drafts of the manuscript.

We were regularly invited to share our learnings with external research groups who had either begun or were contemplating undertaking coproduction in the form of informal discussions or extended presentations. We presented the challenges and opportunities of coproduction in posters at academic conferences, internal seminars, and university meetings (eg, within the Child and Adolescent Psychiatry research group at the Department of Psychiatry, University of Oxford). One such presentation at an internal seminar was led entirely by the advisor and YPAG members. The presence of a full-time advisor was a positive catalyst for learning in other research projects.

Factors that facilitated positive infrastructural impact included greater funding and administrative support to ensure that these tensions were addressed appropriately. Flexible timelines and the timely involvement of youth were also critical in ensuring that youth stakeholders could be fully integrated and included in the project as equal partners in research. This also meant that research funding was critical to timing, as coproduction needed resources available at the funding application stage to be done appropriately.

Infrastructural impacts varied across contexts. For example, the youth advisor and YPAG members in South Africa frequently faced planned electricity outages or "load shedding," which hampered their ability to meet via web-based portals on a regular basis. YPAG members in South Africa also did not consistently have access to the internet, and their agreed remuneration was delayed owing to wider issues with the financial administration, both of which negatively impacted their ability to engage. In contrast, advisors in India and the United Kingdom faced fewer infrastructural issues, which aided regular engagement and advice from YPAG members. These findings underscore the importance of infrastructure in a wider sense, including access to the internet and responsive administrative systems that were essential for facilitating effective coproduction.

An additional infrastructural impact within this study was that we experienced a constant tension between project timelines, deliverables, and coproduction aims. To undertake coproduction with youth fully, we needed to invest significant time and effort on capacity building activities, tailoring existing systems, and mentorship, but these were not always compatible with the study timelines. Pressure to produce reports or updates in line with project milestones were also often at odds with the time that was needed to effectively coproduce a specific aspect of the study, whether that was about the design, data collection, or analysis.

Organizational Impact: Differentiated Communication Practices and the Feedback Loop

Organizational impacts include impacts on rules, norms (culture), practices, and organizational structures [27]. We found that the most critical organizational impact involved changes in communication. Coproduction prompted organizations to engage appropriately with diverse stakeholder groups, including (1) ensuring that a feedback loop was in place to communicate with stakeholders, especially youth, and that this loop was closed in a way that stakeholders felt heard and (2) implementing differentiated communication practices for different stakeholders.

With regard to the feedback loop, we set up an Airtable system to record feedback from YPAG members and advisors. Research and project teams then acted on the feedback. If implementing feedback was not possible, they explained why it could not be done. Although this was an encouraging start, we found that the critical component was ensuring that feedback loops needed to be closed in a way that the youth felt they had been addressed. Data collection on Airtable also had to be made more conversational to engage with youth, so formal data collection platforms were supplemented by meetings where youth could share their feedback verbally, in addition to written feedback:

> *Communication must be done continuously and through multiple channels. Because everyone learns and contributes differently.* [Decision maker]

Given that effective communication meant something different for each stakeholder group, our communication practices needed different frequencies and levels of detail as well as a more inclusive information-sharing strategy to include youth. This sometimes meant that given the large number of stakeholders to consult, decisions needed more time to be taken. We implemented other changes to address these issues, for example, a weekly digest email for important announcements; quick links to project documentation; and a list of the upcoming week's meetings, including any scheduled YPAGs. Importantly, the digest was designed to ensure that everyone, including the advisors, was informed about the decisions to be made, who was making them, and when and in what format feedback would be welcomed. These digests became important tools for increasing transparency and inclusivity, directly impacting communication between stakeholders.

Group Impact and Interpersonal Relationships: Authenticity and Cycles of Engagement

Group-level impacts constitute interpersonal and stakeholder relationships within a system [27]. We observed that due to coproduction, authentic relationships developed between researchers and advisors and between advisors and YPAG members, and YPAG members experienced cycles of engagement and disengagement.

Authentic relationships among the advisors were aided by creating multiple channels of communication with them and among them. The advisors and study team met every week during the course of the study to discuss updates, youth integration, challenges, and learnings. The youth advisors also met each other, together with an external lived experience consultant and advisor (employed by the funder), for regular check-in meetings. They also had a monthly scheduled check-in with each other.

Advisors were responsible for leading their own YPAG and were encouraged to foster authentic relationships with the members. They met the YPAG on a fortnightly basis and conducted individual check-ins with the members to understand any concerns or feedback from them. Overall, the project team treating the advisors and YPAG members with curiosity and professionalism was helpful in fostering these relationships.

Providing the YPAG members with opportunities to upskill and spending time and resources on engagement were important in creating positive group relationships. For example, actively soliciting youth feedback, trying innovative ideas, and offering multiple avenues for youth to engage and contribute to the study beyond the role of an advisor (involvement in capacity building activities, manuscript ideation, and writing) helped increase engagement. Furthermore, closing the feedback loop in a way felt by the youth was helpful, but when this was not possible, it could lead to disengagement if not properly communicated by researchers and decision makers:

> *Some key things to consider when engaging and retaining youth in the MindKind Study—Providing due credit to young people where necessary and allowing them to be key decision makers who hold equal power as adult staff on the team; Providing compensation/reimbursement/honorarium for the time that youth engage with us; Providing young people with constant opportunities to upskill (through workshops, manuscript involvement, consultancies on projects aside from MindKind); Ensuring that young people are given support when needed (emotional/support with work etc.)* [Youth]

Collaboration between researchers and advisors was established over time and was beneficial to overall youth engagement. This was done through multiple channels, such as organizing check-ins between researchers and advisors, as well as directly involving advisors in all research-related activities.

Individual Impact: Better Skills, Knowledge, and Capacities

According to Beckett et al [27], individual impact constitutes the characteristics of stakeholders, including biological and psychological aspects such as improved mental or physical health and improved practice and skills for practitioners. For advisors and YPAG members, major individual impacts included greater insight into one's own mental health; increased knowledge of research concepts and processes; opportunities to harness lived experiences of mental health challenges; remuneration for time and skills; and new academic, presentation, and study skills. The advisors and YPAG members reported developing better insights into their own mental health by participating in project activities and having discussions about a future global mental health databank. Furthermore, they reported increased skills and knowledge development in research-related concepts:

> *One of the most significant changes for me is probably the importance of research and studies which, which I mean, are now involved in but just in general, for the understanding of mental health...it's helped me look at mental health as more collective thing, rather than being more focused on the individual just because, like we, we convene, we talk on a weekly basis, but also the moving parts and the systems which have to be in place for some sort of change to happen. And some sort of, like, insight into mental health and research to actually come to fruition.* [Youth]

These impacts were mediated by the following factors: having site-specific and international YPAGs led by advisors, capacity building activities for advisors to independently coordinate and lead several study components, regular capacity building activities for YPAG members to advise on study, and dedicated spaces for youth to interact with each other. These capacity building activities involved dedicating sessions to demonstrate research in practice. Customized support for advisors to suit their backgrounds and interests was also critical for enhancing outcomes:

> *Young people's social and cultural contexts affect their knowledge and opinions on mental health. While this was something that I had some idea about prior to the study, having regular conversations with advisors and researchers across the sites led to interesting learnings on how social and cultural contexts play a role in shaping a young person's perspective and knowledge on mental health (for example, what mental health means to a young person in a HIC [high-income country] vs what it means to a young person in an LMIC [low- and middle-income country]).* [Youth]

For researchers and decision makers, enhanced coproduction with youth resulted in a much richer understanding of young people's life experiences and contexts:

> *I think we learned a lot about how youth wanted to be engaged...the decision making on the side of the research team needed to happen at a much faster pace than the youth were comfortable (or able) to make decisions. As a result, we sometimes just "told" rather than "asked." I think the youth forced us to slow down and demanded inclusion, which was a very powerful change to the study.* [Decision maker]

This was aided by ongoing reflexivity by the research team and decision makers as well as course correction based on youth feedback.

Discussion

Summary of Findings

Our findings suggest that coproduction with youth in the MindKind study had significant positive impacts for all stakeholder groups (youth, researchers, decision makers, and administrative and support staff). In addition, having a web-based YPAG allowed engagement from a diverse group of panel members, facilitating wider reach and convenience by conducting sessions at suitable times. We found that coproduction impacted, to varying degrees, all 5 domains of practice: paradigms (new or innovative ways of doing research and influence on research priorities, conceptualization, and design), infrastructure (improved dissemination of learning and constant tensions between study timelines and coproduction owing to infrastructural stressors), organizational (differentiated communication needs, practices, and outputs; greater emphasis on closing the feedback loop; and better access between youth and research institutions), group (more authentic relationships among youth and between youth and other stakeholders, and ebbs and flows in engagement), and individual (increased skills and capacities for all, opportunity to use lived experience of mental health for youth, and increased knowledge of youth life experiences for researchers and decision makers). Some impacts, such as societal or infrastructural impacts, occurring beyond the project can be challenging to measure and document but cannot be ignored.

Implications and Recommendations

Youth coproduction generally led to better outcomes overall, not only for youth but also for researchers, decision makers, administrative staff, and the research as a whole. Individual- and group-level impacts included increased knowledge, skills, and capacities for youth and other stakeholders; youth being able to use their lived experience of mental health and feeling heard; authentic relationships between the YPAG and advisors; and ebbs and flows in engagement over the project life cycle. Many of these findings align with the wider literature on the impact of coproduction with youth [4,28,34]. Having a dedicated youth advisor in each site was critical in achieving these impacts. There was no full-time youth advisor in the US study team (ie, not a study site, but the coordination hub); if present, this might have resulted in improved communication and greater youth input into some of the technological decisions.

Coproduction with youth consistently challenged nonyouth stakeholders on their assumptions of what the research could look like. This aligns with the wider literature, which emphasizes that the involvement of stakeholders in research is linked with greater effectiveness, if there is articulation of a shared mission and goals [35]. Our findings further confirm that although a shared mission is critical, establishing clear expectations with funders and organizations in terms of the practical costs of undertaking coproduction and implementing necessary changes in organizational communication practices are critical in achieving better outcomes for all.

Our experience of coproduction with youth as an active process of valuing all types of knowledge and experiences and creating a balance between different stakeholders aligns with others' experiences [36]. However, we encountered several barriers in implementing coproduction with youth according to its tenets and in line with our shared mission [37]. Our systems for reflection and discussion were critical in addressing these barriers effectively, which is a characteristic of effective partnerships [35]. Our findings point to the need for ongoing monitoring and evaluation of impact and to ensure that this is set up as early as practicable in the research cycle. Such monitoring and evaluation should take the form of first articulating outcomes and measurable indicators of what coproduction is meant to achieve, for whom, and by when. Establishing feedback forms and recurring surveys that capture periodic progress toward these goals is a good starting point.

Coproduction was enacted, implemented, and received differently by stakeholders in India, South Africa, and the United Kingdom (MindKind study sites). Equally, public and institutional infrastructure (eg, access to the internet) also played a significant role in the way coproduction was implemented and received in different contexts. Although such challenges broadly map to the literature on coproduction in low- and middle-income countries versus high-income countries [28], we found variations between South Africa and India in this context. Our findings underscore the concept that coproduction is highly "place based" and occurs in particular social, economic, and ecological contexts [38].

An important organizational impact detected was the change in communication practices and outputs needed to undertake coproduced research and ensuring that there was a feedback loop in place and stakeholders (especially youth) felt that this was closed in an appropriate way. This begins with the recruitment and integration of youth advisors, understanding their varied communication needs, and changing communication and decision-making practices. These findings are consistent with previous literature that highlights that effective coproduction is achieved when there are positive working relationships within and between teams, stakeholders feel heard, and tailored communication helps create shared meanings of concepts [35]. Our key mechanisms of achieving this impact included establishing feedback loops and testing them to ensure that they were fit for practice and supporting administrative staff to implement these communication practices. These practices are characterized as "maintenance tasks" in the wider literature that supports the functioning of partnerships by addressing core administrative and support needs [35].

The relatively recent completion of the study limits attempts to describe the wider infrastructural or societal impact as intended in the framework by Beckett et al [27]. Instead, we discuss modest impacts on dissemination and infrastructural constraints while undertaking coproduction with youth. However, to determine the wider infrastructural impact of youth involvement at the societal level, coproduction with youth would need to be assessed at the national scale, where such methods are adopted to measure its public value. Our experiences broadly map the practical costs and challenges of coproduction, such as large administrative burdens, increased researcher time and resources, the lack of training on the implementation of coproduction, and insufficient funds and resources to effectively undertake coproduced research [39]. Although we found significant benefits of undertaking coproduction, we also found that grappling with timelines and costs could lead to a diluted version of coproduction to *coproduction lite*. Despite the focus and funding support, our experience highlights the entrenched structural challenges in undertaking coproduced scientific research more broadly [40]. Our findings highlight the need to cocreate the infrastructure needed to undertake coproduction, resource it appropriately, and recognize the time and skills needed to coproduce research [39].

Youth Involvement

We were committed to ensuring the meaningful involvement of young people, but funding and timeline constraints meant that such involvement needed to be proportional and pragmatic. Therefore, we involved YPAG members in areas where they had particular knowledge, interests, or skills, specifically data collection, analysis, and the interpretation of findings. We analyzed the data in collaboration with advisors and YPAG members who were interested in doing so and jointly interpreted the findings and decided on specific findings to be presented in the paper. In relation to dissemination, we also met YPAG members and advisors who had participated in data analysis and interpretation to understand how they would like to be acknowledged in the paper (in this study, as coauthors).

Conclusions

Although the resources involved in coproduction are significant, they yield several benefits for various stakeholder groups and across several domains. We have attempted to capture these impacts and their enabling or disabling factors in further detail in the context of the MindKind study, which focused on young people's views of mental health data governance in India, South Africa, and the United Kingdom. We found that "effective coproduction emerges in practice" [41], and numerous opportunities and challenges arise in the implementation of coproduction.

There are no one-size-fits-all coproduction efforts. In sharing the impact of coproduction on various stakeholders and outcomes, we hope to have additionally demonstrated the value of measuring and reporting outcomes associated with youth coproduction [28]. We recommend that monitoring, evaluation, and learning systems be designed and implemented early in coproduction studies to enable more systematic reporting of coproduction with youth and its impacts. Future research should also examine how we can standardize the reporting of youth involvement in research; the Guidance for Reporting Involvement of Patients and the Public (GRIPP) checklist provide a useful starting point [42]. More frequent and detailed reporting of the impact of coproduction with youth will likely challenge the current funding and research infrastructure constraints and enable better health research outputs.

Acknowledgments

The authors would like to thank all members of the MindKind Youth Group Advisory Panels in India, South Africa, and the United Kingdom; the International Youth Panel; and the Global Youth Panel for their thoughtful and generous contributions to this project.

The MindKind Consortium includes the following members: Faith Oluwasemilore Adeyemi, Patricia A Areán, Emily Bampton, Elin A Björling, Ljubomir Bradic, Anne-Marie Burn, Emma Grace Carey, Sonia P Carlson, Pamela Y Collins, Tessa Concepcion, Meera Damji, Megan Doerr, Julia C Dunbar, Mina Fazel, Blossom Fernandes, Gillian Finchilescu, Tamsin Jane Ford, Melvyn Freeman, Isabell R Griffith Fillipo, Jay Hodgson, Jasmine Kalha, Minal Karani, Michael R Kellen, Christopher G Kemp, Simthembile Lindani, Lara M Mangravite, Carly Marten, Hedwick Masomera, Felicia Mata-Greve, Emily Moore, Erin Mounts, Lakshmi Neelakantan, Larsson Omberg, Lisa Pasquale, Soumitra Pathare, Swetha Ranganathan, Nichole Sams, Erin Joy Scanlan, Himani Shah, Sotirios Short, Refiloe Sibisi, Solveig K Sieberts, Stockard Simon, Sushmita Sumant, Christine Suver, Yanga Thungana, Meghasyam Tummalacherla, Chandre Van Vught, Jennifer Velloza and Zukiswa Zingela.

Abstract

Background: Functional limitations and disabilities have been associated with a decrease in cognitive function due to increasing age. Gait performance and cognitive function have been associated with gait variability in executive function, the phase domain in memory, and gait abnormalities in cognitive decline.

Objective: Our study aimed to investigate whether gait harmony was associated with cognitive function in the older adult population. Moreover, we aimed to investigate whether gait harmony was associated with cognitive function and explore each cognitive function in a specific harmonic state.

Methods: The study population included 510 adults aged ≥60 years who visited the Department of Neurology at the Veterans Health Service Medical Center, Seoul, South Korea. Gait data were collected using a 3D motion capture device with a wireless inertial measurement unit system. For cognitive function assessments, we used the Seoul Neuropsychological Screening Battery-Core test, which evaluates the level of cognitive function or impairment in 5 cognitive domains.

Results: In general, the association between the Seoul Neuropsychological Screening Battery-Core tests and the stance-to-swing ratio in the >1.63 ratio group yielded lower β coefficients than those in the 1.50-1.63 ratio group. After adjustment for confounders, the odds ratio (OR) for the Digit Symbol Coding test (adjusted OR 0.42, 95% CI 0.20-0.88) and the Korean version of the Color Word Stroop Test: 60 seconds (adjusted OR 0.51, 95% CI 0.29-0.89) for frontal and executive function were significantly lower for the >1.63 ratio group than the reference group.

Conclusions: Our findings suggest that the gait phase ratio is a valuable indicator of walking deficits and may also be associated with cognitive impairment in older adults.

Introduction

The global population is rapidly aging, and the number of people aged 65 years or older is expected to increase from 703 million in 2019 to 1.5 billion in 2050 [1]. With the increasing older adult population, age-related cognitive impairment has increased and will become a public health problem unless prevention and intervention are implemented [2]. The development of many neurodegenerative disorders is usually a feature of the older adult population in the context of aging [3], and age is known as the primary risk factor for many diseases such as Alzheimer disease (AD) and dementia [4,5]. Approximately 50 million people have been diagnosed with dementia, which is one of the leading causes of disability and mortality among aging adults [6]. Moreover, dementia resulting from cognitive decline is an irreversible process, and there are no effective treatments or drugs for dementia [7]. Therefore, it is important to identify factors that can delay the onset of cognitive impairment or impact cognitive outcomes.

Human gait is complicated and divided into 5 primary modal domains: rhythm, phase, variability, pace, and base of support [8]. Safe and effective gaits are important markers throughout life [9]. In older individuals, gait is used as a predictor of health status [10], falls, activities of daily living [11,12], risk of dementia [13], and even risk of early mortality [14]. Functional limitations and disabilities have been associated with a decrease in cognitive function due to increasing age [15]; motor performance may be related to cognitive impairment and dementia [16,17]. Furthermore, impairment of the motor system, such as gait abnormalities, can lead to cognitive decline [16,17] or early stages of dementia with aging [18]. Gait performance and cognitive function have been associated with gait variability in executive function [19], the phase domain in memory [20], and gait abnormalities in cognitive decline [21]. An abnormal gait, which increases the risk of dementia in older adults, suggests low physical fitness in areas such as mobility [22] and balance [23,24]. Therefore, gait cannot be simply explained as an autonomic movement.

A principal issue is that older adults who demonstrate an imbalance in gait are likely to be at a higher risk of cognitive impairment [25]. Gait harmony, which indicates the proportion of stance to swing in kinematic gait, is defined as the capacity to transform the symmetrical human body into alternated, synchronized, symmetric, and rhythmic movements [26]. Previous studies have shown that the proportion of stance to swing is reduced during fast walking and increases under pathological conditions such as Parkinson disease (PD) [27], stroke [28], and spastic cerebral palsy [29]. A ratio from stance to swing of 70% to 30% was found in patients with stroke [28], and a longer stance phase increased gait stability [30]. It has been suggested that a stance between 59% and 70% is a good compromise between fast and stable walking by the harmonic properties of the stance-to-swing ratio [30]. The harmonic ratio property is founded not only in various disparate physical and biological systems, including leaf disposition [31], nucleotide frequencies [32], and cell [33], but also in human sciences, such as body proportions [34] and aesthetic preferences [35]. However, there is a lack of evidence supporting the association between gait harmony and cognitive function.

Therefore, the objective of this study was to investigate whether gait harmony was associated with cognitive function in the older adult population. In addition, we aimed to explore each cognitive function in a specific harmonic state.

Methods

Setting and Study Design

A cross-sectional study was conducted at the Veterans Health Service Medical Center, Seoul, South Korea. Individuals aged ≥60 years who visited the Department of Neurology between March and December 2021 were recruited in this study. The inclusion criteria were as follows: (1) those concerned about cognitive decline, (2) those who could independently undergo all the clinical tests and respond to questionnaires, and (3) those who agreed to participate in this study. Individuals were excluded based on the following criteria: (1) a diagnosis of dementia (International Classification of Diseases, 10th Revision, codes F00-F09 and G30); (2) diagnoses of brain infarction, cerebral hemorrhage, or PD; and (3) a diagnosis of another serious disease (eg, cancer or mental illness). Experienced neurological clinicians evaluated the inclusion and exclusion criteria.

The participants were subjected to a health survey consisting of gait measurements, cognitive examinations, and questionnaires. The survey was conducted at the Veterans Medical Research Institute of the Veterans Health Service Medical Center. A total of 575 individuals volunteered to participate in this study and provided informed consent at enrollment. Of these, 65 participants subsequently dropped out of the study because they were younger than 60 years (n=5) or had missing data on variables (ie, sex, education level, BMI, gait measurements, and cognitive parameters; n=60). After these exclusions, 510 people were eligible for this study.

Ethics Approval

Study protocols were approved by the Institutional Ethics Review Board of the Veterans Health Service Medical Center (BOHUN 2021-02-024 and BOHUN 2021-01-066). All participants provided signed informed consent prior to study enrollment.

Gait Analysis

Kinematic data of gait parameters were collected using the NORAXON myoMOTION sensor, which is a 3D motion capture device used with a wireless inertial measurement unit (IMU) system. The IMU sensor plays a role in transmitting human movement data directly to the myoMOTION receiver to compute the angular changes of the selected body segments. In a particular space, the 3D rotation angles of each sensor on selected body segments were measured from the 3D accelerometer, gyroscope, and magnetometer using *fusion algorithms*; these angles are also known as orientation or navigation angles. The sensor for angular orientation uses a robust fusion algorithm combining the elemental sensor component axes' readings as quaternion element values. This technology mathematically combines and filters incoming source signals at the sensor level and transmits the 4 quaternions of each sensor. Then, using NORAXON's software, the quaternion data are automatically converted into anatomical angles using a rigid body model with joint segments. NORAXON's software also records each sensor's orientation angles and linear acceleration. The system is intended to quantify angular changes of the involved joint and can mathematically derive the x, y, and z displacements in space from linear acceleration data and inverse kinematics modeling. Using this process, the algorithm uses a gyroscope and acceleration data from body-mounted sensors to identify the stance and swing phases in the gait cycle through the signal recorded at a sampling rate of 100-200 Hz. The recoded IMU data were added, filtered, and processed using the myoMOTION software to quantify angular changes in the joints, and the output was exported to Microsoft Excel files [36-38].

For this study, 7 IMU sensors were attached to the participants' feet, frontal tibia bones, quadriceps, and the sacrum on the left and right sides symmetrically (ie, 2 on the feet, 2 on the frontal tibia bones, 2 on the quadriceps, and 1 on the sacrum, respectively). Calibration was performed using an upright posture to determine the value of the 0° angle in the joints. The participants were instructed to walk at their usual pace for the measured distance (10 m), and walking start or stop points for the measured distance were marked on the floor. The participants started walking at the start signal and stopped walking by themselves at the stop point. However, owing to an acceleration and deceleration phase during the 10-m gait test, the first and last steps were removed.

The data transmitted to the myoMOTION software comprised the kinematic parameters of gait variables including the automatically processed average signals for each stance and swing phase. The stance-to-swing ratio was calculated using the average signal values of the stance and swing phases (*stance phase [%] / swing phase [%]*) [30]. The total gait cycle comprises the stance and swing phases. The literature suggests that during stable human walking, with the total gait cycle set to 100%, the stance phase comprises 60% to 62% and the swing phase comprises 40% to 38%, equating to a ratio of 1.50-1.63 [39-41]. These values were then used to determine the harmonic gait group in this study. Therefore, gait ratios were stratified into 3 groups (<1.50, 1.50-1.63, or >1.63). The harmonic group included individuals in the 1.50-1.63 ratio range, whereas the nonharmonic group included those with the other ratios (<1.50 and >1.63).

Cognition Evaluation

Participants performed a brief version of the Seoul Neuropsychological Screening Battery, named the Seoul Neuropsychological Screening Battery-Core (SNSB-C), which evaluates the level of cognitive function or impairment in the following 5 cognitive domains: attention, language and related functions, visuospatial functions, memory, and frontal and executive functions [42]. SNSB-C is made up of 14 subtests, including the Digit Span Test, a short version of the Korean-Boston Naming Test (S-K-BNT), Rey Complex Figure Test (RCFT), Seoul Verbal Learning Test: Delayed Recall (SVLT: DR), the Korean version of Color Word Stroop Test: 60 seconds (K-CWST: 60sec), Controlled Oral Word Association Test (COWAT), Trail Making Test-Elderly: Part B (TMT-E: B), and Digit Symbol Coding [43]. Each SNSB-C score is expressed as standardized percentile, stratified for age, sex, and education.

Other Variables

The questionnaire information included age (≥60 years) and sex (male or female). Health behavior variables included smoking status (current, former, or never), alcohol consumption (drinker or nondrinker), vigorous exercises (yes or no), and BMI. BMI was calculated by dividing the individual's weight (kg) by height squared (m^2).

Statistical Analyses

Statistical differences between the characteristics of the study population were analyzed according to the stance-to-swing ratio (<1.50, 1.50-1.63, or >1.63 ratio group) using the proportion of physiologically comfortable human gait [30,40,41,44,45]. In the analysis, cognitive function and gait ratio were used as the dependent and independent variables, respectively. For each variable, the chi-square test and 2-tailed *t* test were performed for each group of participants. Linear regression analysis was used to evaluate the association between cognitive function tests and the stance-to-swing ratio in each group of gait phase ratio and to provide β coefficients and SEs. The logistic regression model provided odds ratios (ORs) and 95% CIs for each cognitive function test percentiles as the stance-to-swing ratio increased or decreased. The 1.50-1.63 ratio group was used as the reference. Regression models were adjusted for age, sex, education level, smoking status, alcohol consumption, vigorous exercises, and BMI. All statistical analyses were performed with SAS (version 9.4; SAS Institute), and the statistical significance was established at α=.05.

Results

Participant Characteristics

Table 1 summarizes the characteristics of the study population according to the 3 stance-to-swing ratio groups. A total of 510 participants with a mean age of 74.1 (SD 5.6) years were included in the study. Of the participants, 34 (6.7%) were in the <1.50 ratio group, 122 (23.9%) were in the 1.50-1.63 ratio group, and 354 (69.4%) were in the >1.63 ratio group.

Table 1. Characteristics of the study population according to the 3 stance-to-swing ratio groups.

Characteristic	Total population (n=510)	Stance-to-swing ratio group[a]			*P* value[b]
		<1.50	1.50-1.63	>1.63

Cognitive Performance and Gait Balance

Table 2 shows the mean (SE) of each SNSB-C test (percentile) data according to the stance-to-swing ratios. The Digit Symbol Coding (56.31 vs 61.65 vs 52.88; *P*=.02), TMT-E: B (61.77 vs 57.76 vs 51.49; *P*=.02), and K-CWST: 60sec (45.67 vs 48.72 vs 40.87; *P*=.03) tests for frontal and executive functions showed statistically significant differences among the stance-to-swing ratio groups. However, there were no differences in the other cognitive functions.

Association Between Cognitive Performance and Gait Balance

Table 3 shows the estimated β coefficients (SE) of each SNSB-C test based on the stance-to-swing ratio groups. In the Digit Span Test for attention functions, a significant association was observed in the >1.63 ratio group (β=–6.514, SE 3.098; *P*=.04) before adjustment. The unadjusted β coefficients were significant in the >1.63 ratio group for the Digit Symbol Coding (β=–8.773, SE 3.098; *P*=.005), TMT-E: B (β=–6.269, SE 2.890; *P*=.03), and K-CWST: 60sec (β=–7.855, SE 3.075; *P*=.01) tests for frontal and executive functions. In the fully adjusted model, a significant β coefficient was observed in the >1.63 ratio group for the S-K-BNT for language function (β=–6.573, SE 2.813; *P*=.02). Compared with the reference, there were significant β coefficients in the >1.63 ratio group for the Digit Symbol Coding (β=–7.991, SE 3.028; *P*=.009) and K-CWST: 60sec (β=–8.083, SE 3.076; *P*=.009) tests for frontal and executive functions. In general, the association between the SNSB-C test data and the stance-to-swing ratio in the >1.63 ratio group yielded lower β coefficients than those in the 1.50-1.63 ratio group. Most β coefficients showed a decreasing relationship for the SNSB-C test data and the stance-to-swing ratio, whereas there were no significant associations in the <1.50 ratio group (all *P*>.05).

Figure 1 presents the distributions between SNSB-C tests and stance-to-swing ratio groups using box and scatter plots. Overall, the study participants in the >1.63 gait ratio group were distributed across all the percentiles for each SNSB-C test.

The adjusted OR (95% CI) for each SNSB-C test according to the stance-to-swing ratio group is shown in Figure 2. After adjustment for age, sex, education, smoking status, alcohol consumption, vigorous exercises, and BMI, the adjusted OR for the Digit Symbol Coding (adjusted OR 0.42, 95% CI 0.20-0.88) and K-CWST: 60sec (adjusted OR 0.51, 95% CI 0.29-0.89) tests for frontal and executive function was significantly lower for the >1.63 ratio group than for the reference group (the 1.50-1.63 stance-to-swing ratio group). However, most cognitive function tests showed no differences according to the stance-to-swing ratio group.

Figure 1. The box and scatter plots of the gait ratio groups for each SNSB-C test. The red box and scatter plots represent the <1.50 ratio group, the green box and scatter plots represent the 1.50-1.63 ratio group, and the blue box and scatter plots represent the >1.63 ratio group. Discussion

Principal Findings

This study investigated the association between cognitive function and gait harmony in older Korean adults. We found a significantly higher cognitive performance percentile in frontal and executive functions among participants in the harmonic stance-to-swing ratio group. Compared with participants that exhibited a harmonic gait ratio, the cognitive assessment percentile decreased in those who showed the nonharmonic gait ratio, especially for visuospatial, frontal, and executive functions. Specifically, the relationship between the Digit Symbol Coding and K-CWST: 60sec test data on frontal and executive functions and the gait phase ratio remained significant after controlling for covariates. This information supports our understanding that cognitive function is interrelated with gait harmony in the older adult population.

Comparison With Prior Work and Clinical Implications

Our findings on gait balance and cognitive function were partially consistent with the results of previous studies. According to a recent cross-sectional study by Noh et al [21] of 735 community-based individuals (aged 65-89 years), cognitive function was associated with the stance phase at a slower walking speed (β=0.088; *P*=.02). Based on a previous study in Italy on people with and without PD, alterations in gait ratio were expected; Peppe et al [27] suggested that compared with healthy participants, patients with PD have prolonged stance phases (patients with PD: 68.1% vs patients without PD: 63.6%; *P*<.001) [27]. Another study in 31 patients older than 55 years in China [46] investigated the relationship between gait characteristics and dementia, such as poststroke dementia (PSD) and AD. Ni et al [46] showed that in all gait tests, the percentage of time spent in the stance phase was longer (patients with PSD: 63.95% vs patients with AD: 63.09% vs healthy adults: 62.15%; *P*=.002) and in the swing phase was shorter (patients with PSD: 36.04% vs patients with AD: 36.91% vs healthy adults: 37.86%; *P*=.002) among patients with dementia than among healthy controls. Taken together, these studies highlight that older individuals with gait imbalance are relatively susceptible to a decrease in cognitive function.

The mechanism underlying the relationship between proper gait proportion and cognition remains unclear. One possible explanation is that a well-balanced gait is related not only to the motor system, such as muscle strength, but also to cognition, such as memory, attention, executive function, and visuospatial capacity [47,48]. Attention and executive functions are significantly associated with gait speed in older adults with and without cognitive decline [49]. Poor attention and executive processing in the brain are correlated with white matter hyperintensity, which negatively affects gait pace, spatiality, and variability [50]. The variability of gait is related to the stance and swing phases, and the double support phase is more variable in the presence of poor balance. In memory and spatial functions, beyond the primary role of the hippocampus and parahippocampal gyrus, the induction of memory by hippocampal atrophy also influences rhythm, variability, and human balance control [51-53]. Gait reflects the health of individuals in compensating for changes in postural balance and is controlled by well-balanced neural circuits and specific brain structures, including the frontal lobes, basal ganglia, cerebellum, and sensory and motor systems [48,54,55]. Generally, during walking, the complexity of controlling redundant degrees of freedom of bilateral multijoint limbs is reduced by the nervous system [56]. Human gait is structured for specific phases of the gait leg movements [57] that can lead to the maintenance of the basic walking rhythm, which generates alternating activity of the flexor and extensor motoneurons [58]. Simple alternation of flexor and extensor activity is converted into more complex and adaptable walking patterns by hippocampal neurons that receive serotonergic projections from the median raphe nuclei. The projections of serotonergic neurons of the brain stem that innervate the spinal cord stepping generator play a role in activating and influencing the walking rhythm [59]. A decrease in serotonin levels in cerebrospinal fluid and severe gait and posture disorders have been observed in patients with PD [60]. Hence, the stance-to-swing ratios under pathological conditions may be far from the value of the harmonic proportion value.

Strengths and Limitations

To our knowledge, this study demonstrated an association between gait harmony and cognitive function, which has not been reported previously. Additionally, a strength of this study is the use of noninvasive measurement as an index for predicting decreased cognitive function. Moreover, we showed association between gait and cognitive performance using the SNSB-C tests, which includes 5 cognitive functions (ie, attention, visuospatial, language, memory, and frontal and executive). However, the study had some limitations. First, as this was a cross-sectional study, it is difficult to confirm the causal relationship between gait harmony and cognitive function. Therefore, we cannot indicate trends or changes from normal cognitive function to cognitive dysfunction. Second, the study was not free from bias due to self-reported data. As this study was based on an observational investigation, the questions asked to collect data may concern private or sensitive topics, such as education level, smoking status, and alcohol consumption. Thus, self-reporting data can be affected by social desirability. Moreover, we cannot rule out that some variables affecting cognition, such as dietary intake, medication, and occupation, were not analyzed in the statistical model. These unmeasured variables may be residual confounders.

Conclusions

Dementia is one of the most important health issues associated with aging. However, the diagnosis of dementia is expensive and involves complex measurements. Gait, on the other hand, can be measured noninvasively, comparatively conveniently, and rapidly. Therefore, this study can be important for public health management, in that gait performance assessment can be used to screen for potential cognitive impairment.

Our study found that low cognitive function was related to a nonharmonic gait ratio in participants aged 60 years or older in South Korea. In contrast, harmonic gait ratio was associated with good cognitive performance. These findings suggest that the gait ratio may be a valuable indicator of cognitive impairment. The presence of a nonharmonic gait ratio that is different from the general gait ratio may be an indirect marker of cognitive decline, independent of confounding factors in the older adult population. However, more research is required to replicate our results and establish possible mechanisms of a relationship between proper gait ratio and cognitive function.

Abstract

Background: Patients with colorectal cancer (CRC) often present with multiple comorbidities, and many of these can affect treatment and survival. However, previous comorbidity studies primarily focused on diseases in commonly used comorbidity indices. The comorbid status of CRC patients with respect to the entire spectrum of chronic diseases has not yet been investigated.

Objective: This study aimed to systematically analyze all chronic diagnoses and diseases co-occurring, using a network-based approach and large-scale administrative health data, and provide a complete picture of the comorbidity pattern in patients newly diagnosed with CRC from southwest China.

Methods: In this retrospective observational study, the hospital discharge records of 678 hospitals from 2015 to 2020 in Sichuan Province, China were used to identify new CRC cases in 2020 and their history of diseases. We examined all chronic diagnoses using ICD-10 (International Classification of Diseases, 10th Revision) codes at 3 digits and focused on chronic diseases with >1% prevalence in at least one subgroup (1-sided test, *P*<.025), which resulted in a total of 66 chronic diseases. Phenotypic comorbidity networks were constructed across all CRC patients and different subgroups by sex, age (18-59, 60-69, 70-79, and ≥80 years), area (urban and rural), and cancer site (colon and rectum), with comorbidity as a node and linkages representing significant correlations between multiple comorbidities.

Results: A total of 29,610 new CRC cases occurred in Sichuan, China in 2020. The mean patient age at diagnosis was 65.6 (SD 12.9) years, and 75.5% (22,369/29,610) had at least one comorbidity. The most prevalent comorbidities were hypertension (8581/29,610, 29.0%; 95% CI 28.5%-29.5%), hyperplasia of the prostate (3816/17,426, 21.9%; 95% CI 21.3%-22.5%), and chronic obstructive pulmonary disease (COPD; 4199/29,610, 14.2%; 95% CI 13.8%-14.6%). The prevalence of single comorbidities was different in each subgroup in most cases. Comorbidities were closely associated, with disorders of lipoprotein metabolism and hyperplasia of the prostate mediating correlations between other comorbidities. Males and females shared 58.3% (141/242) of disease pairs, whereas male-female disparities occurred primarily in diseases coexisting with COPD, cerebrovascular diseases, atherosclerosis, heart failure, or renal failure among males and with osteoporosis or gonarthrosis among females. Urban patients generally had more comorbidities with higher prevalence and more complex disease coexistence relationships, whereas rural patients were more likely to have co-existing severe diseases, such as heart failure comorbid with the sequelae of cerebrovascular disease or COPD.

Conclusions: Male-female and urban-rural disparities in the prevalence of single comorbidities and their complex coexistence relationships in new CRC cases were not due to simple coincidence. The results reflect clinical practice in CRC patients and emphasize the importance of measuring comorbidity patterns in terms of individual and coexisting diseases in order to better understand comorbidity patterns.

colorectal cancer; comorbidity patterns; prevalence; health status disparities; network analysis; routinely collected health data

Introduction

Colorectal cancer (CRC) is the third most common malignancy and the second most deadly cancer globally, with 1.93 million new cases and 0.93 million deaths estimated in 2020 [1]. China has become one of the countries with the highest incidences of CRC cases and CRC-related deaths worldwide, as a consequence of lifestyle changes and accelerated aging of the population [2]. In 2020, newly diagnosed CRC cases in China accounted for 28.8% of new global cases and CRC-related deaths in China accounted for 30.6% of all CRC-related deaths worldwide [3].

Patients with CRC commonly present at an older age and have a relatively high proportion of other chronic diseases (ie, comorbidities). In a retrospective study in Korea, 49.6% of colon cancer patients had ≥3 comorbidities [4]. In an observational cohort study in the United States, 40% of CRC patients had 1 to 3 comorbidities and 19% had ≥4 comorbidities [5]. In addition, evidence is increasing that the coexistence of various chronic diseases has a substantial effect on the treatment, outcomes, and survival of CRC patients [6-9]. In a retrospective cohort study of 29,733 CRC patients, approximately 9% of deaths were attributable to congestive heart failure (CHF), more than 5% were attributable to chronic obstructive pulmonary disease (COPD), and nearly 4% were attributable to diabetes mellitus (DM) [10]. Several studies have also suggested that CRC patients burdened by comorbidities have higher mortality than those without coexisting diseases [8,11,12]. Thus, increasing the understanding about and attention to patterns of diseases that coexist with CRC is important for disease management and more personalized medicine.

To date, investigations on comorbidities associated with CRC have primarily focused on commonly used comorbidity indices, such as the Charlson comorbidity index and Elixhauser comorbidity index [5,13-15], or defined a comorbid condition as 1 of the 14 selected health conditions [16]. Although some comorbid conditions, such as hypertension and DM, are well recognized [5,15,17,18], many others are likely unidentified. A significant gap in knowledge remains regarding comorbidity patterns with CRC, especially among Chinese populations whose lifestyles and diets differ from those of Western populations.

In recent years, the development of network theory has provided new approaches to understand the complex interrelations between diseases [19-21]. The phenotypic comorbidity network (PCN) also known as the disease co-occurrence network has been widely used to study the comorbidity patterns of various chronic conditions, such as depression [22], ischemic heart disease (IHD) [23], pediatric pulmonary hypertension [24], migraine [25], COPD [26], hip fracture [27], and hepatocellular carcinoma [28]. Additionally, rapid growth in administrative health data (eg, hospital discharge data) offers opportunities to simultaneously assess the entire spectrum of diagnoses in comorbidity studies [29,30]. Administrative health data include a substantial amount of health information in the form of ICD-10 (International Classification of Diseases, 10th Revision) codes, which have tremendous potential to increase the understanding of the nature of comorbidities [30]. Nevertheless, to our knowledge, no study has yet applied network theory with regional administrative health data to systematically exploit the hidden information of comorbidity patterns in Chinese patients with CRC.

The aim of this study was to apply a network-based approach using routinely collected hospital discharge records (HDRs) to identify comorbidity patterns in a general population of newly diagnosed CRC patients. Comorbidity patterns were assessed by measuring the prevalence of individual diseases and the comorbid strength of coexisting diseases and by determining differences in sex, age at diagnosis, region, and cancer site.

Methods

Study Design and Participants

A retrospective cohort study was performed using longitudinal data from a provincial health administrative data set. The data set was mandatorily collected, and it included routinely collected anonymized HDRs from all secondary hospitals and tertiary hospitals in Sichuan Province, China, since 2015 [21]. HDRs are medical record documents with legal effect and cover detailed discharge diagnosis information, which are coded using standardized ICD-10 codes [31]. Each inpatient's longitudinal clinical data were available, including anonymized identity, age, sex, residential address, admission date, discharge date, principal discharge diagnosis, and up to 15 secondary diagnoses. Sichuan Province, one of the most populous provinces in China, is separated into 2 cultural/topographic sections by the Hengduan Mountains, thus providing a scaled-down model of the broader situation in China [32,33].

A previous validation study integrated HDRs in Sichuan Province to identify new cancer cases, and indicated no statistical significance with findings from population-based cancer registry data, but it had important strengths, including a large sample, high accuracy of diagnosis coding, and time effectiveness [34]. In this study, provincial HDRs were used to identify new cases of CRC, where a new case was defined as a patient without any CRC diagnosis code (ICD-10 codes: C18 to C21) for at least 5 years before the first CRC diagnosis [17]. To minimize bias, all inpatients living in Sichuan Province during the study period were considered, with the exception of those with incomplete information or incorrect codes. The inclusion criteria were permanent residence in Sichuan Province, age ≥18 years at diagnosis, and first CRC occurrence between January 1, 2020, and December 31, 2020. Patients with incomplete information, conflicting reports of sex among multiple hospitalizations, conflicts between diagnoses and sex, or a history of a malignant neoplasm but with an unknown or not reported cancer site were excluded. Based on the longitudinal health care data, 29,610 patients diagnosed with first CRC occurrence were identified between January 1, 2020, and December 31, 2020 (Figure 1).

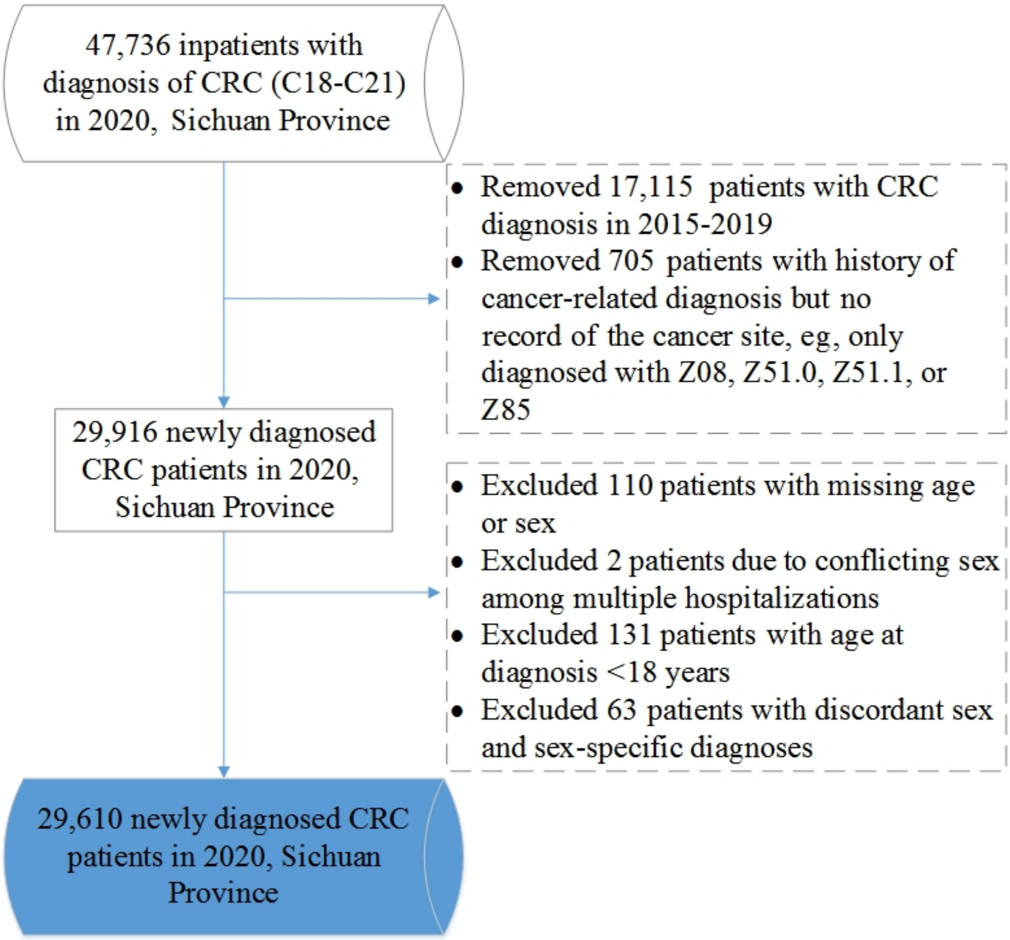

Figure 1. Flowchart of the study participants. CRC: colorectal cancer; Z08: follow-up examination after treatment for malignant neoplasms; Z51.0: radiotherapy session; Z51.1: chemotherapy session for neoplasm; Z85: personal history of malignant neoplasm.

Ethical Considerations

This study was approved by the Ethics Committee of the Health Information Center of Sichuan Province (ZX-EC202100301). The requirement of obtaining informed consent was waived because of the secondary nature of the deidentified data and the retrospective study design.

Definition of Comorbidity

Because chronic conditions are not expected to end in a single hospitalization period, a 5-year look-back period from the first diagnosis was used to identify comorbidities [17]. First, for each CRC patient, an index hospitalization was identified, which was the first hospitalization that occurred or was within 4 weeks after the date of the first diagnosis of CRC [17]. Second, the index hospitalization and hospitalizations during the 5 years before the first diagnosis of CRC were scanned to determine the history of diseases. Lastly, the Chronic Condition Indicator, defined by the Healthcare Cost and Utilization Project, was used to differentiate between acute and chronic ICD-10 codes at 3 digits [20,35]. Diagnostic codes from chapters XV to XXII, which are certain conditions originating in pregnancy, childbirth, puerperium, and the perinatal period or are general symptoms, were excluded, as the study population included mainly middle-aged or older patients. Notably, to exclude the complications of CRC or its treatment, some chronic conditions that occurred in the index hospitalization were excluded [17], including secondary malignant neoplasm, anemia, nutritional marasmus, agranulocytosis, metabolism disorders, and intestinal obstruction. To estimate the effects of different look-back periods on comorbidity patterns, we performed a complementary analysis using a 3-year look-back period.

Comorbidity Prevalence

The prevalence of all chronic diagnoses with ICD-10 codes and the corresponding 95% CIs were calculated. The prevalence cutoff was set to a statistically significant value of >1% (1-sided test, $P<.025$) in at least one subgroup to avoid diagnoses used very rarely or never [36]. The final list of 66 distinct comorbidities and their ICD-10 codes are provided in Multimedia Appendix 1. To assess differences in comorbidity prevalence by sex, region, and cancer site, relative differences in prevalence were calculated and then tested for significance using a Z-test with Bonferroni correction (α level of .05). With relative difference by sex as an example, the calculation was according to the following equation [20]:

where P_{female} and P_{male} are the prevalences of comorbidities in females and males, respectively.

If the relative difference was greater than 0.1 [28] and the absolute difference was significant after Bonferroni correction, there was a significant difference in comorbidity prevalence. Among comorbidities with a significant difference in prevalence, enriched comorbidities were assessed further. When a comorbidity had a ≥0.5-fold increase in prevalence, it was defined as enriched. For example, a comorbidity was enriched in females when there was a significant prevalence difference by sex and a ≥0.5-fold increase in prevalence in females compared with males. A Cochran-Armitage trend test was applied to assess whether the prevalence of comorbidities increased with age. Furthermore, a K-means clustering algorithm was applied to cluster comorbidities in terms of prevalence by age. As the prevalence of comorbidities increased with age, we further adjusted the influence of age in estimating the enrichment comorbidities. The total number of cases in each age group (18-49, 50-59, 60-69, 70-79, and ≥80 years) by sex, region, and cancer site was regarded as the standard population.

PCN Construction

A PCN was constructed to capture the coexistence of all comorbidities (also named connections) as recorded through HDRs. In a PCN, nodes represent chronic disease codes (ICD-10 codes at 3 digits) that are connected through edges. Node size is proportional to disease prevalence, and node color identifies the ICD-10 category. The cosine index was applied to quantify the comorbid strength of coexisting diseases, which considers the co-occurrence and prevalence of comorbidities and thus is not affected by the sample size [37]. To detect comorbidity coexistence measured by the cosine index, a cutoff was defined by assessing the relationship between the Pearson correlation and cosine index, in which the number of significant coexisting comorbidities was equal in both networks measured by the cosine index and Pearson correlation [21,38]. The cosine index and Pearson correlation coefficient were defined as in equations (2) and (3), respectively, and the significance of $\varphi_{ab} \neq 0$ was determined by performing a t test, which was calculated according to equation (4).

In the equations, N is the total number of newly diagnosed CRC patients, and n_a, n_b, and n_{ab} denote the number of patients with disease a, disease b, and both diseases, respectively.

Network Properties

The structural properties of a PCN are measured using network indices, such as network density, degree, average degree of neighbors, and betweenness centrality [39]. Network density is the proportion of significant connections to all possible connections in a network, which measures how compact a network is. A higher network density is associated with a higher number of connections between comorbidities. The number of correlations with other comorbidities is degree (k), which provides a general idea of how involved a comorbidity is with other comorbidities. Median and IQR were calculated to describe the distribution of degree (k). A Kolmogorov-Smirnov test was applied to estimate whether the degree (k) distribution followed a power law. When one comorbidity was directly connected with other comorbidities, the others were named as neighbors. The average degree of neighbors was calculated to measure neighbor connectivity. Betweenness centrality, which is the number of shortest paths between any 2 nodes of which a node is a part divided by all possible paths, indicates how central one comorbidity is relative to all other comorbidities. A high betweenness centrality indicates a high likelihood of forming bridges between other comorbidities or the end points of many comorbidities [25]. To identify the most important comorbidity in a PCN, the PageRank algorithm that considers the edge weight was applied [36]. A higher PageRank value of a comorbidity is associated with a greater effect on the network. Comorbidities with the top 10 percentiles of PageRank values were defined as the most important comorbidities in PCNs.

Abundant Comorbidity Connections in Each Subgroup of CRC Patients

PCNs were constructed separately for males and females, for rural and urban patients, and for rectal and colon cancer patients. Then, comorbid strengths were compared to measure disparities by sex, region, and cancer site. When a coexisting disease was unique to or enriched (with 0.05 higher comorbid strength than another) in a given subgroup, the difference was notable and thus was defined as an abundant connection. With sex as an example, when a comorbidity connection occurred only in males or occurred in both subgroups but the comorbid strength was 0.05 (approximately half of the minimum comorbid strength in the PCN) higher in males than in females, the comorbidity connection was abundant in males.

All analyses and visualizations were conducted using R 4.0.3 (R Foundation for Statistical Computing).

Results

Characteristics of Newly Diagnosed CRC Patients

Table 1 shows the characteristics of the 29,610 newly diagnosed CRC patients. The mean patient age at diagnosis was 65.6 years. Among the patients, 30.1% (8922/29,610) were diagnosed at <60 years of age, 58.9% (17,426/29,610) were male, 45.7% (13,522/29,610) lived in urban regions, and 52.5% (15,543/29,610) had rectal cancer. Overall, approximately one-fourth (7241/29,610, 24.5%) of patients were without any comorbidity, 22.2% (6574/29,610) had 1 comorbidity, and more than half (15,795/29,610, 53.3%) had ≥2 comorbidities. The sex-specified distributions of age at diagnosis, number of hospitalizations during the 5-year look-back period, and number of comorbidities are presented in Figure 2A-C. The frequency of at least one comorbidity was significantly higher in male patients than in female patients (13,495/17,426, 77.4% vs 8874/12,184, 72.8%; $P<.001$), in urban patients than in rural patients (10,542/13,522, 78.0% vs 11,746/15,988, 73.5%;

P<.001), and in colon cancer patients than in rectal cancer patients (10,115/13,064, 77.4% vs 11,528/15,543, 74.2%; *P*<.001). The proportion of patients with at least one comorbidity increased with age (Cochran-Armitage trend test, *P*<.001), and the increasing trend was similar in each subgroup. The mean number of comorbidities by cancer site, region, and sex increased with age (Figure 2D).

Table 1. Descriptive characteristics of patients newly diagnosed with colorectal cancer in 2020 in Sichuan Province, China.

Demographic and clinical factors	Value (N=29,610)
Age at diagnosis (years), mean (SD)	65.6 (12.9)
Age group at diagnosis (years), n (%)	
18-49	3384 (11.4)
50-59	5538 (18.7)
60-69	8308 (28.1)
70-79	8582 (29.0)
≥80	3798 (12.8)
Sex, n (%)	
Female	12,184 (41.1)
Male	17,426 (58.9)
Region, n (%)	
Rural	15,988 (54.0)
Urban	13,522 (45.7)
Unknown	100 (0.3)
Cancer site, n (%)	
Colon	13,064 (44.1)
Rectum	15,543 (52.5)
Anus	813 (2.7)
Multiple sites	190 (0.6)

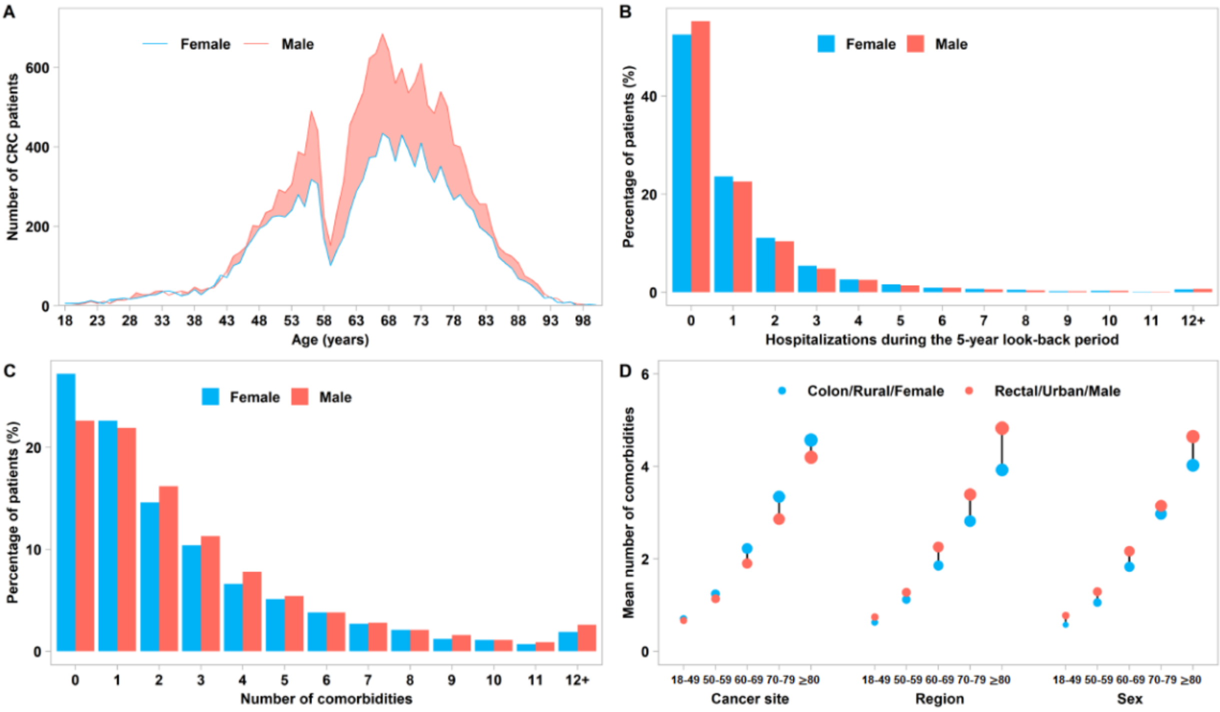
≥6	4224 (14.3)

Figure 2. Number of comorbidities and hospitalizations for newly diagnosed colorectal cancer (CRC) patients in 2020 in Sichuan Province, China. (A) Age at diagnosis by sex. (B) Hospitalizations during the 5-year look-back period before diagnosis. (C) Frequency of patients per distinct number of comorbidities per patient among male and female patients. (D) Age-specific mean number of comorbidities by cancer site, region, and sex.



Comorbidity Prevalence and Differences Between Subgroups

Among the 66 distinct comorbidities (Multimedia Appendix 1), the most prevalent comorbidities were hypertension (8581/29,610, 29.0%; 95% CI 28.5%-29.5%), hyperplasia of the prostate (3816/17,426, 21.9%; 95% CI 21.3%-22.5%), COPD (4199/29,610, 14.2%; 95% CI 13.8%-14.6%), DM (3715/29,610, 12.5%; 95% CI 12.2%-12.9%), and IHD (3200/29,610, 10.8%; 95% CI 10.5%-11.2%). Comorbidity prevalence using a 3-year look-back period is shown in Multimedia Appendix 2, and a scatter plot of comorbidity prevalence using 3-year and 5-year look-back periods is shown in Multimedia Appendix 3. As for subgroup difference, most comorbidities were common in each subgroup, whereas a few comorbidities were only detected in a subgroup and with relatively low prevalence. For example, anxiety disorder (ICD-10: F41) was only detected in females, with a prevalence of 1.3% (156/12,184; 95% CI 1.1%-1.5%). Among comorbidities with significant differences in prevalence (Multimedia Appendices 4-6), differences were large and some comorbidities were enriched (prevalence increased by ≥50%) in a subgroup (Table 2). For example, COPD (ICD-10: J43 and J44), renal failure (N18 and N19), conduction disorders (I44 and I45), and gout (M10) were enriched in males, whereas osteoporosis (M81), gonarthrosis (M17), other nontoxic goiter (E04), and anxiety disorder (F41) were enriched in females. Most comorbidities had higher prevalence and were even enriched (prevalence increased by ≥50%) in urban patients, for example, atherosclerosis (ICD-10: I70), cerebrovascular diseases (I65 and I67), hypertensive heart disease (I11), diverticular disease of the intestine (K57), and spondylosis (M47). Comorbidities had somewhat higher prevalence in colon cancer patients than in rectal cancer patients, and disorders of glycoprotein metabolism (ICD-10: E77), other coagulation defects (D68), angina pectoris (I20), other diseases of the biliary tract (K83), and malignant neoplasm of the liver and intrahepatic bile ducts (C22) were enriched in colon cancer patients. After adjustment with age, osteoporosis (ICD-10: M81) was not enriched in urban patients, and the other comorbidities still showed enrichment (Multimedia Appendix 7).

For age-specific comorbidities, 62 comorbidities with a prevalence significantly greater than 1% in at least one age group were divided into 4 clusters (Figure 3). Comorbidity prevalence increased with age, but the rate of increase varied by cluster. Cluster 1 contained 36 comorbidities with low prevalence (the average prevalence among the 5 age groups ranged from 0.8% to 2.2%), and most had a low growth rate with age, but a few decreased with age (eg, endometriosis) or were stable across ages (eg, chronic sinusitis). Cluster 2 contained 17 comorbidities with moderate prevalence (the average prevalence among the 5 age groups ranged from 1.3% to 8.1%), and most had a relatively high growth rate with age. Cluster 3 contained 7 highly prevalent comorbidities, most of which had a high growth rate with age (the average prevalence among the 5 age groups ranged from 1.4% to 21.5%), including COPD (ICD-10: J44 and J43), IHD (I25), cerebral infarction (I63), heart failure (I50), atherosclerosis (I70), and DM (E11). Cluster 4 contained the 2 comorbidities with the highest prevalence (hypertension [ICD-10: I10] and hyperplasia of the prostate [N40]).

Table 2. Absolute prevalence differences of enrichment comorbidities in subgroups of colorectal cancer patients in Sichuan Province, China.

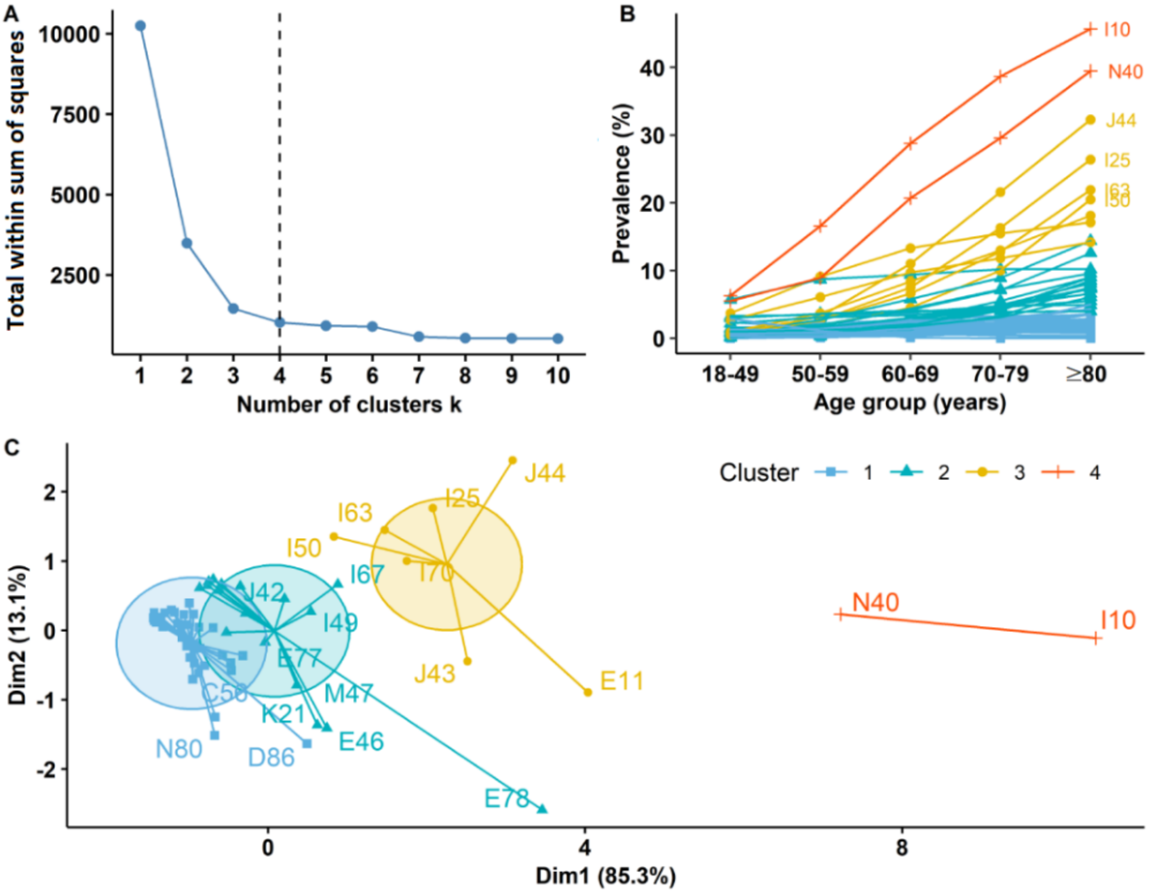
ICD-10 code	Enrichment comorbidity	Prevalence, value (95% CI)	Absolute prevalence difference, value (95% CI)[a]		
			Male-female	Urban-rural	Colon-rectal
J44	COPD[b]	14.2 (13.8 to 14.6)	7.9 (7.2 to 8.7)	—[c]	—
J43	Emphysema	9.4 (9.1 to 9.8)	6.9 (6.3 to 7.5)	—	—
I70	Atherosclerosis	9.2 (8.9 to 9.6)	—	4.2 (3.5 to 4.9)	—
I67	Other cerebrovascular diseases	6.7 (6.4 to 6.9)	—	3.6 (3.0 to 4.2)	—
K21	Gastroesophageal reflux disease	3.8 (3.6 to 4.0)	—	2.3 (1.9 to 2.8)	—
M47	Spondylosis	3.8 (3.6 to 4.0)	—	1.7 (1.2 to 2.1)	—
E77	Disorders of glycoprotein metabolism	3.6 (3.4 to 3.8)	—	—	1.8 (1.3 to 2.2)
M81	Osteoporosis without pathological fracture	3.1 (2.9 to 3.3)	−3.5 (−3.9 to −3.0)	—	—
I11	Hypertensive heart disease	3.0 (2.8 to 3.2)	—	1.6 (1.2 to 2.0)	—
N19	Unspecified renal failure	2.5 (2.3 to 2.7)	1.2 (0.9 to 1.6)	—	—
E04	Other nontoxic goiter	2.2 (2.0 to 2.3)	−2.0 (−2.3 to −1.6)	1.1 (0.7 to 1.4)	—
D68	Other coagulation defects	2.1 (1.9 to 2.2)	—	—	1.0 (0.7 to 1.4)
K83	Other diseases of the biliary tract	2.1 (2.0 to 2.3)	—	—	0.9 (0.6 to 1.3)
I65	Occlusion and stenosis of precerebral arteries	1.9 (1.8 to 2.1)	—	1.1 (0.8 to 1.4)	—
N18	Chronic renal failure	1.7 (1.6 to 1.9)	0.7 (0.4 to 1.0)	1.1 (0.8 to 1.4)	—
K57	Diverticular disease of the intestine	1.5 (1.4 to 1.6)	—	1.5 (1.4 to 1.6)	—
M17	Gonarthrosis	1.5 (1.4 to 1.7)	−1.3 (−1.6 to −1.0)	0.8 (0.5 to 1.1)	
I20	Angina pectoris	1.3 (1.2 to 1.4)	—	0.7 (0.5 to 1.0)	0.6 (0.4 to 0.9)
I44	Atrioventricular and left bundle-branch block	1.3 (1.2 to 1.4)	0.8 (0.5 to 1.0)	—	—
I45	Other conduction disorders	1.2 (1.1 to 1.4)	0.7 (0.5 to 1.0)	—	—
M10	Gout	1.2 (1.1 to 1.3)	1.5 (1.3 to 1.7)	0.6 (0.3 to 0.8)	—
E27	Other disorders of the adrenal gland	1.1 (1.0 to 1.3)	—	0.7 (0.5 to 0.9)	—
C22	Malignant neoplasm of the liver and intrahepatic bile ducts	1.1 (1.0 to 1.3)	—	—	0.5 (0.2 to 0.7)
F41	Other anxiety disorders	0.8 (0.7 to 0.9)	−0.8 (−1.1 to −0.6)	—	—

[a] Absolute prevalence differences by sex, region, and cancer site were statistically significant after Bonferroni correction.

[b] COPD: chronic obstructive pulmonary disease.

[c] The comorbidity was not enriched in this subgroup.

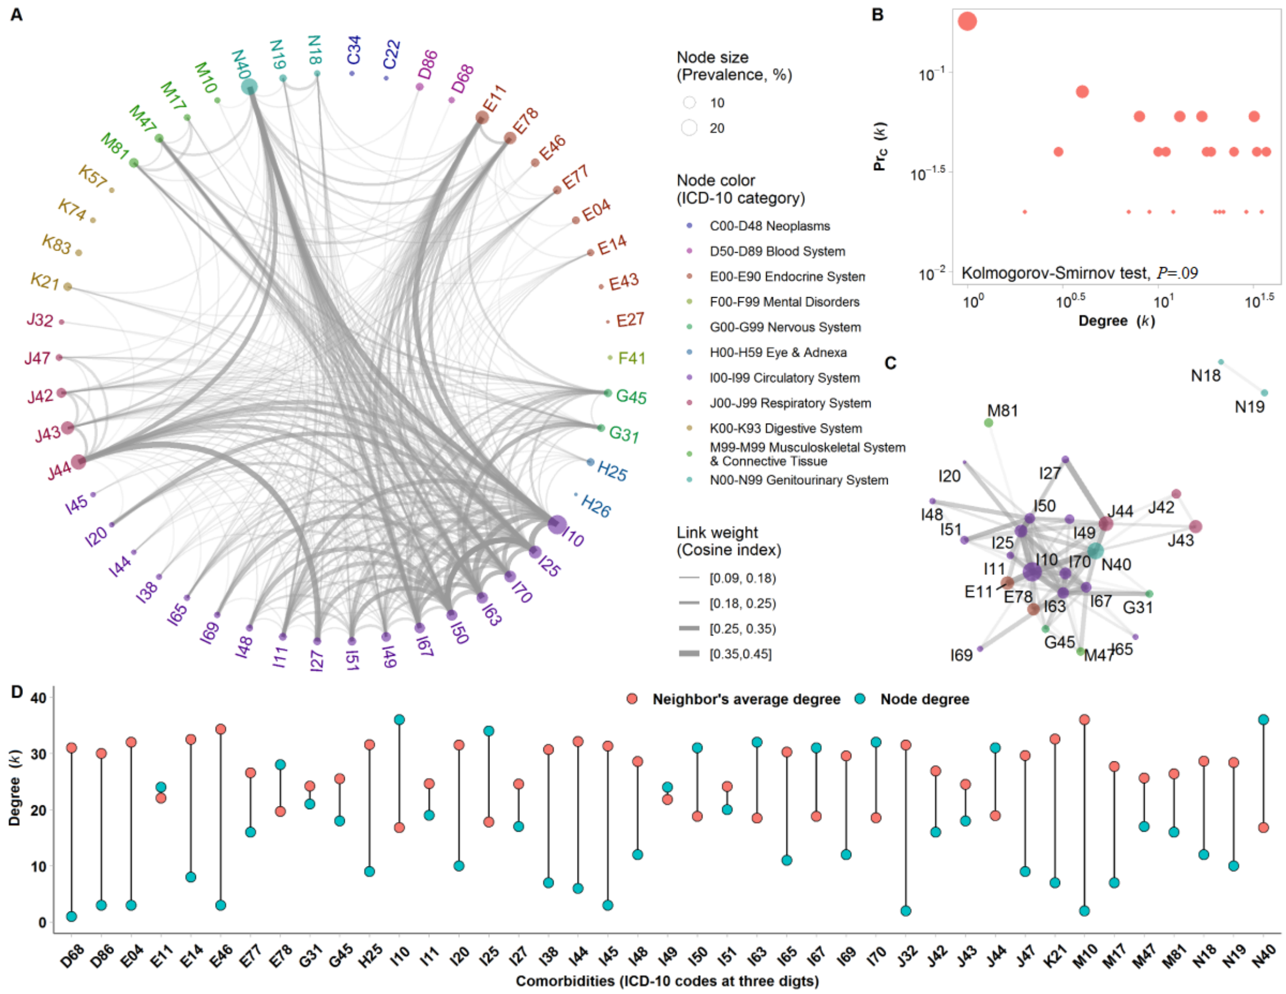
Figure 3. Clusters of comorbidities in colorectal cancer patients based on age-specific prevalence in Sichuan Province, China. (A) Optimal number of clusters using K-means clustering algorithm. (B) Age-specific prevalence of comorbidities in each cluster. Here, comorbidities with a prevalence of >20% in the ≥80 years age group were labeled with ICD-10 (International Classification of Diseases, 10th Revision) codes at 3 digits. (C) Cluster plot. Based on the principal component analysis, comorbidity prevalence in 5 dimensions (18-49, 50-59, 60-69, 70-79, and ≥80 years) was reduced to 2 dimensions (x-lab and y-lab). The ICD-10 codes are clarified in Multimedia Appendix 1.



PCN in Newly Diagnosed CRC Patients

The PCN of newly diagnosed CRC patients contained 50 diseases and 327 significant comorbid disease pairs (Figure 4). The number of significant correlations shared with other comorbidities per diagnosis code was 10.5 (IQR 3.0-19.8). Hypertension (ICD-10: I10), IHD (I25), hyperplasia of the prostate (N40), cerebral infarction (I63), and heart failure (I50) were the most important comorbidities in the PCN, indicating that they often coexisted with one another, had the highest number of coexisting comorbidities, and thus largely increased the complexity of coexisting diseases. Among the top 100 significant comorbid disease pairs with a cosine index ≥0.18, 51 connections occurred within the same disease system (eg, 45 connections occurred within circulatory system diseases) and 49 connections involved 2 disease systems. Across betweenness centrality measures, comorbidities showed the highest values in disorders of lipoprotein metabolism (ICD-10: E78), hyperplasia of the prostate (N40), COPD (J44), other cerebrovascular diseases (I67), and heart failure (I50). The results indicated that those comorbidities mediated correlations between others or were the end points of many comorbidities. When those 5 comorbidities (10% of comorbidities in the PCN) were removed, the scale of the PCN decreased considerably, with the number of significant comorbid disease pairs decreasing by 45%. Notably, hypertensive heart disease (ICD-10: I11), one of the 30 comorbidities with fewer coexisting diseases than their neighbors, connected with all 10 of the most important diseases and thus ranked as the 11th most important disease in the network.

Figure 4. Phenotypic comorbidity network (PCN) in newly diagnosed colorectal cancer (CRC) patients in Sichuan Province, China. (A) The PCN in newly diagnosed CRC patients. Nodes represent comorbidities (ICD-10 [International Classification of Diseases, 10th Revision] codes at 3 digits), such that the node size is proportional to the comorbidity prevalence in CRC patients and its color identifies the ICD-10 category. Link weights are proportional to the magnitudes of the cosine index. (B) Cumulative degree (k) distribution. The degree distribution showed an exponential decay when the degree was ≥12 (Kolmogorov-Smirnov test, *P*=.09). (C) The top 100 edges in the PCN. Here, the top 100 links where cosine index values were ≥0.18 are shown. (D) The degree distribution of the node and its neighbors. Here, the connected nodes (degree >0) in the PCN are shown. The ICD-10 codes are clarified in Multimedia Appendix 1.



Differences in PCNs Between Subgroups

Table 3 shows the network structures of PCNs constructed separately for males and females, for different age groups, for rural and urban patients, and for rectal cancer patients and colon cancer patients. The number of comorbidities with a prevalence of >1% in early onset CRC patients (diagnosis age of 18-49 years) was 15, and comorbidities were not significantly connected. Comorbidity coexistence relationships were more complex in males than females, older patients than those aged 50-59 years, and urban patients than rural patients. Male and female patients had 46 and 43 comorbidities, respectively, with median numbers of connections for comorbidities of 10.5 (IQR 2.0-17.5) and 6 (IQR 0.5-12.5), respectively, and median numbers of connections for node's neighbors of 23.2 (IQR 19.0-25.5) and 17.9 (IQR 15.0-19.0), respectively. Except in the subgroup of CRC patients with a diagnosis age of 50-59 years, the most important comorbidities in the PCNs were similar, with hypertension (ICD-10: I10), IHD (I25), and cerebral infarction (I63) common to each subgroup. In early onset CRC patients (diagnosis age of 18-59 years), the most important comorbidities in the PCN were hypertension (ICD-10: I10) and disorders of lipoprotein metabolism (E78).

Figure 5 shows the abundant connections in a given subgroup of newly diagnosed CRC patients. Without considering sex-specific diseases, 141 connections were common to both sexes, but 9 and 7 connections were separately enriched in males and females (cosine index increased more than 0.05), respectively, and 71 and 14 connections were significant only in males and females, respectively. Abundant connections in females were primarily associated with osteoporosis (ICD-10: M81) or gonarthrosis (M17), whereas abundant connections in males were primarily associated with COPD (J42, J43, J44, and J47), cerebrovascular diseases (I65 and I69), atherosclerosis (I70), heart failure (I50), or renal failure (N18 and N19). Urban-rural disparities in comorbidity connections were very large, with 13 (13/260, 5%) and 117 (117/260, 45%) abundant connections in rural and urban patients, respectively. Abundant connections in urban patients were primarily associated with disorders of lipoprotein metabolism (ICD-10: E78), DM (E11), hypertension (I10), hypertensive heart disease (I11), IHD (I20 and I25), cardiac arrhythmias (I44, I48, and I49), cerebrovascular diseases (I63, I65, I67, and I69), atherosclerosis (I70), gonarthrosis (M17), spondylosis (M47), osteoporosis (M81), renal failure (N18), or hyperplasia of the prostate (N40). Differences in connections according to cancer site were relatively small, with 181 (181/250, 72.4%) connections common to both colon cancer and rectal cancer patients.

Table 3. Phenotypic comorbidity network structures in subgroups of newly diagnosed colorectal cancer patients in Sichuan Province, China.

Subgroup	Nodes, n	Density	Degree, median (IQR)	Degree of neighbors, median (IQR)	Most important diseases in the PCN[a,b]
Sex					
Female	43	0.189	6.0 (0.5-12.5)	17.9 (15.0-19.0)	I10, I25, I63, and I50
Male	46	0.251	10.5 (2.0-17.5)	23.2 (19.0-25.5)[c]	I10, I63, N40, and I25
Age group (years)					
18-49	15	0	0	0	—[d]
50-59	26	0.043	0 (0-1.1)	3.0 (2.8-3.4)	E11 and I10
60-69	42	0.099	1.5 (0-7.8)[c]	11.2 (8.5-13.5)[c]	I10, I63, and I50
70-79	52	0.122	3.0 (0-11.0)[c]	17.1 (13.3-19.2)[c]	I10, I63, I25, and N40
≥80	58	0.099	1.0 (0-9.8)[c]	18.6 (13.5-21.0)[c]	I10, N40, I63, and I25
Region					
Rural	46	0.178	6.0 (0-12.8)	18.5 (15.1-20.0)	I10, I25, I50, and I63
Urban	50	0.202	8.0 (1.0-15.8)	21.7 (18.4-24.7)[c]	I10, I63, N40, and I25
Cancer site					
Rectal	44	0.218	8.5 (1.0-14.0)	19.1 (16.6-20.3)	I10, I25, I63, and I50
Colon	52	0.179	7.0 (0-16.0)	20.3 (17.6-23.0)	I10, I25, N40, and I63

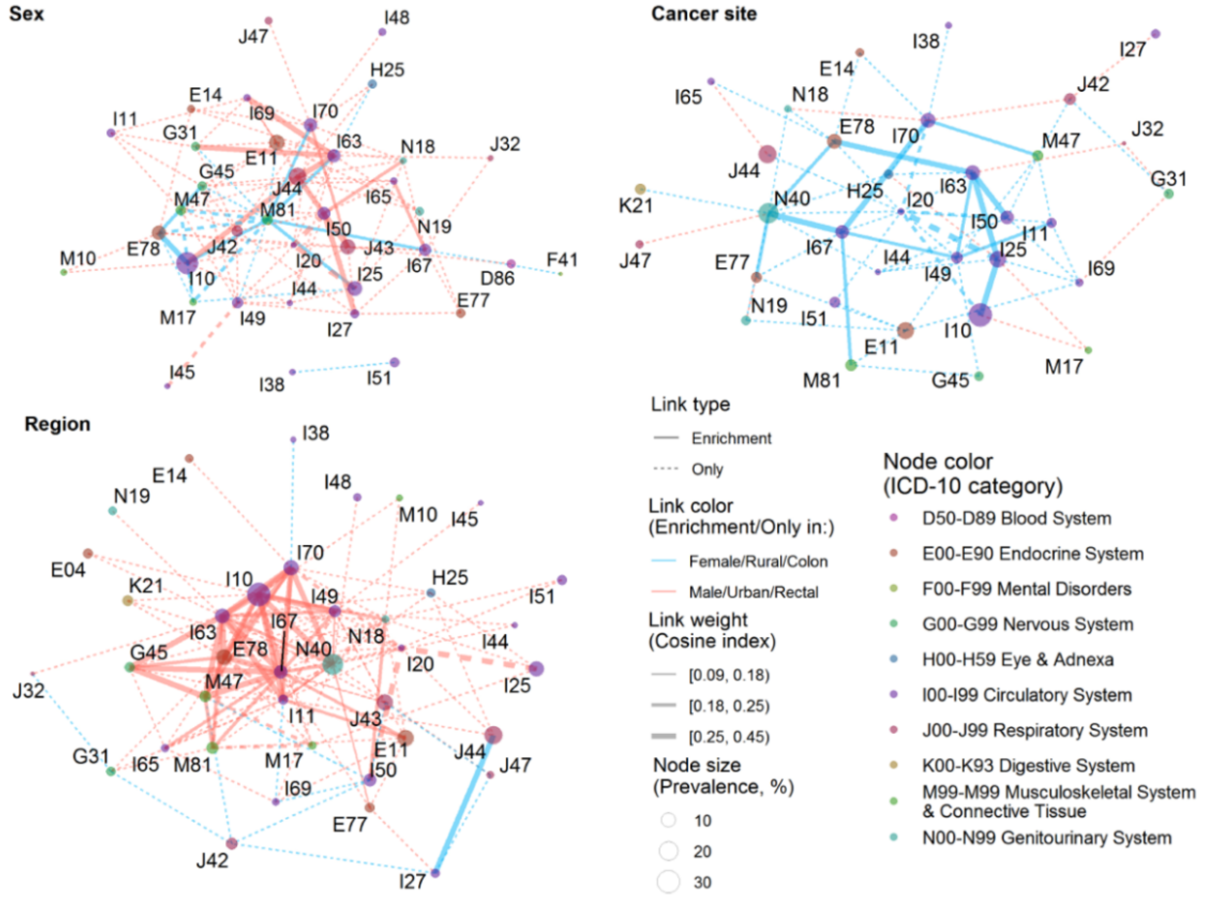
[a] PCN: phenotypic comorbidity network.

[b] Comorbidities with the top 10 percentiles of PageRank values were defined as the most important comorbidities in the PCN, and they were sorted by descending PageRank values. The ICD-10 codes and corresponding comorbidities were are follows: I10, hypertension; I25, chronic ischemic heart disease; I63, cerebral infarction; I50, heart failure; N40, hyperplasia of the prostate; E78, disorders of lipoprotein metabolism.

[c] Greater average degree of nodes or average degree of neighbors in males, older patients, and urban patients than in females, patients aged 50-59 years, and rural patients, respectively (1-sided *t* test with $P<.025$).

[d] Comorbidities were not connected to colorectal cancer patients aged 18-49 years at diagnosis.

Figure 5. Abundant connections by sex, region, and cancer site in newly diagnosed colorectal cancer patients in Sichuan Province, China. Except for those common to both subgroups (link weight difference <0.05), disease pairs were identified as abundant edges in one subgroup, including enrichment (solid lines) or only occurrence (dotted lines). For example, if the link weight difference by sex (female-male), region (rural-urban), and cancer site (rectal-colon) was ≥0.05, the disease pair was enriched in females, rural patients, and colon cancer patients, and the link was colored blue. On the other hand, if the difference was ≤−0.05, the disease pair was enriched in males, urban patients, and rectal cancer patients, and the link was colored red. The ICD-10 (International Classification of Diseases, 10th Revision) codes are clarified in Multimedia Appendix 1.



Discussion

Principal Findings

In this population-based cohort study, the entire spectrum of comorbidities in patients newly diagnosed with CRC was examined by scanning all hospitalizations during a 5-year look-back period before the first CRC diagnosis. Comorbidities were common in CRC patients at diagnosis, and prevalence and complex coexistence relationships varied by sex, age at diagnosis, region, and cancer site. The most prevalent comorbidities were hypertension, hyperplasia of the prostate, COPD, DM, and IHD. There were large disparities in disease co-occurrences in the male-female and urban-rural subgroups. Prevalence, diversity of diseases, and strength of disease coexistence were higher in urban patients, whereas severe diseases were more likely to co-occur in rural patients, such as the sequelae of cerebrovascular disease or COPD co-occurring with heart failure.

It was not surprising that comorbidities were common among newly diagnosed CRC patients, because both CRC and chronic diseases generally occur in older people [40-42]. CRC and comorbid conditions, such as DM and hypertension, may share common risk factors, such as smoking, poor diet, hyperlipidemia, lack of physical activity, and obesity [43-45]. In this population-based study, the most prevalent comorbidities were hypertension, hyperplasia of the prostate, COPD, DM, and IHD. Similar results were found in previous studies in New Zealand and the United States, although the prevalence of comorbidities differed [8,17,46]. Variations of prevalence might be related to differences in the study population (eg, some studies focused only on elderly patients among whom comorbidities are more common) and the definition used for chronic conditions (eg, a 1-year look-back period for hospitalization data resulted in a lower yield of comorbid conditions). Accumulating evidence suggests that sedentary lifestyle, metabolic syndrome (presence of ≥3 conditions among obesity, hypertension, hyperlipidemia, and DM), and antibiotic consumption may contribute to the development of early onset CRC [45,47-49]. In our study, we found 15 comorbidities with prevalences greater than 1% in early onset CRC patients, where hypertension, disorders of lipoprotein metabolism, hyperplasia of the prostate, and DM were the most prevalent comorbidities. Comorbidity is a strong and independent factor in the treatment and survival of CRC patients [5,50,51], for example, CRC patients comorbid with DM continued to receive chemotherapy less frequently than those without DM. Given the survival disadvantage in CRC patients with comorbidities [52], further evidence on the risks and benefits of therapy according to the types of co-occurring comorbidities and the severity of the diseases is needed to foster personalized medical care for those patients.

The complex coexistence relationships that occur among comorbidities are not due to simple coincidence, and therefore, to understand those relations, comorbidities must be studied collectively and not in isolation. Coexisting diseases within the same disease system were primarily within the circulatory system. The highest number of comorbidities was within the circulatory system, and those comorbidities included the highly prevalent diseases of hypertension, IHD, heart failure, and atherosclerosis. Coexisting diseases involved 2 disease systems, and they primarily included diseases of the circulatory system and those of the endocrine, nervous, respiratory, genitourinary, musculoskeletal, or connective tissue system. In a population-based cohort study in Spain, the most frequent comorbidity was DM, and the most frequent disease pair was CHF with DM, followed by CHF with COPD and peripheral vascular disease with DM [53]. In that study, the modified Charlson comorbidity score (only including 12 comorbidities) used to measure comorbidity might have underestimated the comorbidity burden and the complex coexistence relationships, because it did not include some important comorbidities, such as highly prevalent hypertension (I10). According to the network approach in this study, disorders of lipoprotein metabolism and hyperplasia of the prostate were part of some of the shortest paths between 2 comorbidities (mediated correlations between others), and heart failure was the end point of many comorbidities. Those comorbidities had a high likelihood to form bridges between other comorbidities, suggesting possibilities for the management of target comorbidities in CRC patients.

Many disease pairs were unique to or enriched in a sex group. In this regard, coexistence with COPD, cerebrovascular diseases, atherosclerosis, heart failure, or renal failure was predominant in males, whereas coexistence with osteoporosis or gonarthrosis was predominant in females. The prevalence of musculoskeletal disorders was higher in women than in men, resulting in an increased likelihood of co-existence with other highly prevalent chronic diseases (eg, hypertension, IHD, cerebrovascular diseases, or atherosclerosis) in female CRC patients. Notably, the prevalence of some severe diseases (eg, cerebral infarction and heart failure) was similar in males and females, but there were sex differences in coexistence with other chronic diseases (eg, a higher likelihood of cerebral infarction comorbid with the sequelae of cerebrovascular disease, COPD, or degenerative diseases of the nervous system, and heart failure comorbid with other pulmonary heart diseases or renal failure in males). Previous studies have found a prevalence difference in comorbidities by sex among CRC patients [54]. A population-based study using administrative data to describe comorbidities in CRC patients at diagnosis in Spain showed that the prevalence of COPD in males was 23.0%, which was 2.4 times higher than that in females (prevalence of 9.5%) [54]. In China, the prevalence of COPD in males was 19.0% (95% CI 16.9%-21.2%), which was approximately 2.3 times higher than that in females (prevalence of 8.1%, 95% CI 6.8%-9.3%), mainly because of a significant difference in smoking status between males and females (current smokers: 58.2% vs 4.0%) [55]. Such differences might indicate a disparity in lifestyle-related diseases, which may be due to physical, hormonal, or even genetic differences [56]. It is becoming increasingly standard practice to report sex-specific estimates because of the vital importance of gender consideration in precision medicine [56-58].

Notably, sex differences were observed in the prevalence of anxiety and the comorbid strength of anxiety with other diseases, for example, anxiety was enriched in females and had a higher likelihood of co-existence with cerebrovascular disease. Previous observational studies indicated that cardiocerebrovascular modulation and dynamic cerebral autoregulation are compromised in patients with anxiety [59-61]. In addition, evidence from a prospective cohort study indicated that greater anxiety or depression can not only impede adherence to healthy habits in CRC patients, but also be a marker for accelerated CRC progression [62]. Furthermore, in a previous population-based study in New Zealand, the prevalence of anxiety was 1.0% and 0.6% in colon cancer and rectal cancer patients, respectively [17], which were values similar to those in this study. The use of regional hospitalizations to identify the prevalence of clinically significant anxiety as well as other mental disorders might lead to underestimates, because estimated prevalence is generally higher when questionnaires are used [63,64]. Considering the well-known underestimated prevalence of mental disorders, especially in low- and middle-income countries [65], and their negative effects on quality of life, scanning for symptoms of anxiety and depression, implementation of dietary and physical activity interventions, and implementation of social support are of utmost importance among CRC patients at diagnosis and even years after treatment [66-68].

Rural-urban disparities were detected in the prevalence of comorbidities and the comorbid strength among comorbidities. Socioeconomic differences in the prevalence of comorbidities in CRC patients were also reported in England, where at least 11 of the 14 chronic conditions showed increasing prevalence along with the level of deprivation in CRC patients [16]. For example, the most deprived groups had approximately twice the odds of having COPD compared with the least deprived groups, which might be related to the higher prevalence of smoking in the more deprived population, but the association between smoking status and deprivation was not quantifiable as there was no information on smoking prevalence [16]. In our study, the prevalence of most comorbidities among newly diagnosed CRC patients was higher in urban patients than in rural patients, including some highly prevalent comorbidities, such as DM, disorders of lipoprotein metabolism, cerebrovascular diseases, atherosclerosis, and hyperplasia of the prostate, as well as some comorbidities with relatively low prevalence, such as nontoxic goiter, degenerative diseases of the nervous system, hypertensive heart disease, gout, and renal failure. Thus, comorbidities were more closely connected in urban patients than in rural patients, and some disease pairs were unique to or enriched in urban patients. Such differences might be associated with Western lifestyles in urban areas. Compared with the rural lifestyle, the urban lifestyle is more sedentary, with manual labor replaced by computer-based work and walking replaced by driving automobiles. Differences were also likely due to disparities in accessibility to diagnostic and treatment services between urban and rural residents [69,70]. Notably, the prevalences of hypertension, heart failure, and COPD were somewhat higher but without clinical significance in urban patients than in rural patients; whereas the sequelae of cerebrovascular disease comorbid with hypertensive heart disease or heart failure, heart failure comorbid with COPD or spondylosis, and COPD comorbid with pulmonary heart diseases were over-presented in rural patients. The co-occurrence of severe diseases in rural patients might be associated with relatively low adherence to colonoscopy screening among rural residents. Thus, CRC at diagnosis was generally more severe, with a significantly higher risk of diagnosis at a late stage [71]. Given the relatively low participation rate in colonoscopy screening in high-risk populations in China [72] and the coexistence of severe diseases at diagnosis, health promotion campaigns and adoption of noninvasive screening tests should be priorities to improve adherence and diagnosis in population-based programs.

We found that approximately 50% of comorbidities had significantly higher prevalence in colon cancer patients than in rectal cancer patients. A literature review indicated that diet, smoking, and physical activity might have different effects on colon cancer compared with the effects on rectal cancer, for example, physical activity decreased the risk of colon cancer but not of rectal cancer [73]. A population-based register of all primary cancers diagnosed in New Zealand was linked to routine hospital discharge data, and the comorbidity prevalence in colon and rectal cancer patients was identified, with a prevalence difference by cancer site similar to that in our study [17]. A previous study identified differences in patient characteristics and surgical outcomes between colon cancer and rectal cancer [74], and there was a significantly higher proportion of comorbidities in colon cancer patients than in rectal cancer patients (76.3% vs 68.8%; *P*=.02). Among CRC patients in the Central Region of Denmark in 2000-2011, 38% of colon cancer patients and 32% of rectal cancer patients had at least one Charlson comorbidity [75]. These previous studies reported the comorbidity difference by cancer site, but they did not provide a clear definition of comorbidity [74] or just focused on limited chronic diseases [75]. Further studies are needed to systematically explore the impacts of comorbidity patterns or comorbidity trajectories on the treatment choice and survival prediction in patients with colon and rectal cancers.

Limitations

This study had some limitations. First, the results should be interpreted in the context of an inpatient population in a developing country, since the HDRs did not include outpatient records and mental conditions might not be consistently diagnosed and recorded in HDRs [22]. Moreover, Berkson bias is unavoidable when only using an inpatient population to estimate morbidity [76]. Second, stage information is not yet included in HDRs because of the inherent limitation of the administrative database [31,34]. Further studies are needed to explore differences in comorbidity patterns according to TNM stages. Third, we systematically analyzed all chronic conditions and comorbidity patterns in newly diagnosed CRC patients in different subgroups, but did not explore CRC-specific comorbidities. As the emergence of comorbidities increases with age, further studies are needed to explore comorbidities that can be attributed to CRC rather than age, which may be helpful to provide etiological hypotheses or to construct surveillance programs [77]. Lastly, the common comorbidity profile identified in the study appears to be associated with treatment decision-making; however, limited by the available data, the relationships between comorbidities with different disease severities and different outcomes could not be identified in our study. The provincial data set was implemented in 2015 and did not contain proactive patient follow-up. Population-based cancer registries in China mainly report cancer incidence, mortality, expected survival, and trends in incidence and mortality, and comorbidity information is missing [78,79]. If routinely collected health data can be linked to the regional mortality database and even to local cancer registries, future studies may assess the relationships of comorbidities, comorbid disease pairs, and their severities with different outcomes (eg, short-term and long-term mortality, and cancer-specific mortality).

Conclusions

This study applied network analysis to routinely collected health data in order to examine the full spectrum of comorbidities and the complex coexisting relationships in newly diagnosed CRC patients. Some comorbidities, which were enriched in a given subgroup, largely increased the complexity of comorbid relationships, mediated correlations between other comorbidities, and might be the end points of many comorbidities. In addition, some co-occurring disease pairs predominated in a given subgroup. This study systematically analyzed the prevalence of individual diseases as well as the comorbid strength of coexisting diseases to provide a complete picture of comorbidities in CRC patients at diagnosis and also provide new insights into patterns of comorbidity. The data-driven discovery of comorbidity patterns may help improve the understanding of complex diseases, supplement traditional approaches in clinical studies, and help formulate appropriate preventive health measures to address high-risk comorbidities.

Acknowledgments

This study was supported by the Key Research and Development Program of Sichuan Province (2021YFS0112 and 2022YFS0163) and the Technological Innovation Research and Development Project of Chengdu (2021-YF05-01214-SN).

Data Availability

The data sets generated or analyzed during this study are restricted by the Ethics Committee of the Health Information Center of Sichuan Province and are not publicly available.

Authors' Contributions

HQ and XW designed the study, obtained funding, and directed the study. HQ, LW, and LZ contributed to data collection and statistical analysis. HQ and LW created the figures and drafted the manuscript. XW and HQ interpreted the results and revised the manuscript. All authors have read and approved the final manuscript.

Abstract

Background: In response to the SARS-CoV-2 epidemic, a convenient, rapid, and sensitive diagnostic method for detecting COVID-19 is crucial for patient control and timely treatment.

Objective: This study aimed to validate the detection of SARS-CoV-2 with the Pluslife SARS-CoV-2 rapid test kit developed based on a novel thermostatic amplification technique called RNase hybridization-assisted amplification.

Methods: From November 25 to December 8, 2022, patients with suspected or confirmed COVID-19, close contacts, and health care workers at high risk of exposure were recruited from 3 hospitals and 1 university. Respiratory specimens were collected for testing with the Pluslife SARS-CoV-2 rapid test kit and compared with reverse transcription-quantitative polymerase chain reaction (RT-qPCR) and a commercial antigen assay kit. Samples from 1447 cases were obtained from 3 "ready-to-test" scenarios in which samples were collected on site and tested immediately, and samples from 503 cases were obtained from a "freeze-thaw test" scenario in which samples were collected, frozen, and thawed for testing.

Results: Pluslife SARS-CoV-2 rapid testing of samples from the "ready-to-test" scenario was found to be accurate (overall sensitivity and specificity of 98.3% and 99.3%, respectively) and diagnostically useful (positive and negative likelihood ratios of 145.45 and 0.02, respectively). Pluslife SARS-CoV-2 rapid testing of samples from the "freeze-thaw test" scenario was also found to be accurate (overall sensitivity and specificity of 71.2% and 98.6%, respectively) and diagnostically useful (positive and negative likelihood ratios of 51.01 and 0.67, respectively). Our findings demonstrated that the time efficiency and accuracy of the results in a "ready-to-test" scenario were better. The time required from sample preparation to the seeing the result of the Pluslife SARS-CoV-2 rapid test was 10 to 38 minutes, which was substantially shorter than that of RT-qPCR (at least 90 minutes). In addition, the diagnostic efficacy of the Pluslife SARS-CoV-2 rapid test was better than that of a commercial antigen assay kit.

Conclusions: The developed RNase hybridization-assisted amplification assay provided rapid, sensitive, and convenient detection of SARS-CoV-2 infection and may be useful for enhanced detection of COVID-19 in homes, high-risk industries, and hospitals.

Introduction

According to the World Health Organization, cases of COVID-19 caused by SARS-CoV-2 were reported in several regions in late 2019 and early 2020 [1]. The rapid spread of SARS-CoV-2 posed a major public health and economic hazard. Currently, the primary test used by most laboratories to diagnose COVID-19 is a nucleic acid amplification test using reverse transcription quantitative polymerase chain reaction (RT-qPCR) [2,3]. Although the World Health Organization declared on May 5, 2023, that the COVID-19 outbreak no longer constituted a "public health emergency of international concern", this merely demonstrates that the hazard can be effectively controlled with current human capacity—it does not mean that the pandemic is over. The COVID-19 epidemic remains a global health threat, and continued efforts to prevent and control the COVID-19 are still necessary.

For some low-resource primary health care conditions, the application scenarios of traditional nucleic acid testing are limited, and an assay with detection performance comparable to RT-qPCR and less demanding on the testing environment is needed. For high-traffic areas, such as customs and airports, the time required to obtain RT-qPCR results is too long, so a faster and more accurate test is needed to increase the speed of population screening. Therefore, it is essential to develop a rapid, convenient, and accurate method for detecting SARS-CoV-2 with detection performance comparable to that of RT-qPCR for areas where medical resources are scarce and for scenarios with high foot traffic.

Compared with RT-qPCR, thermostatic amplification technology does not require a temperature rise or fall to achieve nucleic acid amplification, which helps to substantially mitigate the cost of the instrument and speed up the reaction process [4-7]. However, while most of the existing traditional thermostatic amplification techniques can solve the problem of instrument cost and fast amplification speed, they suffer from inadequate stability and sensitivity when directly benchmarked against RT-qPCR. Thermostatic amplification technology has been developing for decades, during which a variety of nucleic acid detection methods have emerged [8]. RNase hybridization-assisted amplification (RHAM) is a thermostatic amplification technology developed independently by Guangzhou Pluslife Technology with underlying intellectual property rights. The actual performance of this technology is comparable to that of RT-qPCR, and it is more tolerant and compatible. RHAM can extract, amplify, and detect in 1 step without the opening of the cap after amplification, and it requires a simple professional environment and hardware support. The Pluslife SARS-CoV-2 rapid test kit based on this technology is in lyophilized form, which is easy to transport at room temperature and can achieve extraction-free molecular detection.

In this study, a field trial of the Pluslife SARS-CoV-2 rapid test kit was conducted at 4 centers, including Guangdong Provincial People's Hospital, Zhujiang Hospital at Southern Medical University, Guangdong Second Provincial General Hospital, and Guangdong University of Finance and Economics. Based on the gold standard RT-qPCR assay, we evaluated the diagnostic performance of the Pluslife SARS-CoV-2 rapid test kit and compared it with a commercial antigen assay kit by Wondfo Biotech for the diagnosis of SARS-CoV-2.

Methods

Ethical Considerations

The study protocol was approved by the Ethics Review Committee of Guangdong Provincial People's Hospital (KY2023-067-02).

Candidates

The study population comprised patients with suspected or confirmed COVID-19, close contacts, and high-risk exposed health care workers from 4 centers, including Guangdong Provincial People's Hospital, Zhujiang Hospital at Southern Medical University, Guangdong Second Provincial General Hospital, and Guangdong University of Finance and Economics, from November 25 to December 8, 2022. Nasal swabs or oropharyngeal swabs were collected for SARS-CoV-2 testing. The flow chart of the study protocol is shown in Figure 1. The characteristics of the 2028 candidates who received the Pluslife SARS-CoV-2 rapid test are shown in Table 1.

Figure 1. Study flow chart. We recruited candidates with suspected or confirmed COVID-19, close contacts, and health care workers at high risk of exposure at 4 centers. All participants provided written informed consent. Parallel nasal and oropharyngeal swabs were collected and tested with the Pluslife rapid test, antigen test, and RT-qPCR from November 25 to December 8, 2022. RT-qPCR: real-time reverse transcription quantitative polymerase chain reaction.

[a] RT-qPCR: real-time reverse transcription quantitative polymerase chain reaction.

The RT-qPCR Assay

Viral RNA was extracted from oropharyngeal swabs using the liquid proteinase K magnetic bead method. The BioGerm 2019-nCoV assay (BioGerm) was used to detect SARS-CoV-2 RNA with SARS-CoV-2 RNA-dependent RNA polymerase and nucleocapsid genes according to the product instructions. Briefly, 12 μL of the RT-qPCR mixture, 4 μL of the RT-qPCR enzyme mixture, and 4 μL of the ORFlab/N reaction mixture were combined into a 20 μL master mix for each sample well. The master mix was pipetted into each well of a 96-well optical reaction plate. Then, 5 μL each of specimen nucleic acid, positive control, and negative control were added to the master mix. The tubes were closed securely and centrifuged briefly. Amplification was performed with a fluorescent qPCR instrument for 1 cycle at 50 °C for 10 minutes and 95 °C for 5 minutes, followed by 45 cycles at 95 °C for 10 seconds and 55 °C for 40 seconds. The results of the assay were evaluated with a cycling threshold value, where a value <40 for both target genes was defined as a positive result.

Pluslife SARS-CoV-2 Card Test Procedure

First, the comprehensive nucleic acid test was preheated. The entire absorbent tip of the disposable sampling swab was gently inserted into one nostril approximately 1.5 to 2 cm deep and rotated 3 times on the inner wall or rubbed 3 times on the posterior pharyngeal wall and both sides of the pharyngeal-palatal arch. For the "ready-to-test" method, the tip of the disposable sampling swab was twisted against the bottom and side of the nucleic acid releaser tube 10 times while pinching the tip of the disposable sampling swab. For the "freeze-thaw test" method, the collected pharyngeal swabs were placed in a 500 μL sample tube of Youkang virus preservation solution, shaken and mixed, and frozen in a –20°C refrigerator for 24 to 240 hours. The sample tubes were thawed and 150 μL of Youkang virus preservation solution was added to 2 mL of nucleic acid release agent, the caps were screwed on, and the tubes were vortexed and mixed for 5 to 10 seconds or mixed by inverting 10 to 15 times. After that, the procedure was the same for both methods. The nucleic acid–releasing agent solution was poured into the SARS-CoV-2 reaction card sample tube between the 2 injection lines. The protruding curved air pocket on the SARS-CoV-2 reaction card sample tube was pressed down, and the card was held and shaken up and down 10 times. The SARS-CoV-2 response card was inserted into the device, and the "Start Test" button was pressed. The red indicator light indicated a positive SARS-CoV-2 nucleic acid result, and the blue indicator light indicated a negative

SARS-CoV-2 nucleic acid result. The specific operation process is illustrated in Multimedia Appendix 1.

Antigen Test Procedure

An antigen detection kit (Wondfo Biotech) was used to detect the SARS-CoV-2 nucleocapsid antigen in respiratory specimens. This assay device contained 2 precoated antibody lines: a “C” (control) line and a “T” (test) line. The control area was precoated with chicken IgY antibody, and the test area was precoated with SARS-CoV-2 antibody. Color particle–coupled anti–SARS-CoV-2 antibody was used to detect SARS-CoV-2 antigen. In the assay, SARS-CoV-2 antigen in the respiratory specimen interacted with the color particle–coupled anti–SARS-CoV-2 monoclonal antibody to form a colored antigen-antibody complex. The complex migrated across the membrane by capillary action up to the test line, where it was captured by the pre-encapsulated anti–SARS-CoV-2 antibody. If SARS-CoV-2 antigen was present in the respiratory specimen, a colored test line was visible in the result window, and the intensity of the stained test line varied with the amount of SARS-CoV-2 antigen in the specimen. Colored particles conjugated to chicken IgY were used as the control line.

Statistical Analysis

We estimated the minimum sample size using the single group target value method with the following formula:

where n is the sample size; $Z_{1-\alpha/2}$ and $Z_{1-\beta}$ are the significance level and the fractional positions of the standard normal distribution of the degree of certainty, respectively; P_0 is the clinically acceptable standard of the evaluation index; and P_T is the expected value of the evaluation index of the assessment reagent. The positive and negative compliance rates of the assessment reagents and control reagents should reach 80% and 85% clinically, respectively, and the expected positive and negative compliance rates of the assessment reagents and control reagents can reach 90%. The minimum positive and negative sample sizes were estimated to be 137 and 470 cases, respectively, when the significance level α=.05 and the degree of certainty β=.20. Therefore, the minimum total sample size was estimated to be 607 cases. Sensitivity, specificity, positive and negative predictive values, and positive and negative likelihood ratios were calculated using Microsoft Excel 2021 (Microsoft Corp). Sensitivity was calculated as (true positives) / (true positives + false negatives) × 100. Specificity was calculated as (true negatives) / (true negatives + false positives) × 100. Positive predictive value was calculated as (true positives) / (true positives + false positives) × 100. Negative predictive value was calculated as (true negatives) / (true negatives + false negatives) ×100. The positive likelihood ratio was calculated as sensitivity / (1 – specificity). The negative likelihood ratio was calculated as specificity / (1 – sensitivity). $P<.05$ was considered statistically significant. Figures were constructed using GraphPad Prism 8.0 (GraphPad) and R software (R Foundation for Statistical Computing).

Results

Comparison of the Pluslife Rapid SARS-CoV-2 Detection Kit With RT-qPCR

The results of the Pluslife rapid SARS-CoV-2 test and RT-qPCR in the 4 centers are shown in Table 2. Of 1950 patients tested using RT-qPCR, a total of 1547 (79.3%) were negative and 403 (20.7%) were positive. Of the 1547 negative patients, 1535 (99.2%, 95% CI 98.8%-99.7%) were also negative when tested with the Pluslife rapid SARS-CoV-2 test. Of the 403 positive patients, 318 (78.9%, 95% CI 76.8%-81%) were also positive when tested with the Pluslife rapid SARS-CoV-2 test. The overall compliance rate was 95% (1853/1950; 95% CI 93.9%-96.2%), with a κ coefficient of 0.84 (95% CI 0.82-0.86). The positive predictive value (PPV) was 96.4% (318/330; 95% CI 95.4%-97.3%), and the negative predictive value (NPV) was 94.8% (1535/1620; 95% CI 93.6%-95.9%). Next, we adopted 2 study protocols, namely, the “ready-to-test” and “freeze-thaw test” protocols, for the field trial scenarios, in which Guangdong Provincial People’s Hospital, Zhujiang Hospital at Southern Medical University, and Guangdong University of Finance and Economics were used in the “ready-to-test” scenarios and Guangdong Second Provincial General Hospital in the “freeze-thaw test” scenario. The results of the Pluslife rapid SARS-CoV-2 test and RT-qPCR are shown in Table 3. RT-qPCR results were negative for 1332 (92%) and positive for 115 (8%) of 1447 patients. Of the 1332 negative patients, 1323 (99.3%, 95% CI 98.9%-99.8%) were also negative when tested with the Pluslife rapid SARS-CoV-2 test. Of the 115 positive patients, 113 (98.3%, 95% CI 98%-100%) were also positive when tested with the Pluslife rapid SARS-CoV-2 test. The overall compliance rate was 99.2% (1436/1447; 95% CI 98.8%-99.7%), with a κ coefficient of 0.95 (95% CI 0.94-0.96). The PPV was 92.3% (113/122; 95% CI 91.3%-94%), and the NPV was 99.8% (1323/1325; 95% CI 99.6%-100%). The results of the “freeze-thaw test” for the Pluslife rapid SARS-CoV-2 test and RT-qPCR are shown in Table 4. A total of 215 (42.7%) of 503 patients received negative RT-qPCR results, and 288 (57.3%) received positive results. Of the 215 negative patients, 212 (98.6%, 95% CI 98%-99.2%) were also negative when tested with the Pluslife rapid SARS-CoV-2 test. Of the 288 patients positive, 205 (71.2%, 95% CI 68.8%-73.5%) were also positive when tested with the Pluslife rapid SARS-CoV-2 test. The overall compliance rate was 82.9% (417/503; 95% CI 81%-84.8%), and the κ coefficient was 0.67 (95% CI 0.64-0.69). The PPV was 98.6% (205/208; 95% CI 97.9%-99.2%), and the NPV was 71.9% (212/295; 95% CI 69.6%-74.2%). These data suggest that the “ready-to-test” scenario was better than the “freeze-thaw test” scenario.

Table 2. Performance of the Pluslife SARS-CoV-2 rapid test compared to real-time reverse transcription quantitative polymerase chain reaction (RT-qPCR) for 1950 samples from all trial scenarios.

Pluslife SARS-CoV-2 rapid test results	RT-qPCR results		Performance
	Positive (n=403)	Negative (n=1547)	
Positive (n=330), n	318	12	—[a]

[a] Not applicable.

In addition, we compared the testing time of RT-qPCR and the Pluslife rapid SARS-CoV-2 test in the 4 centers, and the results are shown in Table 5. Among participants with negative nucleic acid test results, the mean testing time for RT-qPCR (534.70, SD 466.94 minutes) was substantially longer than that for the Pluslife rapid SARS-CoV-2 test (35.00, SD 0 minutes). Similarly, among participants with positive nucleic acid test results, the testing time for RT-qPCR (882.20, SD 517.97 minutes) was substantially longer than that for the Pluslife rapid SARS-CoV-2 test (16.49, SD 5.51 minutes). Moreover, similar results were obtained when comparing the testing times obtained using the 2 testing methods for the 4 field trial sites (Multimedia Appendix 2).

Table 5. Comparison of the testing times of the Pluslife SARS-CoV-2 rapid test and real-time reverse transcription quantitative polymerase chain reaction (RT-qPCR) at the 4 centers.

Testing result	Testing time (min), mean (SD)	*P* value
Negative		<.001
RT-qPCR	534.70 (466.94)	
Pluslife SARS-CoV-2 rapid test	35.00 (0)	
Positive		<.001
RT-qPCR	882.20 (517.97)	
Pluslife SARS-CoV-2 rapid test	16.49 (5.51)	

Comparison of the Pluslife Rapid SARS-CoV-2 Test and Commercial Antigen Test With the RT-qPCR Nucleic Acid Test

A total of 283 samples that underwent testing using both the commercial antigen test and Pluslife rapid SARS-CoV-2 test were included. RT-qPCR confirmed that there were 93 positive samples and 190 negative samples. The results of the 2 methodological assays compared with the RT-qPCR results are shown in Table 6. The data showed that, compared to the RT-qPCR results, the sensitivity of the commercial antigen test was 88.2% (82/93; 95% CI 86.5%-89.8%) with a specificity of 100%, and the sensitivity of the Pluslife rapid SARS-CoV-2 test was 98.9% (92/93; 95% CI 98.4%-99.4%) with a specificity of 100%.

Table 6. Comparison of the results of testing 283 samples using the 2 assays (commercial antigen kit and Pluslife SARS-CoV-2 rapid test kit) with real-time reverse transcription quantitative polymerase chain reaction (RT-qPCR) results.

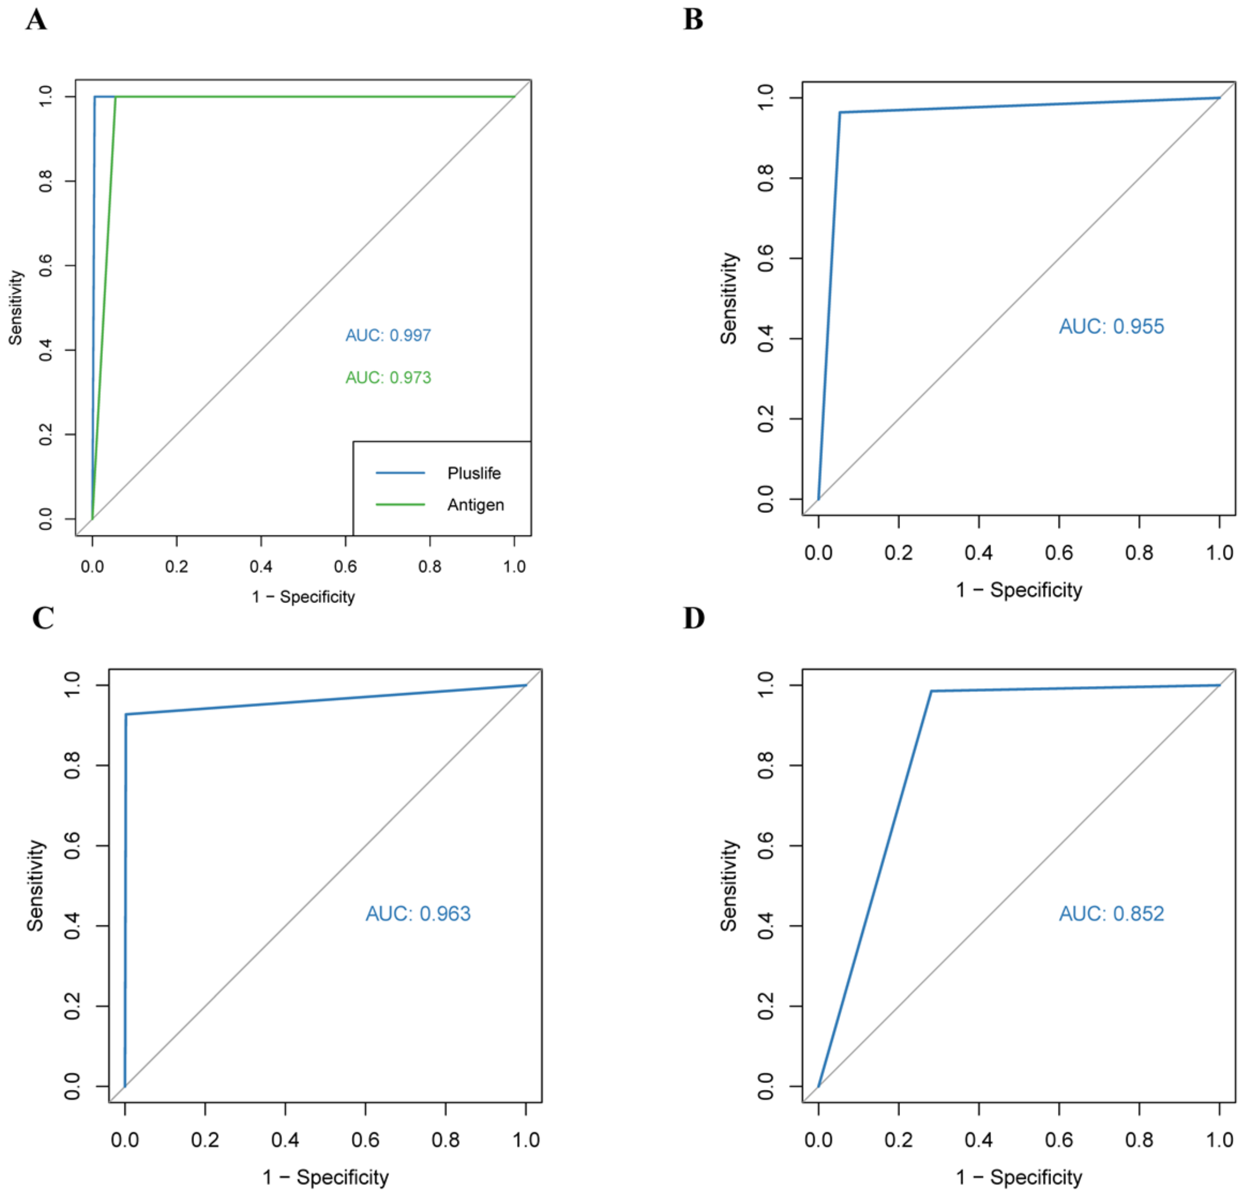
Assay results	RT-qPCR results		Performance
	Positive (n=93)	Negative (n=190)	
Commercial antigen test			
Positive (n=82), n	82	0	—[a]
Negative (n=201), n	11	190	—
Sensitivity (n=93), n (%, 95% CI)	—	—	82 (88.2, 86.5-89.8)
Specificity (n=190), n (%)	—	—	190 (100)
Pluslife SARS-CoV-2 rapid test			
Positive (n=92), n	92	0	—
Negative (n=191), n	1	190	—
Sensitivity (n=93), n (%, 95% CI)	—	—	92 (98.9, 98.4-99.4)
Specificity (n=190), n (%)	—	—	190 (100)

[a] Not applicable.

Comparison of the Diagnostic Value of Different Testing Methods and Different Trial Sites

We performed a receiver operating characteristic (ROC) curve analysis to assess the predictive value of the diagnostic variables. The optimal cutoff values and the area under the receiver operating characteristic curve (AUROC) were first calculated for the commercial antigen test and the Pluslife rapid SARS-CoV-2 test. The AUROCs were 0.973 and 0.997 for the commercial antigen test and the Pluslife rapid SARS-CoV-2 test, respectively (Figure 2A), indicating the higher diagnostic value of the Pluslife rapid SARS-CoV-2 test. After that, the optimal cutoff values and AUROC of the Pluslife rapid SARS-CoV-2 test were calculated for the different study protocols and for each field trial site. The AUROCs were 0.955, 0.963, and 0.852 for the 4 centers combined, the "ready-to-test" scenario, and the "freeze-thaw test" scenario, respectively (Figure 2B-D), indicating that the diagnostic value of testing immediately after field sample collection was higher than that after freezing and thawing samples. The AUROCs of the Pluslife rapid SARS-CoV-2 test for each individual site were 0.959, 1.000, 0.852, and 1.000 for Guangdong Provincial People's Hospital, Zhujiang Hospital at Southern Medical University, Guangdong Second Provincial General Hospital, and Guangdong University of Finance and Economics, respectively (Multimedia Appendix 3).

Figure 2. Analysis of the diagnostic value of different assay methodologies and different study protocols. (A) ROC curve analysis comparing the diagnostic value of antigen testing with that of the Pluslife SARS-CoV-2 rapid test. ROC curves predicting the diagnostic value of the Pluslife SARS-CoV-2 rapid test for (B) the 4 centers, (C) the "ready-to-test" study protocol, and (D) the "freeze-thaw test" study protocol. AUC: area under the curve; ROC: receiver operating characteristic.



Discussion

Principal Findings

Molecular testing is currently the standard diagnostic method for confirming SARS-CoV-2 infection [9], and RT-qPCR for SARS-CoV-2 in respiratory specimens is widely used in COVID-19 diagnostic laboratories [2,10-12]. The easy-to-use and mass-producible nature of the Pluslife rapid SARS-CoV-2 test allows for timely nucleic acid test results and reduces the burden on laboratories [10]. Our objective was to evaluate the performance of the Pluslife rapid SARS-CoV-2 test by comparing it with other tests, such as RT-qPCR and antigen tests, through field trials of the Pluslife rapid SARS-CoV-2 test kit at 4 centers.

First, our results from the 4 field trial sites revealed that RT-qPCR showed 95% (1853/1950; 95% CI 93.9%-96.2%) compliance with the results of the Pluslife rapid SARS-CoV-2 test. The specificity, sensitivity, concordance, positive predictive value, negative predictive value, positive likelihood ratio, and negative likelihood ratio of the Pluslife rapid SARS-CoV-2 test were high (Table 2). To test the optimal conditions for the Pluslife rapid SARS-CoV-2 test, we adopted the "ready-to-test" and "freeze-thaw test" protocols in the field trial sites. Guangdong Provincial People's Hospital, Zhujiang Hospital at Southern Medical University, and Guangdong University of Finance and Economics were used as the test sites for the "ready-to-test" scenario, and Guangdong Second Provincial General Hospital was used as the test site for the "freeze-thaw test" scenario. Our results showed that the RT-qPCR results of the "ready-to-test" and "freeze-thaw test" protocols were 99.2% (1436/1447; 95% CI 98.8%-99.7%) and 82.9% (417/503; 95% CI 81%-84.8%), respectively, and the specificity, sensitivity, concordance, positive predictive value, negative predictive value, positive likelihood ratio, and negative likelihood ratio of the SARS-CoV-2 assay were higher with the Pluslife rapid SARS-CoV-2 test. The above results indicated that freezing and thawing samples after collection and then testing with the Pluslife rapid SARS-CoV-2 test kit is likely to cause false-negative test results, while the diagnostic performance of the test is better when the samples are processed in the field immediately, which may be related to the easy degradation of viral RNA after freezing and thawing. In addition, we validated the diagnostic value of the Pluslife rapid SARS-CoV-2 test by ROC curve analysis for the different study protocols and various field trial sites, and the results also showed that the diagnostic value of the test immediately after field collection was higher than that of the test after freezing and thawing the samples. It is well known that RT-qPCR assay results take a longer time to become available [11]. Our comparison of RT-qPCR and Pluslife rapid SARS-CoV-2 testing times in the 4 centers revealed that the Pluslife rapid SARS-CoV-2 testing time was considerably shorter than the RT-qPCR testing time for both negative and positive results.

Rapid antigen testing is now a valuable alternative to RT-qPCR for the diagnosis of SARS-CoV-2 infection because of its simplicity, speed, low cost, and lack of a need for special equipment or skills [13,14]. However, since viral antigens are expressed when the virus is in active replication, the antigen test is more suitable for the acute infection period, and the accuracy of the COVID-19 antigen test is relatively high for the suspected population within 7 days of the onset of symptoms [15,16]. Therefore, there is a need to develop a test that covers a long period and is fast, accurate, and convenient, which is exactly what the Pluslife rapid SARS-CoV-2 test offers. To compare the diagnostic performance of the Pluslife rapid SARS-CoV-2 test with a commercial antigen test, we compared the 2 assays with RT-qPCR in a field trial scenario at Guangdong Provincial People's Hospital, and the results showed that the sensitivity of the antigen and Pluslife rapid SARS-CoV-2 tests were 88.2% (82/93; 95% CI 86.5%-89.8%) and 98.9% (92/93; 95% CI 98.4%-99.4%), respectively. Thus, the positive detection rate of the Pluslife rapid SARS-CoV-2 test was increased by 10.8% (10/93; 95% CI 9.2%-12.4%) compared to the commercial antigen test. In addition, we validated the diagnostic value of these 2 tests by ROC curve analysis, and the results showed a higher diagnostic value for SARS-CoV-2 with the Pluslife rapid SARS-CoV-2 test than with the antigen test. Therefore, although the detection time of the Pluslife rapid SARS-CoV-2 test is slightly longer than that of the antigen test, the diagnostic performance of the Pluslife rapid SARS-CoV-2 test for SARS-CoV-2 is superior to that of the antigen test.

However, there are some limitations to our study. First, because most of the samples were collected by health care workers in the 4 centers, it was not possible to compare the effects of the 2 sampling methods, namely, nasal swabs and oropharyngeal swabs, on the performance of the Pluslife rapid SARS-CoV-2 test. Second, because antigen testing was only performed in a subset of patients in the fever clinic of Guangdong Provincial People's Hospital, the number of samples for which both the Pluslife rapid SARS-CoV-2 test and antigen test were performed was small.

Conclusion

In conclusion, our multicenter field trial showed that, based on the gold standard RT-qPCR assay, the specificity, sensitivity, concordance, positive predictive value, negative predictive value, positive likelihood ratio, and negative likelihood ratio of the Pluslife rapid SARS-CoV-2 kit were high, and the "ready-to-test" assay conditions were optimal. In addition, the detection time of the Pluslife rapid SARS-CoV-2 test was substantially shorter than that of RT-qPCR, which helps to reduce laboratory pressure and time costs with better performance in the detection of SARS-CoV-2. Furthermore, when compared with the antigen test, we found that the diagnostic performance of the Pluslife rapid SARS-CoV-2 test was better for SARS-CoV-2 with similar detection times. Therefore, under "ready-to-test" assay conditions, the Pluslife rapid SARS-CoV-2 test can be used as a fast, convenient, and accurate method for detecting SARS-CoV-2 with a detection performance comparable to that of RT-qPCR, offering significant application value for grassroots level facilities with poor medical conditions, special application scenarios (eg, traffic checkpoints), and easy home testing, thus reducing pressure on medical institutions.

Abstract

Harmonization and integration of health data remain as the focus of many ongoing efforts toward the goal of optimizing health and health care policies. Population-based patient registries constitute a critical element of these endeavors. Although their main function is monitoring and surveillance of a particular disease within a given population, they are also an important data source for epidemiology. Comparing indicators across national boundaries brings an extra dimension to the use of registry data, especially in regions where supranational initiatives are or could be coordinated to leverage good practices; this is particularly relevant for the European Union. However, strict data protection laws can unintentionally hamper the efforts of data harmonization to ensure the removal of statistical bias in the individual data sets, thereby compromising the integrated value of registries' data. Consequently, there is the motivation for creating a new paradigm to ensure that registries can operate in an environment that is not unnecessarily restrictive and to allow accurate comparison of data to better ascertain the measures and practices that are most conducive to the public health of societies. The pan-European organizational model of cancer registries, owing to its long and successful establishment, was considered as a sound basis from which to proceed toward such a paradigm. However, it has certain drawbacks, particularly regarding governance, scalability, and resourcing, which are essential elements to consider for a generic patient registry model. These issues are addressed in a proposal of an adapted model that promises a valuable pan-European data resource for epidemiological research, while providing a closely regulated environment for the processing of pseudonymized patient summary data on a broader scale than has hitherto been possible.

Context

The World Health Organization (WHO) defines public health as "the art and science of preventing disease, prolonging life and promoting health through the organized efforts of society." Surveillance of population health and well-being is listed as the first point in WHO's list of 10 essential public health operations [1].

In practice, the task of monitoring health status is fraught with difficulty. Health data need to be collected from many different points, raising challenges in data harmonization, data contextualization, and data quality. Depending on the type of public health infrastructure, there may additionally be different regional practices that compound these types of problems. Moreover, the introduction of strict data protection laws adds further layers of complexity in linking data, which is an essential part of the process. A wide range of endeavors has been undertaken to align health data, and a certain level of progress has been made through international collaboration on many different aspects of the underlying challenges. However, within Europe, fragmentation of data still persists owing in part to a rich tapestry of different types of national health care infrastructure in place.

In the field of population health monitoring, population-based patient registries are valuable assets in the surveillance and control of disease. Registries expend substantial effort to ensure accuracy and completeness of data in a given population to limit statistical bias [2]. Moreover, registry data are structured and generally well described using standardized coding classifications, which have positioned registries as key epidemiological resources [3,4]. Although registries are relatively autonomous in the population they cover, an extra dimension in their usefulness and value is created by the integration and comparison of data across registries. Combined registry data use allows studies with large cohorts of patients, thus leading to deep analyses and enhanced knowledge [5,6]. Despite the potential considerable savings in resources and benefits to patients that integrating registry data can bring [7,8], there have been few concerted efforts to support or facilitate such initiatives in a sustainable manner. Moreover, increasingly strict data protection regimes can lead to significant administrative overheads in the collection and processing of pseudonymized data, further exacerbating the challenges.

Epidemiological research is particularly affected by strict data protection paradigms that do not generally differentiate the needs of accessing personal data for data linkage purposes from that for studies on specific individuals. Epidemiology requires data linkage solely to derive the patient cohorts of interest (rather than to conduct studies on specific individuals). Moreover, to ensure unbiased intercomparisons of national data, the necessary data validation techniques require access at least to pseudonymized data, which are also considered as sensitive data by the strict data protection paradigms. In view of the current difficulties and barriers confronting initiatives to monitor disease at a supranational level for the purposes of informing and coordinating strategies for control and prevention of disease at the European Union (EU) level, new mechanisms are required to facilitate the necessary access to data without conflicting with the core intent of EU's general data protection regulation (GDPR) legislation.

EU Member States have committed to the United Nations' sustainable development goals to reduce premature mortality owing to noncommunicable diseases (NCDs) [9], and the European Commission (EC) is addressing the rise in numbers of European citizens experiencing the more prevalent chronic diseases [10]. In particular, EC continues to provide support to the work of cancer registration through the European Network of Cancer Registries (ENCR) to derive statistical indicators used to steer EU policies and coordinate Member States' activities for tackling the cancer burden. EC has also funded several projects among the Member States to further the availability of indicators for other diseases [11-13] and supported registry networks via specific project-related activities [14]. However, these initiatives are of relatively short duration, and EU funding cannot replace national support for recurrent activities within country remits. What is missing is a long-term perspective about patient registry networks leading to a sustainable solution. After the conclusion of the joint action initiative on cross-border patient registries in 2014 [14], the European Medicines Agency launched several follow-on initiatives including the creation of an inventory of patient registries and a draft guideline on registry-based studies, which were open to public consultation [15]. Although the aim is to create an EU-wide framework for patient registries, the framework is with reference to facilitating general, open collaboration between the various stakeholders rather than specifically addressing models for integrating registries' data. Although patient registries in Europe are generally willing to establish supranational networks [16,17], for the most part, they struggle to find the resources and instruments to do so, and an EU-coordinated sustainable and scalable model of patient registry networks would surmount many difficulties. In addition, such a model could scale to other regions of the world in which there are agreements between countries for tackling common public health issues, thus further increasing the potential of the approach.

A Missing Infrastructure

Despite the acknowledgment that policy and decision-making processes should be based on evidence and supported by adequate health information systems, Bogaert and Van Oyen [18] observed that “there is no single comprehensive EU-wide public health monitoring system or health information system that allows policy-oriented research or advice.” Although indicators of NCDs have been, and continue to be, estimated from various sources including hospital discharge records, death certificates, health insurance claims data, and health surveys, the quality of such indicators can be extremely variable. This is particularly the case for health insurance data that can lead to biased coverage of the population where there is no universal national health insurance system. For these reasons, insurance data tend to be used for evaluating and assisting health care planning rather than for generating health statistics [19]. Other difficulties arise from the different disease coding systems used and even different interpretations of codes within the same coding system. Moreover, health surveys have limited sample sizes and tend to miss illnesses with high fatality rates [19]. Although in the absence of any systematic collection of data, these estimated processes play an important role, they also place onerous demands on the institutions involved when conducted on a periodic basis, and there will be a trade-off between the resources required and the cost-benefit of the indicators depending on their quality and veracity. Many challenges facing such initiatives are summarized in the Eurostat report on pilot studies performed for collecting morbidity statistics in EU [19].

Regarding the establishment of a dedicated EU health information system, Rosenkötter et al [20] identified the key features expected from an EU health information system based on a series of interactions with stakeholders from international institutions, national ministries, public health authorities, universities, and EU cofunded projects. In a ranking of 10 features, the most important one was considered to be a permanent and sustainable system (in terms of content, infrastructure, and resources), followed by quality of data and information. The authors note that in spite of the acknowledged relevance of public health surveillance and the numerous requests for a comprehensive EU health information system, there seem to have been considerable barriers to hinder its realization. They cite various possible factors such as the data collection processes through different and fragmented national health information systems and the concerns of oversimplified rankings in data comparisons; the specific types of issues related to both these factors have been described by Tijhuis et al [21]. An even more fundamental problem identified by WHO is that “measuring health is conceptually and technically complex, requiring statistical, public health and biomedical knowledge and expertise unique to each disease or programme area” [22], and therefore dependent upon coordination and integrated strategies across many different entities.

Although population-based patient registries may have variable coverage and comparability [19], they nevertheless provide a well-established and systematic data collection process, with data often stretching back many years. Additional value is obtained through their collaboration within supranational networks, as these provide the means to harmonize indicators via agreement on data alignment, validation, and cleaning processes. This is essentially the approach followed by ENCR in the collection and derivation of European cancer indicators.

Stakeholder discussions have since gained momentum toward the establishment of the European Health Data Space (EHDS) [23], which foresees an infrastructure that facilitates access to health data across EU. It is not yet clear whether the envisaged solutions underlying the implementation of EHDS will be sufficient to provide the level of service needed for an accurate comparison of health indicators across Member States. Many challenges still need to be addressed, including the timely provision of data, ensuring the prerequisite quality and harmonization of data, and issues related to data linkage. The extent of these difficulties can be appreciated from the processes followed by ENCR to ensure the harmonization and quality of cancer indicators for meaningful comparison across national boundaries. In view of the underlying verification and validation processes to ensure harmonized quality indicators, it is likely that ENCR will need to furnish EHDS with precomputed cancer indicators rather than the converse scenario, whereby European cancer indicators can be computed from data made available by EHDS. In this regard, EHDS will not necessarily circumvent the need for a network of cancer registries (CRs) or any other supranational registry network providing harmonized indicators at the EU level. Therefore, agreeing with a sustainable approach toward the operation and resourcing of such networks remains as an important objective.

The advantage of a registry network is precisely that it consists of a network of experts that allows it to function as more than a mere data collection and validation point. The WHO’s Health Metrics Network categorizes a health information system into 6 components (resources, indicators, data sources, data management, information products, and dissemination or use) [22], and these components stand to be addressed more holistically in entities such as registry networks, which also allow for supranational coordination and harmonization. Moreover, given that registries collect hospital discharge records and outpatient records, many of them either do or could collect comorbidity data that are considered to be necessary for a comprehensive picture of public health [19].

Building on the Model of ENCR

Overview

To gauge the practical feasibility of sustainable models enabling the collation of accurate and harmonized indicators for intercomparison at the supranational level, experiences and lessons can be drawn from existing, well-established networks. In this regard, ENCR serves as a prime example. We present the network in terms of how it is organized and how it currently operates, especially in view of the associated advantages and disadvantages.

ENCR Organizational Structure

The members of ENCR are national or local CRs. They are not always public authorities. The participation of registries in ENCR is voluntary and has been promoted by EU initiatives since the 1990s. The funding for participation in the network is obtained from the budgets of each registry and from EU cofinancing.

The organizational structure of ENCR consists of a steering committee, with a 3-year rolling mandate. Members are either elected by the member registries or nominated by some of the participant bodies. The steering committee is responsible for prioritizing the issues facing the network and establishing working groups comprising individuals with specific skills or experience from the individual registries. Examples include review and revision of coding recommendations, agreement of data validation rules, and harmonization of variables extending the common data set. The steering committee is assisted by a secretariat that provides administrative and technical support.

The secretariat was initially provided by WHO’s International Agency for Research on Cancer, which played an instrumental role in the formation of the network in 1990 under EC’s Europe Against Cancer action plan. In 2012, the secretariat was transferred to EC’s Joint Research Centre. ENCR has been essential for coordinating the periodic collection of data for deriving the statistical indicators used at the EU level to compare cancer incidence, mortality, and survival and their trends over time for different types of cancer. The indicators are publicly available on the European Cancer Information System (ECIS) website [24], which is the reference point for monitoring and projecting the burden of cancer in Europe.

Challenges Facing the ENCR Model

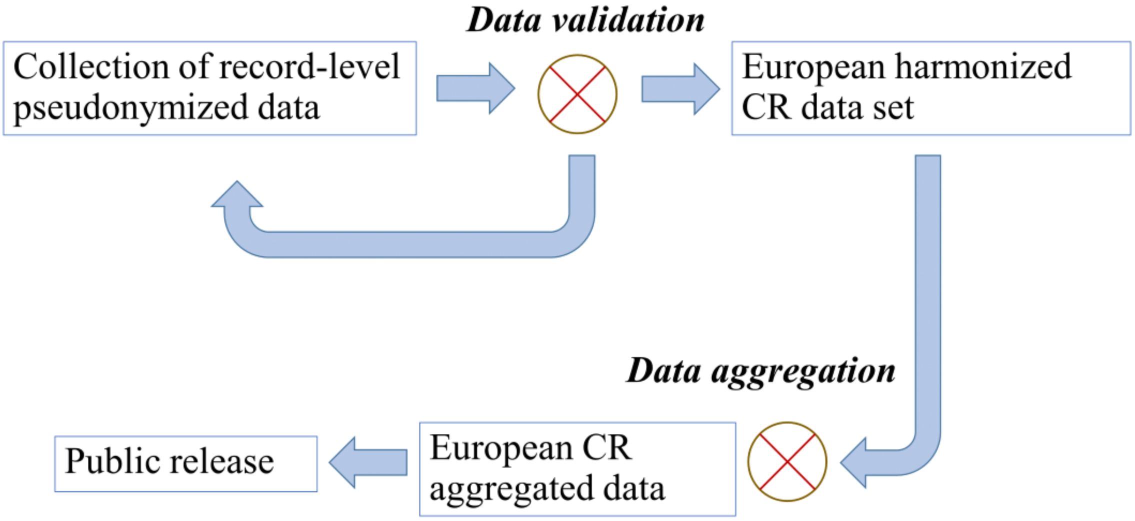
Overview

Ensuring the accuracy of comparable cancer data from many different registries is a nontrivial process. The organizational landscape of CRs is extremely heterogeneous across Europe, and the complexity of the situation can be gauged by the sheer number of registries constituting ENCR (>150 individual CRs). Registries can be nationally based, regionally based, or even metropolitan, and Member State coverage is also quite variable [25]. Challenges relate to data curation, data interfaces, and lack of legal entity status for an informal network.

Data Curation

The collection of data from all CRs relies not only on the good will of the registries to provide their data within a given time frame but also on the legal contracts between the data collector and the data provider. First, the data are provided as pseudonymized patient summary records conforming to a template describing the ENCR common data set, which consists of harmonized variables fundamental for deriving the major statistical indicators. Then, the data are cleaned according to a set of predefined rules; the more basic checks relate to file formatting errors and ensuring that all the mandatory variables have been provided. The more intricate checks verify the accuracy of the variables' data ranges, particularly regarding the values of other variables (intervariable checks). The data cleaning step may require several iterations with the registries until the data are considered to meet the required level of conformity with the data rules, which is necessary for national and international comparisons. Finally, the indicators are derived from the data on a per-registry basis and displayed at an aggregated level that removes the possibility of reidentification. Following a round of final checks with the registries, they are uploaded to the ECIS website. The process is summarized in Figure 1.

Figure 1. Summary of the centralized European cancer-registry data collection and cleaning process.



The processes for collecting, cleaning, and final verification add time delays beyond those already incurred by the CRs in collecting and verifying the data according to their own local processes and requirements. Once the aggregated data are made available at the European level, they are generally 4 to 5 years out of date. Forecasts, based on the historic data, are calculated to cover the intervening time lag; nevertheless, it stands to reason that any possible means of reducing the delays while not compromising the veracity of the data should be promoted. Delayed availability of data compromises their usefulness in feeding back in real time to health care policies, especially in monitoring the immediate effects of the introduction of cancer control initiatives, such as screening programs.

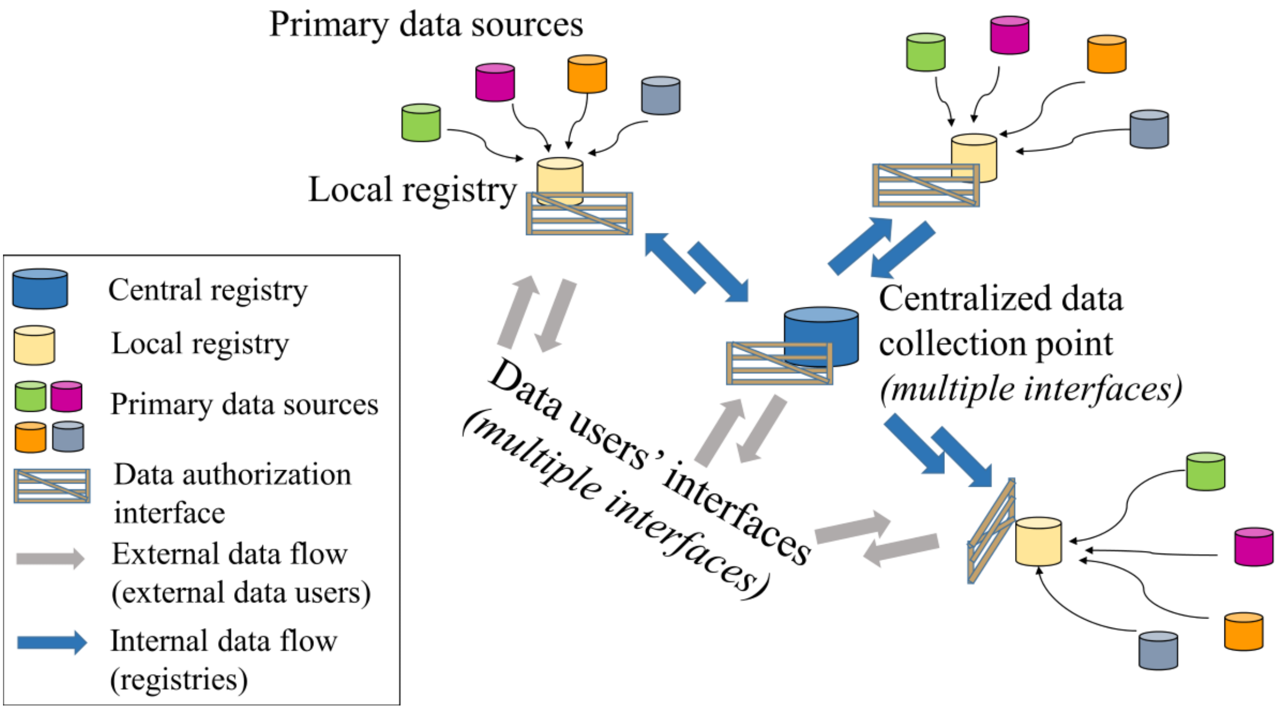
Data Interfaces

Another major difficulty lies with the interfaces between the various independent entities involved in the data chain, especially in terms of data encoding and anonymization.

Encoding of Data

In primary health care settings, clinicians are busy and often may not have the time necessary to complete or verify the summary data that are forwarded to the registry. Medical secretaries entrusted with the work may themselves not have the necessary experience to verify the data or determine the correct codes to use from the case reports. If the data are not encoded accurately, the resulting inconsistencies tend to amplify the inefficiencies as they propagate through the downstream processes. Improved focus and attention given to ensuring the accuracy of the summary case reports at the initial point of encoding could save considerable expense and delay in correcting the data later. However, the same is true for all the interfaces, with each interface adding to the overall delay and inefficiency, as data have to be checked, verified, and corrected via dialogue between both sides of the interface. Figure 2 illustrates the multiple data interfaces in the current registry network scenario. Although these processes are in the domain of national health infrastructure, there are motives for establishing good practices in view of saving cumulative costs, both in terms of time and resources. Data reporting is often viewed as an unnecessary burden in the busy clinical environment, and further efforts could be undertaken to provide the results of data analyses back into the hands of the clinicians to help change such attitudes and demonstrate the practical advantages of accurate data reporting. In addition, measures could be implemented, such as training, data quality audits, or provision of standard templates encapsulating data quality and data semantic contexts following, for example, the model of Findable, Accessible, Interoperable, and Reusable data digital objects [26].

Figure 2. Multiple data interfaces exist in the common pan-European registry model. Each interface adds barriers to the type of data interaction allowed. In particular, the interface presented to general data users is complex on account of the lack of a single access point.



Data Anonymization

Moreover, where the interface bridges different health care authorities, the transfer of pseudonymized data also falls under the data protection requirements of GDPR. Data requesters are required to state explicitly the intended purposes for the data, and these requests have to pass through various overseeing processes to ensure that the purposes are appropriate. The interfaces are further complicated between national boundaries where different legal interpretations and contexts may apply. The way in which GDPR has been enforced across different EU Member States since its introduction in May 2018 means that some registries are no longer able to provide even pseudonymized summary data. However, anonymized data cannot be used for verifying data consistency and bias. This development has profound consequences for the reliable intercomparability of the indicators currently provided in ECIS. Although initiatives are underway to federate the data cleaning processes, which would eventually remove the need to collect record-level data, it is not a straightforward task because there are many exceptional cases to handle and apply through a consistent approach. Moreover, merely federating the centralized entity's processes does not tackle the broad and more important issues of leveraging the full value of the registries' data (in a centralized data collection process, the focus tends to be on only the reduced subset of the core data variables).

The Legal Entity Issue

The ease of acquiring data, at least from the perspective of recognized legitimacy of the data request, can be facilitated via a legal mandate. However, a legal mandate requires a data-requesting entity to be a legal entity, and although this does not pose any problems for individual registries, an informal network of registries is itself not a legal entity. The lack of legal entity status also confounds funding of the network or any financial transaction. This means that the network is fully dependent on the legal entity or entities that perform the administrative affairs of the network.

Proposal for an Adapted Model

Overview

The considerations mentioned in the previous section can be used to frame a proposal toward a more robust and efficient model by streamlining the processes, increasing coordination among the various entities, and providing the capacity to scale across other registry domains. Apart from cancer, other chronic disease domains receiving attention for more coordinated European initiatives include diabetes, cardiovascular disease, and chronic obstructive pulmonary disease. The need to increase the availability and access to NCD data for both policy and research uses has long been argued within Member State public health institutes and by experts and stakeholders in the field. However, important challenges remain before the provision of accurate, comparable data on key aspects can be realized—even of fundamental information such as the prevalence of diabetes, cardiovascular disease, or chronic obstructive pulmonary disease. Moreover, it would be particularly valuable to be able to track and derive geographical and temporal trends of epidemiological indicators (such as prevalence, incidence, mortality, and survival) for all the major NCDs and any comorbidities.

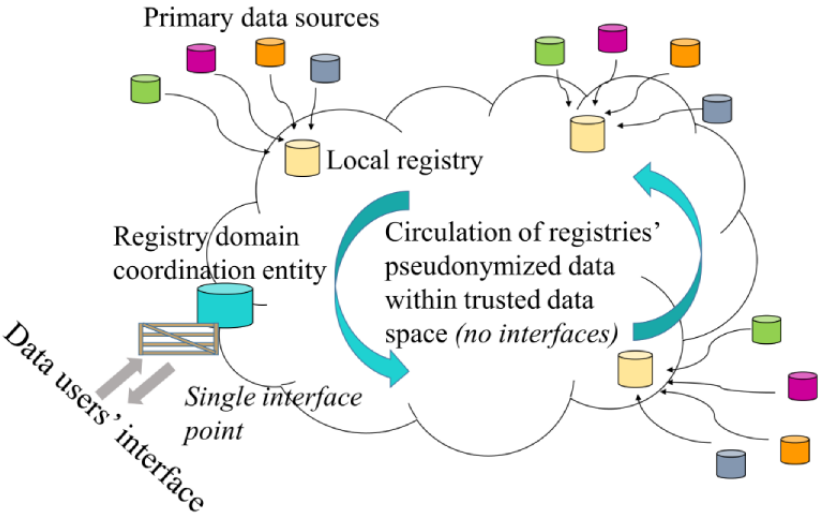
We argue that a paradigm shift with the potential for a significant increase in efficiency is achievable if all the superfluous external interfaces are removed. This could be realized by creating a trusted registry space, for example, similar to trusted research environments (TREs) being established in the United Kingdom for data-driven health research [27]. An environment of this nature would create a secure and trusted working space in which registries within a given disease domain could operate across regional and national boundaries.

Pan-EU TREs

In TREs, researchers can only access the types of data agreed upon within their data sharing agreements. They are also prevented from downloading any record-level data and can only access the data within the TRE. Creating such an EU-wide environment on a registry domain basis would effectively unleash the full potential of registry data for the benefit of all citizens. Given that all registries have the same objectives, albeit within their own specific geographic boundaries, and share the same ethical principles, there is, in principle, no reason why such a pan-EU space could not be set up, especially when safeguarded by data sharing agreements. Moreover, the data space would generally only require access to pseudonymized data, consistent with the principles laid out by GDPR to reduce the risks of patient identification. In any case, the fundamental aim of population-based registries is to provide a monitoring and surveillance function for a particular disease; identification or reidentification of patients is not the purpose, and personal identifiers are only used when it is necessary for linking data to obtain the relevant information for selecting cohorts of patients sharing the specific commonalities to which the epidemiological research is addressed. Furthermore, pseudonymized data need never leave the trusted registry space. The processing would be performed entirely within the data space, and only anonymized data would be made available outside the space.

A means for formalizing the network is also needed such that it is recognized as a legal entity. This could be achieved via an administrative and technical entity within the network (and operating in the space, thereby removing a further unnecessary interface and dependence on an external organization) that could manage the budgeting and financial aspects of the network. A registry network with legal status would resolve various difficulties that are becoming increasingly apparent, especially regarding the interface with EHDS, which foresees data nodes as legal entities either at the national level or formally recognized European agencies or bodies (such as the European Centre for Disease Prevention and Control, European Reference Networks, and European Research Infrastructure Consortia). In contrast, registry networks are informal networks of registries that have no legal recognition even though each individual member registry may be a legal entity in its own right. However, with a legal entity status, the administrative entity of the registry network could be formalized as the network's contact office and serve as the registry domain node in EHDS. Such a contact office may also be able to rationalize the many current access points vis-à-vis the national statistical offices and those offices responsible for providing information to registries. Figure 3 illustrates the benefits of replacing the multiple access points shown in Figure 2 with a single data access point.

Figure 3. A trusted registry environment or data space for a specific disease domain. The registries within the trusted data space are free to exchange pseudonymized data on the condition that no data leave the space and that the purpose of the exchange is legally and ethically compliant. A single interface point is provided by the coordination entity that works in coordination with all the registries in the data space.



Benefits of the Model

A trusted data space on a disease domain basis, in which registries are able to share pseudonymized data, would transform the current processes of working and considerably facilitate supranational research (such as at the EU level) that can currently only be performed with great difficulty and effort. It would also accelerate the provision of statistical indicators by removing many administrative and bureaucratic hurdles impeding the processes for collating data. An additional potential benefit is that it could provide a safe environment for the data, because the data need never leave the trusted registry space, as is the case in centralized collection points, and thereby motivate the sharing of a rich data set with more variables than are currently included in the minimum data set.

The legal status of the contact office forms a critical element in the network's business case, as funding for the activities of the network could be provided via administrative and data processing fees to ensure the long-term sustainability of the network. Regarding this aspect, the benefits should be emphasized on the positive feedback mechanism that secondary data use is likely to provide on the quality of data. The more the data are used, the more resources would be available to the network to reinvest in developing more robust processes and tools for verifying the quality of data and extending the set of harmonized variables. Moreover, these resources could in turn be used to support and improve the quality of the primary data feed processes.

A further strength of the model would be to focus the access point to the registry data on a single entity, not only helping to ensure that the data requested from different registries within the same domain are harmonized to the degree necessary for secondary analyses but also allowing a shared view within the community about the ethical aspects and appropriate use of registry data in the incoming data requests. Individual registries within the network would always retain the right to refuse the use of their data in any specific study. Table 1 summarizes the characteristics and advantages of the proposed model over those of the current ENCR model for some of the main data processes.

Table 1. Characteristics and advantages of the proposed adapted model compared with the characteristics of the current ENCR[a] model for some of the main data processes.

Process	ENCR model	Proposed adapted model	Advantages
Data collection	Centralized data collection point	Data remain federated but accessible in data space	• All registries have access to other registries' data • Parallelization of centralized tasks, thus avoiding serial data pipeline congestion • Improved transparency and verification of data processing • Patients' record-level data remain within the secure data space
Registry interface	Multiple data interfaces between the central data point and registries	No interfaces between registries (data sharing agreements are formalized via initial set of contracts)	• Fast availability of data • Few administrative processes • More rapid derivation of statistical indicators • Avoids the need for duplicating data sets and the consequent data integrity issues
Data access	Only the central data point has access to full set of pseudonymized data	All registries can access other registries' pseudonymized data	• More extensive data use, which in turn improves data quality • Increased collaborative analyses between registries • Deep data pool
Data variables	Data variables are limited to those described in common data set	All data variables are potentially available	• High-resolution analyses • Facilitation of metadata harmonization (improved visibility of nonstandardized metadata)
Users' interface	Multiple data interfaces between external data users and registry sources	Single data interface between external data users and registry network	• Improved control over data collections and versions, thus avoiding discrepancies in data analyses arising from release of different collections or versions of data
EHDS[b] interface	No clear interface with EHDS	Interface with EHDS via legal entity representative of the registry network	• Well-defined point for data query submissions • Fast response times to data queries • Improved coordination between registries for handling external data requests

[a] ENCR: European Network of Cancer Registries.

[b] EHDS: European Health Data Space.

There are other benefits that such spaces could bring to the registries' data feeding processes from the initiating sources, whether from primary sources such as hospitals and clinics or from linkage data (eg, from statistical offices). Registries spend significant amounts of time ensuring consistency and completeness of data [28], both of which are critical processes to remove bias from the data. The time spent in ensuring these particular dimensions of data quality is one of the major contributors to the time delay associated with the provision of validated registry data. Agreeing the common data sets and metadata standards at the European level stand to influence clinical data recording practices across EU to ensure that the common variables are transferred consistently and accurately and to lead to economies of scale by nurturing approaches toward common data quality tools and methodologies. Having 1 point of access to the registry domain would itself facilitate the transfer of death certificate information, which is a piece of critical information required by registries for ensuring data completeness. Therefore, the network could act as a type of data-clearing house, providing a single interface between national statistical offices rather than multiple interfaces that exist currently.

Within the EU at least, there are few reasons to argue against a model that goes in the direction of a trusted data space in which registries are free to exchange pseudonymized data under appropriate and formalized safeguards. It is based on similar arguments as those used to frame the development goals of EHDS but with more justified reason given the very specific aims. The model would provide registries with the autonomy to agree the common data models, metadata, common data sets, and data quality criteria. The latter is essential in any cross-comparison of data and could easily be audited and graded in such a common space, with important ramifications on the trustability of the data in downstream analyses. The model is adaptable to countries at either end of the country income spectrum because it builds on the local registry infrastructure. A study undertaken on the overall costs of CRs for 2010 [29] revealed that costs per inhabitant ranged between €0.03 (US $0.04) and €0.97 (US $1.35), with an average of €0.27 (US $0.37) in comparison with cancer health care of €102 [US $142.8] per EU citizen in 2009 [30]), whereas the costs per registered cancer case ranged between €6 (US $8.4) and €213 (US $298.2), with an average of €50.71 (US $70.9). These figures were comparable with those of registries in the United States. Costs for registries covering large populations were less than those for registries covering small populations, and correspondingly, costs of national registries fared better than regional registries. Increasing expenditure for CRs was associated with the increasing economic wealth of the country, with the greatest proportion of costs being spent on personnel. In view of the health expenditure savings that registry data can bring, the costs are not disproportionate to the total health care costs—at least in the domain of cancer.

Practical Considerations

A framework allowing such seamless pooling and processing of data, even if only pseudonymized data, would require agreement of national authorities at the EU Member State level despite the provisions laid out in GDPR for processing of sensitive data for reasons relating to the public interest. This would be the first major task to accomplish. However, several aspects will also need to be addressed at a practical level. The first aspect is to identify the means by which a network of legal entities could itself become a legal entity in its own right; having the network agree jointly on terms and implementation would not be sufficient. The solution to this could perhaps be bound together with the legal issues defining a trusted patient registry domain data space. The second aspect relates to the technical aspects of creating a secure EU data space accessible to registries across EU, which may be more difficult to accomplish than a trusted data space housed in and limited to a particular country. The legal and technical aspects may further be compounded by the distinction between EU Member States and European non-EU countries, which are also members of patient registry networks such as ENCR. The third aspect relates to the need for funding, at least initially, before a patient registry domain space could become self-sustaining. A more ambitious endeavor could be to realize a single cross–disease domain patient registry data space, in which resources could be combined to realize a large synergistic technical facility for the development of common processes and tools for data cleaning and validation, without reinventing similar processes and tools on a per patient registry domain basis. There is a risk that a multiplicity of TREs without strong coordination can itself lead to duplicated effort, monopolies on access, and obstructive divergence around data curation [31].

Conclusions

To overcome the restrictions severely limiting the benefits to public health that could otherwise be achieved by facilitating interregistry integration, a new model is urgently required. The urgency is precipitated by the introduction of GDPR that has changed the context of the former model of collecting national and regional registry data for EU-coordinated actions. A model has been presented that promises to overcome many current hurdles and provide an improved solution to unlock the full potential of integrated registry data by allowing access to the full set of data variables rather than a restricted set. The model builds on the concept of ENCR that has proved to be a successful and viable means for deriving harmonized cancer indicators at the European level but introduces elements critical to a more sustainable and generic framework that could be applied to other NCD domains. The 2 elements that are especially important in this regard are the provision of a trusted data space to facilitate access to pseudonymized data in a secure environment and the creation of a legal entity as an integral part of the registry network serving as the formal single representative of and interface to the network. Regarding the legal entity acting as the interface to the registry network, there is a certain degree of trust required by the registries that can be ensured via appropriate contracts; it would also be critical to ensure stringent technical measures against unauthorized access to the data space and against any possibility of downloading sensitive data. Although both these aspects would require support and formalization at the national level and interregistry contractual agreements regarding the sharing of pseudonymized record-level data, there is, in principle, no reason why this cannot be achieved given the similar aims of local or national registries and explicit agreements at the EU level to tackle the NCD burden.

However, regardless of the specificities of any particular model, the fundamental requirements are to remove the inefficiencies imposed by the various interfaces within the current registry network models and allow a degree of autonomy within a registry domain to provide timely, reliable, and accurate indicators for steering policies to tackle the societal burden of disease and improve the outcomes of patients. In particular, accelerating the availability of data could save considerable costs by feeding back the results of health care measures and programs early in the implementation cycle. The arguments presented are intended to show how a solution for unlocking the resource-rich assets of interconnected patient registries is within reach and how a single interface to these data can most optimally be organized in supranational frameworks such as those existing in Europe. This interface would also provide a controlled means for ensuring access to the harmonized set of European health data in a given disease domain and could serve as an access node within EHDS.

Ethical Considerations

No ethics approval was applied for since the work described here does not involve research on any of the following: human embryos and fetuses, human cells or tissues, animals, non-EU countries, the environment or health and safety, dual use, or exclusive focus on civil applications. Nor does it contain reference to any personal data and no personal data were collected in the course of the study. Finally, there is no potential for the adverse misuse of the research results here presented. European Commission Horizon 2020 ethical self-assessment [32].

Abstract

The role of antibiotic overuse in intensifying selection pressures and contributing to the emergence of antimicrobial resistance is well established. The Kumbh Mela, a religious festival that occurs in 4 Indian cities of spiritual significance, is the world's largest mass gathering, attracting over 80 million pilgrims in 2013. Digital syndromic surveillance from the 2013 and 2015 Melas demonstrated a consistent pattern of antibiotic overuse, with an antibiotic prescribing rate of up to 31% for all patient encounters. As preparations for the 2025 Kumbh Mela begin, task shifting, point-of-care diagnostic and digital tools, robust clinician training, and community awareness can promote the restrained and evidence-based use of antibiotics, minimizing the potential for the emergence of antimicrobial resistance at the world's largest mass gathering.

Introduction

The World Health Organization's global action plan on antimicrobial resistance (AMR) recognizes that AMR "threatens the very core of modern medicine and the sustainability of an effective, global public health response to the enduring threat of infectious diseases" [1]. The contribution of antimicrobial use and overuse in intensifying selection pressures that lead to the emergence of AMR is well established [2]. India has the highest rate of human antibiotic use in the world and has a substantial burden of antimicrobial-resistant organisms as well [3]. Both the overuse of antimicrobial agents and the emergence of resistant organisms are exacerbated during stressors to population health, as seen during the COVID-19 pandemic [4-6]. These phenomena are also seen in certain regularly scheduled events like large mass gatherings where millions congregate over several days and where wanton prescription of antibiotics has been observed [7].

The Kumbh Mela is one such religious festival held periodically in 4 cities of spiritual significance in India [8]. Millions from across the country visit the weeks-long festival for a religious "dip" in the holy river waters on the banks of which the Melas are held. The Melas were last held in Allahabad in 2013, in Nashik in 2015, in Ujjain in 2016, and in Haridwar in 2021.

Our digital surveillance at 2 of these events in the past, including at the 2013 Kumbh Mela (the world's largest mass gathering to date), shows that antibiotic stewardship at the publicly funded health care facilities at these events is nearly nonexistent [9,10].

Planning for the Melas begins nearly 1 to 2 years in advance, presenting a unique opportunity to strengthen public health systems and improve antibiotic stewardship in time for the 2025 Kumbh Mela in Allahabad, which is again expected to set the record for the largest mass gathering in history. In this viewpoint, we argue for the restrained use of antibiotics; the use of digital tools to monitor, nudge, and support evidence-based prescribing; and for robust clinician training and community awareness to modify expectations and change practice in anticipation of, and during, the 2025 Kumbh Mela.

The 2013 and 2015 Kumbh Melas

Clinical encounters in the 2013 and 2015 Melas in Allahabad and Nashik, respectively, were digitally documented via a syndromic surveillance system deployed at both Melas [8-10]. Some of the authors (SB and AS) were directly involved in extensively studying various aspects of public health preparedness at these Melas and were responsible for the design and implementation of the digital systems, the first of cloud-based syndromic surveillance systems deployed at scale. It is now well documented that significant resources are directed toward public health preparedness and public safety at the Melas, in response to cholera outbreaks and stampedes that have marked previous iterations of the gathering [11]. At each festival, the state and central governments cooperate to provide a range of services for the visiting pilgrims, including temporary shelters, free meals, subsidized transport, and health care. Temporary health clinics are staffed by physicians seconded from other government-run primary clinics across the host state. The clinics are characterized by very high patient volumes, where each provider may see hundreds of patients a day. The doctor-patient encounter is cursory, and patients expect to be prescribed medications for their ailments, in concordance with known health-seeking behavior in India [12,13]. Protocols established by the state health ministry allow the provision of only a 3-day supply of antibiotics, recommending a follow-up visit [9]. With some exceptions, the vast majority of pilgrims only make a day trip to the Mela and return home.

The 2013 syndromic surveillance system was deployed at the 4 busiest of 13 clinics at the Allahabad Mela and at the larger secondary care hospital on site [8,9]. The clinics provided free services to the 80 million pilgrims who visited the Mela over a 55-day period. Roughly 280,000 patients were seen in the clinics during the Mela, and data were captured from 49,131 of these encounters [8,9]. We found that as the number of visitors rose on certain auspicious days, clinic visits spiked with some sites seeing over 2000 patients a day [9]. On February 9, the busiest of all days at the 2013 Mela, over 30 million pilgrims visited the festival. The median age in 49,131 patient encounters recorded at the 5 study sites was 46 years, the majority being men (70%) [9]. The most common recorded presenting complaints were musculoskeletal pain (19%), fever (17%), cough (17%), coryza (16%), and diarrhea (5%) [9]. A total of 91% of patients at the 4 sector clinics and nearly 70% at the central hospital received at least 1 or more drug prescriptions. Of all patient encounters, 31% received an antimicrobial agent [9]. Of patients who presented with a complaint of subjective fever (n=8490), nearly half received a 3-day prescription for antibiotics, empirically, without any confirmatory tests [9].

The syndromic surveillance exercise was repeated 2 years later at the Nashik Kumbh Mela, which was attended by nearly 30 million people [10]. Data were collected from over 40 clinics servicing the visiting pilgrims in the host cities of Nashik and Trimbakeshwar [10]. The clinics mainly ran on the most auspicious days, totaling four 3-day runs of operation, sometimes including both sites. A total of 33,305 unique patient encounters were captured over 9 days. The most common presenting complaints were upper respiratory tract symptoms (n=10,866), joint pain (n=5730), and fever (n=4861). Prescription data were available for 14,725 patient encounters from a subgroup of randomly selected clinics. Within this group, of the 2067 patients who presented with subjective fever, half (n=1111, 53.7%) were prescribed antibiotics empirically (as they were at the 2013 Mela). Among 3921 patients presenting with upper respiratory tract symptoms, 2692 (68.7%) received antibiotics. Of the 1429 patients with gastrointestinal complaints, 668 (46.7%) were prescribed antibiotics (Figure 1).

These findings are concerning for several reasons. Data from these Melas show that antibiotic prescribing rates can be as high as 31% for all encounters. Almost 69% of patients with upper respiratory tract symptoms received antibiotics, an alarmingly high rate, given the overwhelming evidence that the vast majority of upper respiratory tract infections are caused by viral pathogens [14]. These rates are concordant with previously published estimates of antibiotic prescription rates from undifferentiated outpatient settings in India, which range from 39% to 66% [15-17]. There is also substantial interprovider variation in prescribing practices (Figure 2 and Multimedia Appendices 1 and 2). When antibiotics are used, there is little consistency or evidence-based practice to guide decision-making when choosing antibiotics. Across all clinics at the 2015 Kumbh Mela, the rate of fluoroquinolone prescription for patients with upper respiratory tract symptoms ranged from 0% to over 50%, with similar variation in the prescription of other antibiotics. Such use of broad-spectrum antibiotics as empiric therapy is consistent with other observations from India and indicates the need for ongoing education for providers [18,19].

Figure 1. Percentage of patients prescribed antibiotics based on their syndromic presentation.

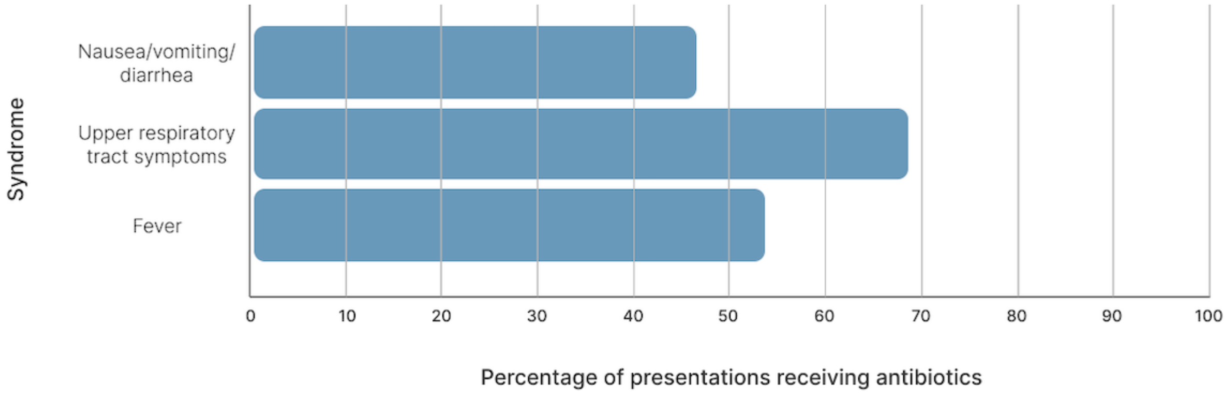

Figure 2. Variation in antibiotic prescription practices across sites for patients presenting with upper respiratory tract symptoms at the 2015 Kumbh Mela.

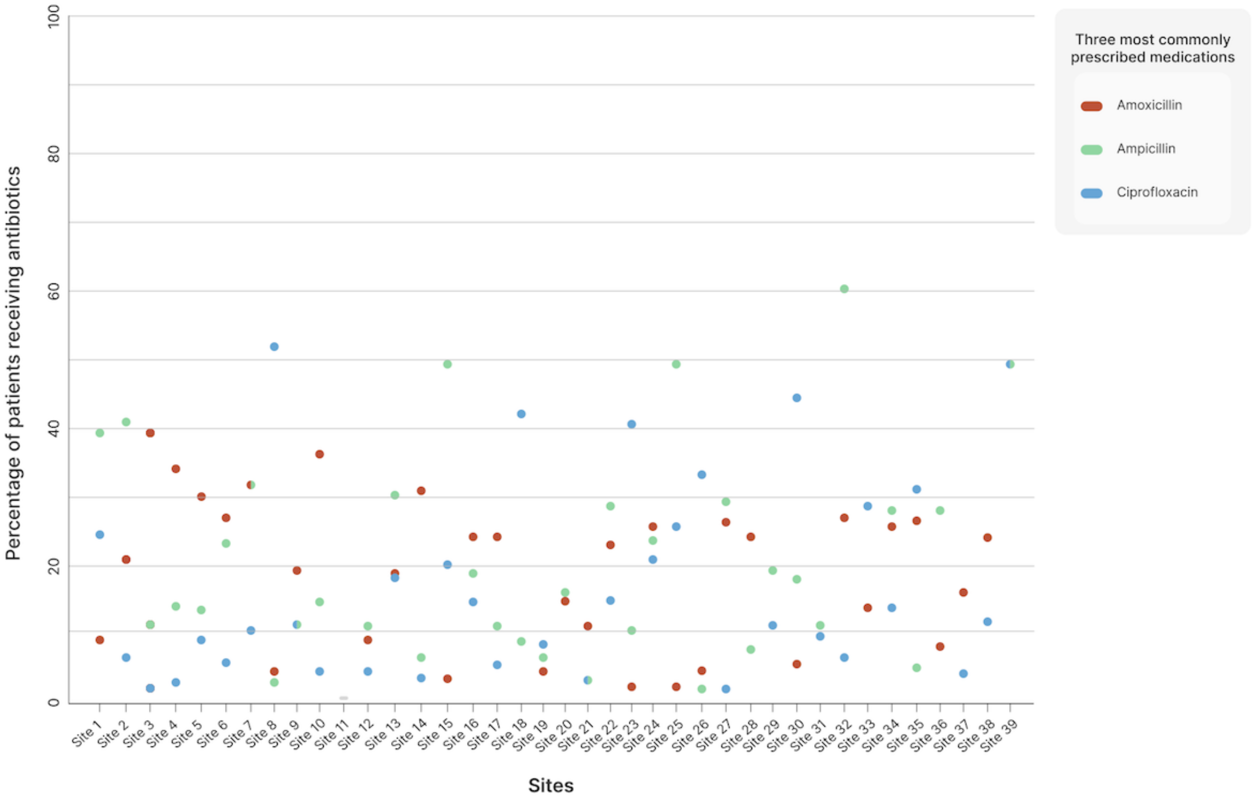


Policy Recommendations

While well intentioned, the provision of health services for low-acuity illnesses at the Kumbh Mela needs urgent reform. Preparation for the 2025 Allahabad Kumbh Mela commences now as the state assembles its administrative team and various contractors begin to reactivate their supply chains. The Mela administration will have a dedicated team dealing with public health preparedness and health services. Now is the time to reimagine what these should look like in 2025, for what is likely to become the world's largest mass gathering.

Evidence from the prior 2 Melas we studied has shown the following: the vast majority of presentations are of low acuity; there are little to no diagnostics available except at the district hospital; there is near universal overprescription of antibiotics; and when prescribed, the choice and dosage of antibiotics chosen appears arbitrary. Each of these observations warrants attention as planning for the Kumbh begins.

Our recommendations to promote antimicrobial stewardship at the Kumbh Mela are summarized in Table 1.

Table 1. Recommendations to promote antimicrobial stewardship at the Kumbh Mela, the world's largest mass gathering.

Intervention	Impact on antimicrobial stewardship
Highly protocolized triage by mid-level providers (task sharing)	Clinically stable patients not requiring medications are discharged with symptomatic management and patient education
Point-of-care diagnostics (technology)	Targeted, rapid diagnostics may prevent unwarranted prescriptions of antibiotics or help better target therapy
Physician education (training)	Simple, user-centered clinical protocols can guide appropriate antibiotic prescription
Technological assistance (technology)	Benchmarking of one's antibiotic prescription rate against peers acts as a behavioral nudge that rationalizes prescribing practice
Patient education (training)	Patient-facing education initiatives address the patient expectations that drive the demand for antibiotics in the Indian context

1. Task Sharing

All clinics are staffed by trained allopathic physicians. As epidemiological data from these 70,000 patient encounters have consistently shown, patients at the Mela often present with low-acuity symptoms, many of which likely warrant no diagnostics or therapeutics, and most likely do not need the attention of a physician—especially one that has been drawn away from a busy clinic elsewhere in the state in order to participate in a fleeting patient encounter.

In recent years, the Ministry of Health and Family Welfare has been promoting task sharing with mid-level practitioners and with trained nonallopathic physicians. Given what is known about the epidemiology of patient presentations at the Mela, highly protocolized triage by mid-level providers, community health workers, and senior medical students can identify patients who do not require any intervention, as well as those that require a detailed physician review. Patients who meet predefined criteria for clinical stability can be discharged. Such task sharing allows for a more effective allocation of limited physician resources. Fewer patient encounters per physician may reduce decision fatigue, which also contributes to antibiotic initiation [20].

2. Point-of-Care Diagnostics

The proposed task shifting will enable richer doctor-patient interactions for those who have been identified by first-line providers as needing additional attention. Physicians at previous Melas spent less than 3 minutes per patient encounter, often prescribing antibiotics without examining the patient [9]. Previous Melas have also been characterized by a lack of diagnostic capacity, with no laboratory or radiology services outside of the central referral hospital [9]. As a result, only 0.3% of patient encounters at the 2013 Mela used x-rays and almost none received blood tests [9]. The absence or underutilization of diagnostic testing may lead to well-intentioned but inappropriate initiation of empirical antibiotic therapy. Many diagnostic tests, including radiography and rapid antigen testing, for example, can now be performed at the point of care. Such diagnostics must be considered for an appropriately triaged subset of patients in whom empiric therapy cannot be justified.

3. Regulating Antibiotic Prescription

Promoting the appropriate use of antibiotics remains a significant challenge, and multiple approaches have been tried around the world. A multipronged approach will be necessary to promote antibiotic stewardship at the Kumbh Mela.

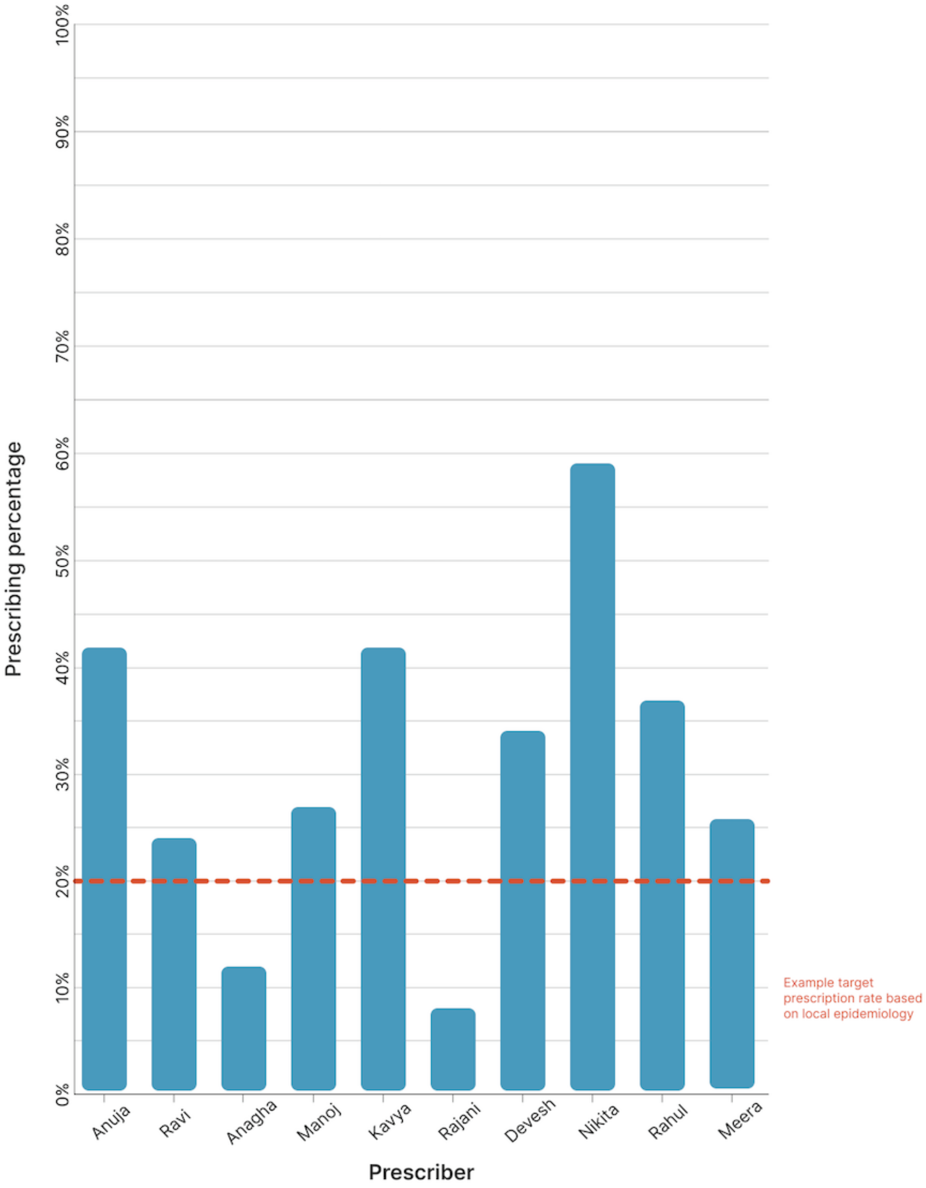
Physician Education

Sustained provider education, streamlined clinical decision support systems, standardized treatment algorithms, and behavioral nudges are core components of antimicrobial stewardship programs [21]. The Kumbh Mela, which runs for several weeks, provides unique access to large numbers of physicians visiting from around the state. The education of prescribers involved in antibiotic use is a core pillar of antibiotic stewardship [21]. Training them in simple, user-centered clinical treatment protocols with standardized thresholds for antibiotic initiation in the weeks leading up to the Mela may help streamline clinical decision-making and promote the rational use of antimicrobial agents. Resources permitting, following a cohort of these physicians over time as they return to their hometowns may offer insights into the sustainability of these interventions and their generalizability to antimicrobial stewardship programs in India at large. Of note, the current policy of providing a 3-day supply of antibiotics for ailments diagnosed at the Mela should be reexamined, as it risks both overtreating patients without bacterial infection and undertreating those that do. In the case of pneumonia, for example, society guidelines in India and abroad recommend at least 5 days of antibiotic therapy [22,23].

Technological Assistance

The Mela provides an excellent opportunity to build on prior successes with lightweight, mobile digital health tools to promote sustainable antimicrobial use. An electronic medical record, which has already been successfully deployed at previous Melas in the form of a tablet-based app, will allow for performance scores and quality metrics related to rates of antibiotic prescribing. Anonymized benchmarking of providers against their peers may serve as an effective behavioral nudge to rationalize prescribing practice (Figure 3). The use of electronic prescribing, as envisioned by the Ayushman Bharat Digital Health Mission (ABDHM), and clinical decision support tools embedded within the electronic medical record could further support good prescribing practice [24]. These initiatives can inform broader efforts to regulate antibiotic sales in India, which is characterized by high levels of over-the-counter dispensing of antimicrobial agents [25].

Figure 3. Proposed end-of-the-day feedback to prescribers at the Kumbh Mela demonstrating their prescribing practices compared to their peers and to a validated benchmark of expected antibiotic utilization, according to local epidemiology.



Patient Education

A particular challenge in the Indian context is that of patient expectations that drive demand for antibiotics, and risk aversion among providers, leading to inappropriate initiation of empiric antibiotic therapy [26]. The Mela provides an ideal opportunity for initiating a conversation about antibiotic use with the broader public, as has been done with other themes at previous Melas (eg, the 2015 Kumbh Mela was designated as an eco-friendly “Harit Kumbh” [Green Kumbh], with a focus on sustainability [27]). Awareness campaigns at congregation spaces and in the vicinity of clinics are likely to be noticed.

Limitations and Ethical Considerations

Digital tools may facilitate responsible antibiotic prescribing through education, monitoring, and surveillance, but they must be combined with other core elements of antimicrobial stewardship, including a strong commitment to stewardship by local and national health authorities, as well as ongoing reporting and feedback [21]. The proposed digital tools will work best as part of the local and national commitment to antimicrobial stewardship.

Ethical issues surrounding digital tools and data privacy in health care records must be considered [28]. In India, there has been a robust debate regarding the governance framework for health data exchange in light of the ABDHM [28]. Similar digital tools to the ones proposed above have been deployed at previous iterations of the Mela without undermining individual privacy [8-10]. Peer-based benchmarking of antibiotic prescription rates will require anonymized and aggregated prescribing data to allow for supportive and nonpunitive learning opportunities [28]. Such anonymization is at least theoretically possible within the digital architecture proposed by the ABDHM.

Future Directions

Despite the scale of the threat posed by AMR, stewardship activities have been difficult to implement not just in India but across the world. India continues to be the world's largest consumer of antibiotics, but there is limited evidence to guide antimicrobial stewardship activities in the Indian context [3]. The government's support for task shifting and focus on technology and public angst over the state of health care in the aftermath of the COVID-19 pandemic provide an impetus for change. Given the tens of millions that are expected to converge at the Kumbh Mela in Allahabad in 2025, bold measures to combat antibiotic overuse and AMR are urgently required. The Mela offers a unique opportunity to deploy and validate digital interventions in an environment with multiple stressors and can act as a catalyst for sustained, larger-scale interventions across the Global South. Lessons learned from the Kumbh Mela may also inform antimicrobial stewardship activities at other organized mass gatherings, such as the Hajj in Saudi Arabia, which face similar challenges related to antibiotic overuse [29,30].

Acknowledgments

We thank the medical student volunteers from the Rotaract Club of the Caduceus, Mumbai, for their role in data collection at the 2013 and 2015 Kumbh Melas, as well as Sujata Saunik, principal secretary of the Public Health Department at the 2015 Mela. Joseph Nallen provided graphical assistance.

The 2013 and 2015 Kumbh Mela studies were supported by grants from the Lakshmi Mittal and Family South Asia Institute at Harvard University and UNICEF (United Nations Children's Fund), Mumbai.

Abstract

Waterpipe tobacco smoking (WTS) is a traditional tobacco use method that originated in the Eastern Mediterranean Region (EMR) and has resurged in recent decades. WTS rates in the EMR are the highest worldwide, especially among youth, exceeding cigarette-smoking rates in select jurisdictions. Despite its documented harm, the growing prevalence of WTS has been met with a poor regulatory response globally. At the epicenter of the WTS epidemic, countries in the EMR are in urgent need of effective tobacco control strategies that consider the particularities of WTS. A roundtable session, titled “Monitoring and Combating WTS Through Taxation and the Global Tobacco Surveillance System (GTSS),” was held as part of the 7th Eastern Mediterranean Public Health Network’s regional conference. The session provided an overview of evidence to date about WTS policy control, the taxation of WTS, volumetric choice experiments for tobacco control research, and monitoring WTS patterns and control policies among adults and youth through the GTSS. The session highlighted the need to update the regulation of WTS in the current global tobacco control policy frameworks and the need for developing tailored, evidence-based, and WTS-specific regulations to complement current tobacco control policy frameworks. Raising taxes to increase the price of tobacco products is the single most effective tobacco control measure, and these taxes can fund expanded government health programs. The effectiveness of taxation can be measured via volumetric choice experiments, which allow for the estimation of a complete set of own-price and cross-price elasticities that are instrumental for fiscal policy simulations. Finally, the surveillance of WTS (for example, through the GTSS) is critical to informing policy and decision makers. The Global Youth Tobacco Survey (GYTS) and Global Adult Tobacco Survey (GATS) are 2 GTSS products that provide nationally representative data among students aged 13-15 years and persons ≥15 years, respectively.

Introduction

The Eastern Mediterranean Region (EMR) has the lowest average prices of tobacco products among all World Health Organization (WHO) regions [1] and is the only region in which smoking prevalence has been projected to increase by 2025 [2]. However, there is little research on the economics of tobacco, and the majority of demand elasticities estimates for tobacco products are for cigarettes [3]. In a recent report on the performance of cigarette tax policies, the EMR as a whole had the second lowest score [4].

Waterpipe tobacco smoking (WTS) is a traditional tobacco use method that originated in the EMR [5], and its use continues to increase globally, especially among youth and young adults [6-8], exceeding cigarette-smoking rates [9]. Despite its documented harm, including its link with lung cancer [9], respiratory illnesses, periodontal diseases, and low birth weight [10], the growing prevalence of WTS has been met with a poor regulatory response globally [9]. At the epicenter of the WTS epidemic, countries in the EMR need effective tobacco control strategies that consider the specific particularities of WTS.

Article 6 of the WHO Framework Convention on Tobacco Control (FCTC) supports taxation, and where appropriate, pricing policies, to curb the use of tobacco products [11]. Additionally, the MPOWER policy package of effective tobacco control policies stresses that raising the price of tobacco products through taxation is the most effective way to reduce smoking [12]. However, evidence to date has been largely limited to cigarettes, and thus, evidence to support fiscal measures to curb WTS is scarce. This evidence gap was acknowledged in a 2015 WHO advisory note and more recently in a National Cancer Institute monograph on the economics of tobacco control [13]. A limited number of published studies exist on the economics of tobacco control in the EMR. For the most part, these studies have generally focused on examining cigarette smoking. Given that WTS prevalence exceeds that of cigarette smoking among certain populations in the region, there is a need for models that more accurately capture WTS particularities. For example, the WHO recommends considering scenarios where taxation is on the individual user (at the consumer level) and possibly taxing the waterpipe parts and accessories [14].

In addition to the importance of raising taxes on tobacco products, the MPOWER policy package stresses the importance of monitoring tobacco use, as it is a cross-cutting activity and involves periodically collecting nationally representative population-based youth and adult data on key indicators of tobacco use [12]. To that end, and to assist countries in establishing tobacco surveillance and control programs, the WHO, US Centers for Disease Control and Prevention (CDC), and Canadian Public Health Association initiated the Global Tobacco Surveillance System (GTSS) [15]. The GTSS aims to build the capacity of countries to plan, implement, monitor, and evaluate tobacco control interventions, providing central targets and indicators for the WHO FCTC and the WHO MPOWER technical package, including exposure to mass media campaigns and cost-related indicators [15]. Currently, the GTSS collects data through the Global Youth Tobacco Survey (GYTS), the Global School Personnel Survey, the Tobacco Questions for Surveys (TQS), and the Tobacco Questions for Surveys of Youth (TQS-Youth) [15]. With the Global Adult Tobacco Survey (GATS) being the nationally representative household survey among individuals 15 years of age or older [16], GTSS data can be used to inform policy makers about the tobacco problem in their country, leading to new policy decisions on tobacco prevention and control.

This viewpoint aims to report on the learnings of a roundtable session that focused on the various evidence-based WTS policies; describe the methods used to assess the price elasticity of demand for WTS and the cross-price elasticity between cigarettes and WTS in Lebanon, Jordan, Palestine, and Egypt; and explain how the GTSS can provide important data for the EMR countries on WTS use and related WHO MPOWER policy measures, including exposure to mass media campaigns and cost-related indicators.

Roundtable Description

A roundtable session was held on November 17, 2021, as part of the 7th Eastern Mediterranean Public Health Network's regional conference to discuss the most recent evidence on WTS in the EMR, including monitoring and controlling demand through taxation. The roundtable included oral presentations and an interactive discussion of questions and comments from participants. The following topics were presented to address the roundtable objectives: WTS policy control, taxation of WTS, volumetric choice experiments (VCEs) for tobacco control research, and monitoring WTS and control policies among adults and youth through the GTSS.

Waterpipe Tobacco Control Policy: Evidence to Date

Mainly driven by youth uptake, WTS has increased over the past 2 decades in many countries around the world, including in the EMR [17]. Factors that may have contributed to the increased use and prevalence of WTS include the introduction of flavoring with reduced harshness, the misperception of it being healthier than other tobacco products, its affordability, the quick lit charcoal, the allure of WTS on social media, the social acceptance of waterpipe cafes, the lack of waterpipe-specific policies and regulations, and the immigration patterns from countries with a high prevalence of use to low-prevalence countries [17]. Some unique features of WTS include the fact that it is a stationary and time-consuming tobacco use method, with the usual duration of each session lasting 30 minutes or more [18-20], often used in dedicated cafes and restaurants; flavor is the main product focus; and sharing it with others is a dominant product feature. WTS involves several accessories, including charcoal, the hose, and the device itself, and is self-assembled.

A systematic review of interventions for WTS concluded that there is a lack of evidence of the effectiveness for most waterpipe control interventions, with few showing promising results, and recommended that higher-quality interventions are needed [21].

The FCTC is an international health treaty adopted by the World Health Assembly in 2003. The WHO FCTC is largely based on evidence collected from cigarette policy effectiveness [22]. Although this framework may help in the regulation of other tobacco products, the global rise in their prevalence, particularly WTS [6], has introduced a number of issues [23]. The expansion of producers, exporters, and manufacturers of waterpipe tobacco and accessories poses a significant challenge to WTS legislation.

This is in stark contrast to the tobacco industry, which is dominated by a few global corporations [24]. WTS also has distinct characteristics from cigarette smoking, such as the use of charcoal briquettes, a large apparatus and hose available in a variety of sizes, and a diverse range of tobacco flavors and packaging modes, all of which may necessitate an alternative regulatory mechanism to supplement the current WHO FCTC–recommended framework [25].

Existing regulations must be adapted to effectively address WTS, in addition to the need for waterpipe-specific legislation to meet these unique difficulties. For example, current tobacco control policy frameworks in many jurisdictions do not define whether health warning labels should be applied to waterpipe apparatuses and other accessories, and if they do, there is no guidance on how to use them in practice [26]. This is essential because persons who smoke at waterpipe-serving establishments are rarely exposed to waterpipe tobacco packages; instead, they are only offered a waterpipe apparatus [26]. Despite this, the health warning labels on present waterpipe tobacco packets include a number of deceptive characteristics [27], including incorrect ingredients labeling [28], and do not follow the WHO FCTC's guidelines [29]. The introduction of dangerous waterpipe tobacco alternatives (called "herbal" or "nontobacco"), which may be excluded from tobacco control legislation but are sold and consumed alongside waterpipe tobacco and may be indistinguishable from it, further complicates matters [30].

There are regulatory gaps in place to regulate WTS across the world, and these gaps could jeopardize existing tobacco control strategies. There is a chance to assess current and prospective policy alternatives for reducing WTS and use that information to establish a new tobacco control policy framework. Tobacco control researchers play a vital role in providing policy makers with the necessary evidence to propose effective legislation. The WHO FCTC secretariat should consider establishing a scientific working group to explore WTS regulatory concerns and propose a complementary framework to the WHO FCTC. Countries that bear the brunt of the load of tobacco-related diseases and have experience in regulating WTS should be involved [31].

When it comes to reducing the uptake of smoking among young people, tobacco product costs are an important aspect to consider because decreasing affordability is the most effective strategy [32]. To minimize tobacco consumption, the WHO FCTC proposes that taxation policies consider the price elasticity of demand, and that all tobacco products be taxed equally to avoid unexpected consequences such as product substitution [2].

Taxation of WTS

There are direct costs associated with tobacco use, including health care cost to treat tobacco-related diseases, and non–health care costs, such as transportation to a clinic and the time of family members providing care [33]. There are also indirect costs of tobacco use, associated with the reduction in potential economic productivity due to morbidity and premature mortality [33,34]. Additionally, there are 3 types of societal costs: external, internal, and indirect. External societal costs are the costs that tobacco users impose on others such as through secondhand smoking. Internal societal costs result from the information failures in the market that can be thought of as external costs. Indirect societal costs are costs paid by tobacco users and their families, incurred as a result of tobacco (eg, out-of-pocket costs for health care to treat diseases caused by smoking) [33]. The latest estimates of the total worldwide economic cost of tobacco smoking are above US $1.4 trillion (2012), which is 1.8% of the world's annual GDP [34]. Direct health care costs alone are estimated at US $443 billion dollars, whereas indirect costs, incurred due to the loss of productivity as a result of morbidity and mortality, are estimated at US $357 billion and US $657 billion, respectively [34].

Taxation is an evidence-based tool for tobacco control. First, taxation promotes public health. Depending on the tax structure, taxation can have a higher impact on demand among vulnerable individuals such as the young population, whose demand is more elastic than the demand of older adults. This is also true for less educated and low-income individuals who are disproportionately affected by the burden of tobacco smoking. Second, taxation is an efficient revenue generation strategy for governments as smoking is relatively inelastic, where consumers have a lower behavioral response when the price is raised compared to products with higher elasticity [35]. Third, from a societal perspective, taxation corrects for the external costs of tobacco borne by members of society other than the smoker.

There is a substantial body of research over many decades and from many countries, showing that significantly increasing the excise tax and price of tobacco products to reduce their affordability is the single most consistently effective tool for reducing tobacco use [13]. There are a variety of tobacco taxes used: some are based on sales taxes or value-added taxes; some are in the form of customs duties on tobacco leaf and product imports or exports; and some are implicit taxes when governments monopolize production and distribution. There are also excise taxes, which are of the most interest given their specificity to the tobacco products. Excise taxes are of 2 types. The first type is the specific tax, which is based on the weight or volume of the tobacco used. The benefit of this type of tax is that it reduces price gaps, deters tax avoidance, is easy to administer, and stabilizes tax revenue. The second type of excise tax is ad valorem, which is based on the commercial value of the product. The benefits of the ad valorem tax are that it adjusts with inflation and is progressive, imposing higher taxes on higher-priced products (ie, taxes higher-income individuals). However, it leads to greater price gaps and incentivizes tax avoidance.

Early efforts to examine the price elasticity of demand for noncigarette products have provided sufficient evidence of the effectiveness of tax and price increase in decreasing demand. A systematic review concluded that there is positive substitution between cigarette and noncigarette products, suggesting that tax and price increase should be simultaneous and comparable across all tobacco products [36].

The Eastern Mediterranean Consortium on the Economics of WTS is an ongoing project examining the economics of WTS. This is a collaboration between the American University of

Beirut, Jordan University of Science and Technology, Birzeit University, and Ain Shams University and is funded by Cancer Research UK and the International Development Research Centre (IDRC). In its most recent study, the Consortium examined the price elasticities of waterpipe tobacco products and cigarette products [3]. The WHO FCTC recommends that the price elasticity of demand be taken into account in taxation policy to reduce tobacco use [2]. The price elasticity of a product measures how sensitive the demand for it responds to a change in its own price (own-price elasticity) or in the price of other related products (cross-price elasticity) [37]. Overall, the price elasticity observed for WTS and cigarette smoking varied by product and across countries, with the demand for premium cigarettes being price elastic (range −1.0 to −1.2) and that for premium waterpipe tobacco being highly elastic in Lebanon (−1.9), moderately elastic in Jordan (−0.6), and inelastic in Palestine (0.2) [3].

VCEs for Tobacco Control Research

The methodology that was used to guide the research of the Eastern Mediterranean Consortium on the Economics of WTS includes VCEs for tobacco control research. All economic problems are rooted in the issue of choices that need to be made as resources are scare (opportunity cost). Choices reveal information about preferences of consumers, which is instrumental for understanding the costs and benefits attendant to health policies and interventions. This informs how responsive consumers would be reacting to changes in prices. The most obvious avenue to observe choices, and thus preferences, is to observe market choices, using the revealed preference methods. The methods involve collecting market data and inferring measures of demand and preference intensities mainly through the vehicle of elasticities. The advantage of these methods is that they have a high face validity as they rely on real-life data [38]. However, in some situations, it is limited by the lack of availability of products, that is, it cannot measure choice preference for products that do not exist on the market. Therefore, economists sometimes rely on observing hypothetical choices by means of stated preference (SP) methods. These methods present consumers with hypothetical products and collect what they state they will buy at experimentally varied prices [39]. However, these methods lack consequentiality, often resulting in respondents inflating their willingness to purchase and pay for the products under study (hypothetical bias) [39].

The most common SP approach used in marketing and economic research is discrete choice experiments (DCEs), which are an attribute-based, hypothetical, and survey-based tool for measuring preference and value [40,41]. DCEs incorporate the notion of opportunity cost and choice. DCEs can be disadvantageous in the demand analysis of certain products such as WTS. Therefore, VCEs were developed as an alternative to the SP methods. DCEs force respondents to choose one and only one option, which is often restrictive compared to real market situations. VCEs, in contrast, accommodate simultaneous choices of multiple options and accommodate “quantitative” or “volumetric” choices (ie, the number of units selected). It does this by simultaneously offering multiple distinct volumetric choices across competing products. Data from Jordan, Palestine, and Lebanon show the elasticity of demand for waterpipe tobacco products and the existence of substitution between tobacco products, which should be considered when formulating tobacco taxation strategies [42]. Thus, VCEs allow for the estimation of a complete set of own-price and cross-price elasticities that are instrumental for the purpose of fiscal policy simulations [3]. This technique is useful in forecasting how consumers will respond to policies that increase the prices of products such as tobacco and by how much such policies may increase revenue to governments. This is illustrated in a study where the elasticity estimates from the VCE were fed to a simulation model that was adapted to forecast the effects of taxation policies. Specifically, the model used country-specific and market share–specific price and consumption data from the WHO and United Nations (UN) Comtrade, in addition to the VCE’s elasticity estimates obtained from nationally representative surveys conducted in Lebanon, Jordan, and Palestine. It then forecasted the effects of specific excise taxes, which met a 35.9% tax burden on waterpipe tobacco in Lebanon and Jordan (in line with the global average) and doubled government revenues from excise duties in Palestine [43].

Monitoring WTS and Control Policies Among Adults and Youth Through the GTSS

As COVID-19 spread in the EMR, there was a renewed focus on curbing smoking as 17 countries/sites temporarily banned WTS in indoor and outdoor public places during the pandemic [44]. Additionally, the CDC, in collaboration with the Eastern Mediterranean Public Health Network and Vital Strategies, launched the “United Against Tobacco and COVID” campaign in Jordan, Egypt, Iraq, and Palestine. This project aimed to warn on the harms of tobacco, in accordance with the MPOWER policy package recommendations [12]. The project intended to raise awareness of the harms of smoking, especially during the COVID-19 pandemic, through media coverage. This project used evidence-based information and data to develop country-tailored and culturally appropriate messages to disseminate, educate, and promote smoking cessation to reduce COVID-19 morbidity and mortality.

This campaign, similar to all antitobacco interventions, programs, and policies, relied on accurate measures of tobacco use to determine the target audience as well as the target messages that need to be addressed within each county. Indeed, to plan any tobacco control strategy or intervention effectively, counties need accurate data to inform implementation and increase the likelihood of success.

One approach of obtaining such data is through globally standardized surveys such as the GTSS, which systematically monitors youth and adult tobacco use as well as key tobacco control indicators (the WHO FCTC and MPOWER) [15]. It also monitors and enhances the capacity to design, implement, and evaluate tobacco control policies. The GYTS, a nationally representative school-based survey of students aged 13-15 years, is the largest public health surveillance system ever developed and maintained [22]. The survey is self-administered in the classroom setting using a paper-and-pencil questionnaire [22]. It contains a core questionnaire with optional modules for countries to add additional questions. Between 1999-2020, the GYTS was implemented in 188 countries/sites [45]. This standard, systematic, and consistent process generates comparable data within and across countries. The GYTS *Shisha (or Waterpipe)* module is an optional module that can be used [46].

These collected surveillance data are helpful in designing, guiding, monitoring, and evaluating tobacco control interventions, programs, and policies at the country level. One key goal for such data is to highlight the extent of the tobacco epidemic in countries, including WTS, and thus generate interest and support for tobacco control policy, and those for WTS, among key policy makers and stakeholders. For example, if policy makers are considering a smoke-free ban, data will serve to educate stakeholders about the extent of exposure to secondhand smoke within the country and thus support the ban.

Additionally, using surveillance data to understand the tobacco market within a country is one of the strategies to ensure that tobacco taxation, including taxation on WTS, is effective. Surveys enable the identification of changes in consumption patterns so that existing policies can be adjusted accordingly. Authorities might ask for more information on certain aspects such as consumption patterns and attitudes toward WTS among youth. This information is crucial to assess the tobacco industry’s marketing power and can inform discussions on elasticities.

In the EMR, GYTS WTS data are available from 20 countries/sites from 2005 to 2016. Table 1 provides the prevalence rates of current WTS among students aged 13-15 years in these 20 countries/sites. The overall prevalence rates ranged from 34.8% in Lebanon (2011) to 3.8% in Morocco (2016). The prevalence rates were significantly higher among boys than girls in all but 2 countries/sites.

The GATS is a nationally representative household-based face-to-face interview survey of individuals aged 15 years or older, using a global standard protocol and electronic data collection methodology [16]. It similarly includes a core questionnaire with optional questions and options for countries to add additional questions [16]. Since 2008, the GATS has been implemented in 36 countries representing more than 70% of the world’s adult population [22]. It contains WTS core questions including *Current WTS* and *Frequency of WTS*, as well as an optional WTS module [16].

In the EMR, GATS WTS data are available from 4 countries from 2009 to 2019. Table 2 provides the prevalence rates of current WTS among individuals aged 15 years and older in these 4 countries. The prevalence rates were as follows: 6.7% in Saudi Arabia in 2019 (9.7% males and 2.3% females); 3.4% in Qatar in 2013 (4.9% males and 1.6% females); 3.3% in Egypt in 2009 (6.2% males and 0.3% females); and 3.0% in Pakistan in 2014 (4.7% males and 1.1% females).

Unfortunately, monitoring rates through standardized national population-based surveillance surveys vary by country income group, with better coverage achieved in higher-income countries. As per the WHO’s most recent global report on trends in the prevalence of tobacco use from 2000-2025, the lowest population coverage by such surveys is in the EMR, with only 88% of the population living in 76% of the EMR having sufficient available data to calculate tobacco use trends [2].

To that end, the TQS is beneficial. The TQS includes a subset of 22 key questions from the GATS for adults [47], and the TQS-Youth contains a subset of 21 key questions from the GYTS for youth [48]. These questions are integrated into ongoing surveys (health or otherwise, such as the WHO Stepwise Approach to Surveillance surveys) for sustainable monitoring and global consistency. Between 2008 and 2021, 100 countries completed surveys with TQS integration.

However, in addition to the data that are collected by the standardized surveillance surveys, policy makers may require data about the composition of tobacco and WTS products, including flavors and their production and marketing costs by brand. This additional information can provide a better understanding of the market power, market share, and behavior of the tobacco industry within a country. It can also inform discussions on elasticities, including how consumers choose specific brands or flavors.

Table 1. Prevalence of current waterpipe smoking among students 13-15 years old, by sex—Global Youth Tobacco Survey, Eastern Mediterranean Region countries/sites, 2005-2016.

Country/site (year)	Current waterpipe smoking			
	Overall (%)	Boys (%)	Girls (%)	*P* value (boys vs girls)
Lebanon (2011)	34.8	39.3	31.0	.03
Jordan (2014)	26.7	34.5	18.4	.001
Syria (2010)	19.2	24.7	13.8	.04
Bahrain (2015)	18.3	26.1	10.2	.001
Palestine—West Bank (2016)	17.9	23.4	12.4	.001
Qatar (2013)	17.1	24.6	10.1	.001
Palestine—Gaza Strip (2013)	16.2	22.0	11.1	.01
Yemen (2014)	14.1	17.1	9.3	.001
Kuwait (2016)	13.9	19.5	9.0	.001
United Arab Emirates (2005)	12.4	16.3	7.6	.001
Djibouti (2013)	11.6	10.2	12.8	.20
Iran (2016)	11.2	14.3	8.5	.03
Iraq (2014)	10.6	15.1	5.3	.01
Sudan (2014)	9.9	13.0	5.4	.01
Saudi Arabia (2010)	9.5	13.3	6.1	.04
Oman (2016)	7.4	11.6	3.7	.03
Egypt (2014)	5.9	7.2	4.1	.09
Tunisia (2010)	5.8	10.1	2.1	.001
Libya (2010)	4.3	6.0	2.6	.001
Morocco (2016)	3.8	5.0	2.6	.04

Table 2. Prevalence of current waterpipe smoking among individuals aged 15+ years, by sex—Global Adult Tobacco Survey, Eastern Mediterranean Region countries, 2009-2019.

Country (year)	Current waterpipe smoking			
	Overall (%)	Male (%)	Female (%)	*P* value[a] (males vs females)
Saudi Arabia (2019)	6.7	9.7	2.3	.001
Qatar (2013)	3.4	4.9	1.6	.001
Egypt (2009)	3.3	6.2	0.3	.001
Pakistan (2014)	3.0	4.7	1.1	.001

[a] Significance at $P<.05$

Conclusion

This paper provides an overview of WTS regulatory and surveillance issues in the EMR and discusses examples of success in taxation at the level of the consumer as well as the methods used to assess the feasibility and effectiveness of taxation on demand. The immense need to collect data on WTS using the GTSS was also stressed, to enable policy makers to make better informed decisions.

Recommendations and Key Areas for Improvement

- There is a need to update the regulation of WTS in the current global tobacco control policy frameworks.
- There is a need to develop tailored and evaluated WTS-specific regulatory frameworks to complement current tobacco control policy frameworks.
- Raising taxes to increase the price of tobacco products is the single most effective tobacco control measure, and this also applies to WTS.
- Increased taxes from WTS can fund expanded government health programs.

- VCEs allow for the estimation of a complete set of own-price elasticities and cross-price elasticities for WTS products, which is instrumental for the purpose of fiscal policy simulations.
- Gaining political buy-in is key to adopting key tax reforms relating to tobacco and WTS, and to this end, data from standardized validated surveillance systems are crucial.
- Data collection on WTS through the GTSS is critical to inform and sensitize policy makers and decision makers from the EMR about the public health and socioeconomic burdens caused by WTS, as well as the growing use among females and youth.
- The GYTS and GATS can provide nationally representative data among students aged 13-15 years and ≥15 years, respectively, on WTS, and countries can include an optional waterpipe module.
- As a cost-effective measure, and to ensure some data on WTS are being collected, it is suggested to include the TQS on WTS within other surveys that countries are already implementing.
- Data on WTS that are generated from the GYTS and GATS are the most valuable when disseminated in a way that will gain the attention of key stakeholders, especially policy makers and the media, as they are the most important audience if these data are to cause a ripple effect. Effective data dissemination is crucial, and so is engaging partners to help translate important information to key decision makers, who have the authority to change tobacco control policy.

Acknowledgments

The authors would like to thank Mr Jeremy Morton (Global Tobacco Control Branch, Office on Smoking and Health, US Centers for Disease Control and Prevention [CDC]) for his valuable insight and input during the roundtable discussion.

Data Availability

Data sharing not applicable to this paper as no data sets were generated or analyzed during the current study.

Abstract

Background: The higher movement of people was one of the variables that contributed to the spread of the infectious agent SARS-CoV-2 during the COVID-19 pandemic. Governments worldwide responded to the virus by implementing measures that would restrict people's movements, and consequently, the spread of the disease. During the onset of the pandemic, the technology companies Apple, Google, and Meta used their infrastructure to anonymously gather mobility reports from their users.

Objective: This study aims to compare mobility data reports collected by Apple, Google, and Meta (formerly Facebook) during the COVID-19 pandemic and a major winter storm in Texas in 2021. We aim to explore the hypothesis that different people exhibit similar mobility trends during dramatic events and to emphasize the importance of this type of data for public health measures. The study also aims to promote evidence for companies to continue releasing mobility trends data, given that all 3 companies have discontinued these services.

Methods: In this study, we collected mobility data spanning from 2020 to 2022 from 3 major tech companies: Apple, Google, and Meta. Our analysis focused on 58 countries that are common to all 3 databases, enabling us to conduct a comprehensive global-scale analysis. By using the winter storm that occurred in Texas in 20201 as a benchmark, we were able to assess the robustness of the mobility data obtained from the 3 companies and ensure the integrity of our findings.

Results: Our study revealed convergence in the mobility trends observed across different companies during the onset of significant disasters, such as the first year of the COVID-19 pandemic and the winter storm that impacted Texas in 2021. Specifically, we observed strong positive correlations (r=0.96) in the mobility data collected from different tech companies during the first year of the pandemic. Furthermore, our analysis of mobility data during the 2021 winter storm in Texas showed a similar convergence of trends. Additionally, we found that periods of stay-at-home orders were reflected in the data, with record-low mobility and record-high stay-at-home figures.

Conclusions: Our findings provide valuable insights into the ways in which major disruptive events can impact patterns of human mobility; moreover, the convergence of data across distinct methodologies highlights the potential value of leveraging mobility data from multiple sources for informing public health decision-making. Therefore, we conclude that the use of mobility data is an asset for health authorities to consider during natural disasters, as we determined that the data sets from 3 companies yielded convergent mobility patterns. Comparatively, data obtained from a single source would be limited, and therefore, more difficult to interpret, requiring careful analysis.

Introduction

The COVID-19 pandemic has affected people worldwide and presented major public health challenges for authorities. Early in 2020, shortly after the emergence of SARS-CoV-2, many countries imposed restrictive measures to limit the movement of populations, and consequently, limit the spread of SARS-CoV-2 infections and the COVID-19 disease [1]. To aid in evaluating the effect of restrictive measures, the tech industry rapidly responded by offering tools to quantify the movement of people using anonymized mobility data. In fact, higher movement patterns have been directly associated with COVID-19 transmission [2-4], rendering this measurement a powerful tool for public health authorities to understand the dynamics of populations when facing a disaster.

With the onset of COVID-19, tech companies, including Apple, Google, and Meta, provided data sets throughout the pandemic, with each company using different methodologies for obtaining mobility data. Such data can be used by scientists and health authorities to understand transmission patterns, identify hotspots, and potentially effectively control outbreaks. The importance of this data is seen as it provides a real-time snapshot of population dynamics. For instance, it was suggested that the early introduction of the B.1.1.529 (ie, Omicron) SARS-CoV-2 variant in Mexico was facilitated by higher movement observed in the end-of-year celebrations [5]. Moreover, in Canada, a so-called successful pandemic management was attributed to the fact that the movement patterns of people were highly reduced during the initial waves of SARS-CoV-2 [6]. Higher transmission of SARS-CoV-2 in India was attributed to an urban exodus of city dwellers that had to return to their villages after lockdown policies were implemented [7]. Apart from COVID-19, crisis management in other natural disasters can benefit from mobility data. For example, in the aftermath of the cyclone Gaja in south India (November 2018), mobility data were used to visualize where displaced people were relocating, so humanitarian efforts could be directed to those areas [8]. Importantly, the in- and outbound flow of people in particular areas during significant events can be quantified by services that capture mobility trends [9].

Comparing distinct data can provide a more comprehensive understanding of mobility trends, which can be crucial for public health measures. Data are commonly seen as abstractions of the real world. For instance, in applications that benefit from data, there is generally a need to promote validation with external data [10]; this reality is widely explored in clinical settings [11], genomic studies [12], among others. Consequently, a model that can react similarly upon different inputs strengthens the conclusions that are derived from such data.

This study aims to explore the hypothesis that different people exhibit similar mobility trends during dramatic events, such as the outbreak of an infectious disease or climatic disasters, and that these trends can be captured by companies such as Apple, Google, and Meta using distinct collection methodologies. To test this hypothesis, the study will compare mobility data reports collected by these companies during the first year of the COVID-19 pandemic and a major winter storm that hit Texas in 2021. Additionally, the study will observe mobility trends in countries with varying shares of the mobile operating system (MOS) penetration market. The ultimate goal of the study is to emphasize the importance of these types of data for public health measures and to provide evidence supporting the continued release of mobility trends data by companies, given that all 3 companies have discontinued these services.

Methods

Apple Mobility Trends Reports

Apple collected daily data from January 13, 2020, until April 14, 2022, in 63 countries or regions [13]. The company obtained the number of anonymous requests for directions (walking, driving, or using public transportation) made to the Apple Maps application, native to Apple's MOS. The collected information was then compared against itself to reflect a change in the volume of people moving, in some cases including a minimum threshold for directions made per day. As of today, the data are not available any longer within the company website.

Google Community Mobility Reports

Google made use of insights obtained from processing data from Google Maps, the company's location service, to provide a response to health authorities regarding COVID-19 [14]. The data were collected from 15 February 15, 2020, to October 13, 2022. The mobility reports encompass data from 135 countries or regions with major metropolitan areas also included. A baseline was established using the data accumulated during the 5-week pre-pandemic period from January 3, 2020, to February 6, 2020. Whenever a user who chose to enable their location services visited a categorized location on Google Maps on a specific date, an anonymous record was assigned. The data were split into the following 6 categories: grocery and pharmacy, retail and recreation, parks, workplace, residential, and public transportation. Even though the company is no longer releasing updated data, their previously collected data set is publicly available within the company's website.

Movement Data From Meta

Non-public data were obtained from Meta [15] as part of an agreement with Dalhousie University. Meta collected data from 198 countries and territories from February 22, 2020, until May 22, 2022. Major regions targeted by Meta were divided into defined units (600 m^2 600 m^2). Whenever a user had location services enabled and moved between 2 units, a movement record was assigned. Regions with 300 or less qualifying users in a 24-hour period were disregarded. A pre-pandemic baseline was established for each country; however, no details of the individual calculation of the baseline are present in Meta's documentation.

2021 US Winter Storm

In 2021, a major winter storm struck North America. In the state of Texas, which hardly ever records snowfall, weather stations in the Dallas-Forth Worth airport recorded at least 139 hours of freezing or below freezing temperatures, characterizing an uncommon phenomena in the region [16]. During the storm, officially, a death toll of 151 was reported. The estimated cost of the storm in Texas was around US $295 billion dollars. For control purposes, we selected the state of Georgia as a representative state that recorded no snowfall in the period of February-March 2021. We inquired snowfall precipitation to data collected from the National Center for Environmental Information, which enables precipitation records of several weather stations in the Southern United States.

MOS Penetration Data

We obtained data from the service StatCounter Global Stats [17] to select the market penetration of the MOS for Apple's iOS and Google's Android. The service is composed of bots installed in over 1.5 million websites. The bots gather stats on operating systems that are accessing a particular website. In this work, we selected the month of April 2022 to analyze the market share of different MOSs, which is when the first tech company (ie, Apple) stopped their mobility data collection. A total of 58 countries were analyzed, which were the countries present in all 3 mobility data sets. A breakdown of the countries is available in Multimedia Appendix 1.

Data Processing and Statistical Analyses

Each one of the 3 companies provided their data in daily batches, which we treated in 7-day periods. As the data from the 3 companies followed different magnitudes, a scaling process was performed by using the scale function in R (version 4.1.2; R Foundation for Statistical Computing). The function calculates the mean and standard deviation of a vector then removes the mean from each element and divides it by the standard deviation. For comparison purposes, we selected the countries that were shared between the 3 data sets.

The statistical analyses performed in this study included Shapiro-Wilk test for data normality, Pearson correlation, as well as *t* test and Wilcoxon rank test for mean comparison. These analyses were performed using the R programming language (version 4.1.2; R Core Team) under the package rstatisx (version 0.7.0). All figures generated in this study were created using the R package ggplot2 (version 3.3.6).

Ethical Considerations

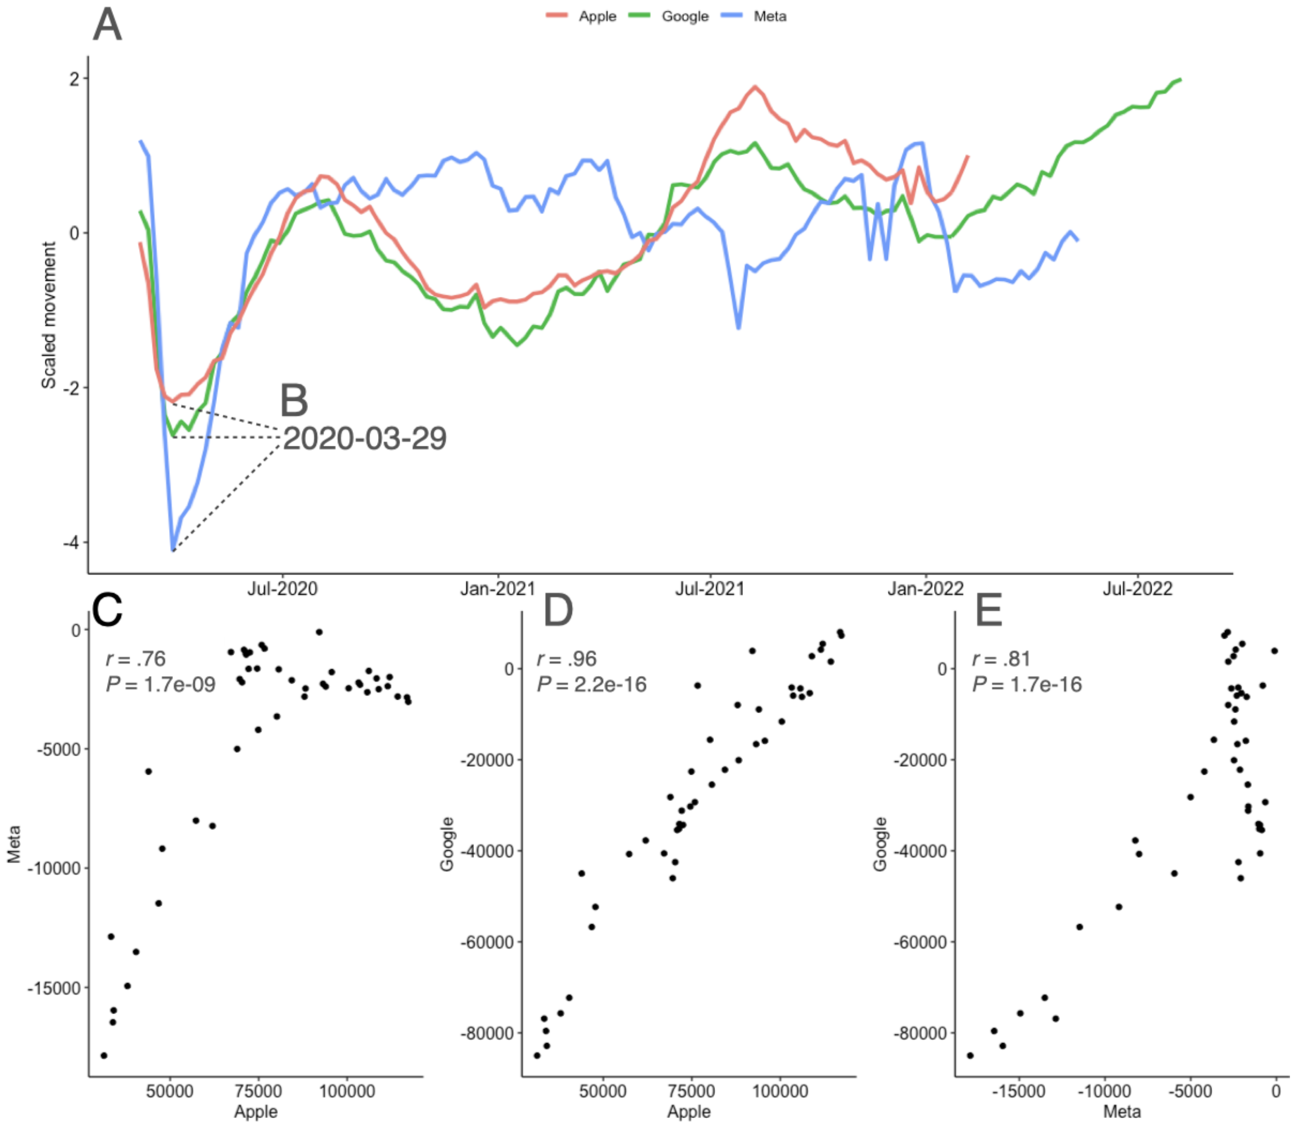
The data collected from Apple, Google, and Meta users were already sampled, anonymized, and depersonalized. Data sources from Apple and Google are publicly obtainable; on the other hand, data from Meta are not publicly available. We, as research partners with Meta, have access only to data formatted to prevent reidentification, which we obtained through a partnership between Meta and author DJK (a licensee at Dalhousie University). Moreover, as users, we commit to using these data only for the purposes outlined in our agreement with Meta and we ensure that any conclusions drawn from these data are based on solely scientific practices.

Results

Mobility Data Well Represent the Initial Onset of the SARS-COV-2 Pandemic

We used the data from the mobility reports of 58 countries collected by Apple, Google, and Meta to perform a comparative analysis to analyze people's movements throughout the first year of the pandemic (ie, 2020; Figure 1). First, we noted the time series of each data collection methodology (ie, company) following the same trend (Figure 1A). Next, we analyzed the point at which each data set presented the lowest mobility score in the first year of the pandemic (Figure 1B). In 2020, the lowest mobility point for the 3 data sets (Figure 1A) occurred on March 29, 2020 (Figure 1B). Next, we performed a correlation analysis on the 3 data sets to depict their convergence or disparity (Figure 1C; Figure 1D, and Figure 1E); we report positive correlations for Apple versus Meta (r=0.76), Apple versus Google (r=0.95), and Google versus Meta (r=0.87), when comparing the data.

Figure 1. The 2020 mobility patterns from Apple, Google, and Meta across 58 countries. We selected the 58 countries that were present in the data from Apple, Google, and Meta. (A) From these countries, the year 2020 was isolated, and a mobility score for each company was assigned and later plotted. (B) The lowest mobility trend indicated in 2020 occurred in the same week for all 3 data sets, on March 29, 2020. (C) Next, we performed a Pearson correlation analysis of the data from Apple versus Meta, (D) Apple versus Google, and (E) Google versus Meta.



The 2021 US Winter Storm Reflects in the Convergence of Mobility Data

We analyzed the movement data from Apple, Google, and Meta to determine the rate of individuals staying at home and not moving during the 2021 winter storm in the state of Texas. Figure 2A shows the period of the storm (depicted by the red-dashed rectangle), indicating low records in movement recorded by the 3 companies. We found the lowest mobility point occurred with no more than a week between each data set, specifically on February 21, 2021 (Apple), February 19, 2021 (Google), and February 14, 2021 (Meta). Additionally, we determined stay-at-home data from Google residential and Meta single tile users (represented by the grey dotted lines in Figure 2); these data were not available for Apple. Both companies noted record highs for stay-at-home data during the same days when record-low mobility was recorded. For control purposes, we selected the dates with the lowest mobility from each data set and compared them with data from the state of Georgia, which presented no snowfall precipitation during the 3 aforementioned days (Multimedia Appendix 2). In Figure 2B, we show that Georgia, unlike Texas, did not record a downfall in data on the dates of February 14, 19, and 21. Moreover, in Table 1, through a 2-sampled statistical test comparing the averages of mobility data from Apple, Google, and Meta over Texas and Georgia, we found low *P* values (Apple and Google: *P*<.001; Google and Meta: *P*=.005).

In Table 1, we present a comparison of the average movement during the months of January and February 2021 in the states of Texas and Georgia. The time series were found to be predominantly normally distributed through Shapiro-Wilk tests (Texas: *P*=.71 for Apple; *P*=.38 for Google; and *P*=.78 for Meta; Georgia: *P*=.71 for Apple; *P*=.04 for Google; and *P*=.51 for Meta). Moreover, the 2-sampled statistical comparison of the averages achieved by a 1-tailed *t* test resulted in statistically significant differences among all comparisons.

Figure 2. Record-low mobility trends recorded during a major winter storm in Texas in 2021. (A) Mobility data in the US state of Texas during the year of 2021. The negative area of the y-axis, indicating movement of data from 3 different tech companies—Apple (green solid line), Google (blue solid line), and Meta (orange solid line)—is considered. The data have been scaled to accommodate different magnitudes. The positive area of the y-axis indicates stay-at-home data, enabled only by Google (light dotted line) and Meta (dark dotted line). We also indicate the period in which a major winter storm in Texas took place (red dashed rectangle), from February 13 to 17, 2021. (B) A control version of part A, for the US state of Georgia. The state of Georgia presented no snow precipitation in the period from February 13 to 17, 2021.

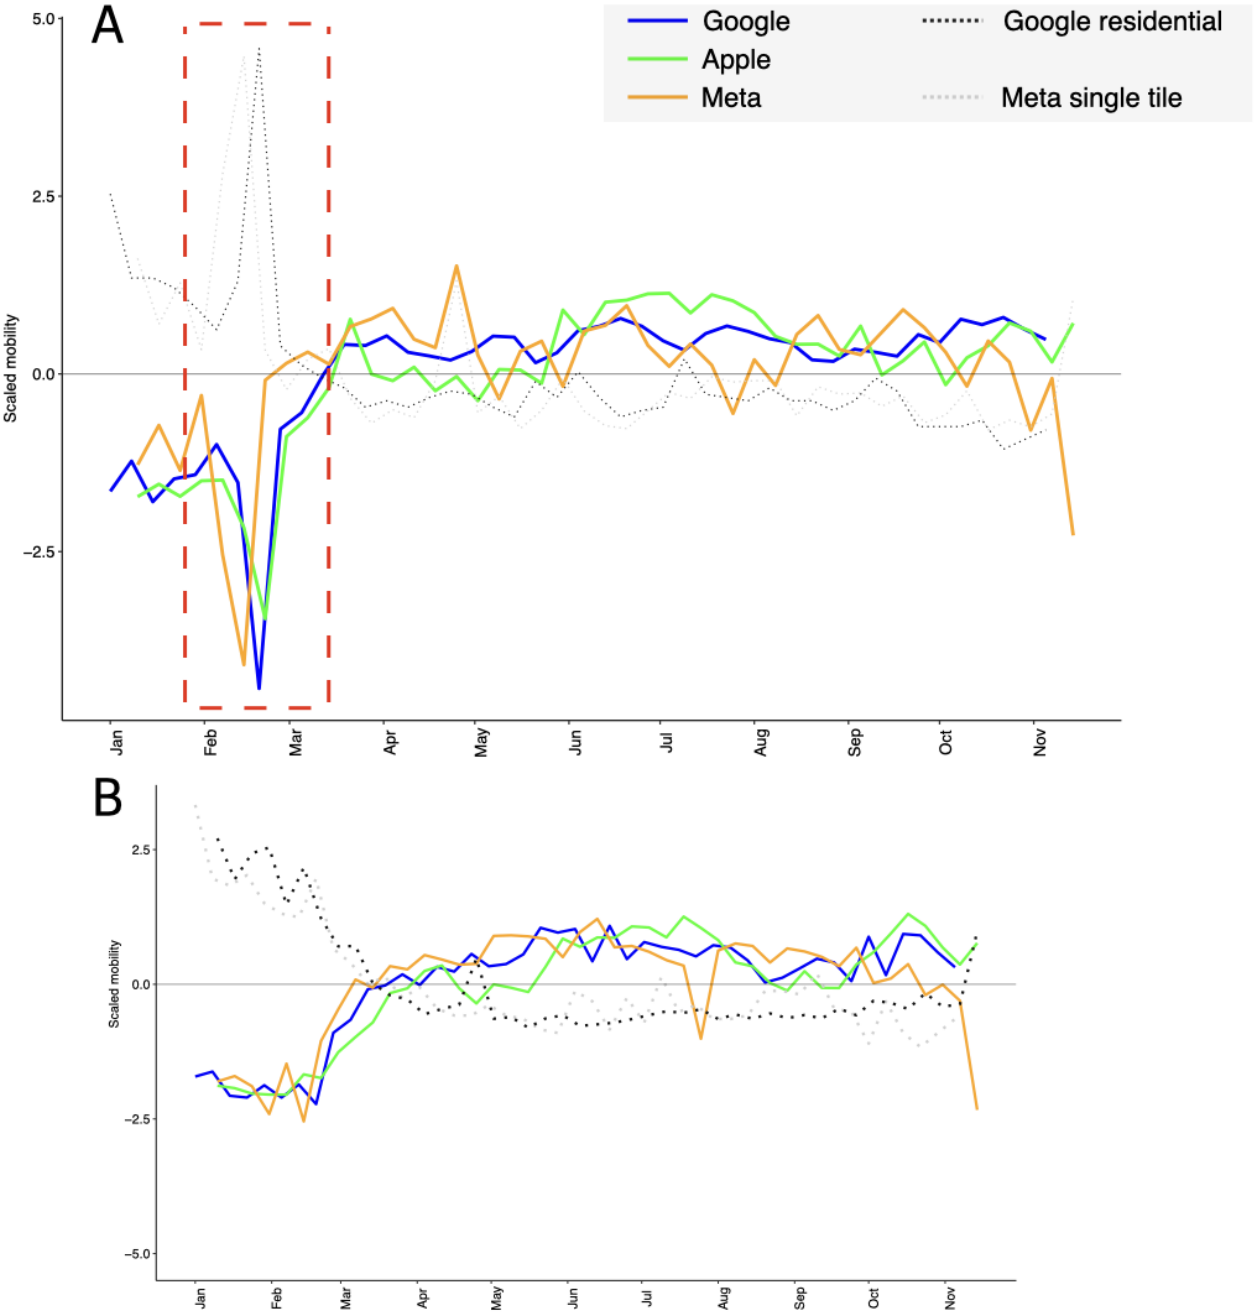


Table 1. Mean comparison of mobility trends during the Texas 2021 winter storm.

Data sets for 2 US states	Mobility average (January to February 2021)	*P* value
Apple		<.001
Texas	215147	
Georgia	135228	
Google		<.001
Texas	–497.4	
Georgia	–250.8	
Meta		.005
Texas	–3.15	
Georgia	–0.81	

Countries With Varied Market Penetration of MOS Have Convergent Mobility Data

To determine if the predominance of an MOS would affect how mobility was recorded, we assessed the market share of mobile users regarding iOS (Apple) and Android (Google) from 54 countries that were common in the mobility data of Apple, Google, and Meta. We found that Android was the predominant platform in India, Argentina, Indonesia, Colombia, and Brazil, with greater than 90% of mobile internet access in April 2022, whereas iOS (Apple's MOS) was the most popular platform in 5 countries—Japan, Denmark, Norway, United States, and Australia (67.6%, 60.3%, 59.3%, 57.8%, and 57.6%, respectively). To assess convergence or disparity between data collection methodologies, we individually correlated the 3 data sets in each country. In Figure 3, we present the time series data from the 5 iOS-predominant countries. The correlation table of these countries' data is found in Table 2. The lowest averaged correlation was found in the United States (0.73, impacted by reduced correlation in the data of Apple and Meta), while the highest averaged correlation was found in Australia (80.66).

Also, in Figure 3, countries with Android predominance are shown and their correlation is presented in Table 2. First, we report an overall convergence in the mobility data collected by Apple and Google (ie, 0.85 average correlation across all the 10 countries considered). Second, we report a higher convergence between the data of Google and Meta (compared to Apple and Meta) in Android-dominated markets (except for Indonesia). This relationship may be attributed to the fact that Facebook is a third-party app that runs on an MOS, which in these countries is Android, thereby boosting the number of devices from which Google collects data. Finally, data from Apple was not as correlated with Meta as Google's data in the iOS-prevalent countries, potentially due to the still higher proportion of Android devices being used in these countries.

Figure 3. Comparison of mobility time series data from Apple, Google, and Meta in distinct countries. We selected the first 5 countries where Android is the most predominant mobile operating system (alphabetically, Argentina, Brazil, Colombia, India, and Indonesia) and the first 5 countries where iOS is the most predominant mobile operating system (alphabetically, Australia, Denmark, Japan, Norway, and the United States) according to data obtained from StatCounter Global Stats [17].

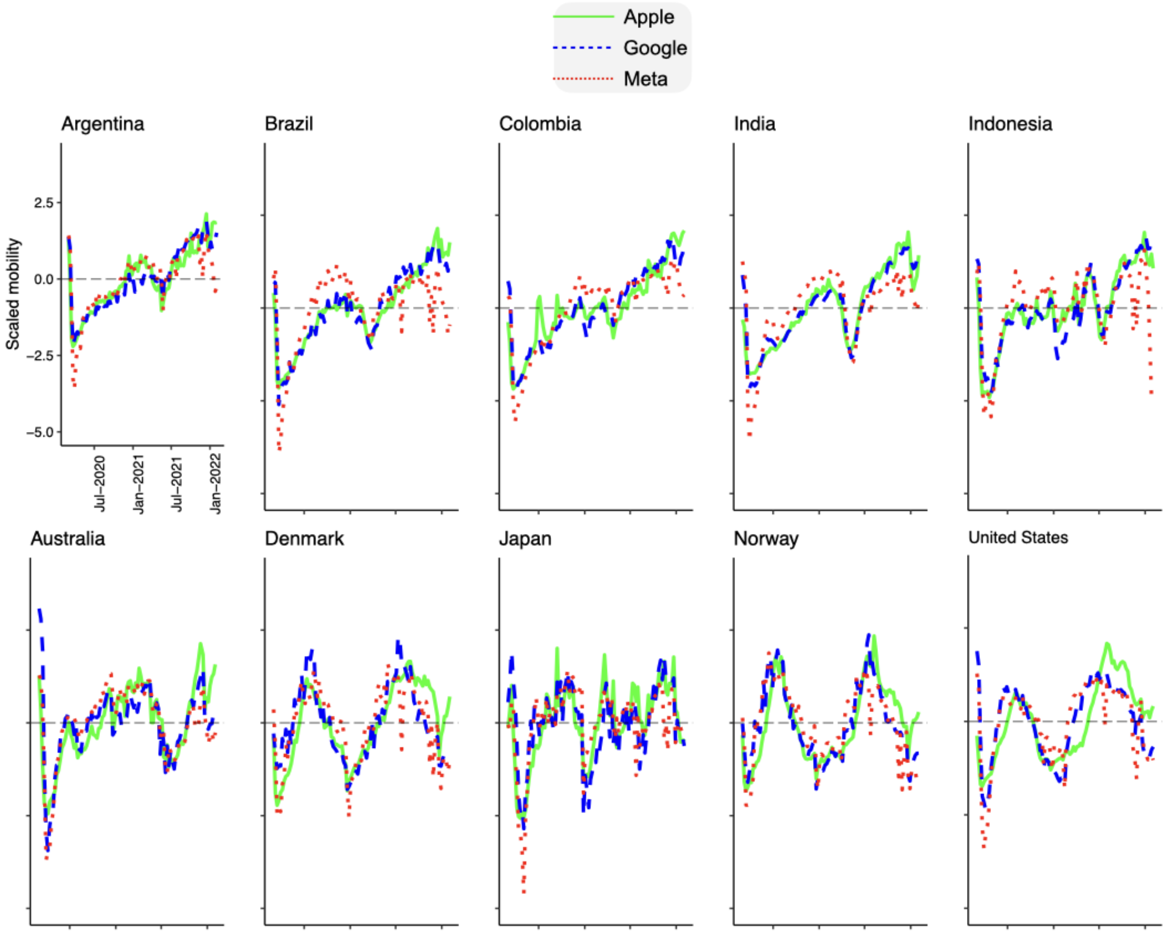

Table 2. Correlation coefficients between data sets in different countries. To compare the time series between each data set, we performed Pearson correlation analyses for the iOS-prevalent countries and Android-prevalent countries.

Country	Comparison			Mobile operating system predominance
	Apple vs Google	Apple vs Meta	Google vs Meta	
Argentina	.91	.77	.84	Android
Brazil	.96	.68	.75	Android
Colombia	.91	.81	.86	Android
India	.95	.77	.84	Android
Indonesia	.93	.69	.64	Android
Australia	.78	.76	.88	iOS
Denmark	.76	.72	.79	iOS
Japan	.79	.76	.75	iOS
Norway	.84	.68	.87	iOS
United States	.71	.59	.89	iOS

Discussion

Principal Findings

In our work, we depicted a convergent behavior in mobility data gathered by distinct data collection methodologies independently of the popularity of MOSs. First, we showed that even over a longer 2-year time span, there is still a similar trend in mobility patterns, as evidenced by the moderate-to-strong correlation analyses in data collection from 3 distinct companies. Moreover, we observed that the mobility data converged more during events that required people to change their movement trends (ie, lockdowns, to avoid the spread of SARS-CoV-2; and a major winter storm that forced people to stay at home), granting this type of measure to be an asset for public health decisions.

We attribute the fact that we observed an alike behavior on data collected by different sources to 2 potential phenomena. First, when people are affected by a catastrophic event, such as the pandemic and the 2021 winter storm in Texas, their mobility and lifestyle will drastically change [10,18]. Considering a large number of people are experiencing the same stressor, the limited ways they develop to cope with stressful events, such as loneliness and social isolation, as reported by Hwang et al [19], will eventually converge. Moreover, it was reported in India and in the United Kingdom that a massive urban exodus took place during the pandemic, forcing many city-working young adults to have to return to their hometowns [20,21], despite being from different backgrounds, their mobility patterns might have converged once they were forced out of their workplaces. In this viewpoint, we argue that this convergence results from people developing ways to cope with their stress and will eventually be reflected in people moving in similar patterns. Next, users of distinct MOSs, whose data are being collected by distinct companies, might not significantly differ in terms of their movement patterns. In fact, behavioral similarities were previously reported among Android and iOS users, adding consistency to our analysis [22].

As a limitation of our study, we acknowledge that we did not have access to general mobility data from periods outside the pandemic, as these data were not being collected. Without these data, it was challenging to establish a solid baseline for comparison during and outside pandemic periods. It would have allowed us to gain a better understanding of the extent to which the observed behavior changes were driven by the pandemic itself or if they represented more general changes in human behavior over time. Furthermore, although smartphones have become increasingly prevalent in recent years, they do not represent the entire population. Therefore, we acknowledge that our sample may not have been a representative of the entire population. Specifically, individuals who do not own smartphones or have limited access to the internet might have different mobility patterns than those who do. Therefore, it is essential to consider the limitations of our sample when interpreting the results of our study. We believe these changes would lead to more robust policy and decision-making in public health.

The Data for Good portal [15], maintained by Meta with infrastructure from the company, provides a valuable data source for public health offices, as it collects data to support and inform efforts to tackle humanitarian and environmental challenges. As such, it is an asset for public health decision makers. For example, the company has been actively releasing their data at times of natural disasters to help inform decision makers, including during the flooding in Samar Island, Eastern Visayas, Philippines; the flooding in Southern California on January 5, 2023; the flooding in Makassar City, South Sulawesi, Indonesia; and the wildfire in Viña del Mar, Valparaíso, Chile, among others. As shown by our results, during these catastrophic events, the behavior of people might converge. Thus, the analysis of people's movement might help answer important questions of public interest to reduce the impact of these events when they happen again.

Conclusions

In our study, we observed that movement data collected under distinct methodologies by different tech companies presented a convergent aspect in depicting catastrophic events in which the movement of people was majorly impacted. The similar behaviors exhibited by different people facing similar stressors add reliability for these types of data, which would be an important asset upon which public health measures could rely. Thus, based on our results, we encourage Apple, Google, and Meta to continue releasing these types of data.

Abstract

Exposure notification applications (ENAs) or digital proximity tracing apps were used in several countries during the COVID-19 pandemic. In this viewpoint, we share our experience of implementing and running the Finnish ENA (Koronavilkku), one of the national ENAs with the highest proportion of users during the pandemic. With the aim of strengthening public trust and increasing app uptake, there was a strong prioritization of privacy and data security for the end user throughout the ENA development. This, in turn, limited the use of the app as a tool for health care professionals and deeper insight into its potential effectiveness. The ENA was designed to supplement conventional contact tracing, rather than replace it, and to serve as an early warning system and a trigger for action for the user in case of potential exposure. The predefined target of 40% uptake in the population was achieved within 3 months of the ENA launch. We consider easy-to-understand information produced together with communication experts crucial during the changing pandemic situation. This information educated people about the app as one component in mitigating the pandemic. As the pandemic and its mitigation evolved, the ENA also needed adapting and updating. A few months after its launch, Finland joined European interoperability, which allowed the ENA to share information with ENAs of other countries. We added automatic token issuing to the ENA as of mid-2021. If added earlier and more comprehensively, automatization could have more effectively saved resources in health care services and prevented overburdening contact tracing teams, while also notifying potentially exposed individuals quicker and more reliably. In the spring of 2021, the number of active apps started to gradually decline. Quarantine and testing practices for asymptomatic vaccinated individuals following exposure to the virus were eased and home tests became more common, eventually replacing laboratory testing for much of the population. Taken together, this led to decreased token issuance, which weakened the potential public health usefulness of the app. A self-service option for token issuance would likely have prolonged the lifespan of the app. The ENA was discontinued in mid-2022. Regularly conducted surveys would have helped gain timely knowledge on the use and effectiveness of the app for better responding to the changing needs during the pandemic.

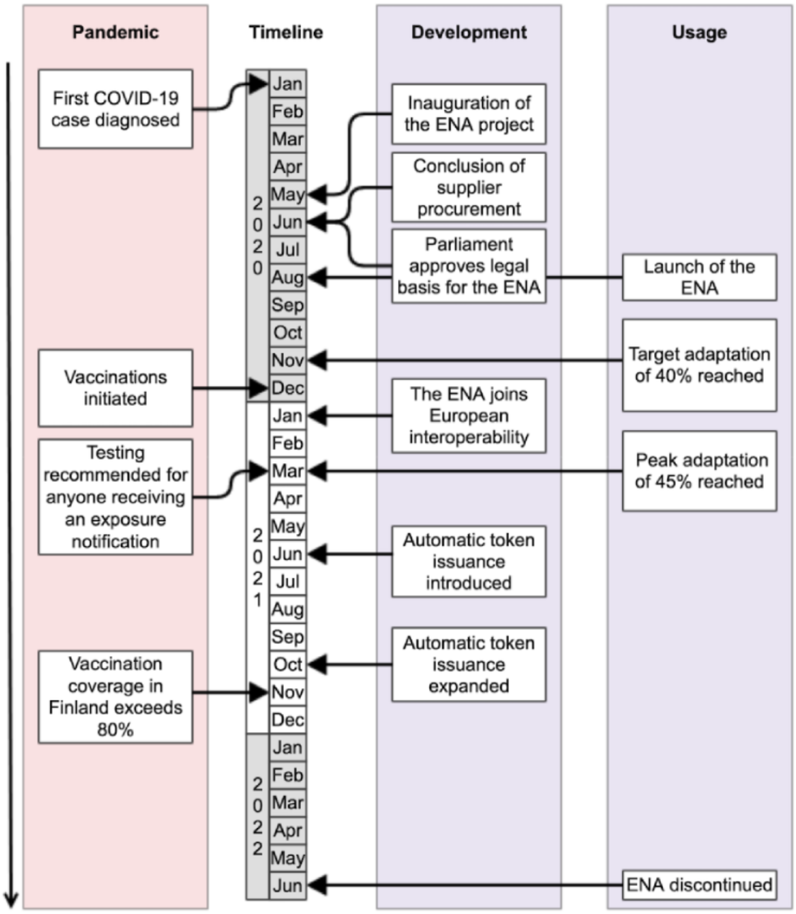
Introduction

Large-scale rollouts of digital proximity tracing (DPT) and exposure notification apps (ENAs) were undertaken hastily in several countries during the COVID-19 pandemic. It is important to gather and document the lessons learned in the process for possible similar situations in the future. In this viewpoint, we share our experiences of implementing and running the Finnish ENA (Koronavilkku). We base our account on the first-hand experiences of developing and maintaining the national ENA that were discussed at the final project workshop. We refer to feedback received from the public, health care professionals, and decision makers during the app's lifetime.

SARS-CoV-2 started to spread in the Finnish population at the end of February 2020 [1]. Like in many countries, in mid-March 2020, the government declared a state of emergency and introduced restrictions due to the coronavirus outbreak [2]. In early April, the European Commission adopted a recommendation on the use of mobile technology to control the COVID-19 pandemic [3], and the Finnish government initiated legislation work related to a national app later that month (Figure 1). The aim of the mobile app would be to promote public health by empowering everyone to participate in breaking SARS-CoV-2 transmission chains, as part of the government's strategy to combat the COVID-19 pandemic [4].

Figure 1. Timeline of key events in Finland during January 2020 to June 2022, related to the COVID-19 pandemic mitigation and the development and use of the Finnish COVID-19 exposure notification application (ENA).



Defining the Aims and Functionality of the ENA

According to the temporary law, the Finnish app would be voluntary and free for the public to use [5]. These principles are in line with findings in a review on best guidance for DPT apps [6]. The national legislation and the European guidelines defined the handling of personal data and directed the Finnish app to use a decentralized model and the Google and Apple Exposure Notification system without collecting location data [5,7]. Privacy and data security concerns have been raised by the public in studies on acceptability [8,9]. Local legislation is needed to ensure suitable and specific safeguards for privacy and data protection to gain public trust [10,11].

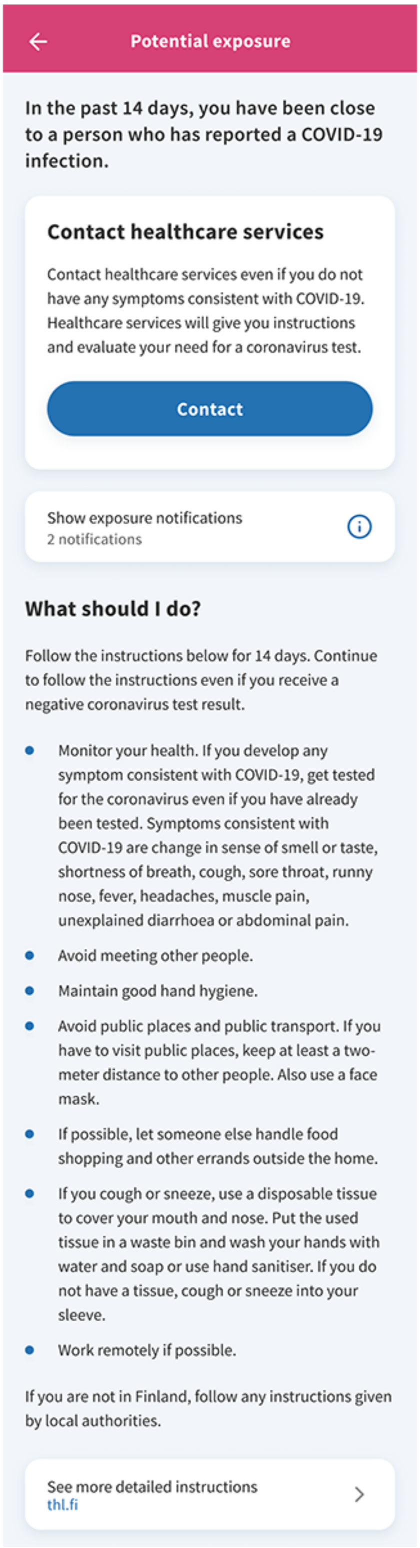
The Finnish app was divided into a mobile app and a backend system [12]. The mobile app calculated the exposure risk based on encounter duration, distance, and the presumed infectivity of the case. If a defined risk threshold was exceeded, the app notified the user of a potential exposure and provided further instructions. This functionality for sending and retrieving identifiers and matching them was similar in all decentralized ENAs in the European Union (EU) [13].

Based on early simulated models on potential for infection control [14,15], a high app download rate by the public was deemed more important than making the app a tool for health care professionals. In a simulation, a 56% app coverage would end the pandemic in the modelled country [14]. At that time, app coverage in other countries was up to 38% [16]. The project steering committee set the objective to 40% of the population in Finland, to have a concrete and realistic target coverage to mitigate the pandemic.

The app was designed to supplement conventional contact tracing, rather than replace it, and to serve as an early warning system and a trigger for end user action. The aim was that upon receiving an exposure notification, the user would change his or her behavior according to the guidance given by the app, and thus, break transmission chains (Figure 2). The instructions were kept in synchronization with the national guidelines.

Already in the planning stage, it was decided that we should emphasize privacy and maximize app uptake, which imposed limits on the development but gave a clear focus to the work. After the launch, several independent data security experts, including the National Cybersecurity Center, evaluated the app against the privacy concerns that had been discussed in the media [17,18]. We believe that the focus on privacy and data security, as well as the open communication about this aim, was instrumental in gaining public trust. The importance of upholding public trust to increase app uptake is consistent with other studies [19]. Distrust and a perceived lack of transparency can increase the belief in inadequate design, and in turn, decrease belief in app effectivity and app adoption [20]. Privacy concerns among the public are understandable, as many COVID-19–related apps required numerous rights, like access to photos, location, or microphone [21].

Figure 2. The guidance shown to users of the Finnish COVID-19 exposure notification app upon receipt of an exposure notification during March 4, 2021, to June 16, 2021. The instructions were updated in line with the national guidelines.



In the past 14 days, you have been close to a person who has reported a COVID-19 infection.

Contact healthcare services

Contact healthcare services even if you do not have any symptoms consistent with COVID-19. Healthcare services will give you instructions and evaluate your need for a coronavirus test.

Show exposure notifications
2 notifications

What should I do?

Follow the instructions below for 14 days. Continue to follow the instructions even if you receive a negative coronavirus test result.

- Monitor your health. If you develop any symptom consistent with COVID-19, get tested for the coronavirus even if you have already been tested. Symptoms consistent with COVID-19 are change in sense of smell or taste, shortness of breath, cough, sore throat, runny nose, fever, headaches, muscle pain, unexplained diarrhoea or abdominal pain.
- Avoid meeting other people.
- Maintain good hand hygiene.
- Avoid public places and public transport. If you have to visit public places, keep at least a two-meter distance to other people. Also use a face mask.
- If possible, let someone else handle food shopping and other errands outside the home.
- If you cough or sneeze, use a disposable tissue to cover your mouth and nose. Put the used tissue in a waste bin and wash your hands with water and soap or use hand sanitiser. If you do not have a tissue, cough or sneeze into your sleeve.
- Work remotely if possible.

If you are not in Finland, follow any instructions given by local authorities.

Development

In most EU countries, ENAs were developed in collaboration between governmental institutions and private software developers [13]. This was also true for Finland, where establishing an ENA required several actors to join forces. The project group consisted of some 2 dozen individuals from the involved organizations. Because of the pandemic-related recommendations to work remotely, meetings were web based, and most team members met in person for the first time only at the final project workshop. One of the key lessons learned was the importance of seamless teamwork. Home organizations were less visible in the web-based meetings and discussions were informal yet structured. This fostered open communication, an excellent team spirit, a low level of hierarchy, and avoided silos, while also engaging project members and their home organizations. In addition to the core project group, nearly 200 individuals worked intermittently on different aspects of the app and related issues.

To support the project group, we set up an expert group of communicable disease physicians representing different municipalities and hospital districts. The group lacked decision-making power, but it was an important organ for keeping in touch with the health care services, where contact tracing was conducted and app tokens issued. The group was informed about the development and consulted on guidance and the calculation of risk factor parameters. The aim was to keep the parameters that defined possible exposure and recommendations in the exposure notifications in line with the national guidelines.

Communication and Deployment

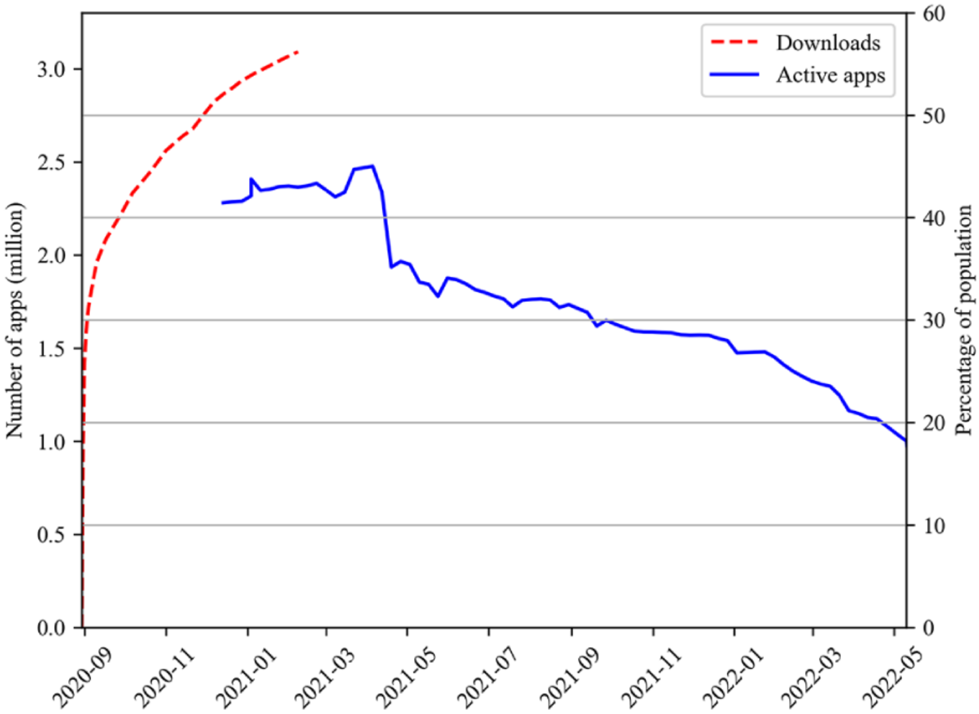
From the start, communication experts planned how to share easy-to-understand information about the ENA with the public. As identified elsewhere, end user benefits of an app and clarifications on how individual privacy will be protected are important to communicate [22]. Communication efforts included a series of public webinars during development and a marketing campaign in connection with the launch, and communication continued throughout the lifetime of the app. The responsibilities of the national COVID-19 helpline were expanded to give advice on the app and its use.

Finland approached advertising the app as part of a bigger strategy against the pandemic and started informing the public about the app at an early stage [13]. However, some other European countries included the public in the development by inviting feedback or carrying out public consultations to generate trust and increase acceptance [13]. Because of time and resource constraints, we were unable to accommodate similar public consultations.

The Finnish ENA was published in late summer 2020 (Figure 1), simultaneously or later than that of many other countries and states [13,23]. Probably largely due to the media attention that the Finnish ENA gained, especially around the launch, the app was downloaded by 1 million users within the first 24 hours. This accounts for nearly a fifth of the Finnish population. In the next 2 weeks, the app reached 2 million users, and the objective of 40% uptake was achieved in early November 2020 (Figure 3) [24]. Over the next few months, the number of active users continued to grow, and by spring 2021, the app had become one of the national or state ENAs with the highest proportion of users [13,25].

The ENA could be used in the 2 official languages of Finland, Finnish and Swedish, and additionally in English. However, some groups were not as frequent users of the app as the general population [26], and making the app available in further languages could have allowed it to have a wider and more inclusive public health impact.

Figure 3. Downloads or active app counts for the Finnish SARS-CoV-2 exposure notification application (ENA) in the period of August 31, 2020, to May 10, 2022. The number of Finnish ENA downloads was collected from mobile app stores. After February 8, 2021, the number of downloaded apps was not followed, as it no longer reflected the number of active apps. Active apps were defined as apps contacting the back end at least once per 24 hours.



Adaptation of the App in an Evolving Pandemic

The ENA was developed on the premise that it would be a short-term app requiring no further releases. In Finland, the legal mandates of several control and mitigation measures related to the COVID-19 pandemic were temporary. If needed, the validity of these laws was extended; during the app's lifetime, its legal basis was extended twice. In the changing pandemic situation, several changes were required in the app.

The project received numerous requests for minor changes and ideas for implementation, and we needed an unbiased method for prioritization and approval of them. Through the use of a structured form, we identified which parts of the app, its backend system or linked information, would be affected; the time and effort required to implement the change; and the estimated public health impact. This helped us reach informed decisions on what to implement.

In the fall of 2020, the national recommendation on quarantine duration was shortened from 14 days to 10 days. In line with this, changes in the app were required, so the duration an exposure notification was visible to the user corresponded with the updated guidelines. Similar changes were implemented 3 times during the lifetime of the app. Other updates were also made, such as a modification to exposure calculations to consider all exposures over the course of a day and changes to the interface to make it more user-friendly; these changes included displaying the number of potential exposures and adding a button to manually launch exposure checking. The motivation for all these updates was to keep the ENA current, attractive, and easy to use, thereby enabling its intended public health impact.

Several European countries launched their own mobile proximity contact tracing and warning apps, and an effort to explore sharing exposure notifications across apps was pursued by the European Commission and the member states [27]. In April 2020, a common approach for contact tracing apps was defined [7], and the first European countries joined the interoperability of apps in October 2020 [28]. Finland joined in early January 2021 (Figure 1) [13].

In accordance with increased laboratory testing capacity for SARS-CoV-2 and an updated national testing strategy [29], testing was extended to asymptomatic users who received an exposure notification, if the local testing capacity allowed (Figure 1). The web-based symptom assessment tool [30] that was linked to the ENA was eventually available for 72% of the population by August 2021. This enabled a majority of the users to book a test using various digital systems or platforms accessible through the internet.

Automatization of Token Issuance

Manual token issuance to laboratory-confirmed COVID-19 cases became an increasing burden on the contact tracing teams in the health care services as the pandemic grew. From the beginning, we recognized that automatization would have been faster, cheaper, and less demanding on health care professionals. Similar observations have also been made elsewhere [31]. We considered automatization unfeasible to implement, due to the decentralized health care and the multitude of information management systems in use. Further, early in the pandemic, there was fear and stigma surrounding contracting COVID-19

[32], and talking to a health care professional was preferred to an automatic text message communicating the positive result of a SARS-CoV-2 test.

We routinely followed the average timespan or delay from symptom onset until app token use, which seemed to depend on the workload of laboratories and contact tracing teams and increased when case numbers grew. This raised concerns about the usefulness of the app in times when fast notification of potential contacts would have been of most importance and made us revisit automatization of token issuance.

Automatic token issuance was pursued as of early 2021 in cooperation with 2 of the largest public health care operators, City of Helsinki and the Helsinki and Uusimaa hospital region, and it was taken into use in June and October 2021 (Figure 1). Tokens could be automatically issued based on digital laboratory results and patient contact information collected during the booking of a laboratory test. This made the process of allowing cases to notify potentially exposed individuals through the app quicker and more reliable, while saving resources in the health care services. Its public health impact would have been even greater if it had started early on. Notifying contacts quickly after exposure substantially affects the effect of quarantine or self-quarantine as a control measure for the spread of SARS-CoV-2 [15,33,34].

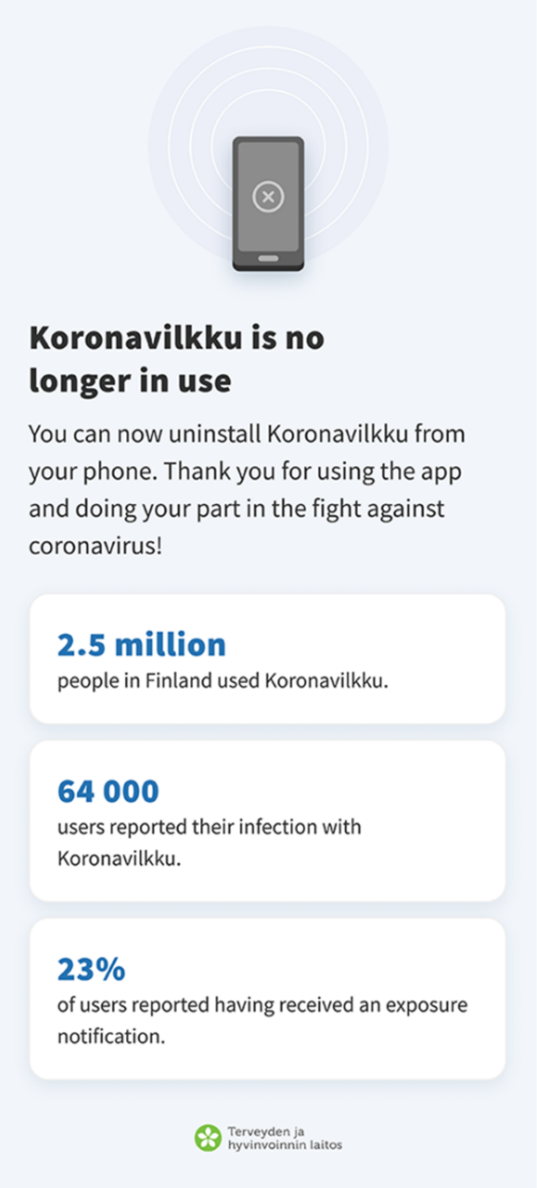
Shutdown

The use of the app slowly dwindled over the year 2021 (Figure 3); the likely reasons were many. Vaccinated individuals were no longer required to observe full quarantine after exposure to SARS-CoV-2 and were not automatically referred to testing if asymptomatic [35]. To many vaccinated individuals, the ENA may have seemed redundant, as the guidance also applied to those who received an app exposure notification [36].

With new SARS-CoV-2 variants causing more transmission, several municipalities and hospital regions stopped issuing app tokens in late 2021 to reduce the workload of contact tracing teams. Home tests for SARS-CoV-2 became more common and gradually replaced laboratory testing for much of the population. Positive home test results could not be registered in the app, as tokens were only issued through health care providers. Implementing a self-service option for token issuance was discussed in Finland and elsewhere [37]. Although it was not feasible for this ENA, self-service options should be considered from the start for any future similar projects to safeguard the longer-term public health use of the app.

We designed the Finnish ENA to gracefully retire by creating a screen that thanked the users and informed them about the shutdown (Figure 4). The ENA was discontinued on June 1, 2022 (Figure 1).

Figure 4. The "Thank you" screen of the Finnish SARS-CoV-2 exposure notification application—Koronavilkku. This screen was shown to users after Finland discontinued the use of the app.



Koronavilkku is no longer in use

You can now uninstall Koronavilkku from your phone. Thank you for using the app and doing your part in the fight against coronavirus!

2.5 million
people in Finland used Koronavilkku.

64 000
users reported their infection with Koronavilkku.

23%
of users reported having received an exposure notification.

Reflections and Recommendations

The development and launch of the Finnish ENA, Koronavilkku, illustrates how a widely used public health app, requiring new legislation, using new technology, and demanding new ways of cooperation, could be successful within a strict time frame. We consider the cornerstones of this success an excellent team spirit, low level of hierarchy within the project, open communication, avoiding silos, and a clearly defined goal. In addition, it required commitment from the project members and their home organizations.

The app was developed with a focus on the end users. Communication and marketing throughout played a key role in ensuring that potential users were familiar with the app, and we believe it contributed to the high number of downloads. Despite this, we received feedback that some health care professionals were disappointed that the app did not provide information to support their contact tracing work. In the literature, mobile apps are considered valuable tools for citizens, health care professionals, and decision makers [38], but there were difficulties in measuring and communicating these potential benefits clearly enough. In retrospect, more resources should have been allocated in the run-up to the app launch to clarify the goal to health care professionals and elaborate on the envisioned role of the app in the larger effort to mitigate the pandemic.

We believe that focusing on privacy and data security in communication and implementation strengthened public trust and, in turn, increased app uptake. However, compared to many other countries, public trust in the national government and public institutions is high in Finland [39]. Building on this trust, it may have been possible to offer the public an ENA that would have collected more information than the current interpretation of the national legislation and EU guidance allowed. In line with this, some user feedback indicated willingness to share more information with the app in exchange for receiving more information about potential exposures. This could have allowed the development of an app using the persuasive design model rather than the control design model that relies on self-monitoring. In another study [19], the persuasive design model, which uses social learning, was found to increase user intention to use the app. Enabling collection of data on exposures could have also benefited health care but would have required transparency and clear communication about the goals of data collection and its intended use. For future similar apps, we recommend enabling the collection of at least aggregated data on the number of exposure notifications generated.

Only some countries have published outcomes on their ENAs [40]. The difficulty of assessing the effectiveness of privacy-preserving DPT apps has been previously raised [23] and was also felt in relation to the Finnish ENA. The restrictions on what information we could collect through the app limited the insight into its potential effectiveness. Evidence of effectiveness may have maintained the number of users for a longer duration by swaying both health care professionals and end users to continue supporting the app. For future similar endeavors, we recommend investing in monitoring and communicating the potential benefits early in the process. If statutory limits constrain the collection of important data, regular surveys can be considered as an alternative to gain some knowledge on the use and effectiveness of such apps.

Other important lessons that we learned along the way include the fact that we did not initially foresee how many updates the app would require as the pandemic and mitigation efforts evolved. Forced updates and feeding text through a dedicated website into the app would have ensured that the guidance to users remained up-to-date, thereby enhancing the potential public health impact of the app. Another lesson learned is how a self-service option or earlier and more comprehensive automatization for token issuing for COVID-19 cases would have eased the burden on contact tracing teams and prolonged the useful lifespan of the app, while also notifying potentially exposed persons quicker and more reliably. Even with lessons learned and reflections on how the app could have been improved, the wide use of the Finnish ENA gave it potential to deliver public health and pandemic mitigation results.

Acknowledgments

We thank all our colleagues who worked on any aspect of the exposure notification application (ENA) or activities related to it for their cooperation and dedication. We acknowledge the users of the app for joining the effort to control the pandemic and for the feedback we received over the course of the lifetime of the app.

The project was funded by the Finnish Government (LTAE III/2020) and an European Union (EU) grant (FINLAND-LC-01590941). Funders had no role in writing or approving this manuscript.

Abstract

The COVID-19 pandemic triggered unprecedented expansion of telemedicine, including in the delivery of opioid agonist treatment (OAT) for people with opioid use disorder (OUD). However, many people with OUD lack the technological resources necessary for remote care, have complex needs, and are underserved, with precarious access to mainstream services. To address the needs of these individuals, we devised a unique program to deliver OAT via telemedicine with the support of community outreach workers in Montreal (Quebec, Canada). The program was co-constructed by the service de médecine des toxicomanies of the Centre hospitalier de l'Université de Montréal (CHUM-SMT)—a hospital-based addiction medicine service—and CACTUS Montréal—a community-based harm reduction organization known and trusted by its clientele. All procedures were jointly developed to enable flexible and rapid appointment scheduling. CACTUS Montréal workers promoted the program, facilitated private on-site telemedicine connections to the CHUM-SMT, accompanied patients during web-based appointments if requested, and provided ongoing holistic support and follow-up. The CHUM-SMT offered individualized OAT regimens and other health services as needed. Overall, our experience as clinicians and community-based workers intimately involved in establishing and running this initiative suggests that participants found it to be convenient, nonjudgmental, and responsive to their needs, and that the implication of CACTUS Montréal was highly valued and integral to patient engagement and retention. Beyond the context of the COVID-19 pandemic, similar programs may present a flexible and accessible means to deliver alternative treatment options for people with OUD disengaged from traditional care, bridge gaps between communities and health providers, and improve access to care in rural or remote settings.

KEYWORDS

opioid agonist treatment; opioid use disorder; medications for opioid use disorder; harm reduction; access to care; retention; telemedicine; telehealth; community-based services; opioid use; remote care; healthcare service; health care service; COVID-19; substance abuse; opioid disorder

Background

The field of telemedicine has a long-standing interest in improving the accessibility and quality of health care for remote and otherwise underresourced communities [1,2]. In response to the COVID-19 pandemic and associated physical distancing measures, the use of telemedicine modalities expanded exponentially to facilitate clinical services for a wide spectrum of health problems [3-5]. Continued integration into regular clinical care is likely, particularly in high-income countries [4,6,7], and could greatly improve service delivery for persons whose circumstances render in-person visits inconvenient or undesirable [7]. A lack of attention to the "digital divide" may, however, exclude groups that have been historically marginalized from experiencing these benefits and could even exacerbate health inequities [7-12]. Additionally, engaging such populations calls for approaches that reduce the social as well as physical barriers to accessing health providers [13-16]. This viewpoint paper describes how integrating a trusted community service into the framework of a hospital-based telemedicine service in Montreal (Quebec, Canada) created a program capable of engaging and retaining vulnerable people with opioid use disorder (OUD) in opioid agonist treatment (OAT) during the COVID-19 pandemic. We recount the success of this program as clinicians and community-based workers involved from its inception and by drawing upon patient testimonials, with a view to inform future service delivery for such populations.

People With OUD, the COVID-19 Pandemic, and OAT Delivery via Telemedicine

People using illicit opioids experience a high burden of disease [17,18] and may be disproportionately impacted by major disruptive events such as a pandemic [19,20], particularly when facing other challenges such as housing instability [21,22]. Apart from risks related to COVID-19 exposure [23], public health responses to the pandemic directly impacted the risk environment shaping drug-related harms [24]: many low-threshold services that people with OUD rely on to meet essential needs or reduce harms associated with drug consumption, such as day shelters and supervised consumption sites, were forced to temporarily close or reduce their capacity, making already scarce resources even less accessible, while pandemic-related prevention measures also affected people's ability to generate income, secure shelter, and obtain safe and secure supplies of drugs [25-29]. In Canada, these combined challenges were reflected in a 95% increase in opioid-related deaths in the first year of the pandemic (April 2020 to March 2021) compared with the year before [30].

Treatment with opioid agonists such as methadone or buprenorphine/naloxone is the first-line treatment for opioid use disorder [31,32] and can be highly effective in reducing illicit opioid use, preventing overdose, and improving multiple other health and social outcomes [18]. Nevertheless, inadequate treatment coverage and poor retention persist worldwide [18,33], with evidence for suboptimal and restrictive delivery practices (eg, inadequate medication dosing, poor access to unsupervised or "take-home" doses, and frequent urine drug screening) in many settings [34,35]. In Canada, as elsewhere, OAT is highly regulated [36] and typically delivered within health institution settings [37]. Prior to the pandemic, an estimated 66% of people who inject drugs nationwide, and 44% of those in Quebec, were receiving OAT [38]. People with OUD in Montreal had called for greater service outreach in places in which they spend their time, while emphasizing increased patient autonomy, flexible scheduling, diversified treatment options, and the implication of peer workers as ways to improve OAT services [39]. Indeed, participants in our program often recounted unsatisfactory experiences with conventional OAT services, describing a lack of responsiveness to their needs and experiences, ineffective communication, an absence of participatory decision-making, and stigmatization, alongside difficulties with medications and dosing, withdrawal symptoms and side effects, and rigid service rules.

OAT delivery in Canada is bound by federal regulations under the Controlled Drugs and Substances Act (CDSA), while provincial and territorial governments regulate the scope of practice for health professionals [40]. Following the declaration of the COVID-19 pandemic in March 2020, federal health authorities issued emergency legal exemptions to the CDSA, enabling verbal prescription of controlled substances alongside expanded authorizations for pharmacists to extend, renew, and transfer such prescriptions [41]. Meanwhile, to support the implementation of best practices, federal health authorities commissioned the Canadian Research Initiative in Substance Misuse (CRISM) to develop a series of national guidance documents, including recommendations for the use of telemedicine in addiction services [42] and prescribing of psychoactive substances to support people with OUD who need to self-isolate [43]. The medical regulatory authority of Quebec rapidly updated their OUD treatment and telemedicine guidelines to integrate these changes, relax restrictions on unsupervised dosing of long-acting opioid agonists, and endorse the use of telemedicine for OAT initiation and continuation [44-46]. Quebec-specific expert recommendations for OAT delivery, including guidance for "safer supply" prescriptions of short-acting opioids, were subsequently released in October 2020 [47]. Together, these changes represent a seismic shift in the regulatory structures and guidance shaping treatment for people with OUD [48]. Evidence suggests a broad uptake of telemedicine prescribing in Canada, with over half of OAT clinics surveyed offering this service by June 2020 [49].

Recognizing a Need for Further Adaptation

The Centre hospitalier de l'Université de Montréal (CHUM) is an academic hospital in downtown Montreal, whose addiction medicine service (Service de médecine des toxicomanies [CHUM-SMT]) offers an integrated model of care for people with substance use disorders and complex social and medical needs. This model spans a wide range of interventions, from harm reduction to specialized multidisciplinary medical and psychiatric treatment, and includes a low-barrier OAT program. From March 2020, OAT practices were rapidly amended in line with the aforementioned recommendations to shift outpatient consultations to web-based or telephone visits and allow initiation of new patients without requiring that they visit the outpatient clinic. Like clinicians in other settings [50-52], however, we noted that access to OAT remained inequitable under a telemedicine model, particularly for individuals unable to access a phone or computer or are otherwise unwilling to access hospital-based services for fear of stigmatization [8,53].

Recognizing the need to actively reach out and build trust with this population that has been socially marginalized, we created a new partnership with a community-based harm reduction organization, CACTUS Montréal. Located in the core of downtown Montreal, CACTUS Montréal is home to one of North America’s oldest needle-syringe programs and takes a pragmatic and humanistic approach to serving people who use drugs through prevention, education, and leisure activities. It was also one of the few such services to remain open in Montreal during the initial months of the COVID-19 pandemic. Together, we co-designed a novel model of care premised on offering easily accessible, high-quality telecare for people with OUD with the support of the CACTUS Montréal community workers they trust.

Procedures were developed jointly to enable a flexible and rapid appointment scheduling system that would meet the needs of this population while ensuring confidential flows of patient information. CACTUS Montréal community workers informed their clients of the program, facilitated initial eligibility screening, and helped interested clients book an on-site web-based appointment with the CHUM-SMT team, generally within the same week. Participants thus remained physically within the CACTUS Montréal facilities, where they could not only access the technological resources and assistance necessary to engage in care but also draw on the support of community workers during and after their appointment. This enabled warm hand off from a trusted person to the CHUM-SMT and equally created an environment in which patients could easily pose questions, reschedule appointments, and follow up with staff about the program throughout their participation. Clinics ran on Tuesday and Wednesday afternoons, allowing some walk-in appointments as needed.

During the web-based appointments, the CHUM-SMT team (comprising a physician and a nurse) evaluated each patient and initiated an individualized treatment regimen. To foster engagement in care, treatment was tailored to the participants’ particular needs and their prior experiences with OAT. An initial regimen typically included a long-acting opioid (eg, methadone, buprenorphine/naloxone, or extended-release morphine) combined with a short-acting opioid (eg, hydromorphone) to manage withdrawal, increase comfort, and reduce the risk of illicit opioid use and overdose during initiation. Prescriptions were sent by fax directly to the participant’s local pharmacy and a follow-up appointment was immediately scheduled. Importantly, the CHUM-SMT team could also assess and treat patients’ other medical needs, with CACTUS Montréal nurses available to draw blood samples (eg, for HIV or hepatitis C testing) as necessary. Participant consent was obtained from the outset to define the nature of information exchange between CHUM-SMT and CACTUS Montréal, who communicated frequently to schedule appointments based on the participants’ needs.

To support implementation, both partners entered a formal collaboration agreement and devised a tool kit including a shared appointment calendar, patient evaluation and referral forms, user guides for connecting to various telemedicine tools, and trainings in the web-based clinic and on OAT for CACTUS Montréal staff. Patient flows were managed with assistance from the CHUM Network Flow Optimization Center (Centre d’optimisation des flux reseau), a service promoting accessibility and continuity of care through various measures including coordination of linkages to the broader health network and telehealth services.

Successes, Challenges, and the Importance of Building Institutional Relationships

A major challenge at the time of implementation was to rapidly organize the aforementioned trainings, tools, and procedures so that CACTUS workers could appropriately support clients initiating OAT through the service. This effort was facilitated by a previously well-established working relationship and institutional support from both partners, with our first patient enrolled just 30 days after the first planning meeting and 45 days after declaration of the COVID-19 public health emergency in Quebec.

The initiative was viewed as transformative by the staff and enthusiastically received by the participants, who, we believe, found the program convenient, flexible, and responsive to their needs despite some reservations about the “impersonal” nature of telemedicine. In our view, the implication of CACTUS Montréal and its community workers was critical to creating an environment of trust, confidence, and nonjudgment; maintaining open lines of communication between appointments; and enabling access to care within a setting that participants were already frequenting. Many participants had long-standing ties and positive relationships with CACTUS Montréal, which contrasted starkly with testimonies of their unsatisfactory experiences with mainstream health services. This appeared to facilitate engagement and lend legitimacy to the program, with telemedicine being a tool enabling us to quickly and easily reach beyond the confines of the conventional health system. Unlike programs delivering OAT through telemedicine alone, our hybrid model also enabled easy access to laboratory testing and subsequent initiation of care for other chronic health problems (eg, HIV and hepatitis C virus) affecting this population.

Partnerships between institutional health services and independent community organizations can be complex to develop because the community approach to health, particularly in the area of harm reduction and prevention of sexually transmitted and blood-borne infections, has developed in response to the inability of traditional services to reach and maintain ties with groups that have been historically marginalized. In this case, a history of constructive engagement between the CHUM and CACTUS Montréal—also in the context of various prior research initiatives—was the critical foundation that allowed us to respond quickly and positively to the disruption caused by the COVID-19 pandemic. Our telemedicine initiative has further strengthened these ties, marking a significant step toward further innovations in service delivery. Indeed, the program proved so popular, it has now expanded to a second harm reduction organization in Montreal. Mobilizing the technical and human resources needed to establish new partnerships and meet client demand has been taxing and confirms a need to develop longer-term plans and infrastructure so that the model, once fully evaluated, can be deployed more broadly.

Conclusion

Facilitated by the COVID-19 pandemic and the ensuing amendments to federal and provincial regulations and recommendations for best practices, our community-based telemedicine program succeeded in bringing OAT to people with OUD within a space where they feel comfortable and accepted. The implication of CACTUS Montréal, an ally who accompanies clients through difficulties at their own pace and based on their own needs and priorities, was fundamental to engaging our patients and responded to priorities previously expressed by local people with OUD.

It is imperative that such initiatives and the emergency-led legal and structural contexts underpinning them persist, evolve, and expand well beyond the pandemic. Emerging evidence suggests that both patients and providers support the continuation of regulatory reforms and telemedicine delivery of OAT and perceive these as facilitating individualized patient-centered care [54,55]. More programs enabled by these innovations must be quickly and thoroughly evaluated to build an evidence base for their safety and effectiveness and guide further adaptation. Investments must then allow the science to move alongside implementation, scale-up, and formalization of such novel care pathways toward a more agile and adaptive response to the continually evolving overdose crisis [56,57]. The success of vaccine development and scale-up initiatives amid the pressing threat of the COVID-19 pandemic, as well as the rapid deployment of telemedicine and other sweeping societal interventions, has demonstrated our capacity to innovate and implement simultaneously. Reducing overdoses among people with OUD deserves the same sense of emergency and commitment to innovative thinking. We firmly believe that programs such as ours can reduce health inequalities and save lives by meeting people “where they are,” bridging gaps to institutional services and shifting patient-provider relationships toward a place of mutual understanding and holistic engagement [58].

Acknowledgments

This work was supported by the Canadian Institutes of Health Research through the CRISM Quebec-Atlantic Node (#SMN-139149). Further support was obtained from the Canada Research Chair in Addiction Medicine, JB. SBH receives salary support from a CIHR project grant (#PJT-165880).

Abstract

Participatory surveillance (PS) has been defined as the bidirectional process of transmitting and receiving data for action by directly engaging the target population. Often represented as self-reported symptoms directly from the public, PS can provide evidence of an emerging disease or concentration of symptoms in certain areas, potentially identifying signs of an early outbreak. The construction of sets of symptoms to represent various disease syndromes provides a mechanism for the early detection of multiple health threats. Global Flu View (GFV) is the first-ever system that merges influenza-like illness (ILI) data from more than 8 countries plus 1 region (Hong Kong) on 4 continents for global monitoring of this annual health threat. GFV provides a digital ecosystem for spatial and temporal visualization of syndromic aggregates compatible with ILI from the various systems currently participating in GFV in near real time, updated weekly. In 2018, the first prototype of a digital platform to combine data from several ILI PS programs was created. At that time, the priority was to have a digital environment that brought together different programs through an application program interface, providing a real time map of syndromic trends that could demonstrate where and when ILI was spreading in various regions of the globe. After 2 years running as an experimental model and incorporating feedback from partner programs, GFV was restructured to empower the community of public health practitioners, data scientists, and researchers by providing an open data channel among these contributors for sharing experiences across the network. GFV was redesigned to serve not only as a data hub but also as a dynamic knowledge network around participatory ILI surveillance by providing knowledge exchange among programs. Connectivity between existing PS systems enables a network of cooperation and collaboration with great potential for continuous public health impact. The exchange of knowledge within this network is not limited only to health professionals and researchers but also provides an opportunity for the general public to have an active voice in the collective construction of health settings. The focus on preparing the next generation of epidemiologists will be of great importance to scale innovative approaches like PS. GFV provides a useful example of the value of globally integrated PS data to help reduce the risks and damages of the next pandemic.

Overview

Digital epidemiology has expanded significantly in recent years [1,2], encompassing not only passive digital disease detection [3], but also active crowdsourcing programs known as participatory surveillance (PS) [4-7]. PS has been defined as the bidirectional process of transmitting and receiving data for action by directly engaging the target population [8]. Often represented as self-reported symptoms directly from the public, PS can provide evidence of an emerging disease or concentration of symptoms in certain areas, potentially identifying signs of an early outbreak. The construction of sets of symptoms to represent various disease syndromes provides a mechanism for the early detection of multiple health threats [9-12]. In addition to sets of syndromes, PS benefits from the acquisition of data on nonsymptomatic individuals, providing some measure of a denominator to make calculations on prevalence, incidence, attack rate, among other metrics [13]. It is also possible to include questions that act as proxies for the identification of risk factors that may be associated with a health threat within a community. For example, questions about seeking health care after reporting symptoms may reveal the severity of the event for those individuals [11-13]. Or asking if a participant reporting into the system has recently traveled may indicate that symptoms are from a disease acquired from another location. Inquiring whether the reporter had recent contact with someone with similar symptoms might reveal a possible contagion network [13]. Additional questions about sociodemographics (eg, age, gender, income, and occupation) or even vaccination status can complement the syndromic information provided by users who participate in such programs to help inform at-risk groups [14]. Another layer that may be emphasized around the benefits of PS is its stability when something goes epidemic. While other surveillance systems rely on the health care system and are not scalable, web-based surveillance remain standing, even when the health care system is flooded. It is very important to have reasonable stable time trends to interpret what is going on. Furthermore, not so much the exact questions of the surveillance is important, but that the system is reasonably flexible including different questions, and that you can survey whatever is necessary, whether it is the uptake of a COVID-19–tracking app or self-tests, or vaccine-sentiment.

By these evidences it seems that PS is an affordable and effective proxy for public health departments to estimate, for example, influenza-like illness (ILI) and COVID-19–like illness numbers, despite the fact that clinical surveillance efforts are receiving far less data.

After the H1N1 pandemic emerged in 2009, PS for ILI became vital for monitoring this health challenge [6,15,16]. Since then, several platforms have expanded around the world seeking to use the participation of citizens in the systematic and periodic collection of symptoms related to influenza [9,17-26]. The numerous programs monitoring ILI have provided evidence regarding the acceptability, reliability, promptness, accuracy, and usefulness of this approach [6,20,22]. On the other hand, the aspects of data integration and interoperability between these systems for the purpose of comparing ILI activity across countries and regions remain a challenge. While several programs have similar objectives, the different governance and data compliance procedures placed operational hurdles to integrate and promote interoperability between the databases. A solution to realize the value of PS in monitoring global ILI activity was desperately needed.

In 2018, the first prototype of a digital platform to combine data from several ILI PS programs was created [27]. At that time, the priority was to have a digital environment that brought together different programs through an application program interface, providing a real-time map of syndromic trends that could demonstrate where and when ILI was spreading in various regions of the globe. After 2 years running as an experimental model and incorporating feedback from partner programs, Global Flu View (GFV) was restructured to empower the community of public health practitioners, data scientists, and researchers by providing an open data channel among these contributors for sharing experiences across the network. GFV [28] is redesigned to serve not only as a data hub, but also as a dynamic knowledge network around participatory ILI surveillance by providing knowledge exchange among programs [28]. The goal of this study is to serve as a viewpoint exploration, dissecting the challenges, solutions, and potential of PS applied in digital ecosystems like GFV.

Connecting ILI Programs Across the Globe in GFV

GFV is the first ever system that merges ILI data from more than 8 countries plus 1 region (Hong Kong) on 4 continents for global monitoring of this annual health threat. GFV provides a digital ecosystem for spatial and temporal visualization of syndromic aggregates compatible with ILI from the various systems currently participating in GFV in near real time (Table 1), updated weekly. In addition, GFV presents a list of features that support using PS as a data layer for enhanced ILI surveillance (Table 2). It is important to emphasize, however, that PS does not aim to replace traditional surveillance systems but rather to complement the information obtained from such systems and to generate actionable data.

Table 1. List of programs that are participating in GFV[a] as of December 2022.

Program's name	Territory coverage	Year of foundation	Description	Outcomes	Host institution
Outbreaks Near Me (formerly Flu Near You) [29]	United States and Canada	2011	A system that allows its users across North America to securely and anonymously self-report ILI[b] symptoms or to report feeling healthy.	• Since users generally report before visiting a health care provider, trends on the spread of ILI are often detected before local and national public health agencies do.	Boston Children's Hospital—Harvard University
FluTracking Australia [30]	Australia	2006	A web-based community-based acute respiratory illness surveillance system that is not biased by health seeking behavior, clinician testing practices, or differences in jurisdictional surveillance method.	• To contribute to community-level acute respiratory illness surveillance in Australia • To provide consistent surveillance of acute respiratory illness attack rates and testing across all jurisdictions and over time. • Provide year-to-year comparison of the timing, attack rates, and seriousness of acute respiratory illness in the community.	Hunter New England Local Health District, Hunter Medical Research Institute—The University of Newcastle
FluTracking Hong Kong [31]	Hong Kong	2021	A web-based health surveillance system used to detect the potential spread of influenza and COVID-19.	• To compare ILI syndrome proportions according vaccination status and seasonality, providing consistent monitoring of influenza surveillance activity.	School of Public Health—the University of Hong Kong
SickSense [32]	Thailand	2020	A network of digital volunteers who participate through anonymous reporting of their own health.	• This system can identify early signs of an emerging epidemic threat, be an assistant to find real time signs of illness, and engage through digital tools.	The Health Promotion Foundation and Open dream
InfluenzaNet[c] [33]	Italy, France, the Netherlands, and Denmark	2009	A web-based survey tool to conduct syndromic surveillance through self-reported symptoms volunteered by participants residing in the InfluenzaNet countries.	• The platforms collect demographic and risk-factor data from participants upon enrollment, capture weekly symptoms, and report analyzed surveillance results. This provides insights about the ILI activity.	Influweb.org, Covidnet.fr, Influmeter.dk, Infecieradar.nl

---

[a] GFV: Global Flu View.

[b] ILI: influenza-like illness.

[c] InfluenzaNet integration is still going on. This is a partial list of countries which enrolled in the platform.

Table 2. Overview of functionalities and main features of GFV.[a]

Feature	Description	Technical specification	Availability
Time-series report (Figure 1)	Temporal distribution of participant's reports and ILI[b] proxy defined by each program. In this feature,[c] it is also possible to filter by specific symptoms, vaccination status, gender, and age range.	Apex charts.JS is an open-source library for AngularJS that enables a smooth user experience loading time-series charts.	Publicly available. For registered partners, download of the line listing data is also possible in .CSV format.
Map (Figure 2)	Spatial distribution of participant's reports and ILI proxy defined by each program. In this view, it is possible to visualize in a (1) cluster view, (2) disaggregated reports by the minimum allowed level (eg, postcode centroids), or (3) heatmap with ILI cases.	For the use of clustering and heatmap view, Mapbox has been used.	Publicly available.
Resources	Library of recent peer-reviewed publications about PS.[d]	Automated scrapper that is connected with PubMed database, looking for keywords associated with PS. Before a paper is displayed on the resource page, a human input is necessary to accept or decline the suggestion. Once accepted, it populates a resource section.	Publicly available.
API[e] documentation (Figure 3)	The documentation for API requests of post-processed data points in the platform. The validation is based on a token generated by each program partner and the authorization is given by passing the key via header. The available requests for postprocessed data are: GET /api_map (returning data pinned to the map); GET /map_dates (returning the dates from the registered data); and GET /surveys (returning chart data from Reports section).	For the map data: Lat (number $double); Lng (number ($double)); Report_count (integer); ILI_count (integer); No_symptoms_count (integer); Some_symptoms_count; (integer); Postcode (string); Country (string); ILI_percentage (integer); No_symptoms_percentage (integer); Some_symptoms_percentage (integer); For the survey data: Match_count (integer); Percentage_count (number); Total_count (integer); Week (string)	Restricted to program partners with approved access to this feature.
Codelab (Figure 4)	Digital space for sharing codes, notes, and snippets across the community of program partners. In addition, this brings the possibility to specify the permission (whether creative commons or GPL[f]) and the language used. The codes are visible for all program partners that may use them for their projects or data analysis pipelines.	Besides the title, description, and tags, one can define the permission that the code has as well as the language the snippet was coded in.	Restricted to program partners with approved access to this feature.

# fit model
model = ARIMA(data, order=(0, 0, 1))
```

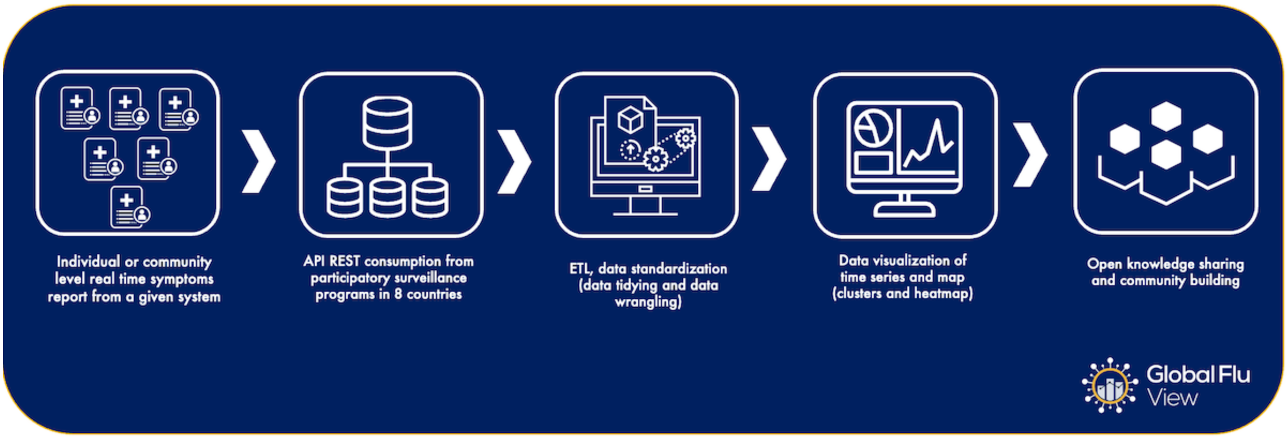
Understanding the GFV Ecosystem

GFV may be best described as an ecosystem with three different layers: (1) program partners, (2) community, and (3) outcomes. PS programs for ILI were informed about the purpose of GFV, and after accepting the data sharing agreement, became part of the core layer by contributing to the availability of real-time data. In the second layer, the "community" of potential consumers of this data can be described in three categories: (1) public health practitioners focused on disease surveillance, (2) data consumers focused on the use and integration of the data for third-party systems and platforms, and (3) researchers, who may use the data for comparative, predictive, or characterization of global epidemiological scenarios about ILI outbreaks as well as the development of forecasting and modeling techniques. Finally, the outcomes layer demonstrates the impact that these data can generate on the knowledge of the current and future ILI landscapes; and the potential of information sharing for constructing and strengthening of the ILI PS community. Pooling data from different regions and integrating them into GFV generates a pivotal tool for participatory surveillance. The collaborative network formed from this international data integration not only fosters shared learning but also strengthens ties between researchers and public health practitioners globally. This community aspect provides a robust response to ILI on an international scale.

The global perspective offered by GFV is especially valuable considering the nature of influenza epidemics. Tracking these patterns across various geographical regions provides critical insights into disease spread dynamics, contributing significantly to our understanding of these epidemics. Further, the collective data from diverse sources amplify the statistical power of analyses conducted using this platform. With a larger, more diverse data set at their disposal, researchers can draw more robust conclusions and gain key insights into influenza trends and variations across different settings. This enriched perspective provides a significant contribution to the global understanding and management of ILI.

The list of program partners is periodically updated, giving opportunities for ILI programs from anywhere to be part of this ecosystem. GFV is also open to the general public, who can use the potential of this tool to understand the importance of their contribution in reports to program partners in the collective construction of information on global health. Figure 5 describes the GFV’s workflow for a better understanding. We will further delve into the intricacies of community building, interoperability challenges, and data governance specific to participatory surveillance in subsequent sections. These important aspects help paint a comprehensive picture of our work and elucidate the significant contribution of GFV to the field of public health surveillance.

Figure 5. GFV’s workflow, describing the steps for data acquisition, API integration, data processing, data visualization, and knowledge sharing among program partners. API: application program interface; AWS: Amazon Web Services; ETL: Extract, Transform and Load ; GFV: Global Flu View.



Community Building and Knowledge Sharing

A community of PS enthusiasts can be connected with knowledge sharing in several ways. First, this community can provide a forum for practitioners to share their knowledge and expertise with each other. This can take the form of discussions and collaboration on specific projects or challenges, as well as the sharing of resources, such as research papers, technical manuals, and training materials. By sharing knowledge within the community, practitioners can learn from each other's experiences and can help to advance the field as a whole. Additionally, a community of health technology practitioners can also facilitate the sharing of knowledge with other stakeholders, such as policy makers, health care organizations, and the general public. For example, a community can organize conferences, workshops, and seminars where practitioners can present their research and findings to a broader audience. This can help to raise awareness of the latest developments in health technology and can encourage the dissemination of new ideas and best practices.

The GFV ecosystem aims to strengthen the use of surveillance data among professionals in various fields. Professionals such as public health practitioners, epidemiologists, data scientists, and software developers may use the GFV data in the routine of disease surveillance. The platform encourages contribution of data analysis techniques, methods, and processes to promote knowledge sharing among partners and ensures that data are used in a reproducible manner.

Interoperability Challenges: Overcoming Hurdles Based on Data Standards

Interoperability for participatory disease surveillance data can help to ensure that data from different systems can be easily exchanged and integrated, leading to more effective and efficient processes. However, several challenges must be considered to achieve this goal, including the following: (1) lack of standardization: different PS programs may collect different types of data, at different granularities, use different data formats and structures, which can make it difficult to exchange data. Moreover, without standardized data definitions and formats, it can be difficult to ensure that data from different PS programs are comparable; (2) complexity of data integration: integrating data from diverse PS programs systems can be a complex and time-consuming process, especially if the systems are not designed to interoperate; (3) limited technical capacity: some PS systems may not have the technical capacity or expertise to integrate data from other systems; and (4) privacy and security concerns: ensuring the privacy and security of sensitive health or disease data is a key concern when integrating data from distinct surveillance systems and are subject to different national or international regulatory frameworks (eg, European Union General Data Protection Regulation).

To overcome these challenges, it is necessary to adopt data standards that provide a common framework for the exchange and integration of data from different surveillance systems. Data standards offer a set of rules and guidelines for defining data elements and formats, which can help to ensure that data from different systems are comparable and can be easily integrated.

In developing GFV, the number of global platforms that use secondary epidemiologic data was considered. Documenting the processes and end points for accessing data on the platform is fundamental to the interoperability of this data with other data streams to allow connections for integration with GFV. Using an API to connect the various systems with GFV was deemed the most efficient mechanism.

Data Governance: Getting Legal Agreements for a Multicentric PS Ecosystem

A data sharing agreement is required for any partner that provides its data to GFV (except for those programs which make the data publicly available). This agreement covers core principles such as (1) preserving data privacy by sharing deidentified data, (2) maintaining data integrity, and (3) respecting the governance structure and compliance required by each program partner.

Data governance is an essential aspect of PS systems to safeguard the integrity, quality, and security of data collected. It includes policies, processes, and practices for data collection, management, and use, with defined roles and responsibilities for data quality assurance and security. Clear and transparent policies and practices can ensure that participants feel confident that their data will be used responsibly.

Looking to the Future

Enabling PS for Digital Public Health Intelligence

The popularization of social media, added to the wave of "big data," creates the opportunity for crowdsourcing participatory disease surveillance in GFV to expand the understanding of ILI and its impact across the globe [19,20].

Several initiatives are integrating diverse data streams to increasingly provide timely information to detect public health events. Low- and middle-income countries, in particular, are greatly benefited by these approaches. Examples of these initiatives include the Integrated Disease Surveillance and Response framework in sub-Saharan Africa. For 20 years it has demonstrated the importance of improving the detection and response of public health threats by combining data from diverse systems and laboratories [34]. In China, another model framework integrates multichannel surveillance, data analysis for early warning, and a specific strategy for sustainability of the surveillance system [35]. Within the scope of PS, it is possible to see the integration of laboratory data for the monitoring of SARS-CoV-2 antibodies seroconversion [36-38]. PS has historically also used data from social media to leverage its sensitivity and detection capability [39,40]. In Netherlands, a strategy to combine PS reports plus self-tests given free of charge and centralized testing of nose or throat samples has been performed, showing another angle of empowering public health intelligence by these approaches [41]. The previous examples show how different ecosystems across the globe are ready to integrate diverse data streams, where GFV may be one of these, enabling a feasible view for PS.

During the first years of the COVID-19 pandemic, the value of other types of data, from wearables, wastewater, and mobility through cellular data for early identification of risks, became evident [42-45]. Approaches like this also show the ability of omnichannel surveillance for other infectious diseases with pandemic potential, such as a novel strain of influenza. Indeed, challenges of integration and interoperability between these data sources will exist and demand that the next generation of epidemiologists be familiar with the format and structure of each data source. The assessment for data standards for collecting comparable data will be crucial to guarantee the unity of such different systems.

Cross-Engagement

Cross-engagement is a term inherited from the marketing industry, which describes the use of multiple marketing channels to seamlessly leverage retention of a target audience [46]. Collaborative platforms can benefit from this concept, as the retention and engagement of users in PS strategies has always been a point of friction. Maintaining engagement and participation in these programs can be challenging, as individuals and communities may have other priorities or may lose interest over time. With cross engagement, the user is motivated on multiple fronts for multiple purposes. The GFV platform provides cross-engagement as user data are seen at a local or national level by the partner platform and at an international level displaying trends for multicentric comparison between countries and continents. The empirical evidence is that people become further incentivized by the knowledge that their data matter both locally and globally.

Programs for monitoring and combating chronic diseases [47] can serve as valuable models for infectious disease PS programs, particularly for influenza, which is a key focus of the GFV platform. These programs can provide valuable insights and lessons learned that can be applied to the design and implementation of infectious disease surveillance programs, helping to ensure that these programs are effective and efficient. By leveraging the experience and expertise of chronic disease surveillance programs, it is possible to learn how to improve the engagement and retention performance of participatory infectious disease surveillance programs [48-50].

Smart Health Communities

Smart Health Communities has been another important trend to consider in the future of disease surveillance [51]. The core features of this approach are (1) empowering individuals to proactively manage one's own health and well-being, (2) fostering a sense of community and belonging, (3) using digital technologies and behavioral sciences, (4) using data for substantial improvements in health outcomes, and (5) creating innovative ecosystems [52].

In this scenario, studies demonstrate how these programs reach the status of social contagion to achieve a collective good [53-55]. This type of social influence can be one of the ways to increase user participation in PS platforms, considerably increasing the potential for using the data that circulates in this environment [53,54]. The parallelism between geographic smart health communities and digital smart health communities enables the possibilities of using the metaverse for PS [55]. By these examples, having a web-based hub that serve as stage for smart health communities look at the data seems realistic and needed. With the open access that GFV promotes through temporal and spatial data, this becomes a concrete example for future interactions in smart health communities.

Opportunities for the Next Generation of Digital Epidemiologists

Given these perspectives, the importance of the next-generation of digital epidemiologists actively participating in the ongoing digital transformation of public health surveillance cannot be overstated. Their role in this rapidly evolving landscape goes beyond merely applying existing tools and systems; they must also acquire a comprehensive understanding of this emerging field. In order to cultivate a new breed of professionals capable of steering this digital revolution, the inclusion of data science, software engineering, mathematical modeling, and data design in academic and technical training programs is vital. This multidisciplinary approach equips future digital epidemiologists with the broad spectrum of skills they require to be self-reliant and innovative in their roles. While collaboration and cross-pollination of ideas are indeed essential in this multifaceted field, it is equally important for these professionals to have the capability to make independent, informed decisions. The interdependence inherent in such a diverse field should not lead to an overreliance on others. These professionals will need to be well-versed in all aspects of digital epidemiology, from disease surveillance to the intricacies of digital public health. GFV is pioneering in this educational journey by providing a platform that fosters collaboration, knowledge exchange, and the cultivation of skills. The GFV Codelab, for instance, is an exemplary feature that demonstrates how digital platforms can be harnessed as digital learning environments. As we navigate this new digital landscape, it is incumbent upon us to ensure that the next generation of professionals is well-equipped to lead the field of digital epidemiology into the future.

Further, the endorsement of participatory surveillance strategies by major health organizations, such as the World Health Organization [56], underscores the pivotal role that this approach plays in global health. It signals an expectation for the next generation of digital epidemiologists to not only understand these approaches but to implement them effectively and innovatively.

Limitations

GFV has several limitations. First, the data in GFV are dependent on the quality of its partners' data. Since PS programs rely on the active involvement of individuals and communities, GFV data are impacted by this reality that not all individuals and communities may be willing or able to participate in these programs. This can lead to incomplete or biased data, which can impact the accuracy and usefulness of the information collected through these programs. Second, data quality and integrity are an issue due to the characteristics of self-reported data, which can be subject to errors, biases, and inconsistencies. Third, the various programs contributing data to GFV often require significant resources, including funding, staff time, and technology. These resources may be limited, which can impact the ability of these programs to effectively collect data on an ongoing basis and share it with GFV.

Conclusions

Connectivity between existing PS systems enables a network of cooperation and collaboration with great potential for continuous public health impact. Thus, it is crucial for professionals engaged in ILI studies, educators, students, and public health practitioners to engage with digital ecosystems. It is an opportunity to make use of these open data channels and contribute to knowledge, and help to enhance the depth and breadth of ILI surveillance. Moreover, it offers a platform for learning, interaction, and collaboration, fostering a more integrated and proactive approach toward public health challenges. The exchange of knowledge within this network is not limited only to health professionals and researchers, but also provides an opportunity for the general public to have an active voice in the collective construction of health settings. The focus on preparing the next generation of epidemiologists will be of great importance to scale innovative approaches like PS. GFV provides a useful example of the value of globally integrated PS data to help reduce the risks and damages of the next pandemic.

Acknowledgments

We would like to acknowledge all participants or users from all programs listed above. We acknowledge Nomita Divi and Jay Atanda for the early contributions in the coordination of Global Flu View program. The authors would also like to thank Rodrigo

Paiva and Bruno Barros, who are the software engineers for Global Flu View. The authors acknowledge all FluTracking team members and the tech leader Stephen Clarke.

Conflicts of Interest

None declared.

Abstract

Monitoring of the mental health status of the population and assessment of its determinants are 2 of the most relevant pillars of public mental health, and data from population health surveys could be instrumental to support them. Although these surveys could be an important and suitable resource for these purposes, due to different limitations and challenges, they are often relegated to the background behind other data sources, such as electronic health records. These limitations and challenges include those related to measurement properties and cross-cultural validity of the tools used for the assessment of mental disorders, their degree of representativeness, and possible difficulties in the linkage with other data sources. Successfully addressing these limitations could significantly increase the potential of health surveys in the monitoring of mental disorders and ultimately maximize the impact of the relevant policies to reduce their burden at the population level. The widespread use of data from population health surveys, ideally linked to electronic health records data, would enhance the quality of the information available for research, public mental health decision-making, and ultimately addressing the growing burden of mental disorders.

Introduction

In line with the motto of World Mental Health Day on October 10, 2022, “Make Mental Health and Well-Being for All a Global Priority,” mental health has become a public health and research priority in different countries worldwide. In the United States and the United Kingdom, for example, the White House and the UK Health Security Agency have included mental health as one of its corporate priority areas on their health and research strategies [1,2]. Such prioritization processes depend on the availability of data and on the quality of the evidence for a specific context and period. However, not all the data are considered equally relevant for this prioritization, and the evidence derived from population health surveys is often considered to be of lower quality than the evidence from other data sources, such as electronic health records (EHRs).

Population health surveys are observational studies designed for research and public health purposes, aimed to obtain a representation of the distribution of different health conditions and the association of this distribution with sociodemographic, lifestyle, and other factors in well-defined populations. Since the second half of the previous century, these surveys have been carried out in different countries worldwide (eg, the National Health Interview Survey [NHIS] in the United States since 1957 [3] and the Health Survey for England in the United Kingdom since 1991 [4]). Due to their population-based nature (ie, based on representative as opposed to convenience sampling), data from these surveys may constitute a helpful resource to determine the burden of different mental health problems in the community, to identify vulnerable populations or population groups, and to inform the planning of health care resources and the development of health policies and targeted preventive measures [5]. Additionally, it must be highlighted that individual-level data from multiple health surveys worldwide, particularly from middle- and high-income countries, are publicly available for researchers to access and use (eg, data from the NHIS [3] or the National Health and Nutrition Examination Survey in the United States [6] and data from the European Health Interview Survey [EHIS] [7] or the European Social survey in Europe [8]). Some examples of the use of data from population health surveys for these purposes include the use of the data from the World Mental Health Surveys as a primary source to calculate the prevalence of major depression internationally [9], the identification of differences in depression among religious groups in Europe using data from the European Social Survey [10], and monitoring of the mental health and suicide prevention reforms in Australia [11]. While the use of data from population health surveys has been successfully implemented for these purposes, these data need to meet certain requirements, including the use of valid and reliable measures for the assessment of mental disorders and the selection of representative samples.

In this context, we propose that extending the use of data from population health surveys would have a considerable impact on improving the evidence base of public mental health decision-making and, hence, could be instrumental in reducing the growing burden of mental disorders in the community.

Public Mental Health and the Use of Population Health Surveys

Monitoring of the mental health status of the population and assessment of its determinants (eg, sociodemographic factors, lifestyle habits, and use of health services) are 2 of the pillars of public mental health [12-14], and the use of harmonized data from multiple sources could be instrumental to support them.

If the quality of the data could be guaranteed, the monitoring of mental health at the population level should be based on all the available data. For example, the Global Burden of Disease study integrates data from several sources, including data from more than 65,000 household health surveys and 87,000 medical records [15]. Although this can be considered the ideal scenario and there is growing interest on the data from population health surveys, particularly due to their potential to reach different population groups with low accessibility by using digital surveys, these data have been used less frequently than data from EHRs for monitoring and informing public mental health decision-making [16,17]. This is the case in several countries, such as Italy and the Netherlands, where EHRs have been used, for example, to monitor the impact of the COVID-19 pandemic on the mental health of the general population [18] and to monitor mental health conditions in children [19], respectively.

One controversial aspect related to the use of data from population health surveys for the monitoring of mental health is the type of mental health measures included within them. Population health surveys commonly include self-reported measures (eg, the 8-item version of the Patient Health Questionnaire) that are considered less valid and reliable than clinical interviews. However, it must be highlighted that, in contrast with other medical conditions, and because of the subjective and self-reported nature of most of the symptoms of mental disorders [20,21], self-reported tools (eg, the 8-item version of the Patient Health Questionnaire) represent valid and reliable measures at the population level (group or aggregate level) and, hence, can be used for timely monitoring and identification of (vulnerable) groups of interest.

Timely assessment and identification of factors related to mental disorders is another strength of the data captured by population health surveys. These surveys usually include within their questionnaires very rich information about sociodemographic and environmental determinants (eg, education and air pollution) and lifestyle habits (eg, diet or physical activity), constituting a valuable resource to assess their potential relationship with mental health. One example of the use of data from population health surveys to assess sociodemographic determinants of mental health is the use of data from the second and third waves of the EHIS (EHIS-2 and EHIS-3, respectively) to identify differences by country in the prevalence of depression across 27 European countries (with a higher prevalence: 1.8 times higher in Germany and 1.5 times higher in Luxembourg relative to the rest of Europe) [22,23]. Additionally, some population health surveys capture data about the use of mental health services (eg, the number of primary care consultations during a specific time), which is a potentially useful resource to inform the planning of public mental health resources [13,24,25]. This information has been previously used to investigate the unmet need of mental health care [9,24] and is particularly relevant for assessing vulnerable population groups that usually have higher rates of mental disorders, lower access to these services or, due to their circumstances, do not use these services when needed (eg, people experiencing homelessness) [26].

Synergistic Relevance of the Data From Population Health Surveys and EHRs

While the use of population health surveys is suitable for different public mental health purposes, in some cases, data from EHRs could be a better option due to their potentially higher completeness and representativeness, the inclusion of richer relevant clinical data, and the possibility of following up with their participants over time (Table 1).

Table 1. General characteristics of population health surveys and electronic health records (EHRs).

	Population health surveys	EHRs
Population included	General population	Clinical population
Representativeness	Household samples to quota samples	Usually public providers
Type of design	Usually cross-sectional	Longitudinal
Assessment of mental disorders	Usually self-reported	Usually diagnostic codes
Range of mental disorders usually considered	Limited	Wide
Other relevant variables	Sociodemographic factors, lifestyle habits, and use of health services	Only clinical variables
Cost	Low	High

One advantage that EHRs have over population health surveys is their potentially higher external validity. In contrast with surveys, which are usually carried out in samples with different degrees of representativeness, data from EHRs are more likely to include entire populations, such as the Hospital Episodes Statistics in England, in which more than 99% of attendees of mental health services from the National Health Service of the United Kingdom are captured [27]. Besides, data from EHRs usually capture high-quality clinical information, such as information about diagnostics (eg, International Classification of Diseases [ICD] codes), treatments (eg, prescribed medication), and other clinical aspects of care (eg, the number of consultations in a specific service), positioning them as the most suitable alternative for the assessment of the use of mental health services and to inform their planning [16,17.24]. Paradoxically, it should be noted that despite the quality of the data from EHRs (particularly to capture severe mental disorders), medical records are not designed for research purposes and focus on clinical populations (ie, not in the general population), thus limiting their generalizability to the general population and even more so to vulnerable population groups less likely to access these services [26]. Additionally, data from EHRs are limited by data capturing systems. However, given the potential differences in codification systems (eg, mental disorders codified using different ICD versions [21]) and across studies, achieving semantic interoperability is a key aspect to consider when leveraging data across multiple data sets [28]. As a consequence, certain relevant outcomes (eg, drug abuse) may be poorly documented and need to be validated for research, or they reach only public mental health service users, thus limiting their generalizability to the growing population groups using private health care services.

Another advantage of EHRs over population health surveys is the possibility of long-term follow-up of participants. While population health surveys are often cross-sectional and anonymous (or anonymized) and participants cannot be followed up over time, the inclusion within EHRs of variables that facilitate the identification of participants and date variables (eg, dates of admission or follow-up consultations) make it possible to follow up with them over time. This is particularly important for correct estimation of the incidence of different health problems, the rates of recovery or relapse of some disorders over time, or the impact on mental health over time on different factors and the establishment inferences about potential causal associations [29]. However, there is an increasing interest in longitudinal surveys, in panel data with repeated assessments of the same individuals over time (eg, the British Cohort Study in the United Kingdom) [30,31], and in the inclusion of variables within the survey questionnaires that allow the follow-up of their participants over their life course (eg, participant identification codes). Thus, while EHRs could be considered currently more suitable for the timely assessment of clinical aspects of mental disorders, complementing their data with those from longitudinal surveys could enhance and enrich such assessment [32,33].

Despite the abovementioned differences between the data from population health surveys and those from EHRs for monitoring of mental health, the complementary nature of these data sources must be highlighted. One successful example of their complementarity for the study of mental disorders has been reported in Denmark [32], where a shared identification number assigned to the individuals included in their information systems allows the linkage between population health surveys and EHRs [33]. The extensive linkage of individual data in the Danish population (including population health surveys; national records from hospitals, clinics, pharmacies, and death registries; and various other public and private data sources) synergistically enhanced the data's overall quality for the assessment and monitoring of mental health conditions.

Moving Forward Toward the Generalization of the Use of Population Health Surveys in Public Mental Health

Given all the potential benefits and applications indicated herein, widespread use of population health survey data (ideally linked with data from high-quality EHRs) could be helpful both for research purposes and to enhance decision-making in public mental health. Their widespread use might be achieved through not only the deployment of large, address-based probability-sampled surveys, similar to the deployment of the NHIS in the United States [3], but also encouraging individual research groups to join forces and carry out large-scale population health surveys or leverage the ones already implemented. However, in order to guarantee adequate and appropriate use of data from population health surveys, the development of a common usage framework and enhance their interoperability with other data sources remains essential.

The development of a common usage framework of data from population health surveys must be in line with widely recognized initiatives such as the GRADE (Grading of Recommendations Assessment, Development and Evaluation) Evidence to Decision (EtD) framework [34], and will need to include unified protocols and guidelines for data collection, data analysis, and interpretation. For data collection, guidelines must consider both the tools used for monitoring of mental health and the minimum set of general domains (eg, socioeconomic and health service use) and specific factors (eg, educational level attained and number of primary care consultations during the last year) included within any population health survey.

It should be also mentioned that the data collection process and the potential biases related to the representativeness of the data and their quality are also key challenges. The use of multistage sample designs and data verification techniques, for instance, would enhance the validity of data from population health surveys for both research and public mental health purposes. Additionally, for the correct interpretation of their results, a set of valid and reliable standard measures for the assessment of a broad range of mental disorders needs to be established, and their cross-cultural equivalence in different contexts should be ensured [10]. Therefore, the development of a common usage framework for the use of population health surveys for monitoring mental health would improve the suitability of their data for this purpose, enhance the comparability of their results and, consequently, increase their impact on public mental health decision-making.

Finally, given the complementing advantages of the data from population health surveys and those from EHRs, another key step forward is to promote the interoperability of these 2 sources. However, to achieve interoperability, it will be necessary to systematically include variables within their data sets, which facilitate the identification and linkage of individuals across them while also ensuring anonymity. This linkage will be helpful to bring together their strengths and potentially improve the accuracy and relevance of both EHRs and health surveys as tools for monitoring mental health at the population level [35]. However, due to the substantial variation between countries in data protection laws, systematically including these types of variables could be challenging, particularly in the case of international surveys, such as the World Mental Health Surveys or EHIS. Hence, promoting the implementation of shared international regulations about data linkage and anonymization could be a helpful way to enhance the quality of administrative health data for monitoring the health status of the population.

Opportunities and Implications of the Use of Population Health Surveys

Monitoring of mental disorders at the population level, identifying their determinants, and determining their association with health care usage are key components for effective mental health prevention. Balancing their advantages and limitations, data from population health surveys are instrumental in addressing these challenges. However, to guarantee the adequate use of these data, there are different aspects that should be considered, including their specific limitations and challenges, the potential adoption of a common and shared framework for their use, and their interoperability with other data sources, such as EHRs, using shared identification variables. Promoting the use of linked data from population health surveys, EHRs, and other public and private data sources could enhance the quality of the information available for public mental health decision-making, particularly in middle- and high-income countries and ultimately improve the planning of mental health resources and maximize the impact of relevant policies to reduce the burden of mental disorders.

Abstract

Digital contact tracing and notification were initially hailed as promising strategies to combat SARS-CoV-2; however, in most jurisdictions, they did not live up to their promise. To avert a given transmission event, both parties must have adopted the technology, it must detect the contact, the primary case must be promptly diagnosed, notifications must be triggered, and the secondary case must change their behavior to avoid the focal tertiary transmission event. If we approximate these as independent events, achieving a 26% reduction in the effective reproduction number R_t would require an 80% success rate at each of these 6 points of failure. Here, we review the 6 failure rates experienced by a variety of digital contact tracing and contact notification schemes, including Singapore's TraceTogether, India's Aarogya Setu, and leading implementations of the Google Apple Exposure Notification system. This leads to a number of recommendations, for example, that the narrative be framed in terms of user autonomy rather than user privacy, and that tracing/notification apps be multifunctional and integrated with testing, manual contact tracing, and the gathering of critical scientific data.

KEYWORDS

COVID-19; SARS-CoV-2; pandemic preparedness; decentralized protocols; smartphone; mobile phone; contact tracing

Introduction

Contact tracing is a time-tested tool to fight an emerging outbreak of infectious diseases such as COVID-19, caused by the virus SARS-CoV-2. If x% of infections are identified and y% of those in contact with a known case are traced in time and persuaded to stay home, then in a well-mixed population, the effective reproduction number R_t will decrease by a factor of x×y. This seems sufficient to reach the level $R_t<1$ needed to quash an outbreak of many emerging pathogens (which have not yet evolved a basic reproduction number R_0>>1) before the outbreak develops too far, especially in combination with modest social distancing. However, SARS-CoV-2 proved to be a particular challenge for contact tracing. With short incubation periods and presymptomatic transmission making it difficult to trace contacts in time, digital contact tracing held tremendous promise, especially when leveraging smartphones that were already in consumers' hands. Here, we reflect on why digital alternatives to traditional contact tracing instead had limited impact on SARS-CoV-2 transmission. We do so with a focus on Exposure Notification (EN) and related protocols, in part by drawing on first-hand experiences from our various involvements with this technology, including material that has not previously been public as well as publicly available documents that are not indexed for literature searches. Our intent is to better inform those who might wish to prepare for and fight a new pandemic with a similar technological approach, allowing them to learn from what happened during the COVID-19 pandemic.

A Brief Note on Terminology

Some digital protocols make it impossible to identify pairs of interacting individuals, even in cases where one transmitted disease to the other—in this case, we refer to *notification* instead of *tracing*. We refer to *proximity* versus *presence* notification and tracing based on whether exposure is assessed on the basis of proximity to an individual versus presence at a shared-air venue. We reserve the term EN for the specific protocol implemented by Apple and Google; this protocol is a form of proximity notification. EN is one of several protocols used to assess proximity based on signals sent and received between pairs of devices using low-energy Bluetooth. Other protocols may use ultra wideband or ultrasound for proximity detection, or detect presence from other information such as QR code scan histories, GPS coordinates, or logs of Wi-Fi access points. These technologies can also be used to warn of future infection risk [1], a use case that is beyond the scope of this study.

Overview of the Six Failure Points

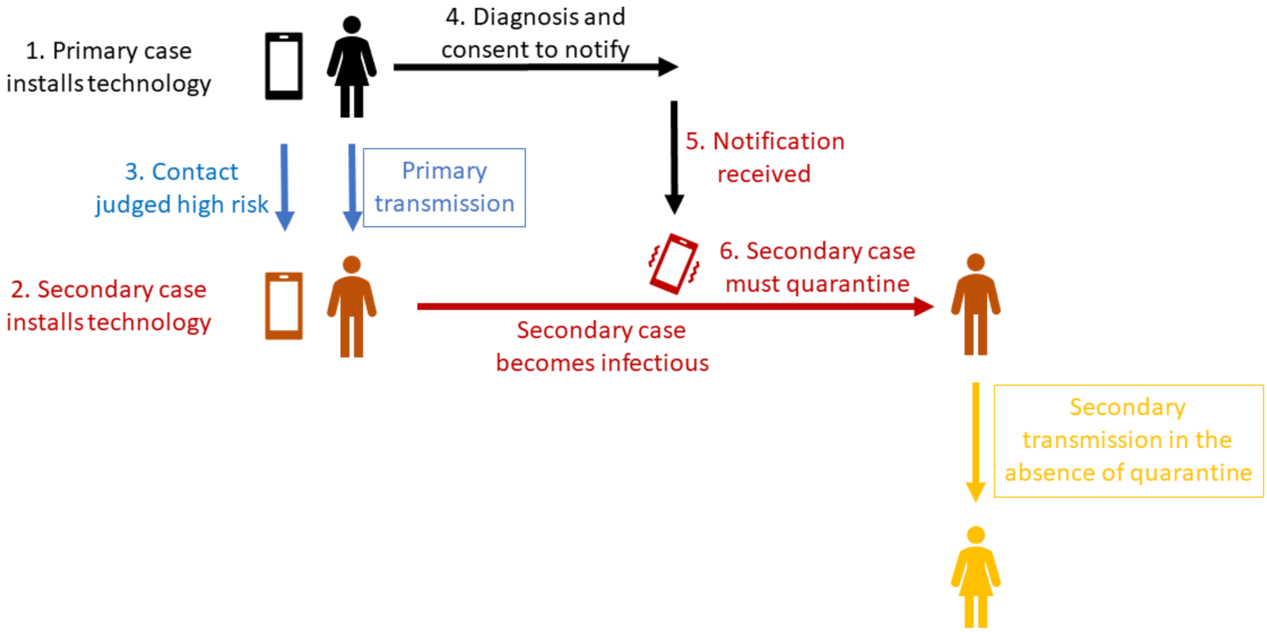
To be effective in stemming a transmission, a notification must navigate six potential points of failure (Figure 1):

1. The primary case must have the technology in place at the time of transmission.
2. The secondary case must have the technology in place at the time of transmission.
3. The exposure that resulted in transmission must be judged to be high risk.
4. The primary case must obtain a positive diagnosis in a timely manner.
5. Notifications stemming from the primary case must be rapidly triggered following a positive diagnosis.
6. After receiving a notification, the secondary case must change their behavior in a manner that prevents onward transmission to tertiary cases.

If each of these steps were successful 80% of the time, and we approximate the 6 steps as independent events, then transmission (R_t) would be reduced by 0.8^6=26%. Although not transformational on its own, this would be a significant contribution to quashing an outbreak, and nonindependence will make this figure somewhat higher. However, if each step were successful a still-respectable 40% of the time, again assuming independent events, R_t is reduced by only 0.4%. Although this can make a valuable contribution to flattening a curve [2] or reducing the stringency of indiscriminate social distancing [3], it falls far short of containing a pandemic. Given this simple mathematical consideration, if the aim is containment such that life is relatively normal while waiting for a vaccine, then we clearly need to achieve low failure rates at all of the 6 failure points.

Next, we discuss each of the failure points. We provide some history of how they were handled, together with speculation about how they might have been handled better.

Figure 1. Chain of viral transmission from primary to secondary to tertiary case. Digital contact tracing and notification must succeed at all 6 critical points to avert transmission to the tertiary case.



Failure Points 1 and 2: App Adoption

We jointly discuss the first 2 points of failure because they are similar; both involve technology adoption among the population destined to become infected. Following media coverage of the model by Ferretti et al [4], more attention was paid to app adoption than to other points of failure, with an odd obsession with 60% adoption in the general population as a magic number [5]. Note that the adoption rate that matters is not that of the general population but that of the population likely to become infected. For SARS-CoV-2, this meant that adoption among essential workers was what mattered during stay-at-home mandates; when staying at home was common but optional, young adults constituted a disproportionate share of cases. However, app adoption among the general population can serve as a rough approximation.

The most straightforward way to achieve low failure rates at points #1 and #2, while still maintaining user autonomy, is to make the broadcasting and reception of appropriate signals opt-out. Opt-in consent of the primary case would still be required at failure point #5 and that of the secondary case at #6. Apple and Google were the only entities with the power to implement an opt-out protocol, with competitors such as Huawei having little market share. Despite a secure EN design that ensures that no information about Bluetooth signals sent or received leaves the phone without subsequent user consent, they chose to make Bluetooth broadcasting and receiving opt-in. We note that Apple's "Find my..." service uses Bluetooth in a similar fashion and is at the time of writing opt-out rather than opt-in [6].

An even lower failure rate could have been achieved by a protocol proposed by one of us (JIMP) to use the Wi-Fi logs already collected by Android and by Apple's iOS operating systems instead of an additional purpose-built Bluetooth layer. Had Google and Apple chosen to allow an app post hoc access to these logs or to build operating system functionality around them, this would have completely eliminated failure point #1 for individuals who regularly carry smartphones. Individuals would still need to have the technology switched on to bypass failure point #2 to receive a notification. Similar to Bluetooth solutions, those who do not regularly carry smartphones (mostly young children and older adults) would need to be provided with other devices that could record proximity or presence; in Singapore, small digital tokens resembling keychain fobs covered smartphone nonusers who would not otherwise have been able to participate.

To understand why Apple and Google did not make the technology opt-out or Wi-Fi based, it is important to consider the incentive structure from Apple's and Google's point of view. Cooperation requires time from their employees and has no apparent commercial upside (beyond the economic gains to the company should efforts succeed in containing a pandemic). From their perspective, the primary consideration is the effect of their actions on brand perception. The upside impact on their brand is gained primarily from doing *something* (eg, working together), but there is no proportionate impact from doing something more rather than less effective. The potential for downside impact is substantial and focused mostly on privacy concerns, exacerbated by any ceding of control over the technology and its marketing to public health authorities. They are thus incentivized to do *something*, to carefully manage perceptions of that something, and to avoid brand risk, but not to increase effectiveness against disease transmission. In future, if companies such as Apple and Google are to be gatekeepers of such technology, governments should devote urgent attention to aligning their incentive structures.

Achieving high opt-in adoption was difficult. Singapore's non-EN solution succeeded, with opt-in adoption >90% even before the app became required for entry into public spaces [7]. In contrast, the highest EN adoption rates are of Germany's

Corona-Warn-App, used by approximately 34% of the population [8], and the National Health Service (NHS) COVID-19 app, with 17% to 25% of the population of England and Wales having activated Bluetooth exchanges in 2020 and 2021 [9]. Lower rates were reported elsewhere: 8% in Canada, 13% in New Zealand, 10% to 16% in the Netherlands, and 19% in Switzerland [10].

A positive caveat to this fairly bleak assessment of uptake is that if one individual has adopted the app, it is more likely that other members of their social network have also adopted it. In other words, failures at points 1 and 2 are correlated, making the probability of overall failure lower than it would be if each failure were an independent event [11]. Both for this reason and as part of good marketing practices [12], it can make sense to look at adoption rates within smaller communities. Adoption by 46% of the cases was achieved in a campus setting with an intensive marketing push [13] and adoption by >33% of the population was achieved in an island setting [14].

Key to the relatively high adoption of the NHS COVID-19 app and the Corona-Warn-App were their additional functionalities. When entering a venue, scanning a QR code with the NHS COVID-19 app was offered as an alternative to writing down contact details. Although subsequent presence tracing on the basis of either form of information was conducted relatively rarely (refer to *Failure Point 5: Triggering Notifications* section), the requirement to check in to a venue did prompt app installation [15], especially in the subset of the population most likely to become infected through contact with strangers. The NHS COVID-19 app was also useful for ordering tests, and both it and the Corona-Warn-App offered a rapid and secure system for receiving test results. Later, the integration of European Union digital COVID-19 certificates (for vaccination, recent negative test result, or recovery from infection) triggered another wave of app adoption. Near-universal adoption in Singapore was achieved only after the proximity tracing app became the only means for compulsory venue check-in [16]. Similarly, adoption rates in India skyrocketed after the government made the app mandatory for smartphone owners to move freely in public areas. We believe that to achieve high adoption, future pandemic apps need to seamlessly integrate services that are useful and convenient for users.

In late 2020, Apple and Google launched the “Exposure Notification Express” (ENX) system. In Androids, this is a simple app that public health authorities can autogenerate from a small set of choices. In Apple’s iOS, this is part of the Settings. Apple claimed that placing the scheme in the Settings created less friction for opt-in than was present for an app, and hence, ENX should be preferred to a custom app. However, ENX never reached use levels comparable with those of more successful European EN apps. This is despite the fact that the phones of residents of adopting US states were pinged to promote activation and installation. Such pings were used to promote ENX but not custom EN apps. When this situation was pointed out, Google immediately offered the same adoption promotion pings for custom apps as for ENX, whereas Apple declined to do so.

A number of players, including but not limited to Apple, argued that the key to persuading people to adopt lay in ensuring the privacy of the system. Fortunately, decentralized protocol designs offer powerful solutions to the privacy problem. Centralized approaches send information about who went where with whom to a central database. This breach of privacy, although clearly facilitating contact tracing, also poses risks of abuse as part of a mass surveillance state. Under a decentralized protocol, information about a user is stored on that user’s device and, to some degree, the devices with which it was in contact. Users can be given autonomy over the use of data on their own devices so that, for example, the data cannot be accessed without consent and can be deleted at any time. Far from threatening privacy, apps that use decentralized protocols are among the safest apps on users’ smartphones.

Interestingly, privacy-invasive schemes, such as QR code check-in presence tracing in Australia, were well accepted and widely used (self-reports of 61.9% always checking in either digitally or on paper, 26.3% mostly, 4.7% sometimes, 3.3% occasionally, and 3.8% never [17]). This achieved acceptably low failure rates far superior to any EN implementation, even with enforcement left to the venue and peer pressure. Indeed, supported by celebrity-driven public relations pushes, 40% had downloaded or were willing to download even the ineffective but convenient Luca QR code check-in app in Germany [18,19]. Perhaps, these much higher adoption rates for presence tracing than for proximity notification are because what was recorded was considered public information that a user was in a public space, rather than also capturing who had interacted with whom even in private. A simpler explanation is that the QR code check-in system is easy to understand as equivalent to writing down your name and number; decentralized privacy-preserving schemes, by being harder for the public to understand, run the paradoxical risk of decreasing rather than increasing trust and hence adoption.

Trust in government predicts adoption more strongly and consistently than privacy [15,20-23]. Although 20% to 25% of respondents to cross-sectional surveys cited privacy concerns as a reason for not installing a contact tracing app [23,24], a longitudinal study found no causal relationship (although it did for health concerns and social norming) [25], and a focus group found that health concerns were more important than privacy considerations [26].

High trust in the government in general [27] as well as in the government’s response to the COVID-19 pandemic [28] was critical to Singapore’s high adoption. When trust in governments is low, it might help if more trusted entities, such as primary care providers [29], were used to promote adoption. Singapore’s explicit policy to relax certain pandemic restrictions once adoption increased from 50% to 70% might also have helped drive adoption, together with the scheme’s high profile as a clear government priority.

Privacy is not the only aspect of trust salient to potential users; many also wanted to know that an app was effective before they downloaded it. Even if they decided to take a chance at first and install it, they wanted subsequent reassurance that it had proved effective to keep it active on their phones. Multifunctional apps, such as the NHS COVID-19 app and the Corona-Warn-App, can also provide reassurance via interaction that there is a point to maintaining the app on the user's phone. Although it is clearly important to hire good marketing and public relations professionals to promote adoption, it is just as important that scientists and engineers do not make product decisions in isolation from their impact on marketing. This is because achieving high adoption is part of the science of making these apps effective.

Distinct from the scientific study of app effectiveness in stemming transmission [30] is the study of viral transmission itself to learn its incubation period, infectious period, and mode of transmission [31]. An obstacle to such a study was that some *privacy-first* rhetoric rejected making the study of SARS-CoV-2 transmission an aim of the scheme, even if the science could be done in a manner that preserved privacy.

The only reliable way to learn about transmission to and from humans is to observe it, either in human challenge trials (directly observing incubation periods and also the infectious period if the study includes transmission to cohoused animals) or in natural circumstances (ie, via contact tracing). Given ethical concerns about the former, an unacknowledged corollary of rejecting the use of digital schemes to study transmission is that studies must be performed via manual contact tracing (ie, in a more privacy-invasive way) or not at all. Unfortunately, even the more basic functions of manual contact tracing were quickly overwhelmed, leaving little capacity for the more intensive investigations required to study transmission dynamics. Not using digital approaches to fill this void was a lost opportunity. This left early manual contact tracing studies as the only source for basic transmission parameters, even after the incubation time and infectious period of SARS-CoV-2 were suspected to have shifted because of viral evolution and immunity.

Even an app whose failure rates across the 6 points were too high to substantially reduce transmission could have been enough to generate valuable information about evolving incubation periods and infectious periods in close to real time [31]. Apps can also help with epidemiological surveillance; for example, the Indian government combined location (with a random error added for privacy; EN apps were banned from accessing location) and symptom information to identify emerging hot spots before seeing spikes in test positivity. Singapore used the number of detected contacts per case to inform changes in social distancing policies. Support for the scheme, both from the public and from public health authorities, might have been shored up by evidence that it was at least doing good for science or disease surveillance, and this might have created a virtuous circle of adoption.

A prevailing narrative described the technological choices in terms of a trade-off between privacy and effectiveness, in which any collection of more data can increase perceived privacy risk and hence reduce public acceptance [30]. We believe that this framing is harmful, especially when it comes to promoting app adoption; for example, the public might conclude that because the technology is private, it cannot be effective. Regarding substantive risks beyond those of perception, with flexibility and creativity, effectiveness can be achieved by a decentralized, privacy-preserving design that does not risk expanding mass surveillance. With sufficient ingenuity, there may be no need for compromise at all, which makes the privacy versus effectiveness trade-off narrative misleading. *Privacy first* should therefore not be used as grounds to support the status quo to the point of refusing to engage in ongoing dialog regarding how to safely proceed with iterative improvements to effectiveness, its measurement, and the gathering of broadly valuable scientific or epidemiological surveillance data. Given that harms from technology are not limited to privacy concerns [32], a privacy-preserving design does not relieve governments of their duty to monitor effectiveness [33].

Furthermore, privacy is merely a component and a means to the more important end goals of autonomy and protection from abuse. The latter need not be a serious issue because a well-designed, decentralized solution can offer both effectiveness and protection from abuse. However, trade-offs between effectiveness and autonomy are real, that is, coercion can increase effectiveness, whereas autonomy can weaken it. The option to maintain privacy while extracting benefit from the system is an important but not the only aspect of autonomy.

Although the privacy approach of EN provides excellent protection from abuse, it actually limits autonomy by denying users the right to share their data with public health authorities if they wish to. This became clear when one of us (JIMP) proposed a small change to the EN protocol that could convert it from proximity notification to proximity tracing, without significantly raising the danger of misuse. As described in the *Failure Point 3: Detecting and Evaluating Exposure* section, this modified protocol would allow certain users to share more data with public health authorities. This would apply to users who gave explicit consent to sharing after both receiving a notification and testing positive. By helping manual contact tracers do their job of pairing cases and identifying superspreading events, this change would presumably have generated more buy-in from public health authorities (discussed in the *Failure Point 5: Triggering Notifications* section). More buy-in from the local public health authorities responsible for manual contact tracing could have set up a virtuous circle by which they, in turn, promote adoption in the community. This small modification was rejected by Apple as being a threat to privacy, despite the fact that any privacy loss is triggered by users exercising autonomy over the use of their data. Contributing to this dynamic is the fact that privacy is part of Apple's brand, aligned with the broader deployment of antitracking as a business strategy [34-36]. A preference for privacy over autonomy, by disallowing the opt-in sharing of more information with public health authorities, has also been expressed by some academia-based protocol designers [37].

The slogan *privacy first* is an odd one. We believe that autonomy and protection from abuse are better-framed goals than privacy. Furthermore, the best way to put privacy first is self-evidently to have no digital system at all, raising the possibility that privacy first schemes were designed primarily to displace more invasive options, with stemming transmission almost an afterthought. For each proposed scheme, one should assess the nature and scope of any vulnerabilities versus the anticipated impact on disease transmission.

Failure Point 3: Detecting and Evaluating Exposure

Point of failure #3 concerns the need to record an interaction at which viral transmission took place, but viewing it this way is not sufficient. Total success could trivially be achieved by a general stay-at-home order, which is equivalent to telling everyone that they are potentially exposed. This illustrates the importance of avoiding false positives, that is, alerts received by people who are not infected. The primary purpose of proximity or presence notification is best seen as identifying and alerting people at a sufficiently high risk of infecting other people such that they should change their behavior in response to that information. This benefit applies only to secondary cases who would not otherwise know of their exposure in a timely manner, that is, it excludes household contacts and other social networks that perform rapid do-it-yourself tracing. A major advantage of digital schemes is their complementary ability to notify strangers.

One aspect of this is to detect any contact at all. With core (ie, regular) Bluetooth, iPhone-to-iPhone communication does not work in the background. Apple's cooperation in setting up EN was needed to overcome this serious obstacle. Apple could have chosen to enable iPhone-to-iPhone communication in the background in the same way that they already allowed background communication between iPhones and Androids, which would have allowed app developers to implement their own protocols. Indeed, India launched the Aarogya Setu app using core Bluetooth rather than EN, given that iPhones are rare in India compared with Androids. Singapore stuck to its own BlueTrace protocol (based on core Bluetooth), given the sacrifice of epidemiological utility that switching to EN would have implied [38], eventually leveraging Android-iPhone background communication into a gossip protocol that effectively allowed iPhones to see each other in the background whenever an app-using Android was also present [39]. Other non-EN jurisdictions such as France pivoted away from proximity notification and toward presence tracing. In Australia, state-specific centralized presence tracing apps were the dominant response, whereas a federal app based on TraceTogether, despite a respectable early download rate, languished once it became apparent that it failed at other steps.

The lack of interoperability among jurisdictions can also interfere with contact detection. For example, if each person is far from home for 5% of their interactions (eg, being away for 18 d/y), the corresponding contact detection failure rate will be approximately 10%. Thus, when viewed quantitatively, the considerable attention devoted to this issue seems disproportionate relative to other sources of failure. As an alternative to immediate global standardization, metropolitan or other highly interconnected areas spanning multiple jurisdictions (eg, Washington, District of Columbia combined with adjacent counties in other US states or the Navajo Nation spanning multiple US states) could choose to roll out a joint product. Multiple apps need not interfere with each other, making this an option for some commuters. A common server was set up to enable communication among the EN implementations of different US states and another common server to communicate among implementations of different European nations [40], but despite the attention to this issue, global interoperability was never achieved. Perhaps the best model for a new pandemic is to allow divergence in the early stages as part of a process of innovation at the cost of interoperability, to learn from the different experiments performed by different jurisdictions, and then to use the desire for interoperability as the catalyst for switching from lower-performing systems to higher-performing systems through app updates. An advantage of postponing interoperability is to ensure that premature standardization does not suppress innovation.

Beyond detecting exposure at all, doing a better job in assessing the infection risk posed by a given exposure can be seen as an ethical imperative, given the harms caused by unnecessary quarantine [32]. Better risk analysis means more precise resolution as to which individuals pose how much statistical risk to others on a given day and using a risk threshold to trigger notification. In other words, good risk analysis means improving the receiver operating characteristic (ROC) curve with respect to infection and then choosing a socially optimal point along the ROC curve.

Under reasonable assumptions, the socially optimal approach is to alert those who are significantly more likely to infect others than is the average member of the population not already in quarantine or isolation [3]; for the NHS COVID-19 app, notified individuals were 2- to 20-fold more likely to subsequently report a positive test [41]. Under the assumption that some form of regulation maintains a geometric mean of approximately R_t=1 while waiting for a vaccine, the total value of both manual contact tracing and digital notification schemes is highest at low case prevalence [3] when fewer individuals need to quarantine to achieve the same population benefit. Digital contact tracing also becomes more important when social restrictions are few, and interactions among strangers are thus more common. Unfortunately, in many jurisdictions, attention to all pandemic measures tended to rise and fall with case counts rather than fluctuating between a focus on contact tracing during lulls and on population-wide measures when case counts were high. This interfered with effective planned implementation.

One obstacle to good risk analysis was public health guidance that ignored evidence for airborne transmission in favor of the droplet theory that physical distancing of 2 m (or 1.5 m or 6 feet) was effective protection. As a result, significant technological research focused on calibrating EN Bluetooth settings to a threshold of 2 m or similar [42-45]. A number of unpublished analyses suggest close to superimposable ROC curves, regardless of Bluetooth settings. Superior distance assessment via Bluetooth could likely have been achieved using all 3 Bluetooth channels instead of 1 or by using the median attenuation instead of the mean (decisions made within the EN application programming interface [API] and hence not available to app developers). Ultra wideband or ultrasound would assess the distance more precisely than Bluetooth. However, none of these tweaks change the fact that distance only moderately predicts infection risk, and proportionate effort was not invested in integration with predictors such as local carbon dioxide levels. Nor were users provided with information such as the time or location of exposure, although this information was present on their phone. This prevented users from integrating information about masking and ventilation into their personal assessment of the risk of infection. Not allowing this, even with the permission of the primary case, is another example of privacy being put before autonomy.

After coming up with *good enough* Bluetooth settings, a better approach would have been to deploy an app that collected data both on the parameters of exposure and on whether it was followed by infection. These data could have informed the risk settings better than any experiment on Bluetooth-distance relationships. We note that a protocol might flag an individual as high risk on the basis of an exposure other than the one that infected them; real-world calibration will include such cases, potentially increasing impact beyond that of causal connections.

An ongoing process of data collection and risk calibration would have taught us much about transmission, for example, any changes to the timing of infectiousness as new strains appeared and as individuals acquired prior immunity. This is important because exposure dose, and hence infection risk, depends not only on the physical characteristics and duration of an encounter but also on how infectious the primary case is at that moment. The main data used to assess this were the date of symptom onset or, if asymptomatic, the date of the first positive test. The infectiousness window was initially estimated to run from approximately 2 days before to ≥5 days after symptom onset [46]. Unfortunately, a bug in the code of the original analysis concealed the earlier onset of infectiousness. Although this was rapidly identified and corrected [47,48], public health guidelines, describing the days for which the primary case should be considered infectious for contact tracing purposes, did not change accordingly. Nor did they modify the contact tracing window following the emergence of new SARS-CoV-2 variants, nor for reinfection or breakthrough cases. To re-estimate this window, they would need to repeat the same type of intensive manual contact tracing studies; this did not occur. Other information about infectiousness could, in principle, come from the Ct count (which was not reported in standard laboratory SARS-CoV-2 polymerase chain reaction testing protocols) or connection to a superspreading event, but neither was used in practice.

EN version 1 allowed the app that is installed on the smartphone of the primary case to assign 1 of 8 levels of infectiousness to each day during which others might have been exposed. This integer is the only metadata regarding the primary case that is available to the exposed contact. EN version 2 enabled some improvements to risk analysis by lifting the previous 30-minute cap on exposure reported by the contact's phone but reduced the number of levels of infectiousness to 2 (although Germany repurposed other bits of information to reclaim the use of 6 [49]). When asked to make the infectiousness metadata easier to use for both risk analysis and scientific study, specifically to propagate the timing of exposure relative to symptom onset or test date, from the server to the exposed contact, Apple replied that they could not do so because of a vulnerability whose details had been worked out by Google but which they could not remember.

Beyond EN, some jurisdictions acknowledged airborne transmission to the point of performing not just proximity tracing but also presence tracing. In corresponding presence tracing schemes, people going to venues such as restaurants would either write down their name and contact details or use an app to check in by scanning a QR code. For Singapore's SafeEntry, they could also use a Bluetooth-based sensor (to detect a TraceTogether app or token) or scan a barcode. With a low-risk threshold, for example, a jurisdiction with a zero COVID-19 policy, all individuals who were present at the same venue as an infectious individual could be alerted.

A better strategy for a higher risk threshold is to focus on *cluster busting*, that is, prioritizing those venues at which at least 1 transmission event is already known to have occurred. These generally correspond to gatherings at which the primary case was highly infectious, ventilation was poor, and there were other risk factors such as speaking, singing, and exercising and lack of mask use. There are compelling arguments for the effectiveness of such *backward tracing* for pathogens such as SARS-CoV-2 [50-52]. This requires cases to be linked.

A decentralized protocol such as EN could have contributed to cluster busting, had the app of a user who was first exposed then tested positive been allowed to upload the cryptographic key responsible for triggering the exposure. EN chose to keep this key sequestered within the operating system, with no option to notify the server. If a key associated with a transmission event were uploaded, the infectiousness score of that key could then be significantly upgraded on the server, triggering follow-up notifications with stronger wording as well as additional notifications following briefer exposures to the possible superspreading event. If users were additionally given the option of sharing their identity with public health authorities, paired with the cryptographic key that served to link them, then both members of the pair could be prioritized for interviews and the location of the superspreading event identified to assist manual contact tracers.

Failure Point 4: Test Access

No form of contact tracing, digital or manual, will work unless we are able to identify who is likely infected and, thus, whose contacts should be notified and traced. Although some countries such as South Korea did better, in many countries, SARS-CoV-2 tests were slow to roll out, testing capacity was quickly overwhelmed, test shortages persisted for a surprisingly long time, and not all symptomatic individuals sought testing [53-55]. It is obviously critical to improve pandemic preparedness in this regard, independent of its relationship with digital notification or tracing.

Improving the allocation of scarce testing resources by identifying which individuals were most likely to test positive was a primary use case for India's Aarogya Setu, with the highest-risk individuals having positive predictive values >40%. To achieve this, Aarogya Setu used a sophisticated risk algorithm to trace not just direct contacts but also contacts of contacts and so on (multiple-degree tracing) in a risk-consistent manner, faster than testing could keep up [56]. In EN, functionality for contacts of contacts was limited, relied on self-reporting, and was never used. Another important factor for allocating scarce testing resources is utility for onward contact tracing and notification, for example, by abandoning samples more than a certain number of days past symptom onset to rapidly turn around tests whose results will be more actionable.

For some pandemics, there may be one or more hallmark symptoms (such as loss of taste and smell) that are sufficiently distinctive to warrant presumptive diagnosis. In other cases, the symptoms might be suggestive but less definitive. Strategies for triggering notifications given contact with an unverified case, in the absence of test results, overlap with the next point of failure, namely, how to manage the verification of positive test results.

The CoEpi app [57] attempted to launch on the basis of symptoms alone using core Bluetooth (it was designed before EN). It was rejected by the Apple Store on the basis of a lack of public health authority involvement, with the suggestion to seek public health authority support from a “city or county.” Its resubmission with explicit support and endorsement from the public health department of a county in Washington state (from a different nonprofit account because Apple suspended the primary developer’s account without explanation) was also rejected. Apple representatives told developers that unwritten and nonpublic rules stood in the way and that it was the desire of Apple to not have “competing” approaches.

When test turnarounds take several days, but each day is critical, it might be helpful to issue *preliminary* notifications on the basis of exposure to an exposed, symptomatic individual awaiting test results to be converted later to a confirmed exposure. The same principle can be expanded deeper into a social network. We note that recursive protocols can incidentally achieve some of the functionality of backward contact tracing, showing up as multiple social network paths via all attendees to the index case.

Failure Point 5: Triggering Notifications

Following a positive diagnosis for SARS-CoV-2 in a primary case, speed is essential to notify secondary cases before they transmit onward to others. The simplest option is to allow any app user to self-attest that they are infected. An issue with this is the potential for abuse. For example, before an election, a coordinated set of individuals could intentionally socialize widely in a setting that tends to vote in a particular way, for example, a college campus, and then falsely report positive diagnoses timed to trigger quarantine on the day of the election. This was a specific concern for the US November 2020 elections. Disruption of essential workers at core infrastructure might also be achieved through targeted attack.

In this light, and to ensure trust in the system, all EN jurisdictions launched with systems that ensured that only verified positive test results could be used to trigger notifications. Many jurisdictions initially relied on manual contact tracers to issue a time-sensitive secure code over the phone to individuals who tested positive. This led to extremely high failure rates, given that case investigation was overwhelmed. EN imposed extra work on case investigators in issuing verification codes but provided nothing back to them in return, for example, by helping link cases into transmission chains, as could be done by the protocol tweak described earlier. Even when the code was successfully delivered and entered into an app, it tended to occur with a significant delay. This defeated much of the purpose of a digital scheme, whose motivation was to make contact tracing faster [58]. Primary care can similarly become overwhelmed, and in a controlled, nonoverwhelmed setting, voluntary adherence even once a code is provided was only 64% [14]. In contrast, Singapore’s solution was fully integrated with both testing and manual contact tracing, speeding up the latter from 4 days to <2 days [59] and switching to primarily automated alerts only after case counts increased during the Delta wave in late 2021.

Google and Apple insisted on having only 1 EN app per country or, in the case of the United States, 1 per state. However, test and trace programs are run by counties and tribal nations in the United States, by provinces in Canada, by cantons in Switzerland, and so on. This disconnect did not encourage buy-in by the local public health authorities charged with distributing secure codes; app design choices were made by a different level of government than the level responsible for implementing the test and trace policies.

Presumably, Google and Apple preferred to limit the number of relationships they needed to maintain and of EN apps whose code they needed to review. However, this could also have been solved via a flexible global app (or an ecosystem of several at least partially interoperable apps); Google and Apple would only need to deal with 1 or several app developers, who in turn would deal with the customizations requested by the various jurisdictions. Such an ecosystem began to spontaneously appear through players such as NearForm, PathCheck, and WeHealth. A bottleneck in many US states was the slow process of government procurement to pay such players. One reason many US states opted for ENX was that because no payment was required, it bypassed delays in the procurement process, despite the fact that running ENX and associated verification code distribution still generally required a state public health authority to internally dedicate full-time staff. With the advent of ENX, Google and Apple ended up needing to maintain more relationships than they would have with private-sector middlemen.

Given the difficulties in providing verification codes by phone, most US implementations, beginning with the state of Colorado, shifted to a system based on SMS text messages. Positive test results reported to the state were collated, and cases were then, in batches, each sent an SMS text message with a deep link that acted as a verification code. Vague language and a few decoy SMS text messages were used to comply with the Health Insurance Portability and Accountability Act. There was still some posttesting delay associated with reporting and collating, some SMS text messages were caught by spam filters, some were lost to the SMS delivery network during peak use periods, and the system was confusing for recipients who had never heard of EN. However, it was faster and had a higher success rate than having a manual contact tracer issue a code over the phone. The ratio of #claims/#cases (measuring a combination of failure points 1 and 5) went up, for example, from 1.8% to 9.6% in the state of Washington (with the caveat that both are upper bounds on success because the total neglects delays in receiving codes and includes codes claimed by individuals who installed EN only after receiving the deep link) [60].

An alternative way to issue verification codes was to integrate them with testing, that is, with the health care system rather than the public health system. The best solution is to make the app into a test result delivery system, that is, to link test samples to QR codes, with the app knowing the ID of its user's test and checking a server for matches. This shortens the time from a sample testing positive in the laboratory to notifications being triggered. It still requires the user to check their notifications for a positive test result and to consent to have their contacts notified. In Singapore, the median time from SMS text message notification of test results to consent to upload data was <30 minutes, with a consent rate of 70% to 80%. EN was eventually modified to allow an even better preauthorization workflow, whereby consent could be given at the time of testing, and notifications were sent as soon as the app became aware of the positive test result, with no further user input required. This system was used in Germany. Germany also offered free supervised antigen tests; the unvaccinated required a recently verified negative result to permit access to some venues, and positive results could be verified by the same system for use in EN.

Integration with testing was easier for the NHS COVID-19 app than for many others, given an already centralized system. However, it was also possible elsewhere; Germany integrated its app with >10,000 different test providers. The speed and convenience of obtaining a polymerase chain reaction test result back through the app helped prompt download, although some users opted only to use this feature and not to trigger notifications. It is important to investigate the cause of this refusal, for example, did it stem from distrust regarding anonymity, were people trying to avoid pushing friends and family into uncompensated quarantine, or was it simply an instinctive "no" under time pressure in a stressful situation, for which a different workflow might have elicited a different decision?

Two EN pilots at US universities explored integration with campus testing programs, which provided rapid test turnaround before adequate testing became available to the general public. The University of Alabama linked test results to phone numbers and then allowed individuals to use their phone number as their verification code through the use of a 1-way hash. The University of Arizona provided verification codes as part of the web-based portal from which the test results were distributed, with 25% of cases claiming a verification code [13]. As part of an (abortive) expansion to the state at large, API integrations were created not only with the state's largest test providers (LabCorp, SonoraQuest, and others) but also with Doximity, an app believed to be used by 70% of the state's physicians. Surveys show higher trust in health care providers than in public health authorities [29,61], making physicians' involvement potentially useful.

In retrospect, all these schemes were too complex to work reliably from the outset, at least in most jurisdictions. Better might have been to allow self-attestation of positive test results or even self-attestation on the basis of symptoms alone at times during which tests are in short supply (refer to the *Failure Point 5: Triggering Notifications* section). To avoid the potential for malicious use, unverified reports could trigger notifications with different messaging: not requiring quarantine, merely warning the recipient, and including the fact that the person who exposed them had self-attested to their infected or symptomatic status. Once postexposure quarantine was relaxed and home testing became the norm, many EN jurisdictions switched to self-attestation.

All the same difficulties arise with presence tracing. Many QR code check-in schemes required manual contact tracers to identify locations of interest to trigger app notifications. Similar to other forms of manual contact tracing, including pen-and-paper check-in at venues, this process was often overwhelmed. Although fully automated systems would have been faster and more reliable, they were not permitted for apps that also ran EN. New Zealand implemented this functionality early on, that is, users who tested positive were able to upload the set of QR codes they had scanned to public health authorities. However, when the NHS COVID-19 app attempted to follow suit, its app update was rejected [62], and New Zealand was also forced to make changes. Google and Apple allowed EN app users to store a local copy of their check-in history on their phone and to read it over the phone to manual contact tracers, but they did not allow an opt-in upload button, which is again a rejection of user autonomy on the grounds of privacy. They did permit an alternative automated QR code check-in system in the German EN app that was designed to never be linked to identities; however, because this system did not satisfy laws in the many German states requiring the collection of identity information, this limited its adoption.

Finally, many systems assumed that once an individual tested positive, they would enter isolation such that only past contacts and not future contacts would need to be notified. This turned out to be overly optimistic. We recommend that future systems anticipate nonadherence, with daily prompts of "Did you succeed in isolating today?" leading to the option to upload new data to anonymously notify that day's contacts, in addition to contacts from the initial upload.

Failure Point 6: Behavior Change

To stem transmission, notification needs to result in behavioral change by secondary cases. Rates of quarantine can be low, estimated at 28% for asymptomatic individuals in Norway adhering for at least 1 day [63], and 11% in the United Kingdom for quarantine adherence on all recommended days [64] (albeit much higher in the app-using subset [65]). Quarantine adherence was 40% among the app-using subpopulation in the Netherlands [61]. Adherence increases with trust in the government's response to a pandemic [66].

Short of outright coercion, quarantine adherence might be improved by paying people, whether paid directly by the government or via employer mandates. Adherence might also be higher if, out of respect for their time, rigorous risk analysis (including the use of negative tests) were used to reduce quarantine duration to a minimum, with a risk threshold set on a rational basis. Some European countries gave quarantine pay to individuals traced by contact tracers but not those notified by EN. It is important to make such choices rationally, that is, to estimate the positive predictive value of an EN with given characteristics and to treat individuals with the same risk of infecting others similarly, regardless of the mode of risk detection.

There can still be substantial utility to issuing low-exposure warnings to individuals whose positive predictive value does not warrant quarantine. Short of full quarantine, more modest behavior changes also help stem transmission, for example, testing and isolating if positive [67], being more alert for symptoms and isolating if they appear, mask wearing, or avoidance of large groups and individuals who are vulnerable to severe disease. However, adherence to even these more modest requests is also far from universal, for example, in the state of Washington, only 40% of the subset of EN recipients who responded to a survey intended to get tested and 67% intended to watch for symptoms; rates were 58% and 84% on the smaller subset that also replied to a follow-up survey about actual behaviors [68]. With Paxlovid or other antivirals most effective when taken early, we note that even if notification fails to stem transmission, it can be of direct benefit to an individual who makes no changes other than monitoring for symptoms, then testing and treating if positive. Adoption rates (points of failure 1 and 2) might be higher if this direct benefit were stressed rather than relying on altruistic motives.

Even without complexities such as recommending quarantine for some but not all exposures, effective communication of *next steps* at a low reading grade level is surely important for adherence. In contrast, some EN implementations launched with quarantine recommendations that did not specify an end date, leaving users to assume that it began with the date of notification receipt rather than the unknown date of exposure. Other recommendations gave the date of exposure and left the user to perform the calculation of the quarantine end date.

Although the purpose of this piece is to present lessons learned, the better to inform responses to the next airborne pandemic, we note that the SARS-CoV-2 pandemic remains unpredictable in its evolution and that EN has not yet been sunsetted in all jurisdictions. In that light, we note that the end of quarantine does not mean the end of EN. If notification caused individuals to mask, avoid those most vulnerable to severe disease, or test then isolate if positive, then the technology would still be doing something useful, should sufficiently low rates of failure at stages 1 to 5 be achieved.

Governance for Effectiveness

To contain a pandemic, that is, to achieve $R_t<1$ through digital tracing and notification, an implementation must keep all 6 failure rates low, for example, <20%. This will require good governance, for which it can be instructive to learn from the best implementations thus far. The NHS and Germany had among the best EN implementations, even though their failure rates remained far higher than this benchmark. Singapore's non-EN implementation was more successful, with a failure rate of <5% for failure points 1 and 2 and acceptably low failure rates for 4 and 6. We hope that more scientific data might eventually emerge from it.

It is notable that both the German and NHS COVID-19 app projects engaged not only software developers, privacy experts, and applied public health practitioners but also well-respected academic epidemiologists with significant track records of directly related research and that these epidemiologists had substantial (but not sole) influence on decision-making. They might be in the best position to balance ambition of scope (to achieve $R_t<1$ not "we did something") with realistic expectations about how things will play out on the ground. This follows a more general pattern during the COVID-19 pandemic in which applied public health institutions such as the Centers for Disease Control and Prevention performed poorly, but many universities and research institutions such as the Robert Koch Institut performed relatively well, as did biosecurity-run initiatives such as Operation Warp Speed, and the pharmaceutical industry when given a good incentive structure.

The fact that iPhone-to-iPhone low-energy Bluetooth communication did not initially run in the background meant that some response from Apple was needed for effective Bluetooth-based proximity tracing and notification using iPhones. Once that response took the form of EN, countries that did not capitulate to Apple's extensive conditions for access often ended up focusing on presence tracing and notification systems instead (eg, France and Australia), unless they used a gossip protocol (Singapore) or issued alternative hardware (Singapore) or had few iPhones in their country (India). Apple's ability to exert power over EN protocol design and over API access substantially restricted the scope for innovation among individual apps. Whatever the best form of governance is, few would argue that it is best done behind the closed doors of a technology company. Given that Apple exerted its power to dictate terms and limit innovation, it is a tragedy that Apple did not use its power to enact an opt-out system. For example, the NHS COVID-19 app is estimated to have saved 10,000 lives in its first year [41], and it is estimated that for every 1% increase in uptake, it could have reduced cases by a further 1% to 2% [2].

Future success will require the measurement of failure rates at all 6 points and rapid on-the-fly adaptations to improve them. Ideally, we would invest now in these technologies, perhaps within island nations or other close-knit communities as test cases, to iteratively improve systems as part of pandemic preparedness while at the same time attempting to reduce SARS-CoV-2 and potentially influenza transmission in the short term. An iteratively improved technology is more likely to be successfully deployed should a new pathogen begin transmitting between humans, one that combines Severe Acute Respiratory Syndrome–1 or influenza A virus subtype H5N1 mortality with SARS-CoV-2 presymptomatic transmission. In the absence of current investment, we hope that this document will help kickstart the design of effective strategies at such a time.

Acknowledgments

Abstract

The purpose of this article is to build upon prior work in social media research and ethics by highlighting an important and as yet underdeveloped research consideration: how should we consider vulnerability when conducting public health research in the social media environment? The use of social media in public health, both platforms and their data, has advanced the field dramatically over the past 2 decades. Applied public health research in the social media space has led to more robust surveillance tools and analytic strategies, more targeted recruitment activities, and more tailored health education. Ethical guidelines when using social media for public health research must also expand alongside these increasing capabilities and uses. Privacy, consent, and confidentiality have been hallmarks for ethical frameworks both in public health and social media research. To date, public health ethics scholarship has focused largely on practical guidelines and considerations for writing and reviewing social media research protocols. Such ethical guidelines have included collecting public data, reporting anonymized or aggregate results, and obtaining informed consent virtually. Our pursuit of the question related to vulnerability and public health research in the social media environment extends this foundational work in ethical guidelines and seeks to advance research in this field and to provide a solid ethical footing on which future research can thrive.

(JMIR Public Health Surveill 2023;9:e49881) doi:10.2196/49881

KEYWORDS
research ethics; social media; vulnerable populations; public health; ethical guidelines; algorithms; manipulation

Introduction

In October 2021, the Senate Subcommittee on Consumer Protection, Product Safety, and Data Security convened a hearing titled "Protecting kids online: testimony from a Facebook whistleblower" [1]. While this hearing focused on the protection of children, highlighting the amplification of content related to eating disorders targeting teenagers as well as the platform's "blind eye" toward age verification, broader takeaways included the platform's ability to create and cultivate a manipulative environment on social media. In part, this senate hearing, which examined questions about the inner workings of the social media ecosystem, was spurred by the 2016 election scandals [2], the spread of misinformation during the COVID-19 pandemic [3], and the mental health crisis that has most notably affected our young people [4]. While public health efforts have played a critical role in combatting misinformation on social media as well as addressing the mental health crisis, little has been done to examine the fundamental question that prompted congress' interest in social media: can social media create a manipulative environment that makes us vulnerable to undue influence? The short answer is yes, as documented by congressional hearings [1,5-7], independent research [8-11], and investigative journalism [12-15].

Algorithms and Vulnerability

The driver behind the discussion of social media manipulation appears to hinge on one key idea: algorithms. While research has examined how algorithms create an inescapable environment and thus an extensive network primed for digital discrimination, systematic bias, unethical targeting, and misinformation and disinformation campaigns [16-18], we still do not know enough about how algorithms function, what goals inform these functions, or the impact of algorithms on public health research and practice.

While algorithms and their ethical concerns have entered various dialogues, from congressional hearings to investigative journalism, little discussion has taken place in the field of public health. To date, public health ethics has focused largely on practical guidelines for writing and reviewing social media research protocols. Such ethical guidelines have included collecting public data, reporting anonymized or aggregate results, and obtaining informed consent virtually, to name a few. Susser [19] extends these considerations by discussing the role of manipulation, autonomy, and bias for digitally targeted public health interventions. Ethical considerations when using social media for public health research must expand alongside our increased understanding of how the social media environment functions, specifically concerning the presence of algorithms and how these may contribute to issues related to vulnerability. Privacy, consent, and confidentiality are important hallmarks for ethical frameworks in social media research [20], but we must move beyond these foundational questions and begin unpacking how our research and practice may or may not contribute to and benefit from the manipulative environments that many experience on social media.

The use of social media in public health has advanced the field dramatically over the last 2 decades. Traditional public health methods in surveillance and outbreak investigation [21], approaches in health education and promotion [22], and strategies in policy advocacy [23] and community organizing [24] have all been applied, refined, and adapted for the social media environment. Social media research, or the process of using social media data to conduct quantitative or qualitative research, ranging from observational data collection to experimental designs, is an invaluable tool in public health research and practice and continues to expand both in terms of how it is conducted and where it takes place [20]. Decades of applied public health research in the social media space have led to more robust surveillance tools and analytic strategies, more targeted recruitment activities, and more tailored health education [21]. However, more must be done to advance our understanding of algorithms and how they may ultimately compromise data for public health research and practice.

The potential use of compromised information in public health research is relevant to both observational and intervention research on social media. For instance, when conducting observational research that collects public data from individual accounts related to a specific topic (eg, vaccine safety), how do we disentangle the extent to which content was shared due to behind-the-scenes platform manipulation (ie, due to algorithms that place content in a user's thread with the goal of increasing interaction and engagement and with little regard to the content itself)? Adding to this complexity is the presence of social media bots, or automated programs, that artificially amplify or spread content based on an array of goals (eg, to spread disinformation, notify of emergencies, share advertisements, or aggregate news articles) [25].

Similarly, for intervention research, do we know how interacting with social media content produced for a research study may influence the platform's tailoring of future content for that same individual (eg, joining a vaccine-related research study may place the individual at greater risk of being exposed to future highly engaging vaccine information, which is more often than not misinformation)? Intervention research often takes place in closed or "private" groups on social media, making it easier to moderate and monitor the content directly administered by the study; however, the closed group exists within the larger ecosystem of the platform, and we do not yet know how participation in a research study may impact content exposure outside of that closed environment. Furthermore, when using social media to recruit study participants, we must also consider the potential collection and use of compromised information. For example, how much do targeted recruitment ads rely on interactions by users with content that was manipulated or artificially placed in a user's thread to solicit interaction? These questions highlight very practical ways in which our seemingly innocuous research activities (eg, public data collection or targeted recruitment) may in fact be interacting with and relying on compromised information, thus creating a scenario where researchers are relying on information that is, to an undetermined extent, artificially manipulated by opaque algorithmic intervention, contributing to vulnerabilities that have yet to be considered by public health research taking place on social media.

Moving Forward

We wish to move the field of public health and social media research forward by posing the following question: how should we consider vulnerability when conducting public health research in the social media environment? We pose this question not to limit or stifle public health research in the social media environment; in fact, quite the contrary—we pose this question to activate our collective understanding and consciousness to strengthen research in this environment in part due to the ever-changing social media landscape. At its core, the primary goal of the social media ecosystem is to keep users on the platform, interacting and engaging with content, for as long as possible, often at any cost [16]. Our hope is that the issues raised here will do the following: (1) contribute to frameworks that more clearly describe how vulnerability, much like privacy, consent, and confidentiality, is an essential concept for conducting ethical social media research; and (2) establish the need for partnerships with social media companies, supported through federal resources, that will facilitate collaborative yet independent research led by academic partners. While algorithms themselves are not nefarious, it is the intent behind the use of algorithms, and the goals and parameters set forth to use the algorithms in particular ways, that evokes concerns surrounding manipulation that may contribute to and enhance various vulnerabilities.

Abstract

Background: Influenza causes considerable disease burden each year, particularly in children. Monitoring school absenteeism has long been proposed as a surveillance tool of influenza activity in the community, but the practice of school absenteeism could be varying, and the potential of such usage remains unclear.

Objective: The aim of this paper is to determine the potential of monitoring school absenteeism as a surveillance tool of influenza.

Methods: We conducted a systematic review of the published literature on the relationship between school absenteeism and influenza activity in the community. We categorized the types of school absenteeism and influenza activity in the community to determine the correlation between these data streams. We also extracted this correlation with different lags in community surveillance to determine the potential of using school absenteeism as a leading indicator of influenza activity.

Results: Among the 35 identified studies, 22 (63%), 12 (34%), and 8 (23%) studies monitored all-cause, illness-specific, and influenza-like illness (ILI)–specific absents, respectively, and 16 (46%) used quantitative approaches and provided 33 estimates on the temporal correlation between school absenteeism and influenza activity in the community. The pooled estimate of correlation between school absenteeism and community surveillance without lag, with 1-week lag, and with 2-week lag were 0.44 (95% CI 0.34, 0.53), 0.29 (95% CI 0.15, 0.42), and 0.21 (95% CI 0.11, 0.31), respectively. The correlation between influenza activity in the community and ILI-specific absenteeism was higher than that between influenza activity in community all-cause absenteeism. Among the 19 studies that used qualitative approaches, 15 (79%) concluded that school absenteeism was in concordance with, coincided with, or was associated with community surveillance. Of the 35 identified studies, only 6 (17%) attempted to predict influenza activity in the community from school absenteeism surveillance.

Conclusions: There was a moderate correlation between school absenteeism and influenza activity in the community. The smaller correlation between school absenteeism and community surveillance with lag, compared to without lag, suggested that careful application was required to use school absenteeism as a leading indicator of influenza epidemics. ILI-specific absenteeism could monitor influenza activity more closely, but the required resource or school participation willingness may require careful consideration to weight against the associated costs. Further development is required to use and optimize the use of school absenteeism to predict influenza activity. In particular, the potential of using more advanced statistical models and validation of the predictions should be explored.

Introduction

Influenza virus causes substantial morbidity and mortality in humans each year on average [1,2]. Influenza activity and hence infections decreased due to public health and social measures of COVID-19 [3]. However, rebound of influenza virus activity is expected [4,5], given the relaxation of public health and social measures [6,7] and low population immunity of influenza [8]. Therefore, monitoring influenza activity is important in the post–COVID-19 era. Common modes of surveillance for influenza activity include the following: (1) sentinel surveillance, in which the consultation rates or the number of influenza-like illness (ILI) in outpatient and private medical practitioner clinics is recorded and (2) laboratory surveillance, in which respiratory specimens are collected and the proportion of positive tests of the influenza virus are recorded.

Children are believed to be a major driver of influenza virus transmission since they have more frequent person-to-person close contacts with low preexisting immunity [9-11]. Therefore, school is a high-risk setting for the transmission of influenza and other respiratory viruses. Preventing transmission in schools could block transmissions to family members and further reduce community epidemics [12]. School surveillance offers an opportunity for the early detection of these viruses [13]. In some regions, student absenteeism surveillance could be in real time, and hence it could have minimal reporting delay, with relative low cost [14,15].

Some studies explore the potential use of school absenteeism to monitoring the influenza activity in the community. In some regions, school absenteeism has been integrated as a part of routine disease surveillance, particularly for respiratory virus infections [16-21], although there are also usages for other diseases [22,23]. However, the component of school absenteeism surveillance could be different, such as the use of all-cause and illness-specific absenteeism. Moreover, their performances are rarely assessed. Therefore, validating and optimizing the performance of the use of school absenteeism on the surveillance of influenza activity would be critical.

In this paper, we conducted a systematic review to collect information on studies that described both school absenteeism surveillance and community surveillance. We summarized the types of school absenteeism surveillance and community surveillance methods to assess the relationship between these 2 surveillances, and the potential use of school absenteeism surveillance to predict influenza activity in the community.

Methods

Definition of School Absenteeism Surveillance and Community Surveillance

School absenteeism surveillance was defined as the time series recording the absent rate per day or week in a school. Absenteeism could be all-cause, specific to ILI, or specific to respiratory illness but not limited to ILI.

Community surveillance was defined as the time series monitoring the influenza activity in a region. There were the following two main types of surveillance: (1) ILI rate or count per day or week and (2) the proportion of laboratory specimens testing positive for influenza virus.

Search Strategy and Selection Criteria

This systematic review was conducted following the PRISMA (Preferred Reporting Items for Systematic Review and Meta-analysis) statement [24]. A standardized search was done in PubMed, Embase, and Web of Science, using the search term “((school AND (absent OR absence OR absenteeism) AND (flu OR influenza))”. The search was done on May 12, 2022, with no language restrictions. Additional relevant articles from the reference sections were also reviewed.

Two authors (XH and YG) independently screened the titles and extracted data from the included studies. Disagreements were resolved by consensus with a third author (TKT). Studies identified from different databases were deduplicated.

Eligible articles were those reporting daily or weekly student absenteeism data and community ILI surveillance in the same region. There was no restriction on the methods used for finding the relationship between school absenteeism and influenza surveillance in the community. Studies without both school absenteeism and community surveillance data were excluded. Articles that met the following were also excluded: (1) the study summarized the findings published elsewhere; (2) the study used data generated from simulation or prediction; (3) the study analyzed the combination of data from studies published elsewhere; or (4) the full text was not available.

Data were extracted from included studies using a standard form, with the following information in following 3 major components: school absenteeism, influenza surveillance in the community, and comparison between school absenteeism and influenza surveillance in community. Each mentioned variable below was a column in the standard form. For school absenteeism, the number of schools, the school size, the grade of students, methods used for school absenteeism surveillance, the types of absenteeism (all-cause, ILI-related, or illness-specific), illness ascertainment methods for illness-related absenteeism, and the treatment of holiday in the analysis were extracted. For influenza surveillance in the community, the extracted data included the types of surveillance (influenza-like illness with or without laboratory test) and the information of laboratory surveillance (influenza strain and the use of test-positive number or proportion). For comparison between school absenteeism and influenza surveillance in the community, information included methods, period and lag time (day/week) of comparison, and estimated correlation coefficients.

Data Analysis

For studies reporting regression coefficients, we used the approach by Rodgers and Nicewander [25] to transform them to Pearson correlation coefficient. We conducted random effects meta-analyses using the inverse variance method and restricted maximum likelihood estimator for heterogeneity to obtain the pooled correlation between school absenteeism and community surveillance [26-29]. Cochran Q test and the I^2 statistic were used to identify and quantify heterogeneity among included studies [30]. An I^2 value of more than 75% indicated high heterogeneity [31]. We conducted subgroup meta-analyses by the types of school absenteeism surveillance (all-cause vs ILI-related vs illness-specific), by the type of community surveillance (ILI vs lab-confirmed), with or without considering the delay effect of school absenteeism on community influenza. Meta-analysis on subgroups was only performed when there were at least 5 estimates. However, it should be noted that as I^2 could be biased in small studies, we only quoted the I^2 estimate when the number of studies was at least 10 [32]. We also conducted metaregressions to explore the impact of the following factors: types of school absenteeism, types of community surveillance, primary school or lower grade in school absenteeism surveillance, use of count data in school absenteeism surveillance, use of weekly data, and study type (prospective vs retrospective) in the analysis.

For studies using qualitative methods, in which only plots or tables of time series of school absenteeism and influenza activity in the community were provided without using any statistical comparison such as estimating correlations, a qualitative description of the relationship between these 2 surveillance systems was extracted. The used terms for the relationship in those articles was summarized. For the studies attempting to predict community surveillance by using school absenteeism, the following information about prediction was extracted: the types of data and its time period used for training for the models for prediction, data type and prediction methods, the type of data for validating the developed models and its time period, and the evaluation method.

Results

Overview

In the systematic review, we identified 3579 studies in our search, and 1144 duplicated articles were excluded (Figure 1). After screening the titles and the abstracts of the remaining articles, we identified 171 studies that may contain relevant information for full-text screening. Among these, 35 articles (Table S1 in Multimedia Appendix 1) met the inclusion criteria and were included in this review [15-19,33-62], of which 9 [19,33,37,41,46,48,54,61,62] and 6 [17,18,40,42,51,53] were prospective and retrospective studies, respectively. In terms of school absenteeism surveillance, 22 [15,16,34-39,41,47-49,51,53-57,59-62], 12 [15,17-19,35-37,44,45,50,54,61], and 8 [33,40,42,43,46,52,58,61] of the studies provided counts on all-cause, ILI-related, and illness-specific absenteeism, respectively. In terms of community surveillance, 25 [16-19,33-37,39-45,47,49-51,55,58-60,62] and 26 [15-17,19,33,34,36-43,46-49,52-54,56,57,59-61] studies provided the number of ILI cases and laboratory-confirmed cases, respectively. Moreover, 24 [15,17,19,33,35-38,40-45,47-49,51,54,56-58,60,62] and 11 [16,18,34,39,46,50,52,53,55,59,61] studies used weekly and daily scale of time series for analysis, respectively. In total, 7060 (we excluded 5 studies that did not provide this information) schools were included in our study. Of these, 2 articles [16,56] did not provide any comparison between school absenteeism and community surveillance; 16 articles [17-19,33,37,40-42,46,48,51,53-55,61,62] with 7703 school years performed quantitative analysis by using statistical method to compute the correlation between school absenteeism and community surveillance; and 19 articles [15,16,34-36,38,39,43-45,47,49,50,52,56-60] with 2123 school years performed qualitative analysis comparing their trends visually by figures or plots. In addition, 6 [17,18,42,46,54,61], 5 [17,18,42,46,61], and 1 [37] articles considered time lag and reported comparisons of school absenteeism and community surveillance with 1-week, 2-week, and 3-week lags, respectively. Moreover, 25 studies excluded holidays in the comparison, while 10 studies did not provide any information. Among the 25 studies that excluded holidays in the comparison, 15 of them [16-18,33,37,45,48-53,55,61,62] used weekly absolute count in school absenteeism surveillance, which may not have accounted for the reduction in denominator due to holidays within the week. Overall, among 16 and 19 studies using quantitative and qualitative analysis, 15 and 17 studies supported the association between school absenteeism and community surveillance, respectively (Table 1).

Correlation Between School Absenteeism and Community Surveillance

For quantitative analysis, all studies used regression coefficient or Pearson or Spearman correlation coefficient for evaluating the relationship between school absenteeism and community surveillance, except 1 [63], which used receiver operating characteristic to determine the accuracy of using school absenteeism to predict the occurrence of influenza outbreak, which was not included in our calculation of pooled correlation. Overall, 14 studies [17-19,33,40-42,46,48,51,53,54] provided 33 correlation estimates (Figure 2 [17-19,33,40-42,46,48,51,53,54,61,62] and Table S2 in Multimedia Appendix 1), and 30 estimates supported a positive correlation between school absenteeism and community surveillance [18,42]. The correlation (without lag) between school absences and community surveillance was 0.44 (95% CI 0.34, 0.53), with high heterogeneity (Figure 3). In terms of community surveillance, the correlation between school absences and community surveillance using laboratory-confirmed cases (correlation: 0.45; 95% CI 0.33, 0.57) was higher than using the number of ILI (correlation: 0.41; 95% CI 0.23, 0.59), which was less specific. In terms of school absenteeism, the correlation between community and ILI-specific absenteeism (correlation: 0.51; 95% CI 0.30, 0.73) and illness-specific absenteeism (correlation: 0.43; 95% CI 0.30, 0.57) was higher than all-cause absenteeism (correlation: 0.36; 95% CI 0.11, 0.62). While there was a positive relationship between school absenteeism and the community surveillance with 1-week (correlation: 0.29; 95% CI 0.15, 0.42) and 2-week lag (correlation: 0.21; 95% CI 0.11, 0.31), the positive correlation was smaller compared with those without lag.

In the metaregression (Table 2), we estimated that the correlation between school absenteeism and the community surveillance with 1-week and 2-week lag was 0.19 (95% CI 0.04, 0.34) and 0.26 (95% CI 0.10, 0.41) lower than without lag. We found that the correlation between community surveillance and ILI-related absenteeism was 0.25 (95% CI 0.04, 0.45) higher than that between community surveillance and all-cause absenteeism. The correlation between school absenteeism and laboratory-confirmed community surveillance was 0.17 (95% CI 0.04, 0.30) higher than that between school absenteeism and ILI surveillance. We found that the correlation between school absenteeism and community surveillance from prospective studies was 0.19 (95% CI 0.05, 0.33) higher than from retrospective studies.

Figure 2. The temporal correlation between school absenteeism and influenza activity in community from identified studies. ILI: influenza-like illness; PCR: Polymerase Chain Reaction.

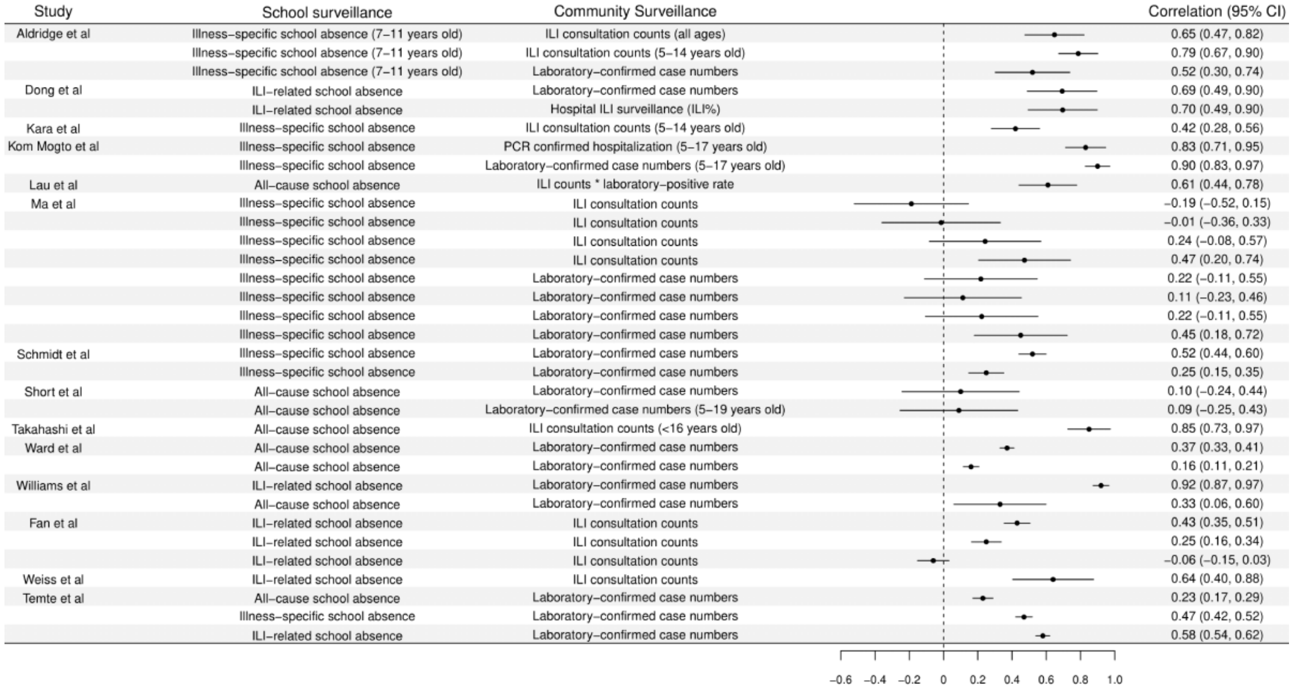

Figure 3. The pooled estimate of temporal correlations between school absenteeism and influenza activity in the community by types of school absenteeism surveillance and types of surveillance of influenza activity in community. ILI: influenza-like illness.

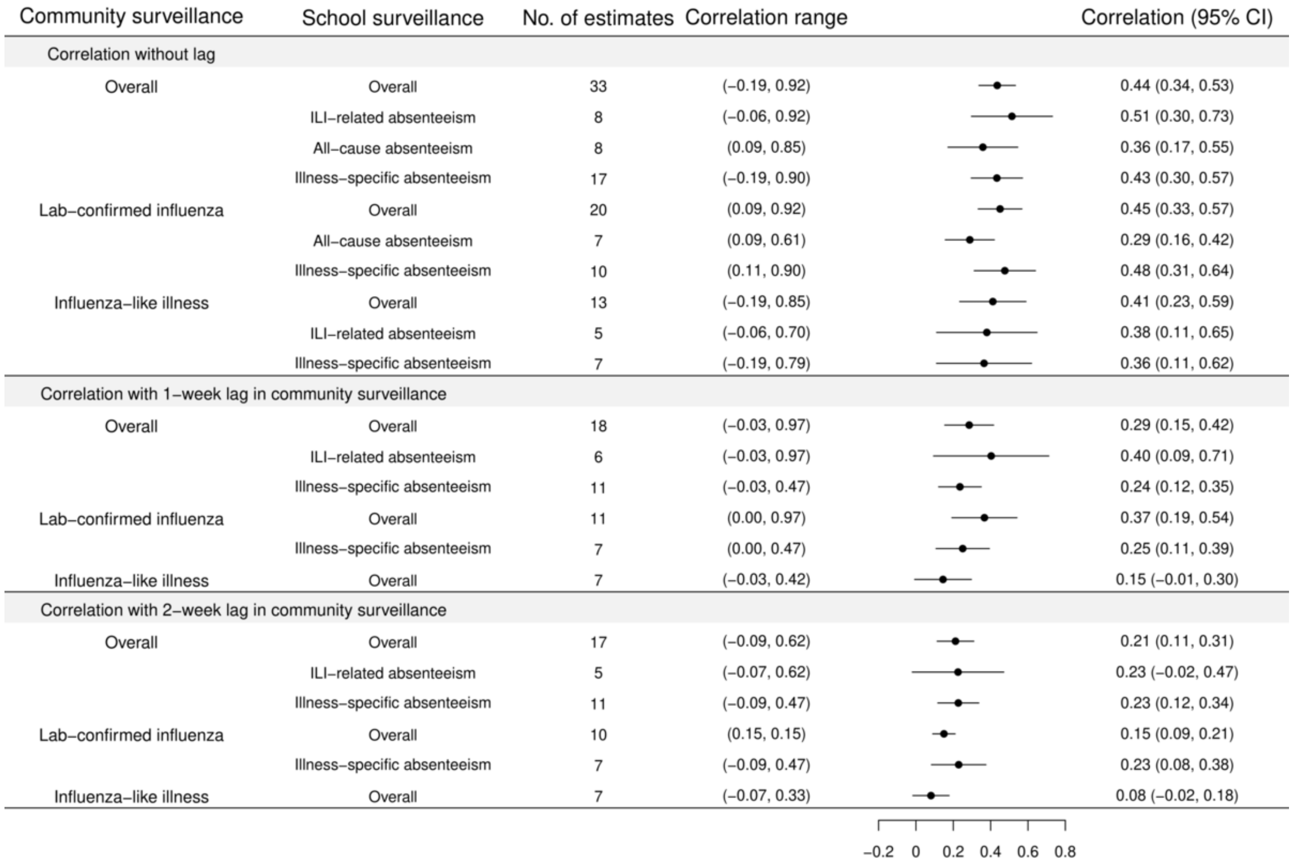

Community surveillance	School surveillance	No. of estimates	Correlation range	Correlation (95% CI)
Correlation without lag				
Overall	Overall	33	(−0.19, 0.92)	0.44 (0.34, 0.53)

Qualitative Analysis for the Relationship School Absenteeism and Community Surveillance

In the qualitative analysis, there were 19 articles that reported the relationship between school absenteeism and community surveillance by presenting the time series of these surveillances (Table 3). Of these 19 studies, 2 [16,56] did not compare the relationship in plots of time series. Overall, a similar pattern was reported within school absenteeism and community surveillance in all studies (Table 3), except 2, which reported no detected association [15,52]. Moreover, 6 studies [35,36,43,47,49,50] compared the peak of school absent and peak of epidemics. Among these, 4 [35,36,43,50], 1 [49], and 1 [47] studies found that school absenteeism peaked before, at the same time, and after the peak of community surveillance, respectively. In addition, 15 studies concluded that school absenteeism was in concordance with, coincided with, or was associated with community surveillance, using terms including “trends are coincident” [34,47,59], “associated with” [16,34,36,56,57,60], “concordance with” [38,43,58], “similar trend” [39,44,50], or ‘’mirror” [45].

Table 3. Summary of term count for qualitative results.

Term combined and term used	Study	Comparison	Count
School absenteeism is in concordance with, coincided with, or is associated with community ILI[a]			16
Increases in absences coincided with community-wide ILI outbreaks	Besculides [34], 2005	All-cause absenteeism vs community influenza isolates	1
The second wave of school absenteeism coincided with the second round of community ILI	Schoub [47], 1994	All-cause absenteeism vs laboratory isolations	1
The drop in school absenteeism coincided with the epidemic	McCormick [59], 2010	All-cause absenteeism vs community ILI surveillance or virus-confirmed influenza	1
School absenteeism is associated with community ILI			6
The extent of school absenteeism is associated with the extent of community ILI peak	Besculides [34], 2005	All-cause absenteeism vs community influenza isolates	
School absenteeism is associated with community ILI	Cheng [36], 2012	ILI-related absenteeism vs laboratory isolations	
Influenza activity was reflected by the school absenteeism rates	Chin [57], 1974	All-cause absenteeism vs laboratory-confirmed influenza	
Influenza activity was associated with or reflected by school absenteeism	Rubin [60], 1975	All-cause absenteeism vs community ILI surveillance	
School absenteeism was less timely than laboratory data	Chu [16], 2013	All-cause absenteeism vs laboratory-confirmed influenza	
Close temporal correlation between school absenteeism and the isolation of strains of influenza virus	Olson [56], 1980	All-cause absenteeism vs laboratory-confirmed influenza	
School absenteeism is concordant with community ILI			3
	Jaeger [38], 2011	All-cause absenteeism vs laboratory-confirmed influenza	
	Mook [43], 2007	Illness-defined absenteeism vs community ILI surveillance	
	Lenaway [58], 1995	ILI-related absenteeism vs community ILI surveillance	
Similar trend			3

	Suzue [50], 2012	ILI-related absenteeism vs community ILI surveillance	

Term combined and term used	Study	Comparison	Count
Virus isolation commence and peak before the school absenteeism	Schoub [47], 1994	All-cause absenteeism vs laboratory isolations	1
No detected association			2
No related outbreaks were detected, and no peaks were found	Tan [52], 2014	ILI-related absenteeism vs laboratory-confirmed cases	1
Within seasons, cases peaked in winter, whereas county-level absences varied throughout the year	Quandelacy [15], 2021	ILI-related absenteeism or all-cause absenteeism vs community virus–confirmed influenza	1

[a] ILI: influenza-like illness.

Prediction of Community Surveillance From School Surveillance

Six studies attempted to predict community ILI from school absenteeism (Table S3 in Multimedia Appendix 1), 3 of which [15,41,62] predicted the influenza rate (case number), and 3 [18,53,55] predicted the occurrence of outbreaks. All the studies agreed that school absenteeism surveillance was of good use for influenza outbreak detection [15,18,41,53,62], except 1 using all-cause absenteeism [55]. Among these, 4 studies [15,53,55,62] and 2 studies [18,41] used the all-cause absenteeism and ILI-related absenteeism for prediction, respectively. Moreover, 1 [18] and 5 [15,41,53,55,62] studies used mechanistic models (SEIR) and statistical models, respectively, 3 of which [41,53,62] considered the autocorrelation of the time series. In term of evaluation, those studies that predicted the occurrence of outbreaks used receiver operating characteristic curves [18,55] and false-positive rate (1 minus sensitivity) [53]. For those studies that predicted the number of cases, 1 used the model fit [41], 1 used mean absolute error [15], and 1 used Akaike Information Criterion value [62]. Two articles [15,53] conducted out-sample testing to evaluate the performance.

Discussion

Principal Findings

In this study, we summarized the practice of school absenteeism surveillance and their potential use on monitoring and predicting influenza activity in the community. Studies could broadly be classified as quantitative and qualitative. In quantitative studies, most studies used temporal correlation to quantify the relationship between school absenteeism and influenza activity in the community. In qualitative studies, time series between these 2 data streams were compared visually. Overall, we found a moderate correlation between school absenteeism and influenza activity in the community based on quantitative studies. This suggested the potential to use school absenteeism data to monitor or predict influenza activity in the community.

The measure of school absence could be classified to nonspecific (all-cause absent) and specific (illness- or ILI-specific absence). We found that ILI-specific absenteeism had a higher correlation with the community surveillance, compared with all-cause absenteeism, which was consistent with the findings from another review [64]. While using specific measure of school absenteeism could be slightly more accurate [54], the implementation of using more specific absenteeism surveillance in schools should be considered jointly with the associated costs. Those specific measures may require more resources to obtain, such as follow-up of the reasons of absence, which may also jeopardize the timeliness of the school absence data. Moreover, the willingness of school participation may be lower due to the higher requirement of resource; hence the sample size may decrease. Such factors should be considered when deciding the use of all-cause absence or ILI-specific absence to monitor influenza activity. The actual cost of implementation of using more specific absenteeism surveillance in schools was likely different by regions and countries; therefore, our studies could not provide recommendation on this.

A number of studies proposed that one of the values of school absenteeism surveillance was its lead on the traditional surveillance [35,36,43,50]. However, we found that the correlation between school absenteeism and community surveillance without lag was the highest. In addition, the correlation between school absenteeism and 1-week lag of community surveillance was only marginally smaller than community surveillance without lag. Hence, the school absenteeism surveillance could at most lead influenza outbreaks by 1 week. Therefore, despite the moderate correlation between school absenteeism and community surveillance, the use of school absenteeism as a surveillance tool may require further exploration and development of methodology. In particular, we found that the correlations between school absenteeism and community surveillance from prospective studies were higher than from retrospective studies, suggesting that prospective data collection could improve the accuracy by carefully checking the data with timely correction.

More than half of the studies only use qualitative approaches to explore the relationship between school absenteeism and influenza activity in the community, in which only figures of time series of these 2 surveillances were compared visually. Such approaches were relatively subjective, and further quantitative comparison should be performed. Furthermore, almost all quantitative comparisons were based on temporal correlation, which required further steps to determine the usefulness of school absenteeism for monitoring or predicting influenza activity in the community, such as the development of prediction or forecasting tools.

Only 6 out of 35 studies attempted to develop methods to use the school absenteeism data to predicted influenza activity in the community. However, those applied approaches were suboptimal compared with other influenza-forecasting approaches [65,66]; particularly, the potential of more advanced statistical approaches was less explored, as well as the lack of validation. In terms of modeling fitting, only 2 out of 6 studies conducted out-sample evaluation on their forecasting approach to avoid overfitting. In terms of model evaluation, all studies evaluated the point forecast, but none of them evaluated the prediction intervals from those models. The evaluation of interval forecast by some proper score rules would also be important to use the prediction performance [66,67] and to support the accuracy of the predictions. In future studies, using school absenteeism data in more well-developed models should be explored, including mechanistic models (ie, SIR-type) [65,66], and statistical models, such as generalized additive model and random forecast regression, which could particularly handle nonlinear relationship [68].

Limitations

Our study may have some limitations. First, we did not summarize the change of rule on the school attending in the identified studies. For example, many regions may not allow students to attend school when they have fever, particularly during or after the 2009 pandemic influenza outbreaks. Therefore, our study may not be able to evaluate this impact on the relationship between school absenteeism and community surveillance. Second, we did not stratify the analysis by type of reported correlation coefficients (Pearson or Spearman). However, we expected that the direction of correlation should be the same. Third, most studies did not report information of burden or costs of implementing school surveillance. Therefore, it was impossible for us to determine the real-life impact or cost-effectiveness of different types of surveillance. Finally, we could not rule out other potential cofounders in the identified relationship between school absenteeism and influenza activity in the community. For example, information of school or class size was not available.

Conclusion

We found there was a moderate correlation between school absenteeism and influenza activity in the community. We found that the correlation between influenza activity and ILI-specific absenteeism was higher than all-cause absenteeism. However, implementing more specific surveillance in school may require careful consideration, since more resources may be required, and it may have a negative impact on the willingness of school participation. There was potential for using school absenteeism as a surveillance and prediction tool of influenza activity. A further development of methodology was required to use and optimize such usage. In particular, more statistical models should be explored, and the validation of prediction performance is missed in most studies.

Acknowledgments

We thank Can Wang for technical assistance. This study was supported by the Theme-based Research Scheme project no. T11-712/19N from the Hong Kong Government, the Health and Medical Research Fund, Food and Health Bureau, Government of the Hong Kong Special Administrative Region (grant no. 21200292 and 11101092).

Abstract

Background: After the rapid spread of the novel SARS-CoV-2, the short-term and long-term mental health impacts of the pandemic on the public, in particular on susceptible individuals, have been reported worldwide. Although digital mental health services expand accessibility while removing many barriers to in-person therapy, their usability, feasibility, acceptability, and efficacy require continued monitoring during the initial phase of the pandemic and its aftermath.

Objective: In this study, we aimed to understand what mental health services are offered, whether they are practical or acceptable, and to what extent digital mental health services are effective in response to the COVID-19 pandemic across high-income and low- and middle-income countries.

Methods: This study followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines and the PRISMA Extension for Scoping Reviews (PRISMA-ScR) guideline. We implemented searches in PubMed (MEDLINE), Embase, PsycINFO, and Cochrane databases for studies that were published between December 2019 and November 2021 and that involved the use of digital mental health services. Two review authors screened, assessed, and extracted studies independently. The protocol was registered on the International Prospective Register of Systematic Reviews.

Results: This review identified 7506 articles through database searching. In total, 65 (0.9%) studies from 18 countries with 67,884 participants were eligible for the scoping review. Of the 65 studies, 16 (24.6%) were included in the meta-analysis. A total of 15 (23.1%) studies measured the usability; 31 (47.7%) studies evaluated the feasibility; 29 (44.6%) studies assessed the acceptability; and 51 (78.5%) studies assessed the efficacy. Web-based programs (21/65, 32.3%), videoconferencing platforms (16/65, 24.6%), smartphone apps (14/65, 21.5%), and SMS text messaging (5/65, 7.7%) were the main techniques. Psychotherapy (44/65, 67.7%) followed by psychoeducation (6/65, 9.2%) and psychological support (5/65, 7.7%) were commonly used. The results of the meta-analysis showed that digital mental health interventions were associated with a small reduction in depressive symptoms (standardized mean difference=−0.49; 95% CI −0.74 to −0.24; *P*<.001) and a moderate reduction in anxiety symptoms (standardized mean difference=−0.66; 95% CI −1.23 to −1.0; *P*=.02) significantly.

Conclusions: The findings suggest that digital mental health interventions may be practical and helpful for the general population, at-risk individuals, and patients with preexisting mental disorders across high-income and middle-income countries. An expanded research agenda is needed to apply different strategies for addressing diverse psychological needs and develop integrated mental health services in the post–COVID-19 era.

KEYWORDS

digital medicine; COVID-19; mental health services; psychological well-being; COVID-19 pandemic

Introduction

Background

As of October 5, 2022, there were 624.4 million confirmed cases of COVID-19 spread over 228 countries and territories, and COVID-19 has claimed the lives of 6.6 million individuals [1]. After the rapid spread of the novel SARS-CoV-2, known risk factors for mental health impacts have been reported worldwide. Fear of the virus and containment strategies might challenge psychological well-being [2]. Social isolation, loneliness, unemployment, and loss of income after the incidence of COVID-19 have become common. These risk factors might result in mental health problems, such as anxiety, depression, and insomnia, particularly in susceptible populations that include patients with COVID-19, first-line health professionals, and older adults [3]. In a cross-sectional study by Lai et al in China [4], 50% (634/1257) of health care workers reported experiencing depressive symptoms; 45% (560/1257) had anxiety; and 34% (427/1257) reported experiencing insomnia. Increased symptoms of mental health disorders and limited access to mental health care services and social support have also been reported in people with preexisting mental health disorders [5]. Furthermore, emerging reports suggested the possibility of the long-term effects of pandemics on psychological well-being [6,7].

Although most evidence has been on the negative mental health impacts of COVID-19, a parallel area of research interest has explored how mental health services change when exposed to such stressors [8]. Web-based digital mental health services expand accessibility while removing many barriers to in-person therapy; thus, digital mental health services might be a solution in response to the challenge. Recent efforts in implementing digital mental health services have shown promising applications based on efficacy results from randomized controlled trials (RCTs). In a systematic review [9], internet-based cognitive behavioral therapy (CBT) was linked to a higher reduction in depressive symptoms at posttreatment than treatment as usual and the waiting list. Usability, feasibility, acceptability, and efficacy results at the time of pandemics, however, require continued monitoring. Knowing what mental health care service is available, whether it is feasible and acceptable, and to what extent digital mental health services take effect is crucial to inform policy decisions, such as the delivery, implementation, and target areas for applying mental health resources during the pandemic and its aftermath.

Objective

Against this background, the objective of this scoping review and systematic review was to qualify and quantify the usability, feasibility, acceptability, and efficacy of digital mental health interventions applied for infectious disease outbreaks in the initial phase of the pandemic. We focused on the assessment of whether each of the applied techniques was usable, feasible, acceptable, and effective. We also separately synthesized data from high-income countries and low- and middle-income countries (LMICs). As there is no standard definition of usability, feasibility, acceptability, and efficacy, we considered comprehensive and broad definitions of these terms. We defined usability as program use, user engagement, and the ease of use of the services being tested, as followed in prior research [10,11]. We measured feasibility by attrition, attendance, adherence, retention, and qualitative feedback. We defined acceptability as user satisfaction, intent to continue use, and the perceived appropriateness of the intervention [12]. We defined efficacy as the intended effects and effect size estimation of the services [12].

Methods

Overview

This report includes a scoping review of studies on digital mental health interventions applied for infectious disease outbreaks and a systematic review of studies assessing commonly reported mental distresses identified in the scoping review. We followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines and the PRISMA Extension for Scoping Reviews (PRISMA-ScR) guideline when appropriate (Multimedia Appendix 1).

Data Search

We sought to include original studies focusing on digital mental health services applied during or in response to COVID-19. We implemented searches in PubMed (MEDLINE), Embase, PsycINFO, and Cochrane between December 2019 and November 2021 using a combination of search terms relating to both digital mental health services and COVID-19. The complete search strategy is provided in Multimedia Appendix 2. We performed a manual search of the reference lists of relevant reviews, eligible studies, and relevant conference abstracts.

Study Selection

We removed duplicate citations across electronic databases before the screening. Initially, pairs of 2 review authors (SZ, XY, ZP, and YF) independently screened the titles and abstracts for eligibility. We referred to full texts if titles and abstracts did not provide information for eligibility based on the inclusion and exclusion criteria. The full texts of the potentially included studies were screened by 1 review author and checked by another author for agreement. In case of disagreements, the opinion of a third reviewer was sought, and a consensus was reached through discussion.

We included qualitative, quantitative, and mixed methods studies that involved the use of digital mental health services. Eligible interventions included health education, evaluation, consulting, helplines, psychological interventions, and telemedicine. The intervention was delivered by any means of digital technology, including SMS text messaging, smartphones, websites, social media, videoconferencing, wearable devices, or mobile apps. We excluded comments, protocol papers, systematic reviews, preprints, conference papers, and studies that did not provide any qualitative or quantitative data for defined outcomes. We excluded studies that were conducted before December 2019. There was no exclusion for age, gender, ethnicity, socioeconomic status, professions (health workers or not), or any type of mental disorder (clinical or nonclinical). For the meta-analysis, we included parallel RCTs and crossover RCTs that provided adequate data for analyses, using the same aforementioned criteria.

Data Extraction

We developed a data extraction form that could be used by all review authors, as recommended by the Joanna Briggs Institute Scoping Review methodological guidance [13]. The data extraction form included information on study characteristics (authors, publication year, study design, study period, geographic regions, and study aim), participant characteristics (age, gender, sample size, and type of mental illness), digital mental health services characteristics (types of techniques and type of mental health services), and outcome characteristics (type of outcomes and their measurements). Owing to the diverse outcomes identified across eligible studies, we extracted the study results in 2 phases. In phase 1, we extracted the key findings for all reported outcomes. For effectiveness data, we extracted the results for significant differences between digital mental health services and comparison groups or trends between postintervention and preintervention outcome measurements for digital mental health services. In phase 2, we identified RCTs that reported similar digital mental health services and outcomes for the systematic review and meta-analysis. Here, effectiveness data from the comparison groups and intervention arms were retrieved using separate extraction forms. The data were extracted by 2 reviewers (XY and ZP) independently. Disagreements were resolved by discussion. A third reviewer (SZ) was involved when necessary.

Risk of Bias Assessment

Two reviewers (XY and ZP) independently assessed the risk of bias using the Cochrane Risk of Bias (RoB 2) tool for all included RCTs. Disagreements were resolved by discussions. In case of uncertainties, a third reviewer (SZ) was consulted. The 5 domains included bias owing to the assignment of intervention, adherence to the intervention, missing outcome data, outcome measurement, and selection of reported outcome that were measured. Studies were rated as “low” risk, “some concerns,” or “high” risk.

Data Synthesis

Owing to the nature of the research question and the heterogeneity of the studies, we synthesized qualitative and quantitative results separately. For the scoping review, we descriptively summarized the included studies with a narrative synthesis of individual studies. We summarized the overall number of included studies, the total number of study populations and their basic characteristics, countries, study design, type of digital mental health services, and the objectives and findings of the included studies. We clustered the studies by the type of techniques used and location (high-income countries vs LMICs). For each type of technique, the findings on usability, feasibility, acceptability, and effectiveness data were narratively synthesized by a textual approach.

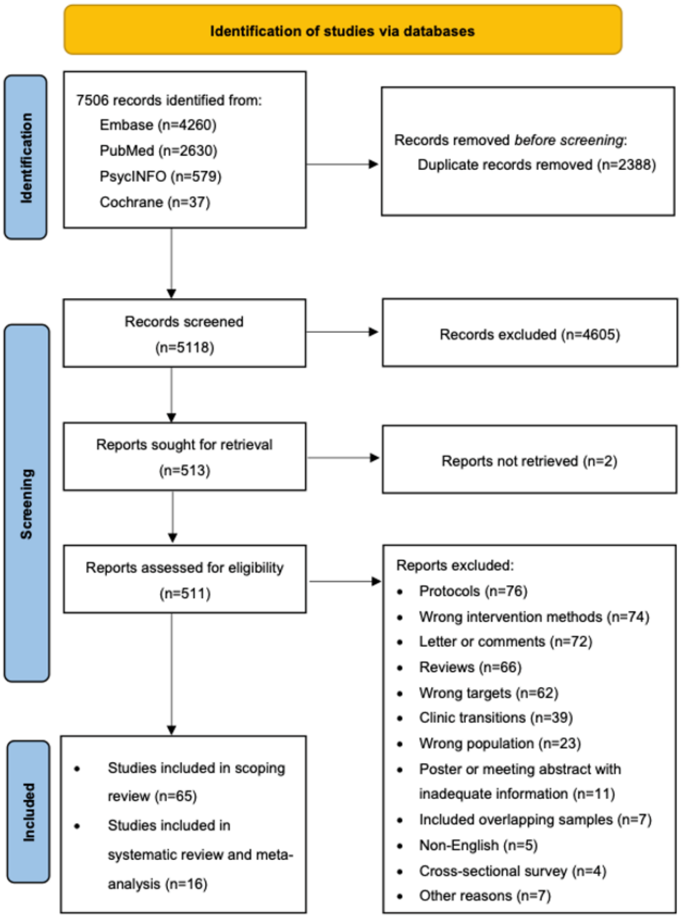
For meta-analyses, we synthesized findings on similar efficacy outcomes that were measured by >3 RCTs. Outcomes, such as loneliness, burnout, or psychological well-being, that were measured by 1 or 2 RCTs were not synthesized. We pooled continuous outcomes as standardized mean differences (SMD) with 95% of CIs using a random-effects meta-analysis. The values of 0.2, 0.5, and 0.8 in SMDs denote minor, medium, and large effects, respectively [14]. Cochran Q and the I^2 statistic were used to assess heterogeneity. An I^2 value of ≥60% can be considered a substantial level of inconsistency across studies [15]. The analyses were stratified according to the reported outcomes. For each of these, we pooled the evidence from all eligible RCTs, regardless of the techniques applied, measurements used, and population studied. We conducted subgroup analyses to examine whether there were differences in outcomes on the basis of sample size (as a dichotomous variable), measurement of the outcome, location, duration of follow-up, and duration of intervention. We also performed meta-regression analyses to explore the effect size by sample size (as a continuous variable), age, and proportion of females in the population studied. We used funnel plots and ran the Egger test to look for asymmetry to detect publication bias that might impair the validity of our findings. We performed all analyses with R statistical software (version 4.2.2; R Foundation for Statistical Computing) [16].

Results

Study Selection

The PRISMA flowchart shows the study selection process (Figure 1). This review identified 7506 articles that were identified through database searching. After removing duplicate records, we screened 5118 (68.19%) records and identified 65 (1.27%) eligible studies for the scoping review, and the results were synthesized narratively. Of the 19 RCTs, 17 (89%) studies reported depressive symptoms and 18 (95%) studies reported anxiety symptoms as the outcome. In total, 3 (16%) studies were not included in the meta-analyses; 2 (67%) studies [17,18] that reported on depression and anxiety disorders did not provide adequate data, and 1 (33%) study that reported anxiety scores using state anxiety was with a very large estimate [19]. Accordingly, of the total 65 eligible studies, 16 (25%) studies that reported depressive symptoms or anxiety symptoms were included in the meta-analysis.

Figure 1. Flowchart of study selection.



Study Characteristics

Table 1 presents the characteristics of participants and studies included in the review. The 65 included studies were conducted in the following 18 different countries: 24 (37%) studies from the United States (participants: 54,245/67,884, 79.9%), 8 (12%) studies from China (1114/67,884, 1.6%), 6 (9%) studies from Canada (5490/67,884, 8.1%), 5 (8%) studies from Italy (315/67,884, 0.5%), 3 (5%) studies from Australia (1004/67,884, 1.5%), 3 (5%) studies from France (2235/67,884, 3.3%), 2 (3%) studies from India (654/67,884, 1%), 2 (3%) studies from Malaysia (123/67,884, 0.2%), 2 (3%) studies from Greece (164/67,884, 0.2%), 2 (3%) studies from Turkey (121/67,884, 0.2%), and further 9 (14%) studies were conducted in other countries (ie, Dominican Republic, Israel, Japan, Oman, South Africa, Spain, Sweden, and the United Kingdom). Of these, 49 (75%) studies were from high-income countries, and 16 (25%) studies were conducted in middle-income countries. None of the included studies reported data from low-income countries.

The participant pool consisted of 67,884 participants; most (44,125/67,884, 65%) were female. There were 2663 (3.9%) people with a mental illness or mental distress, 713 (1.1%) people with or suspected of COVID-19, and 748 (1.1%) hospital workers.

Of the 65 studies, a total of 15 (23.1%) studies measured usability; 31 (47.7%) evaluated feasibility; 29 (44.6%) assessed acceptability; and 51 (78.5%) assessed efficacy.

Web-based programs (21/65, 32.3%), videoconferencing platforms (16/65, 24.6%), smartphone apps (14/65, 21.5%), and SMS text messaging (5/65, 7.7%) were the main techniques applied. There were other studies that used social media (3/65, 4.6%), hotlines (3/65, 4.6%), a chatbot (1/65, 1.5%), virtual reality (VR; 1/65, 1.5%), and robotic telemedicine (1/65, 1.5%). Most studies provided psychotherapy (44/65, 67.7%), followed by psychoeducation (6/65, 9.2%), psychological support (5/65, 7.7%), psychological assessments (4, 6.1%), and psychiatric clinical services (4/65, 6.1%).

Table 1. Characteristics of participants and studies included in the qualitative systematic review.

Author and year	Design and study type	Sample size, n	Age (years), mean (SD)[a]	Female, %	Intervention vs control group

[a] Where mean (SD) was not available in the original study, mean or ranges were used where applicable.

[b] RCT: randomized controlled trial.

[c] CBT: cognitive behavioral therapy.

[d] Not applicable.

[e] iCBT: internet-based congnitive behavioral therapy.

[f] MoST-MH: Mobile Support Tool for Mental Health.

[g] mHealth: mobile health.

[h] ASD: autism spectrum disorder.

Qualitative Synthesis of Results

Overview

This section summarizes the findings from 65 studies that reported the feasibility, acceptability, and effectiveness of digital mental health services during the COVID-19 pandemic. The synthesis was organized according to the type of digital technique used. Table 2 presents a summary of usability, feasibility, acceptability, and efficacy by the types of techniques in high-income countries and LMICs. Table S1 (Multimedia Appendix 3 [17-81]) presents summaries of individual studies on mental health interventions and major findings and their measurements.

Table 2. Summaries of usability, feasibility, acceptability, and efficacy by type of techniques in high-income countries (HICs) and low- and middle-income countries (LMICs).

Techniques and groups	Usability	Feasibility	Acceptability	Efficacy
Videoconferencing platforms				
HICs (n=11)	—[a]	• Three studies reported a completion rate between 92% and 100%. • Three studies reported qualitative feedback of highly perceived benefits. • Three studies reported technology-related challenges.	• Five studies reported high levels of overall satisfaction.	• Nine studies reported psychotherapy improved depressive levels and 5 studies found improved anxiety symptoms. • One study found no effects on decreasing anxiety symptoms.
LMICs (n=5)	—	• Two studies reported the mean attendance ranges from 6.4 (SD 2.8) to 10.26 (SD 7.02).	• One study reported high levels of satisfaction.	• Three studies reported improvements in depressive symptoms or negative effects. • Two studies reported no effects on decreasing depression levels.
Web-based programs				
HICs (n=17)	• Two studies reported a significant increase in registered users. • One study reported a high rating in usability.	• Five studies reported the completed rate ranged from 30.5% to 85%. • Three studies reported retention rate, which ranged from 30.5% to 85%. • One study reported high attrition rate of 13%. • One study reported strong attendance. • Two studies reported that retentions were strong. • Two studies reported high ratings of feasibility, and one study reported technical difficulty.	• Five studies reported high satisfaction. • One study reported that acceptability scores were significantly better than average. • Three studies reported high acceptability and rated the interventions as acceptable, helpful, appropriate, and positive.	• Eight studies reported improvement in anxiety symptoms and anxiety-related social impairment neither with nor without controls. • Two studies indicated no effects on reducing anxiety. • Five studies indicated improvement in depression symptoms and depression severity. • One study reported no difference in depressive symptoms when compared with onsite groups. • Three studies reported improved stress-related symptoms. • Two studies reported reductions in COVID-19–related worry. • One study indicated improvements in insomnia.
LMICs (n=4)	• One study reported the mean time spent was 35.63 (SD 25.41) min.	• One study reported a completion rate of 87.4%. • One study reported high attendance and high retention rates (91.2%).	• One study reported high ratings of acceptability and the other a high level of satisfaction.	• Four studies indicated improvement in anxiety symptoms neither with no controls nor control groups. • Two studies reported improvement in depressive symptoms with no controls. • One study reported a reduction in stress and burnout.
Smartphone apps				
HICs (n=11)	• Two studies reported high usability scores. Two studies reported user engagement. The time ranged from 36.7 min over 12 weeks to 1424 min over 14 weeks.	• One study reported the number of days retained was 42.44 (SD 44.40). • Three studies reported a retention rate that ranged from 28.3% to 85.7%.	• Two studies rated the intervention as acceptable, and 2 studies rated the intervention as satisfied. • One rated the intervention as good. • One rated the intervention as helpful.	• Four studies reported reduced depressive symptoms compared with the preintervention and waitlist groups. • Five studies reported similar improvements in anxiety symptoms compared with the preintervention, waitlist group, and a control app with limited access to psychoeducational content.

Techniques and groups	Usability	Feasibility	Acceptability	Efficacy
LMICs (n=3)	—	—	• One study indicated high satisfaction and would recommend the service. One study reported helpful and enjoyable.	• Two studies reported improvements in depressive symptoms, insomnia, psychological flexibility, and self-compassion, either with no controls or in comparison with the waitlist group.
Texting				
HICs (n=5)	• One study reported high usability.	• Two studies reported a completion rate of 16% and 78%, respectively.	• One study reported a high level of overall satisfaction.	• Four studies reported an improved mood rating was observed at posttreatment assessment either with or without the control group.
LMICs (n=0)	—	—	—	—
Social media				
HICs (n=1)	—	• One study reported high retention.	• One study reported high acceptability.	• One study reported an effect on psychological distress, quality of life, functioning, loneliness, and physical activity without a control group.
LMICs (n=2)	• One study reported an average user time of 18.7 hours.	—	—	• Two studies reported improvements in anxiety and depressive symptoms when compared with either the usual care or the waitlist group.
Hotline and telephone calls				
HICs (n=2)	• One study reported 5.73 (SD 3.22) calls/day.	• One study reported a dropout rate of 7.5%.	—	• One study reported improvements in loneliness, depression, anxiety, and general mental health.
LMICs (n=1)	—	—	• One study reported high satisfaction, and the participants would use again, and would recommend it to others.	—
Robotic telemedicine and VR[b]				
HICs (n=2)	• One study reported an average of 78 (SD 24.8) times.	• One reported a completion rate of 58%.	• One study reported high satisfaction.	• One study reported a decrease in anxiety symptoms and stress symptoms.
LMICs (n=1)	• One study reported an overall positive impression of the multimodal robotic system.	• One study reported the need to adjust some features.	—	—

[a] No evidence found.

[b] VR: virtual reality.

Web-Based Programs

Overall, 21 (32.3%; 5480/67,884, 8.1% out of total participants) out of the 65 studies included in this scoping review used web-based programs. In 17 studies that were conducted in high-income countries, a significant increase in registered users (n=2) and a high rating in usability (n=1) were reported. The completion rate ranged from 30.5% to 85% (n=5); the retention rate ranged from 30.5% to 85% (n=3); and the attrition rate was 13% (n=1). Quality checks of feasibility reported strong attendance (n=1), strong retentions (n=2), and high ratings of feasibility (n=2). Studies presented preliminary support for the feasibility of web-based programs yet with possible technical difficulty (n=1). In terms of acceptability, there was high satisfaction (n=5); the interventions were perceived to be acceptable, helpful, appropriate, and positive (n=3); and the acceptability scores were significantly better than average (n=1). Most studies, either when no control group is involved or when compared with the control group, reported improvements in anxiety symptoms and anxiety-related social impairment (n=8), while no effects on reducing anxiety were reported as well (n=2). The same patterns were found in outcomes measuring depression. Most studies reported improvements in depressive symptoms and depression severity (n=5), and there was no difference in depressive symptoms when the intervention group was compared with onsite groups (n=1). Improvements in stress-related symptoms (n=3), COVID-19–related worry (n=2), and insomnia (n=1) were identified.

In 4 studies conducted in LMICs, the mean time spent was 35.6 (SD 25.4) minutes (n=1) and the completion rate was 87.4% (n=1). High attendance and high retention rates (91.2%) were reported (n=1). With regard to acceptability, high ratings of acceptability and a high level of satisfaction (n=2) were reported. Studies, either when no control group is involved or when compared with the waitlist group, reported improvements in anxiety symptoms (n=4); some studies reported improvements in depressive symptoms (n=2), and 1 study reported reduction in stress and burnout.

Videoconferencing Platforms

Among the 65 studies, 16 (24.6%; participants: 1973/67,884, 2.9%) used teleconferencing platforms, including Zoom [30,39,49,55,59,60,62,72,73,81], Skype [25], Microsoft Teams [1,49], Google Meet [45], Tencent Meeting [19], and other platforms [41,42]. In 11 studies that were conducted in high-income countries, a completion rate between 92% and 100% (n=3), qualitative feedback of high perceived benefits (n=3), and technology-related challenges (n=3) were reported in terms of feasibility. High levels of satisfaction were reported (n=5). Studies reported improvements in depressive levels (n=9) and anxiety symptoms (n=5). No effects on decreasing anxiety symptoms were reported in one study. In 5 studies conducted in LMICs, the mean attendance ranged from 6.4 (SD 2.8) to 10.26 (SD 7.02; n=2). High levels of satisfaction (n=1) were reported. There were improvements in depressive symptoms and negative affect (n=3), yet no effects on decreasing depression levels were identified (n=2). No evidence was found in usability for LMICs or high-income countries.

Smartphone Apps

Of the 65 studies, 14 (21.5%; participants: 53,786/67,884; 79.2%) developed smartphone apps to deliver mental health services. In 11 studies conducted in high-income countries, studies reported high usability scores (n=2), and user engagement time ranged from 36.7 minutes over 12 weeks to 1424 minutes over 14 weeks (n=2). Feasibility was reported in terms of the average number of days retained (mean 42.4, SD 44.4; n=1), and the retention rate ranged from 28.3% to 85.7% (n=3). In terms of acceptability, the interventions were rated as “acceptable” (n=2), “satisfied” (n=2), “good” (n=1), and “helpful” (n=1). Studies reported a reduction in depressive symptoms compared with the preintervention and waitlist group (n=4). Similar improvements were reported in anxiety symptoms compared with preintervention, waitlist group, and a control app with limited access to psychoeducational contents (n=5). In 4 studies in LMICs, no evidence was found for usability and feasibility. Acceptability was reported as high satisfaction (n=1) and helpful and enjoyable (n=1). There were improvements in depressive symptoms, insomnia, psychological flexibility, and self-compassion, either when no control group is involved or when compared with the waitlist group (n=2).

SMS Text Messaging

Of the 65 studies, 5 (7.7%; participants: 5537/67,884, 8.1%) used the SMS text messaging technique. All studies were conducted in high-income countries. Studies reported high usability of ecological momentary intervention (n=1), and the completion rate ranged from 16% to 78%. An overall high satisfaction was reported (n=1). Studies suggested that an improved mood rating was observed at posttreatment assessments either with or without the control group (n=4). No evidence was found of studies conducted in LMICs for the technique of SMS text messaging.

Social Media

The use of social media as a technique to deliver mental health services was described in 3 (4.6%; participants: 116/67,884, 0.2%) out of 65 studies [44,54,79]. In one study conducted in high-income countries, high retention, high acceptability, and an effect on multiple outcomes (psychological distress, quality of life, functioning, loneliness, and physical activity) were reported (n=1). In the 2 studies conducted in LMICs, an average user time of 18.7 hours (n=1) was reported. Evidence suggested improvements in anxiety and depressive symptoms when compared with either usual care or the waitlist group (n=2). No evidence was found for other outcomes.

Hotline and Telephone Calls

Of the 65 studies, 3 (4.6%; participants: 886/67,884, 1.3%) reported using hotlines and telephone calls to deliver mental health services during the COVID-19 pandemic [36,47,65]. In 2 studies conducted in high-income countries, an average of 5.73 (SD 3.22) calls per day was reported (n=1). A dropout rate of 7.5% was reported (n=1), and there were improvements in loneliness, depression, anxiety, and general mental health, as reported in the same study (n=1). In one study that was conducted in LMICs, participants reported high satisfaction and mentioned that they would use the service again and would recommend it to others (n=1). No evidence was found in terms of usability, feasibility, or efficacy for the techniques of hotline and telephone calls by the studies conducted in LMICs.

Robotic Telemedicine and VR

Of the 65 studies, 3 (4.6%; participants: 106,67,884, 0.2%) used robotic telemedicine and VR. Two studies conducted in high-income countries reported an average use of 78 (SD 24.8) times (n=1) and a completion rate of 58% (n=1). High satisfaction was reported (n=1). Evidence suggested a decrease in anxiety symptoms and stress symptoms for all participants after the intervention (n=1). In 1 study conducted in LMICs, an overall positive impression of the multimodal robotic system was reported (n=1), yet the need to adjust some features was suggested (n=1). No evidence for acceptability or efficacy was found by studies conducted in LMICs.

Meta-analyses

Of the 65 studies, 15 (23.1%) that reported depressive symptoms were included in the meta-analysis. Digital mental health interventions were associated with a small significant reduction in depressive symptoms (SMD −0.49, 95% CI −.74 to −.24; *P*<.001; Figure 2) with substantial heterogeneity (I^2=87%, 95% CI 80%-91%; *Q*=107.57; *P*<.001).

The effectiveness of digital mental health interventions on anxiety symptoms was reported in 15 RCTs. The pooled SMD showed a moderate and significant effect of these interventions in reducing anxiety symptoms (SMD=−0.66, 95% CI −1.23 to −.10; *P*=.02; Figure 3) with substantial heterogeneity (I^2=93%, 95% CI 90%-95%; *Q*=207.22; *P*<.001).

We examined the sources of heterogeneity by studying covariates across studies (Tables 3 and 4). Subgroup analyses revealed that reduced depressive symptoms were associated with the measurement of depression (using Depression Anxiety Stress Scales-21: SMD=−0.13, 95% CI −0.31 to 0.06 vs other measurements: SMD=−0.61, 95% CI −0.91 to −0.30; *Q*=7.04; *P*=.008). Reduced anxiety symptoms were not associated with sample size, location, measurement of anxiety, duration of follow-up, or the duration of intervention.

Meta-regression analyses are reported in Multimedia Appendix 4. There was no significant association between SMDs of depression and sample size, age, and proportion of females in the study population. Meta-regression analyses did not reveal differences in the SMDs of anxiety depending on sample size, age, and proportion of females in the study population.

For the main analyses of depression and anxiety, we observed evidence of funnel plot asymmetry, which could suggest no publication bias (Egger test: *P*=.57 and *P*=.50, respectively; Multimedia Appendix 5).

Figure 2. Effectiveness of digital mental health interventions in reducing depressive symptoms. BDI-II: Beck Depression Inventory-II; BSI: Brief Symptom Inventory; CCAPS: College Counseling Center Assessment of Psychological Symptoms; DASS-21: Depression Anxiety Stress Scales-21; EPDS: Edinburgh Postnatal Depression Scale; HAMD: Hamilton Rating Scale for Depression; MADRS-S: Montgomery Åsberg Depression Rating Scale-Self rated; PHQ: Patient Health Questionnaire; and SDS: Self-rating Depression Scale; SMD: standardized mean difference.

[b] LMICs: low- and middle-income countries.

[c] GAD-7: Generalized Anxiety Disorder-7.

[d] Other measurements including Beck Anxiety Inventory, Brief Symptom Inventory, Child Behavior Checklist, College Counseling Center Assessment of Psychological Symptoms, Hamilton Anxiety Rating Scale, Self-rating Anxiety Scale, and State-Trait Anxiety Inventory.

[e] DASS−21: Depression Anxiety Stress Scales-21.

Risk of Bias Assessments

For the meta-analysis, we evaluated the risk of bias for the included RCTs, and the results are presented in Multimedia Appendix 6 [22,24,29,32,34,43,44,47-49,62,67,69,74,79,81]. Overall, the included studies showed low risk of bias. Of the 16 RCTs included, 6 (38%) studies were rated "low" risk; 7 (44%) studies were rated "some concerns"; and 3 (19%) studies were rated "high" risk. Owing to the absence of previously published analysis plans, bias in reporting was assessed as "some concerns" for all 16 studies.

Discussion

Principal Findings

To our knowledge, this is the most comprehensive review of the evidence examining the feasibility, acceptability, and efficacy of digital mental health services during the COVID-19 pandemic. The 65 studies identified in the scoping review reported using videoconferencing platforms, web-based programs, smartphone apps, SMS text messaging, social media, hotline, robotic telemedicine, and VR to deliver mental health services among 67,884 participants across 18 countries. Psychotherapy, psychoeducation, and psychological support were among the most common mental health services delivered during the infectious disease outbreak. Overall, digital mental health services delivered during the initial phase of COVID-19 were usable, feasible, and acceptable and improved psychological well-being in participants across the included studies in high-income countries and LMICs. Sixteen RCTs that reported comparable outcomes, including for depression or anxiety, were systematically reviewed and meta-analyzed. The results indicated that digital mental health interventions were significantly associated with a small reduction in depressive symptoms and a moderate reduction in anxiety symptoms. The significance and effect sizes of the interventions differed among the measurements of the depression.

Our study suggested that the feasibility, acceptability, and effectiveness of digital mental health services during the pandemic were similar to those before the pandemic [82,83], indicating the potential for digital intervention to respond to the mental health needs of the people during the pandemic. These needs include addressing mental health problems among people experiencing COVID-19–related symptoms of anxiety, depression, and stress; patients with suspected or confirmed COVID-19; health workers; and patients with preexisting mental disorders. The advantages of digital mental health services in promoting psychological well-being depend on the ability to overcome the physical distance between people with mental health needs and providers and increasing the accessibility of mental health services. Although the use of digital mental health services has long been advocated, it has not yet been widely adopted because of a lack of support from both service users and health care professionals. In most nations, the situation has changed after the COVID-19 pandemic [84]. In China, for example, increased use of web-based mental health assessments, psychoeducation, and psychological counseling were observed during the COVID-19 pandemic [85].

Different strategies should be used for applying suitable techniques to digital mental health services. In our review, we found that smartphone app outreach was used by most service users (79.2%). Individuals with mild to moderate mental health symptoms, which may be addressed by psychosocial support and psychological interventions based on a stepped-care approach, are the target populations for the expanded use of smartphone apps to improve the delivery of mental health services. The technology with broad reach could also be used for psychoeducation [46], which is necessary for the support and prevention of mental disorders. Previous research has found that using apps or other web-based treatments for the older adult population can be challenging. Our study found that older adults have positive attitudes toward and may benefit from the electronic device–based mental health services, including videoconferencing platforms [45,62], social media [54], and web-based programs [77]. We suggest that smartphone apps and other web-based interventions should be considered for the older age population if technical assistance could be provided for people with difficulties with these devices. Telephone calls that are easy to use should also be considered for older adults [47].

The use of digital mental health services was reported across high-income countries and middle-income countries, but there were no studies from low-income countries. Digital mental health services have great potential in LMICs because of the limited availability of mental health services to cover the population needs [86] along with diminished health system capacity during the pandemic. Promising findings were reported for digital mental health services (videoconferencing platforms, web-based programs, and smartphone apps) in most high-income countries and some middle-income countries. However, these techniques rely on the internet and may be difficult to replicate in low-income areas. In addition, limited studies have examined the use of SMS text messaging and telephone calls in middle-income countries. Techniques that do not rely on the internet are a priority in low-resource areas. For instance, owing to their great accessibility and low cost of use, SMS text messaging and hotline might be considered for use in resource-limited or isolated locations. The benefits of delivering digital mental health services in remote and low-resource areas, in terms of potential impact and resource savings, must be considered alongside the feasibility of achieving high coverage of mental health services.

The finding that digital mental health services are associated with the amelioration of anxiety and depressive symptoms is consistent with previous evidence examining their effects [9,87]. Subgroup and meta-regression analyses allowed us to identify the effects of the study and population characteristics. For instance, there was no evidence of differences in SMD based on sample size. We found that depression measures contributed to heterogeneity. The posttreatment effects of digital mental health interventions differed from Depression Anxiety Stress Scales-21 (DASS-21) and other measurements. Although the current evidence supports the short-term effectiveness of most digital mental health services, a few studies have evaluated long-term outcomes after the interventions [43,69,79]. The long-term benefits of receiving digital mental health services should be assessed through practical evaluations. Along with the viability of reaching high coverage, it is important to weigh the potential impacts and resource savings of providing digital mental health care in rural and underresourced regions.

Our review sheds light on future research. First, further efforts should be focused on how digital mental health services can be integrated with existing traditional treatment modalities to form a complementary and integrated service model. In particular, the integration of medication and digital services remains to be further validated for safety and feasibility. Second, most studies included in our review were digital psychotherapy interventions, suggesting that digital technologies may have facilitated the accessibility of psychotherapy during the pandemic. We found evidence supporting the efficacious delivery of psychotherapies, either guided [62,77] or self-help therapy [31,34,64,74]. In a study by Al-Alawi et al [18], therapist-guided web-based therapy was associated with greater effectiveness than self-help therapy for people with anxiety and depressive symptoms during the COVID-19 pandemic. Future studies should focus on determining whether people require a guided web-based psychotherapy approach and promote individualized treatment to ensure the optimal allocation of treatment resources. Third, despite the diversity of mental disorders, only a few are covered in this review. Depression and anxiety were the most common outcomes measured. Thus, the role of digital services for many severe mental illnesses, including schizophrenia and bipolar disorder, needs to be further examined.

Our study has implications for policy development in health care. During a pandemic, digital mental health technology can be used as a backup to address psychological demands and broaden service coverage. We urge policy makers to create future industry regulatory laws so that the digital health sector can grow in a way that provides security and effectiveness testing. The development of digital health infrastructure, including information transmission facilities and technical testing methods for data security issues, is also a crucial prerequisite for the future development of digital mental health. If digital mental health services are to continue, there is a need to specify the minimum level of privacy and security that is acceptable. For example, in the United States, digital mental health services have rapidly made changes in response to policies and regulations concerning confidentiality and privacy to promote telehealth delivery of care [88].

Limitations

Our study has several limitations that should be noted. First, owing to the nature of our research question, the scoping review demonstrated substantial heterogeneity. In the pool of included studies, there was a high heterogeneity in terms of study design, type of techniques, type of mental health services, intervention components, target conditions, populations, and outcomes. Most studies did not have comparisons, and their effectiveness remains to be examined in future studies. For meta-analyses, we found only a few factors that contribute to heterogeneity between studies. The subgroup analyses were based on outcomes and limited by the variations in the type of techniques and type of mental health services. As a result, the findings should be interpreted with caution and read in terms of implications for future research.

Second, most participants in our scoping review were from high-income nations, primarily the United States and European countries. There is an urgent need for more independent research that examines the viability, acceptability, and efficacy of digital mental health as a response to pandemics in LMICs, particularly in low-income countries.

Third, although the current evidence supports the short-term effectiveness of most digital mental health services, only 2 studies have evaluated the long-term outcomes. A practical evaluation of the long-term benefits of digital mental health services should be undertaken, particularly in urban contexts.

Fourth, this study did not include preprint servers in the search, which may lead to the overestimation of our findings. However, a methodological research study of systematic reviews and meta-analyses revealed that including unpublished data (such as preprints) may add new sources of bias, although it does not change the results of reviews [89]. In addition, there is a possibility that the findings in preprints will be changed further, which leads to the results of the review being amended as well.

Finally, the target of this study was to evaluate the usability, feasibility, acceptability, and initial efficacy of digital mental health services in the initial phase of the pandemic. Therefore, we limited the data search to the first 2 years of the pandemic. We recommend that future studies should assess whether these services will remain the same or be further refined during other phases of the pandemic.

Conclusions

In summary, we have reported a range of digital mental health services delivered during the initial phase of the COVID-19 pandemic. We found that digital mental health services were usable, feasible, acceptable, and effective in response to mental health needs in the initial phase of pandemic across high-income countries and middle-income countries. Our findings also highlight the amelioration of depressive and anxiety symptoms based on the pooled results of the RCTs. To date, the strategies to lessen the COVID-19 pandemic's negative impacts on mental health remain a subject of much debate. We suggest that policy makers develop, implement, and assess different strategies for addressing the long-term mental health needs of the pandemic and its aftermath. Digital mental health services as novel strategies for promoting psychological well-being can purposively address physical barriers and provide a promising element for future integrated mental health service models in the post–COVID-19 era.

Abstract

Background: In the context of the digital transformation of all areas of society, health care providers are also under pressure to change. New technologies and a change in patients' self-perception and health awareness require rethinking the provision of health care services. New technologies and the extensive use of data can change provision processes, optimize them, or replace them with new services. The inpatient sector, which accounts for a particularly large share of health care spending, plays a major role in this regard.

Objective: This study examined the influences of current trends in digitization on inpatient service delivery.

Methods: We conducted a scoping review. This was applied to identify the international trends in digital transformation as they relate to hospitals. Future trends were considered from different perspectives. Using the defined inclusion criteria, international peer-reviewed articles published between 2016 and 2021 were selected. The extracted core trends were then contextualized for the German hospital sector with 12 experts.

Results: We included 44 articles in the literature analysis. From these, 8 core trends could be deduced. A heuristic impact model of the trends was derived from the data obtained and the experts' assessments. This model provides a development corridor for the interaction of the trends with regard to technological intensity and supply quality. Trend accelerators and barriers were identified.

Conclusions: The impact analysis showed the dependencies of a successful digital transformation in the hospital sector. Although data interoperability is of particular importance for technological intensity, the changed self-image of patients was shown to be decisive with regard to the quality of care. We show that hospitals must find their role in new digitally driven ecosystems, adapt their business models to customer expectations, and use up-to-date information and communications technologies.

KEYWORDS

digital transformation; digitization; health care provision; hospital; trends

Introduction

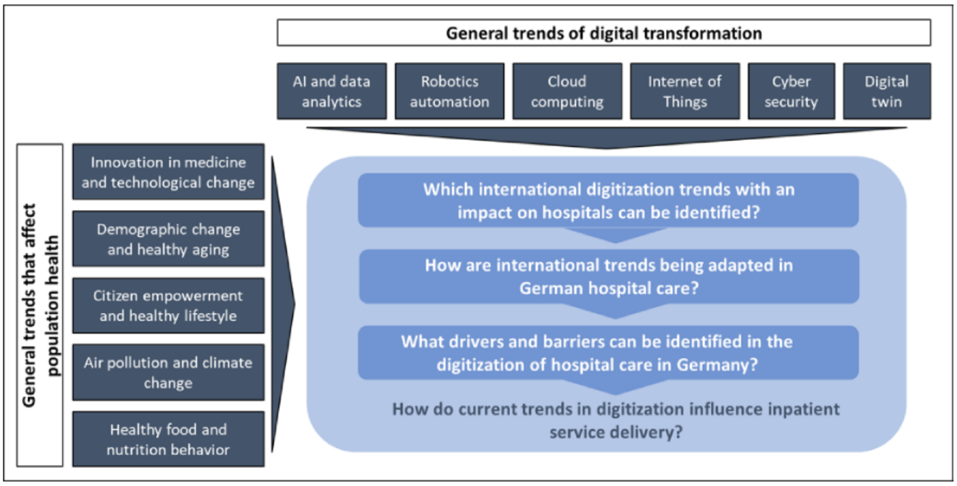
Background

Digital transformation is permeating all areas of society [1,2]. Scientific circles also refer to it as the Fourth Industrial Revolution [3]. On the basis of the latest advancements in medicine and in the context of general technological progress, digital trends also influence the provision of services in health care [4-7]. Health systems have become the focus of political and social debates in industrialized Western countries for a number of reasons [8,9]. Demographic developments have led to an increase in life expectancy [10]. This increase in life expectancy is primarily due to the medical-technical progress in the past as well as the comprehensive access to health care services in most high-income Western countries [11]. The result is an expansion in the use of services with an upward trend [12]. Furthermore, high life expectancy and the associated decline in the birth rate have led to a shift in the overall population structure in recent decades [10,11]. Fewer younger people have to care for a growing proportion of older people. This is already resulting in numerous bottlenecks [13]. Certain constraints include the financing of increasing health and nursing care services, the provision of comprehensive care even in less populated regions, and the staffing of health and nursing care facilities [14,15]. Owing to the personnel intensity of health services, many industrialized Western countries are already dependent on immigration for medical professionals. The use of new technologies and digital applications can reduce the financial and personnel burden on health care systems, especially on inpatient care [4-6,16].

On the one hand, there are numerous current trends resulting from digital transformation [17]. Artificial intelligence (AI), data analytics, further automation and robotization, and cloud computing or the Internet of Things (IoT) are driving digital permeation in society and the economy [17-20]. This is also accompanied by visionary technologies such as digital twins for use in virtual worlds such as the metaverse [18,21]. These trends are also creating a greater need for cybersecurity.

In contrast, general trends related to population health are leading to changing framework conditions [12,13]. Leap innovations in medicine and technological change, the aforementioned aging population with a need for healthy aging, the empowerment of the population, changing lifestyles, and healthy nutrition are influencing current developments in health care [22-24]. Environmental influences such as air pollution and climate change are also creating pressure for action in some health care fields [25-27]. As a result of these trends, various questions are being asked to better assess and control future developments. We make a special reference to German health care delivery as the German hospital and health care system can definitely be seen as a reference model for many other European and international health care settings [28,29]. This study considered the emerging trends for the future provision of care in hospitals and beyond in a patient-centered or outcome-oriented health care system that incorporates digital technologies [30-32]. Figure 1 shows the relationships between the general trends that have developed, with the purpose of deriving the research question.

Figure 1. Derivation of the research objective. AI: artificial intelligence.



Objectives

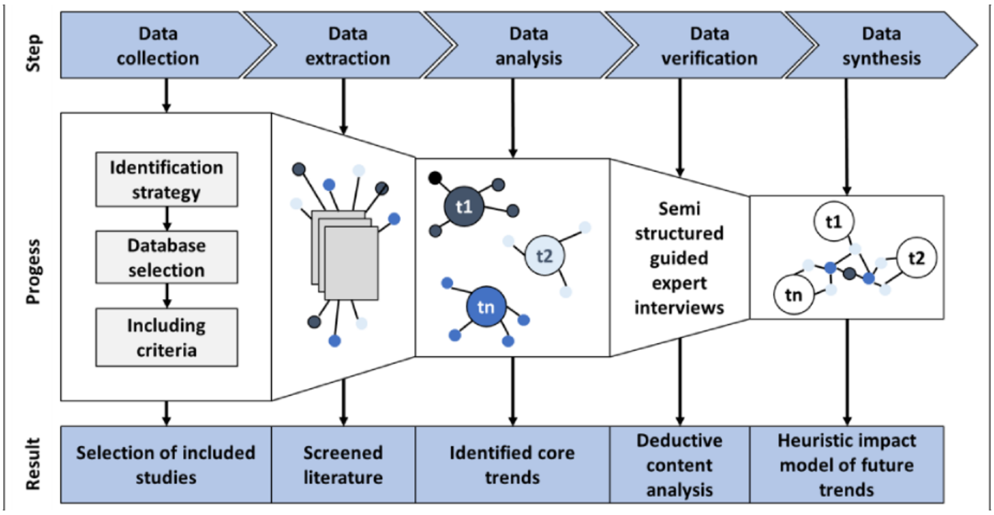
Our central research question addressed how current trends in digitization influence inpatient service delivery. We approached this question in 3 steps. First, we identified the international trends in digitization that have an impact on the hospital sector. Second, we addressed the adaptation of these trends with regard to the German hospital sector. Finally, we derived drivers and barriers and concluded which developments result from these trends.

Methods

Overview

We conducted a sequential study. Our mixed methods approach consisted of a scoping review and a qualitative survey. Our research design was based on 5 steps, as shown in Figure 2. The first step involved fundamental data collection. This resulted in the inclusion of studies, which was the starting point of our analysis. In the second step, data extraction took place. The available studies were compared, suitable classification features were determined, and their contents were exploited. The third step was data analysis and synthesis using a narrative approach, resulting in core trends. In the fourth step, a classification, verification, and discussion of the selected trends took place. The data obtained were subjected to a deductive content analysis. In the fifth step, a higher-level synthesis of both data collection points was performed. A heuristic logic model was used as an instrument.

Figure 2. Research methodology.



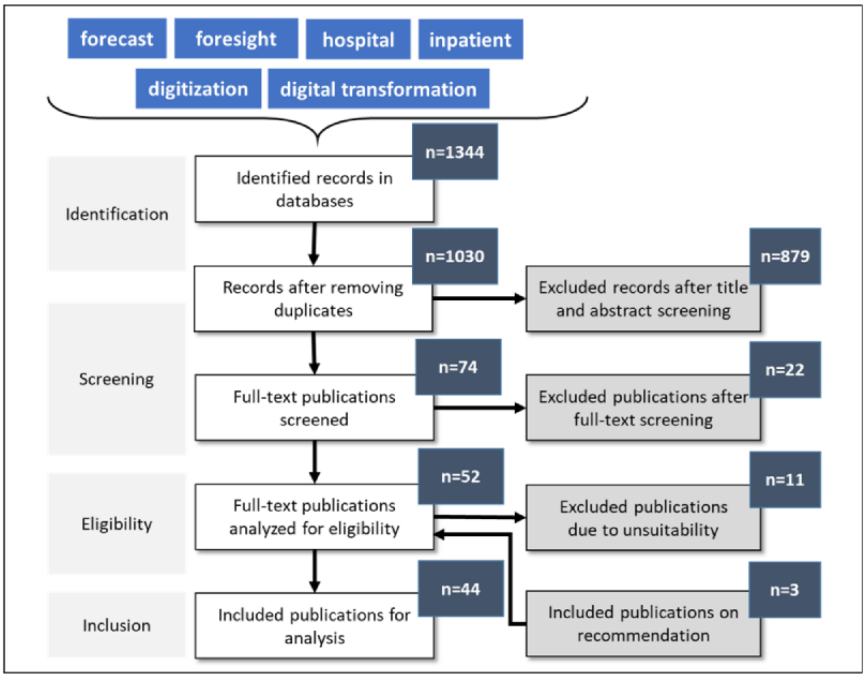
Scoping Review

Search Strategy

The scoping review is reported according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [33]. Accordingly, the following work stages were fulfilled: (1) definition of the research question, (2) systematic search, (3) selection of relevant studies, (4) data extraction, (5) data analysis and synthesis, and (6) interpretation of the results. We conducted our scoping review based on the extended current recommendations [34,35] and presented the results of our search strategy in a flowchart (Figure 3). Between October 2020 and February 2021, we conducted a systematic search of the following databases: PubMed, MEDLINE, EconLit, EconBiz, and ScienceDirect. An initial search was conducted in September 2020 to select an appropriate search strategy. Our search was limited in time to the last 5 years. Papers published between 2016 and 2021 were included. The inclusion of earlier papers would lead to bias in the results as the consideration of trends is only meaningful over a manageable period in the past [36,37]. The language was restricted to English. After screening the titles and abstracts, all articles dealing with future trends as well as those dealing with inpatient care or the service provision of the health care system and digitalization were included in the full-text search. In total, 2 reviewers performed the full-text screening according to these inclusion and exclusion criteria. Disagreements were discussed between the 2 reviewers to reach a consensus. In the case of a possible disagreement, a third author was appointed.

Our scoping review referred to current and future trends related to digital transformation on the one hand and service delivery in hospitals on the other. The words “forecast” and “foresight” were searched in combination with other terms (eg, “digital transformation,” “digitization,” and “hospital”). The search terms used in the various databases are shown in Multimedia Appendix 1. In a further step, the reference lists were searched backward for other relevant publications not listed in the aforementioned databases. In our review, we also included manuscripts that were recommended by authors or experts. Some search terms were discarded in the process of developing a search strategy. For example, the search terms “trend” or “future” were not included as they were too nonspecific and triggered too many irrelevant hits. The concept of service provision also had to be differentiated more precisely. The search strategy was ultimately refined to focus on hospitals.

Figure 3. Flowchart of literature search strategy.



Inclusion Criteria

Articles were included if the following 3 factors applied: a reference was made to the future or trends, a reference was made to the terms “digital” or “technology,” and a reference was made to inpatient service provision or hospitals. The documentation is shown in Multimedia Appendix 2 [20,38-80]. Articles were excluded if the terms “trend” or “future” were used to refer to a possible new treatment or diagnostic procedure; the prediction of the spread of disease; or specific developments in the fields of brain, genetic, or biotechnology research. Very frequently, the overall search showed the use of AI and machine learning (117 studies); IoT, wearables, and mobile health apps (86 studies); or big data (70 studies). Publications from a medical discipline or on medical indications were not included. The most common indications were related to cardiovascular disease (79 studies); oncology (96 studies); or imaging, particularly radiology (89 studies). However, of these, 1 study was included that was related to the organization of radiology departments in hospitals. Psychiatric indications and mental health were also not included in the study. Case studies and feasibility studies related to individual countries or organizations were also excluded, as were studies on trends in education and training in clinical settings (eg, the future of medical staff training). Publications related to the COVID-19 pandemic were not included. In total, the search provided 77 studies linked to COVID-19. The particular use of technology, such as blockchain or cybersecurity, was only included when there was genuinely a direct link to inpatient care. This occurred in only 1 case.

Study Inclusion

The identified articles from all databases were uploaded to the EndNote software (Clarivate Analytics), and duplicates were removed. In total, 2 researchers independently performed the first step of the screening process based on titles and abstracts, as reported in Multimedia Appendix 3. In the second step, 2 independent researchers carefully read the articles with available full texts to decide which would ultimately be included in the systematic review. Articles that met the eligibility criteria were selected for inclusion in the systematic review. The reasons for the exclusion of full-text articles were recorded and included in the PRISMA flow diagram [33]. The reference lists of the included articles were carefully searched by hand to identify other appropriate articles. In total, 2 researchers independently extracted the following data from each article: (1) study identification (study author and year of publication), (2) main trend of the study (technology, innovation, or process), and (3) key statements of the study (fields of application, opportunities, risks, and recommendations for action).

Any discrepancies that arose during the data extraction process were clarified through discussion among the authors. Subsequently, the extracted contextual factors were labeled according to their topic, and the studies were summed up so as to show the respective factors. In addition, the studies were classified using 2D scales. The first dimension described the inclusion of the user within the trend. The second dimension related to the intersectoral component. Furthermore, the trend factors were grouped into the 3 application fields: planning and steering, core clinical processes, and communication and data connection. For each of these areas, individual trend factors were described as having an impact on inpatient care. Each factor was double-checked by the 2 researchers, and incongruities were resolved through discussion. We used a narrative approach to synthesize the data [81]. Finally, the results of the synthesis were presented in a trend chart to contextualize the trends’ influences on other trends and illustrate the factors affecting each trend. In addition, barriers that contributed to the deceleration of the trends were extracted from the studies.

Expert Interviews

The identified trends were further processed for in-depth analysis and verification. The transfer of the trends that were extracted based on international scientific literature resulted in a qualitative survey of experts [82]. In this methodological component of our study, we focused on the German setting. Later, we will put these results back into a generalizable context so that the findings can also be applied to a broad spectrum of other countries. The expert interviews were conducted in the form of semistructured, guide-based interviews [83]. The interview guide was largely based on the identified core trends. The experts were selected based on the 2 decisive criteria of digitization experience in the health care sector and experience in or knowledge of the area of service provision.

Experts from 4 specific groups were interviewed in equal numbers: first, the group of inpatient care suppliers; second, the group of digital service providers in the health care industry; third, overarching institutions in the health care sector; and fourth, the group of relevant scientists. The number of interviews that needed to be conducted was not determined in advance. After 12 interviews, information saturation was reached [84]. The guide was tested for suitability in advance in a pretest with 3 participants and adjusted before final use. The data generated over the course of the interviews were analyzed deductively [85,86] in a sense-reconstructive, interpretative manner. The statements to be analyzed were compiled using the MAXQDA software (VERBI GmbH). The data analysis was performed by 2 independent researchers following a theory-driven definition of structuring dimensions to form the main categories and subcategories. An iterative process was used to establish definitions, identify anchor examples, and generate coding rules. The generated codes were subjected to a reliability test in several steps until the summary test of all the quality criteria was completed.

Data Synthesis

The extracted data from the literature and the obtained research data from the interviews were synthesized into a heuristic logic model [87,88]. Heuristic logic models are used in designing systematic review questions and collecting research results and as analytical tools [89]. Analytical logic models demonstrate a logical chain between inputs and outcomes. When the influences of the overarching relationship are demonstrated, it may not be necessary to examine all the individual components and their connections. We show a logical sequence of effects, including possible adverse effects, that influence inpatient care in a chain of identified trend characteristics. The model was used to illustrate the authoritative impact of the core trends on inpatient service delivery. This enabled the sketching of a trend development corridor and a more detailed description of the impact relationships [90]. Finally, the decelerating factors were also shown based on the data material.

Ethical Considerations, Informed Consent, and Participation

The study did not meet the need for ethical review as it did not involve special categories of personal data. All procedures performed in this study were in accordance with the ethical conducts of the General Data Protection Regulation and *Bundesdatenschutzgesetz* (German implementation of European Union regulations). Email invitations were sent to prospective candidates. The invitation included an overview of the project and the research scope. The voluntary nature and anonymity of participation were pointed out, together with complete information on the European Union General Data Protection Regulation. We requested written informed consent from all participants to record the interviews and use the information provided in our research.

Results

Results of the Scoping Review

The search strategy identified 1344 articles from the 5 databases, as shown in detail in Figure 3. After duplicates were removed, 76.64% (1030/1344) of the articles were retained for title and abstract screening. A total of 74 articulated full-text articles were read. After screening, 59% (44/74) of the studies [20,38-80] met the eligibility criteria for this systematic review.

The main characteristics of the included studies are listed in Multimedia Appendix 4 [20,38-80]. The classification into the topic field was performed to categorize a rough content assignment of the article. The core statements reflected the main contribution of the article and were later used to categorize the trends. The topic of AI and machine learning was addressed in 14% (6/44) of the studies [47,49,57,58,61,69] in different contexts. A total of 30% (13/44) of the studies [42,43,48,51,52,60,64,66,67,72,76,79,80] were originally related to data-driven topics (eg, data-driven resource use). The change in processes used by digitization was the subject of 25% (11/44) of the studies [40,44,46,50,55,63,68,70,74,75,78]. Among other things, processes in inpatient care that use electronic health records played a role. Mobile apps and IoT were the subject of 14% (6/44) of the studies [20,39,41,59,62,71]. These studies also showed close connections to data use and process redesign. The use of robots in clinical settings was addressed in 7% (3/44) of the studies [38,45,54]. The establishment of platforms or the development of a digitally connected ecosystem was considered more closely in 9% (4/44) of the studies [53,65,73,77]. A total of 2% (1/44) of the studies dealt explicitly with personalized medicine [56]. However, this topic was also addressed in numerous other studies (eg, with the use of AI or IoT). In all the studies, trends were described, and future developments were derived from them. In addition, they identified problem areas that will be compared at a later stage in this paper as internal and external trend barriers. In some cases, recommendations for action were derived or inferred from the barriers.

From the included studies, 8 trends were identified that affect hospitals as a result of digital transformations. For this purpose, 44 studies [20,38-80] were analyzed, the core topics were classified, the most important technologies were pinpointed, and the fields of application and hurdles were extracted, as reported in Multimedia Appendix 5 [20,38-80] (Textbox 1).

The core trends are presented in Table 1. In addition to naming the trends, the essence of each trend is described, as well as the most important and relevant technologies and the affected application fields within the hospital setting.

To illustrate the interrelationships between the individual trends, we presented the connecting factors in a matrix according to the number of times they were mentioned in the studies. Figure

4 illustrates which trends have a close linkage and shows the intensity with increasing red coloring. The closest links are between trends 3 and 4, with 15 common factors. Dense relationships were also evident between trends 4 and 7. Trend 1, in contrast, shows the fewest connections with other trends. The matrix represents an initial basis for further processing in the synthesis of the results, which will later also include the results of the interviews.

Textbox 1. Trends identified from the systematic review.

Trend 1—changing the patient role

- Patients are taking on a new role in the entire care process from prevention to diagnosis and therapy. They participate in decision-making, generate and use data, and have transparent information on diseases and available health care services. The most important technologies are the internet, smart devices, and mobile health apps.

Trend 2—connected, integrated delivery of care

- Connected technologies and cross-provider data exchanges promote intersectoral collaboration. Providers exchange and share data across the care process. Important technologies include electronic health records, the Internet of Things (IoT), and e-prescriptions.

Trend 3—data-driven resource allocation

- A data-based allocation of resources by means of predictive models enables the precise planning and control of care capacities. As a result, available resources are better allocated and used across an organization. Consequently, waiting times can be reduced, and patient throughput can be optimized. The most important technologies are data mining, machine learning, and predictive analytics.

Trend 4—performance optimization in primary processes

- The performance of core clinical processes in diagnostics and therapy is optimized. This involves using available data in real time to deploy equipment, rooms, or personnel efficiently. Relieving systems are used for the staff. In addition, services are patient-centric to meet the individual needs of patients within an institution. The most important technologies are electronic health records, machine learning, and assistive robots.

Trend 5—new information and communications media

- Emerging information and communications technologies are transforming the interactions between all stakeholders in the care process. They promote information transfer and facilitate the understanding of complex interventions through visual media. The most important technologies are avatars, mobile health, and IoT.

Trend 6—increased technological intensity

- The intensity of technology is increasing rapidly at all levels. The hospital is becoming a high-technology digital institution. Intensive data use leads to intensified collaboration with digital service providers and the extensive use of software or algorithms. The most important technologies are smart devices, robots, and cloud services.

Trend 7—outcome improvement and personalized treatments

- The quality of outcomes is rising in the context of increasing data use and the associated optimization of treatment procedures focusing on predictive forecasting models for the early detection of diseases. The perspective of personalized diagnostics and therapy is at the heart of the treatment process. The most important technologies are data analytics, machine learning, and predictive medicine.

Trend 8—emergence of new ecosystems

- Digital networking is leading to new providers and new business areas so that health care is evolving into an ecosystem in which established service providers have to maintain their competitive position and find their role in providing care. Platforms for exchanging data and mediating health care services play an important role in these ecosystems. The most important technologies are mobile health, machine learning, and predictive analytics.

Table 1. Identified trends in the scoping review.

Trend number	Core trend	Description	Key technologies	Fields of application
1	• Changing the patient role	• Patients have an active role in the entire care process. They participate in decision-making processes and have comprehensive transparency in their own data and available services.	• Internet, smart devices, and mobile health	• Decision support [78] • Increase in patient compliance [63,71] • Integration into the therapy and monitoring process [68]
2	• Connected and integrated delivery of care	• Service providers collaborate without sector barriers. They are connected to each other and provide all necessary diagnostic and therapeutic information to one another.	• EHRs[a], smart devices, IoT[b], and e-prescriptions	• Integrated data exchange between providers [77] • Full use of the EHR [46] • Transmission of upstream and downstream treatment information [51,66]
3	• Data-driven resource allocation	• The capacities of service providers are optimally used. They analyze real-time data and make decisions based on currently available resources beyond their own institution.	• Big data, machine learning, data mining, EHR, HISs[c], and predictive analytics	• Process optimization [42,48] • Planning and control of resources by data-driven decision models [44,48,52,55] • Predictive forecasting for capacity planning and the identification of bottlenecks and potential risks [48,52,69,80]
4	• Performance optimization in primary processes	• Hospitals manage their internal processes efficiently and in a patient-centric manner. They use technology to support staff in diagnostics and therapy decisions.	• EHRs, robotics, IoT, machine learning, and data platforms	• Development of personalized treatment pathways [42,44] • Optimization of diagnostics and outcomes across the care continuum [50,58,76,79] • Robotics in several clinical areas [38,45,54]
5	• New information and communications media	• Service providers are broadening the range of information and communications channels. They create shared and low-threshold ways to convey information and meet patients' communication needs.	• Avatars, virtual reality, augmented reality, EHRs, mobile health, and IoT	• Transfer media for data exchange between providers and patients [41,77] • Enhancing patient engagement [68,78] • Creation of new barrier-free communication channels [63]
6	• Increased technological intensity	• Hospitals are deploying an increasing number of technological solutions. They are exploiting the potential of innovative technical applications and raising the level of technological complexity.	• Smart devices, IoT, robotics, machine learning, and cloud services	• Expansion of the inventory of hardware and technical equipment [38,54] • Building partnerships with digital service providers [39,77] • Connection to external systems for permanent data exchange in real time [48,57,77]

Trend number	Core trend	Description	Key technologies	Fields of application
7	• Outcome improvement and personalized treatments	• The outcomes of patient care are steadily improving. Early detection and disease prediction systems enable an optimal treatment sequence according to the personalized needs of the patient.	• Big data, machine learning, predictive analytics, personalized medicine, and 3D printing	• Evaluation of incoming monitoring data from patients [20,50,62] • Connection to databases and data platforms for the training of AI[d] [58,61,79] • Individual therapies [53,65,76]
8	• Emergence of new ecosystems	• Service providers are linked together in an ecosystem to provide care. They use platforms to exchange data and optimally allocate services to the right place at the right time.	• Digital platforms, mobile health, machine learning, and predictive analytics	• Appointment management [66] • Reduction in waiting times [46,79] • Assignment of appropriate experts [65,69] • Distribution of available materials [69,73] • Switching on of suitable gatekeepers [56,70]

Results of the Expert Interviews

The qualitative approach to analyzing the impacts of trends brought to light additional aspects aside from the findings from the literature. On the basis of the core trends shown, Table 2 presents the positive and negative trend effects, conditions for trend realization, and trend drivers. This made it possible to describe additional characteristics for each individual trend, enabling a holistic approach to the impact mechanisms of the trends resulting from the digitization of inpatient care.

The changed patient role leads to an increase in transparency, more patient autonomy, better opportunities for participation in the treatment process, and an expansion of self-competence. However, in the case of an overload of information, this can also lead to excessive demands or the communication of incorrect information. Therefore, the decisive conditions are to strengthen trust in acting institutions and make information available through public authorities. The driving factors are good health literacy and a high level of digital competence. Connected and integrated cooperation between providers leads to better access to health care services and faster data exchange between them. However, this may lead to increased competitive pressure, resulting in the exit of market players. The key conditions for this trend are incentives to cooperate so that individual providers are not disadvantaged. To achieve this, compensation systems must be adapted so that network-integrated collaboration is worthwhile and the necessary interfaces for data exchange are available. Driving factors include easy market access and existing supply gaps. Data-driven resource allocation leads to increased efficiency, a better use of capacity, and offsetting of skill shortages. However, there are strong dependencies among service providers regarding the extent to which they are willing to collaborate and share information. The intensive exchange of data at various levels between institutions can lead to data protection and data security risks. The governing conditions include the availability of data, interfaces, and technical expertise. The driving factors include scarce capacities, high data density, and public data platforms.

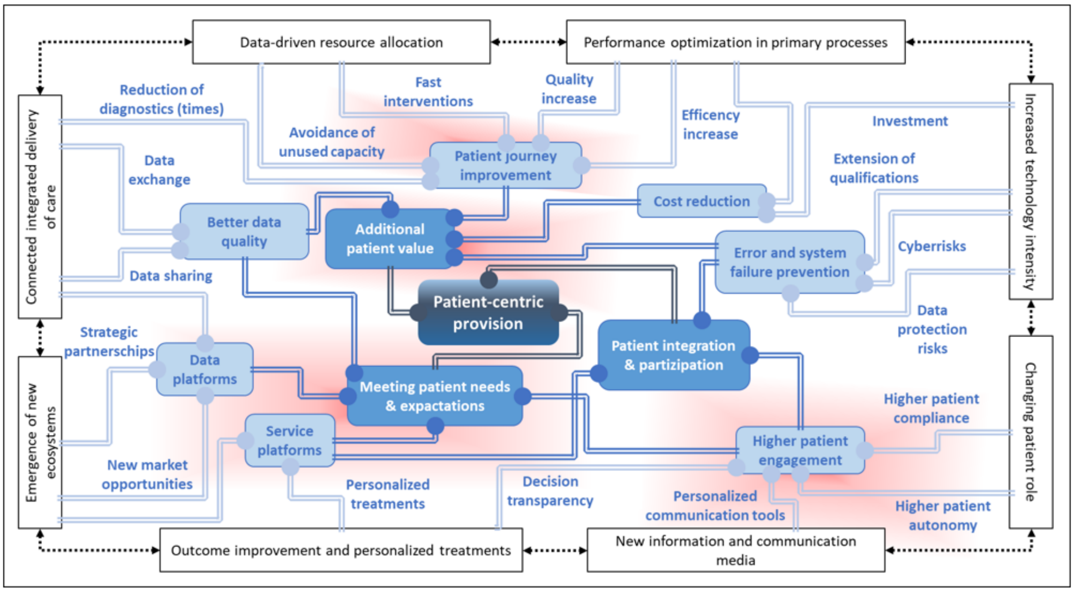
The performance optimization of core clinical processes leads to higher productivity, increases in quality, and higher patient and employee satisfaction. In contrast, there is a high internal dependency on a wide range of factors and the need for a continuous process of adaptation and optimization. The decisive conditions are investments in new systems and the associated qualifications of the workforce. Acceptance and openness are essential for success. The driving factors are medical progress, falling costs of innovations, and new job profiles. New information and communications technologies are accompanied by a change in patients' need to interact with providers. They lower communication barriers and lead to better information delivery. For clinics, the wide range of media may result in higher costs for their operation, and additional qualifications may be necessary. The key conditions are an understanding of communication needs and an acceptance of media use by all stakeholders. The driving factors are the digital competencies of all stakeholders and the current general societal trends in media preferences. Increasing technology intensity ensures higher productivity and compensates for a lack of skilled workers. This is accompanied by greater complexity and the associated requirements for cybersecurity and employee qualifications. Comprehensive long-term investments and the acquisition of new knowledge are required as decisive conditions. The driving factors are technological progress and rising patient expectations. The application of personalized medicine leads to an improvement in outcomes as well as the possibility of specialization and the opening up of new fields of treatment. In contrast, there is an adjustment of care-oriented business models, which, among other things, also include prevention to a greater extent. The key conditions are high data quality and availability, the market maturity of innovative technologies, and confidence in new treatment procedures. The driving factors are medical and technical progress as well as the service offerings of competitors.

The emergence of new ecosystems has led to new customer-centric health care services, an exploitation of the potential of the platform economy, and the associated opportunities to increase customer value. This creates new competitive situations that can put pressure on providers and lead to inappropriate power relationships among individual market participants. The decisive conditions are an understanding of digital ecosystems also on the part of the legislator, transparency, and fair conditions on platforms for all service providers. The driving factors are low barriers to market entry, little regulation, and a strong focus on customer needs. Figure 5 shows the trend correlations in a heuristic impact model.

Table 2. Trend characteristics from expert interviews in Germany.

Trend number	Core trend	Positive effects	Negative effects	Prerequisites	Trend drivers
1	• Changing the patient role	• Increasing transparency • Growing patient autonomy • Better participation opportunities • Growth of self-competence	• Risk of disinformation • Overwhelming media diversity	• Trust in institutions • Public provision of information • Comprehensive education	• Health literacy • Digital competencies • Information access
2	• Connected and integrated delivery of care	• Better access to services • Faster data exchange • Reduction in interface problems	• Additional competitive pressure between providers	• Performance incentives • Adjustment of reimbursement systems • Data exchange interfaces	• Easy market access • Existing supply gaps • Integrated planning tools
3	• Data-driven resource allocation	• Increasing efficiency • Optimal use of resources • Compensation for the shortages of skilled workers	• Dependence on service providers • Data protection risks • Increasing complexity	• Data availability • Interface availability • Specialist availability	• Scarce resources • High data density • Public data platforms
4	• Performance optimization in primary processes	• Efficient provisioning • Increasing quality • Higher satisfaction (patients and staff)	• Dependencies of many factors • Constant change process	• Investments in new systems • Acceptance of new processes • Permanent qualification	• Medical progress • Decreasing costs • New professions
5	• New information and communications media	• Meeting the needs of patients • Reduction in communication barriers • Improving the availability of information • Higher satisfaction	• High expenditure for the maintenance and provision of the media • Additional need for qualification	• Acceptance of the parties involved • Knowing and understanding needs • Quality assurance	• Digital skills (patients and staff) • Demand for contemporary media from everyday social life
6	• Increased technological intensity	• Achieving advances in productivity • Compensation for the lack of skilled workers • Relief of the workforce	• High effort for cybersecurity • Increasing complexity • Need for technical knowledge	• Extensive investments • Comprehensive qualification • Acquisition of new areas of knowledge	• Technical progress • Patient expectations
7	• Outcome improvement and personalized treatments	• Increasing outcomes • Development of new service areas • Opportunities for specialization	• Adjustment of the business model	• Data quality and availability • Market maturity of technologies • Confidence in new treatment procedures	• Medical progress • Technical progress • Competitors’ offers
8	• Emergence of new ecosystems	• Creation of customer-centric proposals • Exploiting the potential of the platform economy • Increasing customer value	• Highly competitive pressure • Inappropriate market power of some players • Inadequate regulation	• Understanding digitally controlled ecosystems • Transparency of the service offering • Fair conditions on platforms	• Low barriers to market entry • Minimal regulation • High customer interest and demand

Figure 5. Heuristic impact model of digital transformation trends in hospitals.



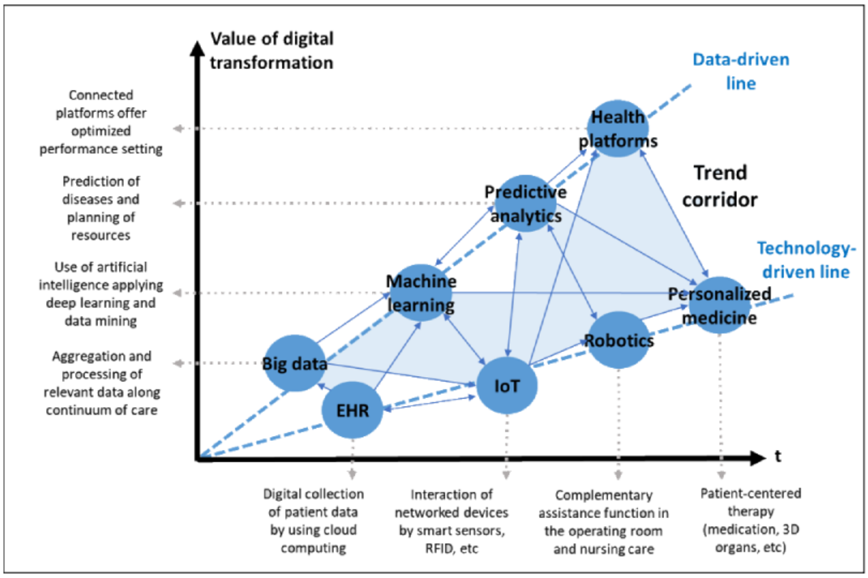
Results of the Data Synthesis

The interrelationships between the trends are very complex and require an adequate form of representation to be able to understand the trend effects. We show these relationships in a heuristic impact model in Figure 5. The 8 core trends are plotted on the outer level. They form the starting point of the interaction. At the next level inward, the first-degree effects are derived. The links there are underpinned with the help of the extracted factors from the literature and the expert interviews. At the next level, in medium blue, the second-degree effects are shown. The characteristics of additional patient value, meeting patient needs and expectations, and patient integration and participation emerge. At the last level, the third-degree effect is derived, which provides patient-centric care. This representation illustrates the positive foresight of future development predicted in the literature and in the expert interviews. The data synthesis shows that, as a result of the digital transformation, the value of care for patients will increase considerably. The nodes highlighted in red show a concentration of related parameters. They are based on the trend correlations shown in Figure 4 and the qualitative responses from the interviews.

For a more intuitive illustration of the trend development perspective, we placed the value of care as a result of digital transformation in a temporal context. Figure 6 shows the development horizon with increasing digital transformation progress and the associated added value. On the one hand, this is driven by technological intensification [38,39,41,45,54,59,71]. The primary manifestation of this is the use of digitally controlled and networked devices as well as software and algorithms. In contrast, a rise in the quality of care is to be expected [20,43,44,67,72,76]. The availability of large amounts of data enables better predictability of diseases and possible therapies and better control of the care itself. Machine learning leads to a continuous improvement in outcomes and decision-making [47,57,58,61,69].

The convergence of personalized medicine as a result of better diagnostics and individualized therapy decisions, incorporating the spectrum of technological innovations of today and the future, results in an adapted range of care offered by hospitals [56,58,61]. Thus, hospitals are increasingly becoming players on a health care platform on which various providers offer health care services depending on their competencies [53,65,73,77]. The schematic diagram illustrates the successive stages and draws 2 elementary trend lines along which the progress runs. Within this is the trend corridor. Along the time axis, both lines contribute to a higher value of care, with the contribution of technologies being lower than the value contribution of data. This is because technologies can provide additional benefits on their own. However, the higher overall benefit comes from the networked use of the data.

Figure 6. Schematic trend development perspective. EHR: electronic health record; IoT: Internet of Things; RFID: radio frequency identification.



Detected Trend Decelerators and Barriers

The analyses described numerous blockades and barriers that slow down the trends. Textbox 2 classifies these decelerators according to internal and external hurdles. External hurdles are defined as factors that are not under the hospitals' control and usually have to be removed by a higher-level institution. This primarily refers to state institutions or self-governance. These aspects include the regulatory framework for health care services [60,65] or data protection regulations [40,46]; access to and the interoperability of data [41,46,49,55]; and an insufficient investment in hospital infrastructure [68,70,74], especially in technical equipment.

Internal hurdles are factors that occur within the hospital setting and can largely be solved there. The most frequently cited obstacle is a lack of knowledge of the use of digital applications [41,50,68,74]. The changes resulting from digital transformation are also accompanied by a shift in tasks and processes, some of which are not widely accepted by the workforce [44,63,67,75,76]. Furthermore, ensuring cybersecurity to avoid risks is an elementary component that clinics must accommodate to an increasing extent [20,42]. Finally, there is often a lack of perspective on how hospitals can position themselves in a new digital ecosystem of service providers as part of the digital transformation and how they can develop new business models and exploit the potential of digital provision [56,65,79].

Textbox 2. Type of hurdle and description of the results.

External hurdles

- Regulation of service delivery [60,74]
- Data protection regulations [40,46]
- Uniformity of data structures [41,46,49,55,75]
- Lack of interfaces for data exchange [50,71,76]
- Insufficient investment in technical infrastructure [68,70,74]
- Lack of political understanding of appropriate frameworks [64,74]

Internal hurdles

- Inadequately qualified personnel [41,50,68]
- Low acceptance of substantially changing processes [44,63,67,75]
- Unwillingness to make large investments [38,55,63,68]
- Failure to ensure cybersecurity [20,42]
- Continuous training needs [49,55,59,71]
- Availability of suitable business models [56,65,79]

Discussion

Principal Findings

We included 44 studies in our analysis, drawing a picture of hospital trends. Subsequently, the trends in the German hospital care setting were discussed, validated, and refined through expert interviews. A wide range of aspects were considered, covering the use of new technologies, the implementation of process innovations, and behavior changes or role shifts among patients and hospital staff. The trends shown provide a framework for better assessing current and future developments from the perspective of clinics and other health care stakeholders. This allows for a snapshot of one's own point of view or an assessment by higher-level authorities as to which changes in the framework conditions can accelerate or slow down the trends. For this purpose, trend barriers and developmental hurdles were also extracted from the studies. These can be used to derive policy options.

The trends described were not examined in terms of their positive or negative impact. Nevertheless, a positive trend is discernible in the development horizon, which is improving inpatient care and steering it in a patient-centered direction. Therefore, it is conceivable that not all trends will lead to a positive development for all stakeholders involved. The increased use of technology, automation, and AI systems will in some cases entail job losses or a restructuring of work [91]. Therefore, for hospital staff (employee representatives or trade unions), change through digital transformation is not necessarily associated with improvements. These aspects must also be considered. In contrast, digitization leads to the extensive aggregation of data, which can restrict people's freedom of data self-determination. In addition, one-sided power positions of companies that have very large amounts of data at their disposal can lead to imbalances [92]. This can also preclude better patient care or unfair competition in the market [93]. The constant change in the course of the digital transformation of hospitals will in the future involve staff and decision makers in the qualification and further development of the range of services as the speed of change is increasing and the demands on service providers are continually rising [94]. The positive aspects of digital transformation should also be emphasized as they have the potential to prevent illnesses in the future, improve outcomes, and relieve staff of nonmedical tasks. In view of the impending shortage of skilled workers in health care professions around the hospital and beyond, this can unleash tied-up resources. Technical systems and algorithms can take over assisting tasks and, thus, optimize internal clinical processes as well as improve the entire spectrum of care from prevention to individualized therapy [95]. We are already seeing how technical innovations and digital applications are changing the professions in hospitals [96-98]. With the help of these tools, the high future demand for skilled workers can be partially compensated or substituted. In addition, dealing with innovations can lead to a higher attractiveness of the professions. The included studies tended to show a positive overall picture in which the opportunities dominate over the risks. The trend development was partly based on specific findings from Germany. However, overall, the trend perspectives can also be applied to other countries. In Europe, there are countries such as Switzerland, Austria, and the Netherlands, among others, that have similar health care system conditions. The analogs of the perspectives of digitally controlled hospital care can also be transferred to almost all other countries.

Implications for Public Health and Future Medicine

Our study shows that there is enormous potential for public health to make care in hospitals more patient-centric as a result of digital transformation. This means that diseases can be detected and treated earlier. At the end of a successful transformation, there is a healthier population that takes advantage of the opportunities offered by preventative and precautionary health care. Clinics contribute to realizing this goal and must be prepared by decision makers for their changed role. As a result, comprehensive savings are possible, which can relieve the pressure on the health care system [99]. Strained health care systems such as those in Germany and other European countries could be relieved as a result. The shortage of specialists in inpatient care can be slowed down. For medical professions, this transformation means, on the one hand, relief through new technologies or support in diagnostics and therapy. Therefore, more time can be spent on advising and caring for patients, and the quality of care can be improved. In contrast, increasing digitization requires the learning of new skills and a change in working methods from physical to technical or technology-supporting activities. In the continuing education of physicians, it is essential that these competencies are sharpened. The increased interaction of patients, who, in the future, will collect their own data, monitor the progress of their illnesses with data support, and use mobile devices to contact hospitals, requires a high level of health literacy and digital competencies. School education should prepare children for this and also offer programs for older people to acquire the necessary knowledge. A low-threshold access to information and guidance should also be established.

Limitations

The included studies already cover a comprehensive range of current and future trends. Nevertheless, the individual aspects may not have been considered. The analysis was primarily conducted from the perspective of inpatient service provision. The patient, as an important participant in the care process, was not explicitly examined. For example, sociological trends with regard to the use of digital applications could lead to findings that were not reflected [100]. These include the acceptance of new technologies and the willingness to use them. This aspect can also be extended to personnel in clinics. The distinction between trends, future forecasts, and expectations is not entirely clear-cut. Trends comprise medium-term developments in a relatively delimited subject area. We tried to apply this reference position as best as possible in our study. Some developments also refer to a longer time horizon as the initial situation varies greatly among countries. Thus, this study only showed the general developments that are possible in the next 5 to 10 years. The extent to which these developments can be realized or which other influencing factors accelerate or slow down individual aspects must be assessed individually for each health care system [49]. Therefore, a generalization to all health care systems is not conceivable. The German perspective could lead to minor distortions here in some cases. However, Germany's reference role in many respects supports our argument. The reference period of the past 5 years covers a relatively short time horizon. We decided to carry out our study in this way as, in our view, studies conducted before 2016 with data from previous years are not informative about future trends [36,37]. The screening of databases also revealed that most studies on trends in the digitization of health care were published in the past 3 years (2018 to 2020) in particular. Owing to the COVID-19 pandemic, there may have been additional trends in 2020 that we did not explicitly include in our analysis [101]. As little, or at best rudimentary, research was available in the fall of 2020 when we conducted our database search, we excluded this option from our analysis. Nonetheless, we cannot rule out that new trends for clinics may have emerged as a result of the pandemic that have not yet been adequately considered in this work.

Conclusions

In our study, we showed the influence of digital transformation on inpatient care. In the process, the high complexity of the interacting players became clear. We extracted 8 core trends from the international literature and validated them with experts in relation to the change in hospital care provision in Germany. We presented the interrelationships in a heuristic impact model. Our study highlights the barriers to successful transformation based on internal and external factors. We provide recommendations for action for decision makers on how public health can be improved by a digitally transformed hospital landscape and which hurdles need to be overcome.

Abstract

Background: Population-based esophageal cancer (EC) screening trials and programs have been conducted in China for decades; however, screening strategies have been adopted in different regions and screening profiles are unclear.

Objective: We performed a meta-analysis to profile EC screening in China by positivity rate, compliance rate, and endoscopy findings, aiming to provide explicit evidence and recommendations for EC screening programs.

Methods: English (PubMed, Embase) and Chinese (China National Knowledge Infrastructure, Wanfang) language databases were systematically searched for population-based EC screening studies in the Chinese population until December 31, 2022. A meta-analysis was performed by standard methodology using a random-effects model. Pooled prevalence rates were calculated for three groups: high-risk areas with a universal endoscopy strategy, rural China with a risk-stratified endoscopic screening (RSES) strategy, and urban China with an RSES strategy. Positive cases included lesions of severe dysplasia, carcinoma in situ, intramucosal carcinoma, submucosal carcinoma, and invasive carcinoma.

Results: The pooled positivity rate of the high-risk population was higher in rural China (44.12%) than in urban China (23.11%). The compliance rate of endoscopic examinations was the highest in rural China (52.40%), followed by high-risk areas (50.11%), and was the lowest in urban China (23.67%). The pooled detection rate of positive cases decreased from 1.03% (95% CI 0.82%-1.30%) in high-risk areas to 0.48% (95% CI 0.25%-0.93%) in rural China and 0.12% (95% CI 0.07%-0.21%) in urban China. The pooled detection rate of low-grade intraepithelial neoplasia (LGIN) was also in the same order, being the highest in high-risk areas (3.99%, 95% CI 2.78%-5.69%), followed by rural China (2.55%, 95% CI 1.03%-6.19%) and urban China (0.34%, 95% CI 0.14%-0.81%). Higher detection rates of positive cases and LGIN were observed among males than among females and at older ages. The pooled early detection rate was 81.90% (95% CI 75.58%-86.88%), which was similar to the rates in high-risk areas (82.09%), in rural China (80.76%), and in urban China (80.08%).

Conclusions: Under the current screening framework, a higher screening benefit was observed in high-risk areas than in other regions. To promote EC screening and reduce the current inequality of screening in China, more focus should be given to optimizing strategies of high-risk individual assessment and surveillance management to improve compliance with endoscopic examination.

KEYWORDS

esophageal cancer; screening; high-risk individuals; detection rates; China

Introduction

Esophageal cancer (EC) represents a global public health burden, with the primary pathological type being esophageal squamous cell carcinoma (ESCC) [1]. More than 50% of global ESCC cases occur in China, causing severe disease and an economic burden for the country [2,3]. A series of prevention and control strategies for EC have been implemented in China since the 1960s, especially in well-known high-risk areas such as Linzhou of Henan Province, where the incidence and mortality of EC were estimated to be approximately five times higher than the national average levels [4]. These strategies and actions have brought success, contributing to an average 4.5% reduction in the incidence and mortality of EC in China since 2000 [5]. In addition, the results of a screening program in high-risk areas in China demonstrated the effectiveness of EC screening with endoscopy examination in reducing EC incidence and mortality [6], which provided high-quality evidence and strong application recommendations for international EC screening and early detection and treatment.

Three organized screening programs have been launched based on the National Key Public Health Project since 2005 to conduct population-based EC screening in the high-risk areas of Huaihe River and urban China [7]. The primary aim of these programs is to reduce the incidence and mortality of EC and to explore a suitable and feasible EC screening strategy. In practice, two main EC screening strategies have been adopted and implemented in China. One is the universal endoscopy screening strategy, which is used in high-risk areas. The other is the risk-stratified endoscopic screening (RSES) strategy, which provides endoscopies for a limited group of individuals at high risk of EC and is currently widely implemented in nonhigh-risk areas [7]. These programs and other population-based ESCC screening studies have covered more than 150 counties or cities in China [7], providing and accumulating a great deal of experience and real-world data for ESCC prevention and control in China and internationally.

Clear and comprehensive knowledge of the profile of EC screening, including the positivity rate of high-risk individuals for EC, compliance with endoscopy screening, and endoscopy findings in real-world EC screening programs, has potential public health value. For instance, such knowledge would help health policy makers understand the actual acceptability of EC screening, direct benefits from EC screening, and burden of surveillance endoscopy. In addition, this crucial real-world evidence would promote the further implementation of EC screening programs in China and other countries that face a high EC burden. To the best of our knowledge, EC screening profiles in China are unclear based on existing studies and the literature. To obtain a comprehensive profile of EC screening in China, we performed this systematic review and meta-analysis to estimate the positivity rate of EC among high-risk individuals, compliance with endoscopy screening, and endoscopy findings by high-risk and nonhigh-risk areas (rural China and urban China). By summarizing these indices, we hope to provide more explicit evidence and recommendations for Chinese EC prevention and control and to promote further EC screening in other countries facing the threat of a high EC burden, which has great importance for public health.

Methods

Design

The protocol for this systematic review was published in the International Prospective Register of Systematic Reviews (PROSPERO; registration number CRD42022375720) and the review was designed following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines 2020 [8].

Data Sources and Search Strategy

The English-language (PubMed, Embase) and Chinese (China National Knowledge Infrastructure, Wanfang) databases were systematically searched for population-based EC screening studies in the Chinese population until December 31, 2022, in any language. The following relevant Medical Subject Heading (MeSH) terms and key words were used for the search: esophageal neoplasms, screening, and China (see Table S1 in Multimedia Appendix 1 for the full search strategy). Two researchers (HL, YT) performed the literature search independently and discrepancies were resolved by consultation with a third researcher (XY).

Study Selection

Inclusion Criteria

Studies were selected based on the following inclusion criteria: (1) studies that reported compliance with endoscopy examination and/or endoscopy findings from population-based EC screening in the Chinese population without restrictions on age; and (2) cross-sectional studies, cohort studies, and randomized controlled trials that reported baseline findings.

Exclusion Criteria

Studies were excluded if they (1) were nonpopulation-based screening studies, (2) lacked information on compliance rates with endoscopy exam and endoscopy findings of positive cases or low-grade intraepithelial neoplasia (LGIN), and (3) were studies with duplicated data for all outcomes of interest published elsewhere or parts of another study from the same geographical location.

Data Extraction and Quality Assessment

For each included study, two reviewers (HL, YT) independently assessed the studies and extracted the data for analysis. The extracted information included the first author and year of publication, study periods, study region, number of study centers, screening strategy (universal endoscopy screening/RSES), sex (proportion of males), age, available data of sex-specific and age-specific subgroups, and available data of early detection among patients with positive screening results.

The study quality and risk of bias were assessed using an instrument developed by Hoy and colleagues [9] for population-based prevalence studies. The tool has 10 questions, and a score of 1 (yes) or 0 (no) was assigned for each item (see Table S2 in Multimedia Appendix 1). Scores were summed across items to generate an overall quality score that ranged from 0 to 10, and studies were then classified as having a low (scores≥8), moderate (scores of 6-7), or high (scores≤5) risk of bias. This method has been used in previous systematic reviews. This assessment tool was tested in previous studies; it is easy to use and deals with risk of bias well.

Outcomes Assessed

The pooled outcomes assessed included the positivity rate of high-risk individuals for EC/upper gastrointestinal (UGI) cancer, compliance rates to endoscopy examinations, prevalence of endoscopy findings (positive cases, LGIN, and negative endoscopy), and early detection rate. The definition of each index is described in Table S3 of Multimedia Appendix 1. Positive cases included lesions of severe dysplasia, carcinoma in situ, intramucosal carcinoma, submucosal carcinoma, and invasive carcinoma. LGIN included lesions of mild dysplasia and moderate dysplasia. Negative endoscopy findings were defined as a baseline endoscopic examination that did not reveal any of the dysplasia lesions mentioned above.

Statistical Analysis

We used meta-analysis techniques with logit transformation to calculate the pooled proportions along with the corresponding 95% CIs under a random-effects model. We calculated the pooled prevalence in three populations with different screening strategies: (1) high-risk areas with a universal endoscopy strategy, (2) rural China with an RSES strategy, and (3) urban China with an RSES strategy. Analyses of the pooled prevalence of endoscopy findings by sex and age group (40-49, 50-59, and 60-69 years) were also performed. We performed sensitivity analyses by publication year, sample size, and the number of study centers to evaluate the robustness of the study.

Heterogeneity between studies was assessed with the I^2 statistic, which estimates the percentage of the total variation across studies due to true between-study differences. Generally, I^2values greater than 60%-70% indicate the presence of substantial heterogeneity. Publication bias was inspected visually on a funnel plot and by the Egger test; *P*<.05 was considered statistically significant. All meta-analyses were carried out using R software (version 4.1.0; R Foundation for Statistical Computing, Vienna, Austria).

Ethical Considerations

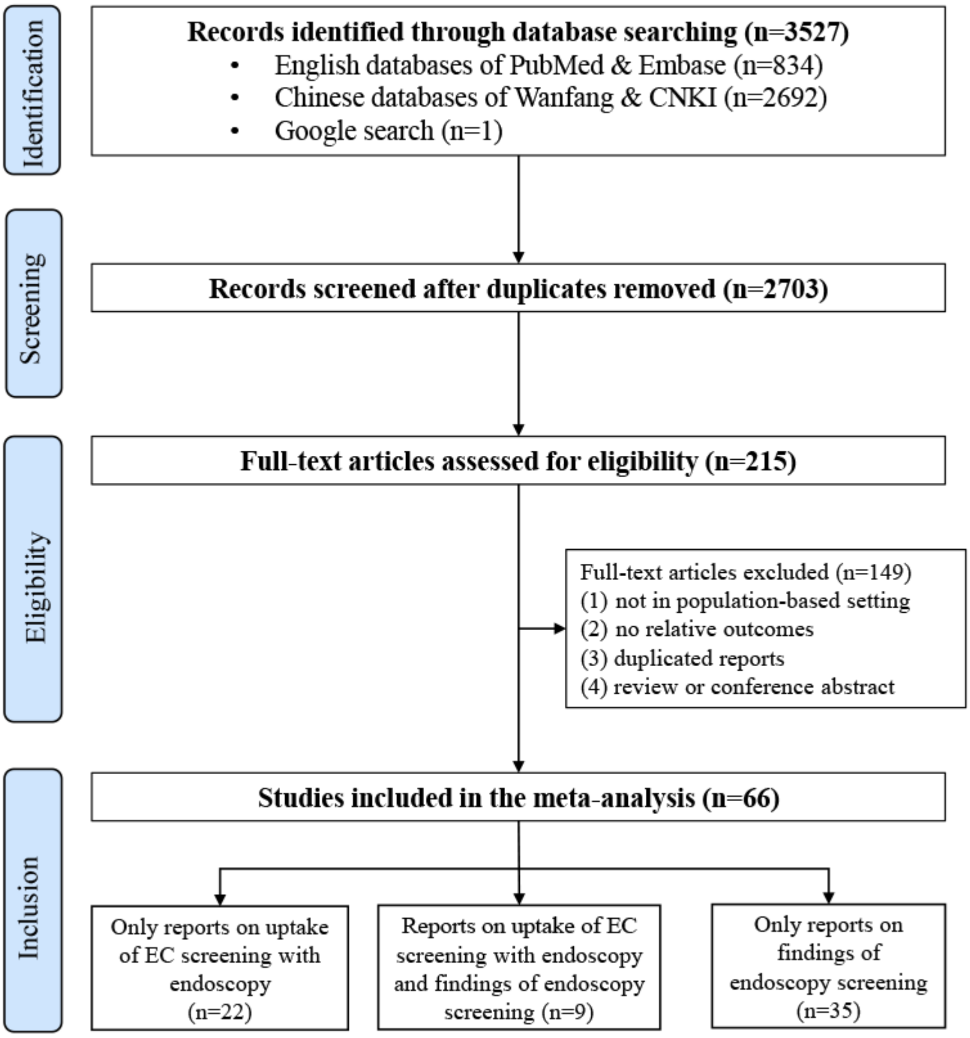
This is a meta-analysis of published studies and data, and did not involve active human participants and/or animals. The present study used only publicly available summary-level statistics and did not involve individual information. Therefore, formal consent, informed consent, institutional review board approval, and ethics approval are not applicable and/or not needed.

Results

Search Results

A schematic diagram of study selection is provided in Figure 1. The initial search identified 3527 records, and 2703 titles and abstracts were screened after removing duplicates. A total of 215 full-length articles were evaluated in detail and 66 studies were included in the final analysis. Among these studies, 22 studies only reported the compliance of EC screening with endoscopy, 35 studies only reported the findings of endoscopy examinations, and 9 studies reported both outcomes.

Figure 1. Flowchart presenting the selection of studies for inclusion in the systematic review and meta-analysis. CNKI: China National Knowledge Infrastructure; EC: esophageal cancer.



Study Characteristics and Quality Assessment

The characteristics of the 66 included studies are outlined in Table S4 of Multimedia Appendix 1, and the summary characteristics about reporting compliance with endoscopy examinations and endoscopy findings are summarized in Table 1 and Table 2, respectively. Eligible ages for EC screening were 40-69 years in all studies conducted in high-risk areas and rural China, except for one study performed in Hua County with an age range of 25-65 years [10]. Eligibility ages in urban China were primarily 40-74 years, and the remaining studies recommended 40-69 years.

A total of 2,472,920 asymptomatic individuals were included in 31 studies that reported compliance with endoscopy examinations, one of which reported data from both rural and urban China [11]. Therefore, 2,006,235 individuals were from high-risk areas during 1999-2017 (n=12) [6,10,12-21], 125,473 individuals were from rural China during 2010-2017 (n=2) [11,22], and 341,212 individuals were from urban China during 2012-2019 (n=18) [11,23-39], as shown in Table 1 and Table S4 of Multimedia Appendix 1. The details of the high-risk assessment strategy to select targets to undergo further endoscopy screening are summarized in Table S5 of Multimedia Appendix 1.

A total of 997,004 individuals had reports of endoscopy findings in 44 studies, among which one study reported endoscopy findings in high-risk areas, rural China, and urban China [11]. Therefore, a total of 876,170 individuals aged 40-69 years (n=36 studies) [6,11,12,14-17,40-68] from high-risk areas underwent endoscopic examinations, where a universal endoscopy strategy was adopted. A total of 102,413 individuals with a high risk of EC (n=4 studies) [11,69-71] aged 40-69 years in rural China and 18,421 individuals with a high risk of EC/UGI cancer (n=6 studies) [11,29,33,72-74] aged 40-74 years in urban China underwent endoscopic examinations where the RSES strategy was adopted (Table 2). The number of individual study samples ranged from 1151 [74] to 116,630 [67] across all included studies. Study participants were enrolled from 1999 to 2019 in high-risk areas, followed by 2007 to 2017 in rural China and 2015 to 2019 in urban China. Study regions also presented disparities: study regions in high-risk areas mainly consisted of north China (22%) and southwest China (22%), followed by eastern China (19%), central China (17%), and northwest China (11%). Study regions in rural China were mostly concentrated in east China (50%) and central China (25%). Study regions in urban China were relatively evenly distributed across the country, except in central and northeast China (Table 2, Table S4 in Multimedia Appendix 1).

Of the 31 studies reporting compliance with EC screening using endoscopy, 12 (39%) and 19 (61%) were classified as having a low and moderate risk of bias, respectively (Table S6 of Multimedia Appendix 1). Of the 44 studies that reported findings of endoscopy examinations, 39 (89%) and 5 (11%) were classified as having a low and moderate risk of bias, respectively (Table S7 in Multimedia Appendix 1).

[b] The age of eligibility of one study in high-risk areas was 25-65 years and that of the others was 40-69 years.

Pooled Outcomes

Pooled Positivity Rates of the High-Risk Population and Compliance With Endoscopic Examinations

All pooled results are summarized in Table 3. A total of 373,516 (in rural China) and 1,449,536 (in urban China) individuals of the asymptomatic population completed individualized risk assessment by professional staff from EC screening programs or trials. The pooled positivity rate of the high-risk population in rural China was higher than that in urban China; the details are shown in Figure S1 of Multimedia Appendix 1. The overall compliance rate with endoscopic examinations among the 31 included studies was 35.39% (95% CI 27.96%-42.82%), covering 2,472,920 eligible individuals for endoscopic examinations. The compliance rate was the highest in rural China, followed by high-risk areas, and was the lowest in urban China, as shown in Figure 2 and Table 3.

Table 3. Summary of pooled positivity rates of high-risk individuals, compliance rates of endoscopy examinations, and prevalence of endoscopy findings in population-based esophageal cancer (EC) screening in China by region.

Assessed metrics in population-based EC screening	High-risk areas		Rural China		Urban China	
	Pooled rate, % (95% CI)	I^2	Pooled rate, % (95% CI)	I^2	Pooled rate, % (95% CI)	I^2
Positivity rates of high-risk individuals in EC screening	—[a]	—	44.12 (28.76-60.69)	100%	23.11 (19.52-27.13)	100%
Compliance rates of endoscopy examinations	50.11 (36.65-63.58)	100%	52.40 (44.58-60.22）	100%	23.67 (18.24-29.10)	100%
Endoscopy findings

Pooled Rates of Endoscopy Findings

The prevalence of endoscopy findings varied widely by region. Specifically, the pooled detection rates of positive cases decreased from high-risk areas to rural China and urban China (Table 3, Figure S2 in Multimedia Appendix 1). The pooled detection rate of LGIN was also in the same order, being the highest in high-risk areas, followed by rural China and urban China, as shown in Table 3 and Figure S3 in Multimedia Appendix 1. Consequently, the detection rates of negative endoscopy findings increased from high-risk areas to rural China and urban China (Table 3, Figure S4 in Multimedia Appendix 1).

Pooled Rates of Early Detection Among Positive Cases

A total of 34 of the 44 included studies reported early detection cases, covering 8445 patients diagnosed with positive cases at endoscopy screening (Figure S5 in Multimedia Appendix 1). The pooled early detection rate was approximately 81.90% (95% CI 75.58%-86.88%), which was similar to the rates in high-risk areas, rural China, and urban China (Table 3).

Pooled Detection Rates of Endoscopy Findings by Subgroups

Table 4 summarizes the pooled rates of endoscopy findings of sex-specific and age-specific subgroup analyses. Overall, males had higher detection rates of positive cases (1.65% vs 0.82%) and LGIN (5.71% vs 3.66%) and a lower detection rate of negative endoscopy findings (92.33% vs 95.38%) than females. The detection rates of positive cases and LGIN increased with age group, as the rates of positive cases were 0.52% in the 40-49 years group, 1.26% in the 50-59 years group, and 2.73% in the 60-69 years group, and the corresponding rates of LGIN were 2.62%, 4.24%, and 7.13%, respectively. The sex-specific and age-group detection rates of endoscopy screening in the three specific areas are also shown in Table 4, demonstrating the highest detection rates of positive cases and LGIN in high-risk areas, followed by rural China and urban China in each subgroup.

Table 4. Prevalence of negative endoscopy findings, low-grade intraepithelial neoplasia (LGIN), and positive cases in different subgroups in population-based esophageal cancer screening in China.

Validation of the Meta-analysis Results

Sensitivity Analysis

To assess whether publication year, sample size, and the number of study centers had a dominant effect on the meta-analysis, we additionally analyzed their effect on the detection of positive cases (see Table S8 of Multimedia Appendix 1). The findings in this analysis showed that studies with publication years before 2009 and sample sizes less than 5000 had a significantly higher detection rate of positive cases in high-risk areas. In addition, multicenter studies presented lower heterogeneity in urban China.

Heterogeneity

High heterogeneity (I^2) among studies was observed for all estimated indices, and these findings remained unchanged in the subgroups (Table 4; Table S8 in Multimedia Appendix 1).

Publication Bias

Publication bias assessment was performed based on the prevalence of positive cases. Visual inspection of the funnel plots (Figure S6 in Multimedia Appendix 1) and the two-tailed Egger test (P=.10) demonstrated no evidence of publication bias.

Discussion

Based on this systematic review and meta-analysis of 66 studies covering over 2 million asymptomatic Chinese populations participating in population-based EC screening, we summarized a series of crucial indices to profile the status of EC screening in China. Under the current EC screening practice, the positivity rates of the high-risk population and compliance rates with endoscopic examinations, yields from EC screening, and burden of surveillance endoscopy varied greatly in populations from high-risk areas and other nonhigh-risk areas (rural China and urban China). These findings not only show the actual situation of current population-based ESCC screening in China but also reflect corresponding challenges and potential future directions in scientific research and policy-making to promote EC prevention in China.

Identifying high-risk individuals for EC to undergo further endoscopic examinations has been one of the most critical factors for the success of ESCC screening programs. Selection of assessment items and the threshold to define endoscopic examination eligibility are essential but troublesome tasks in this field [75]. In nonhigh-risk areas of EC where the RSES strategy was adopted, the pooled positivity rate of high-risk individuals for endoscopic examinations in the rural Chinese population was approximately twice that in the urban Chinese population (44.12% vs 23.11%), fully reflecting the rural-urban inequality of exposure to EC risk factors. However, the existing individualized assessment tool in EC screening programs or trials in China differed in the assessment items, thresholds, and definition of outcomes (EC or UGI cancer), as summarized in Table S5 of Multimedia Appendix 1. Few assessment tools have estimated the accuracy and effectiveness of EC screening. In addition, all the existing prediction models for EC presented a high risk of bias and none of these models was estimated in diverse populations, which limited the implementation values in large-scale population-based EC screening programs or even the national EC screening program [75]. Before implementing the national EC screening program, development of a specific high-risk assessment strategy to define eligible individuals for endoscopy screening should be prioritized. Through comprehensive estimation and validation in diverse populations with national representatives, updated individualized EC risk assessment strategies could be developed in the future, serving EC screening in China and other countries.

Optimal compliance for endoscopic examinations in eligible asymptomatic individuals is essential to confer benefits from EC screening, as shown in cohort and modeling studies [6,76,77]. However, the overall compliance of endoscopy screening in existing population-based EC screening programs or trials in China was found to be suboptimal, especially in the urban Chinese population, with a compliance rate of less than 24%. Therefore, improving the endoscopic compliance rate by adopting comprehensive strategies is an urgent need for EC screening programs. Several available measures could be taken in the future. First, from the aspect of providers of EC screening programs, there is an urgent need to conduct multifaceted actions to promote and improve the core knowledge of cancer prevention and control in Chinese residents and help them correctly understand cancer and prevent it [78]. A previous EC screening study among 28,543 high-risk individuals for EC showed a positive association between cancer prevention awareness and compliance with endoscopic examinations [79]. This highlights the importance and feasibility of raising eligible individuals' awareness of cancer prevention in improving compliance rates in population-based EC screening programs. Second, for community servers in population-based EC screening, more attention and interventions should be paid to several vulnerable populations in health literacy to improve their compliance rate with endoscopic examinations. These populations included males, cigarette smokers, and those with low socioeconomic status, who had a higher risk of developing EC but lower compliance rates of endoscopic examinations, as observed in previous population-based EC screening studies [31,33,79]. In addition, optimization of the screening procedure, such as shortening the waiting time for endoscopic examinations, may be considered another effective measure to improve compliance, as indicated in population-based cancer screening programs [80].

The endoscopy findings exhibited apparent disparities among studies, mainly due to the heterogeneous study populations in the disease burden of EC, different EC screening strategies, and varying compliance rate for endoscopic examination, which were mentioned above. Specifically, a higher screening benefit was obtained in high-risk areas, followed by rural China and urban China, with pooled prevalence rates of positive cases being 1.03%, 0.48%, and 0.12%, respectively. In addition, early detection among positive cases was more than 80% in all studies, which emphasizes the importance of EC screening in improving survival and quality of life. In terms of the surveillance endoscopy burden, a higher burden of LGIN was also observed in high-risk areas, followed by rural China and urban China, with pooled rates of 3.99%, 2.55%, and 0.34%, respectively. A much larger fraction of the baseline endoscopy screening population comprised those diagnosed with negative endoscopy findings, with prevalence higher than 90% in all previous reports. These results will help policy makers grasp the profile of population-based EC screening under the framework of current strategies in different regions and provide essential benchmarks for health economic evaluation models or other studies. Moreover, there is a considerable need for managing the vast population identified with negative endoscopy findings and LGIN [7]. The current Chinese guidelines for EC screening recommend surveillance intervals of 1-3 years for patients with LGIN and 5 years for individuals with negative endoscopy findings [81]. However, these recommendations were developed based on limited studies with different findings on observational or modeling studies from ESCC high-risk areas in China [76,77,82-84]. More high-quality studies are urgently needed to estimate and update these recommendations.

To the best of our knowledge, this is the first study to provide a comprehensive profile of the available research on population-based EC screening in the Chinese population, which offers comprehensive and objective evidence for policy makers. Findings in this study have important implications for better conducting EC screening in the future. First, development of high-risk assessment criteria for selecting eligible individuals for endoscopic examinations for diverse populations should be prioritized. Second, multidimensional attempts are urgently needed to improve compliance with endoscopic examinations, including improving residents' cancer literacy and optimizing and simplifying screening procedures. Third, more robust and high-quality cohort and modeling studies are urgently needed to estimate or optimize the current surveillance strategy, which will essentially compensate for the limited evidence in the Chinese population.

Our study also has several limitations. First, significant heterogeneity was observed in all pooled indices. Understandably, high heterogeneity is unavoidable given that study-related factors (screening strategy and population-based disease burden of EC) and individual-related factors (individualized risk of EC, compliance with endoscopic examinations, age, and sex) could not be controlled for in all studies. In this meta-analysis, we performed several subgroup analyses with consideration of these significant factors contributing to heterogeneity. Second, a detailed comparison of exposure factors related to developing EC and determinations of compliance with endoscopic examinations in rural-urban Chinese populations were not performed due to data limitations in the existing studies. Third, subgroup analysis of endoscopy findings was limited to sex-specific and age-specific findings. Other potential essential factors, including individual-related (such as smoking status, family history of cancer, and disease history of the digestive system) and procedure-related (such as endoscopist and pathologist performance and quality of endoscopic examinations) factors, were limited due to the lack of data. In addition, available studies and data under different EC screening strategies need to be more balanced. Data on endoscopy findings in high-risk areas were sufficient; however, data to profile EC screening in nonhigh-risk areas were limited. There were only four studies in rural China that reported compliance with endoscopy, and only 18,421 individuals with endoscopy screening were reported in the urban Chinese population. These limited data could not comprehensively profile actual population-based EC screening in this population, and an updated meta-analysis will be performed when more evidence is available.

In summary, in this meta-analysis, the current profile of population-based EC screening in China and potential challenges were summarized with a series of indices in screening procedures (positivity rates of high-risk individuals, compliance rates, and endoscopic findings) by different regions. Under the current screening framework, a higher screening benefit was observed in high-risk areas than in other regions. To promote EC screening and reduce the current inequality of screening in China, more focus should be given to optimizing strategies of high-risk individual assessment and surveillance management to improve compliance with endoscopic examination.

Abstract

Background: Contact tracing (CT) represented one of the core activities for the prevention and control of COVID-19 in the early phase of the pandemic. Several guidance documents were developed by international public health agencies and national authorities on the organization of COVID-19 CT activities. While most research on CT focused on the use digital tools or relied on modelling techniques to estimate the efficacy of interventions, poor evidence is available on the real-world implementation of CT strategies and on the organizational models adopted during the initial phase of the emergency to set up CT activities.

Objective: We aimed to provide a comprehensive picture of the organizational aspects of CT activities during the first wave of the pandemic through the systematic identification and description of CT strategies used in different settings during the period from March to June 2020.

Methods: A systematic review of published studies describing organizational models of COVID-19 CT strategies developed in real-world settings was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement. PubMed, Embase, and Cochrane Library were searched. Studies not providing a description of the organizational aspects of CT strategies and studies reporting or modelling theoretical strategies or focusing on the description of digital technologies' properties were excluded. Quality of reporting was assessed by using the Template for Intervention Description and Replication Checklist for Population Health and Policy. We developed a narrative synthesis, using a conceptual framework to map the extracted studies broken down by target population.

Results: We retrieved a total of 1638 studies, of which 17 were included in the narrative synthesis; 7 studies targeted the general population and 10 studies described CT activities carried out in specific population subgroups. Our review identified some common elements across studies used to develop CT activities, including decentralization of CT activities, involvement of trained nonpublic health resources (eg, university students or civil servants), use of informatics tools for CT management, interagency collaboration, and community engagement. CT strategies implemented in the workplace envisaged a strong collaboration with occupational health services. Outreach activities were shown to increase CT efficiency in susceptible groups, such as people experiencing homelessness. Data on the effectiveness of CT strategies are scarce, with only few studies reporting on key performance indicators.

Conclusions: Despite the lack of systematically collected data on CT effectiveness, our findings can provide some indication for the future planning and development of CT strategies for infectious disease control, mainly in terms of coordination mechanisms and the use of human and technical resources needed for the rapid development of CT activities. Further research on the organizational models of CT strategies during the COVID-19 pandemic would be required to contribute to a more robust evidence-making process.

COVID-19; SARS-CoV-2; contact tracing; public health; infectious disease; disease control; community engagement; digital tool

Introduction

Background

Contact tracing (CT) has historically been one of the key public health response actions to control the outbreak of a novel virus, particularly in the absence of a vaccine [1]. As with other person-to-person infectious diseases, early case detection, identification, and management of contacts through CT was one of the top priorities for interrupting the chain of infection and controlling the spread of SARS-CoV-2 [2,3]. Before effective vaccines against SARS-CoV-2 became available in December 2020, CT was one of the few tools globally applied to prevent the spread of infection, combined with physical isolation of infected persons and their close contacts (the so-called quarantine), social distancing, and the use of protective devices in public places.

Several guidance documents were produced and disseminated by international public health agencies and national authorities on the organization of CT activities for COVID-19 control, including indications on the type of human and technical resources needed for the different steps of CT (case notification, contact identification, information, management, and surveillance of contacts) [3-10]. Reports on CT activities implemented in several countries suggest marked differences in the organizational models adopted in different settings based on the characteristics of the local health systems and structures, as well as the diagnostic and tracking capabilities [8,11]. Although adapting CT strategies according to the local epidemiological situation and available resources has been emphasized [1,12-14], little evidence is available on the actual implementation of CT activities in real-world settings. In fact, most published studies on CT for COVID-19 have focused on the combination of traditional CT and digital technologies and on cost-effectiveness, ethical concerns, and governance issues related to the use of digital tools [15-20]. Several studies, including systematic reviews, were aimed at estimating the effectiveness of CT strategies for SARS-CoV-2 control, but they mainly relied on modeling techniques [15,21], given the difficulties in measuring real-world effectiveness [22].

Aim of the Study

Further understanding the real-world implementation of CT strategies under different conditions, including measures adopted to scale-up activities, would be relevant to support future planning of CT activities for infectious disease control. Therefore, we conducted a systematic review of the literature to provide a comprehensive picture of the organizational aspects of CT activities during the first wave of the pandemic through the systematic identification and description of CT strategies used in different settings from March to June 2020. We decided to focus on the first wave of the pandemic, when CT represented one of the core public health activities for COVID-19 containment, to describe actions taken for the rapid set up of CT strategies and scale up of resources.

Methods

Study Protocol

We conducted a systematic review of studies describing organizational models of CT strategies for the surveillance and control of SARS-CoV-2 infection. This systematic review was registered in PROSPERO (International Prospective Register of Systematic Reviews; CRD42021279172). The review was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement [23] and the Template for Intervention Description and Replication Checklist for Population Health and Policy (TIDieR-PHP) [24].

Literature Search Strategy

A preliminary exploratory search was carried out restricting the research field to systematic reviews and meta-analyses only, which did not return any noteworthy results. Subsequently, a more specific research strategy was developed to identify primary studies, adapted for each database, using both Medical Subject Headings (MeSH) terms and free text keywords in the title and abstract fields. We searched relevant databases including PubMed, Embase and Cochrane Library from January 1, 2020, to July 31, 2021, for published studies in Italian and English with the terms "contact tracing," "contact investigation," "case finding," "case detect*," "contact examin*," "contact screen*," "COVID-19," "coronavirus," and "SARS-COV-2," with no limitations on study design. The complete search strategy is detailed in Multimedia Appendix 1.

Inclusion and Exclusion Criteria

Studies were included if they provided a description of the organizational aspects of real-world CT strategies (eg, resources involved and activities conducted in each step of the CT process) applied during the first pandemic wave, with no restrictions on study type, setting, or population. The eligibility criteria (Textbox 1) for this review are described according to the PICOS (Population or Problem, Intervention, Comparison, Outcome, and Study Type) framework. Studies that did not provide a description of the organizational aspects of CT strategies or reported or modeled theoretical CT strategies were excluded. Comments, opinions, editorials, and news reports in which no original information was reported were excluded. In the initial screening phase, we classified studies describing CT strategies focusing on digital application tools such as exposure notification, Bluetooth, GPS, or big data management technologies. Because of their peculiarity, studies focusing on the description of the technological features of digital applications were evaluated separately and were therefore excluded from this review.

Textbox 1. Inclusion criteria for this review.

Population or problem

- Organization of contact tracing (CT) activities in populations hit by COVID-19 during the first pandemic wave.

Intervention

- Any real-world CT strategies for the control of COVID-19 during first wave not centered on exposure notification, Bluetooth, GPS, or big data management technologies.

Comparison

- Either no or any type of real-world CT strategy for the control of COVID-19, depending on whether comparative analyses are available in the included studies.

Outcome

- Identification of the main elements characterizing the organization of CT activities for COVID-19 control.
- Description of the main types of CT strategies for COVID-19 control.

Study type

- All types of studies.
- Papers published in peer-reviewed journals, in Italian or English, available in full-text.

Data Extraction and Study Quality

Search results were imported into a reference management database (EndNote 7.8 [Clarivate Plc]). Duplicate articles were removed, and the titles and abstracts of all the collected records were screened by 2 reviewers (AMVA and AR). Studies that clearly did not meet the inclusion criteria were excluded. Full texts of potentially relevant articles were retrieved and independently examined by the 2 researchers. The reference lists of retrieved articles were also searched to identify other potentially relevant studies. All excluded articles and reasons for exclusion were recorded (Multimedia Appendix 2) and any disputes between the 2 researchers were resolved through discussion.

A standardized data extraction file was developed, including the following information: main author, year of publication, country, study design, study period, epidemic phase, type of CT program (institutional level or local level), study population, study setting, activities carried out during the various steps of the CT process (case notification, contact identification, information, management, and surveillance), human and technical resources used, main features of the CT model, and quantitative results.

The quality of reporting was assessed by 2 reviewers (AMVA and AR) using the TIDieR-PHP checklist [24]. The checklist enables clear and comprehensive reporting of population health and policy interventions, providing 11 items to capture pertinent features of these interventions. Adherence to these 11 items was assessed in each of the included studies.

We developed a narrative synthesis using a conceptual framework to map the extracted studies broken down by the target population.

Results

Overview

We retrieved a total of 1638 studies. After duplicate removal and title abstract selection, 130 full texts were assessed, and 17 of them were included in the narrative synthesis [25-41] (Figure 1).

Studies focusing on the organizational models of CT apps and other digital tools were not included in this study and will be addressed in a different review. The main features of the included studies are summarized in Table 1.

All included papers were descriptive accounts of CT strategies implemented in various settings, except for a qualitative study [25]. A total of 8 studies were conducted in the United States [26,27,29-32,36,41], 3 in Asia [34,35,39], 3 in Europe [33,37,40], 2 in Africa [25,28], and 1 in Australia [38].

One study reported information on implemented CT strategies disaggregated for the first and second waves [33], and 1 study did not clearly report the timing when the CT model was implemented [35]. A total of 10 studies described organizational models implemented by national or local governments or public health agencies [25,26,28,29,31,37-41]. The remaining studies described strategies implemented locally in specific contexts [27,30,32-36]. In addition, 7 studies targeted the general population [25-31], and the remaining 10 studies described CT activities carried out in specific population subgroups (workers, travelers, and vulnerable populations) [32-41]. Further details are provided in Table S1 in Multimedia Appendix 3 [25-41].

Quantitative results of CT activities were seldom reported, and the available data were not comparable across the studies (Table S2 in Multimedia Appendix 3).

The results of the assessment of reporting quality are included in Multimedia Appendix 4 [25-41].

Table 1. Characteristics of included studies.

Study	Country	Epidemiological scenario	Target	Setting	Institutional level
Asiimwe et al [25], 2021	Africa–Ghana (Greater Accra Region)	First wave	General population	Regional territory	Government
Breeher et al [32], 2020	United States–Minnesota, Florida, and Arizona	First wave	Health care workers and patients	Hospital (Mayo Clinic)	Specific context
Clarke et al [40], 2020	Europe–Ireland	First wave	Detainees	Prison	Government
de Laval et al [37], 2021	Europe–France	First wave	Workers	Working environment (Creil Air Base–MSFAC[a])	Government
Draper et al [38], 2021	Australia–Northern Territory	First wave	Travelers entering Australia and general population	Airports, ports, and communities	Government
Fields et al [41], 2021	United States–Utah (Salt Lake County)	First wave	General population and PEH[b]	County territory and accommodation for PEH	Government
Hall et al [36], 2021	United States–Virginia	First wave	Workers and their external contacts	Work environment (US Navy Medicine, the Bureau of Medicine and Surgery, Falls Church)	Specific context
Zirbes et al [33], 2021	Europe–Germany	First and second wave	Patients, employees, and health care workers	Marburg University Hospital	Specific context
Kalyanaraman and Fraser [26], 2021	United States–County in Maryland	First wave	General population	County territory	Government
Koetter et al [27], 2021[c]	United States–Central Pennsylvania	First wave	General population, with CT[d] starting from hospital-diagnosed cases—Penn State College of Medicine	Territory of the region	Specific context
Mak et al [35], 2021	China–Hong Kong	Not clearly stated	Patients	Department of Ophthalmology—United Christian Hospital Hong Kong	Specific context
Mueller et al [28], 2020	Africa–Lagos State	First wave	General population	Territory of 5 subareas with the highest number of cases	Government
Niccolai [29], 2020	United States–Connecticut (New Haven)	First wave	General population and university community	City territory and university (Yale University)	Government
Pelton et al [30], 2021[c]	United States–central Pennsylvania	First wave	General population, with CT starting from hospital-diagnosed cases—Penn State College of Medicine	Territory of the region	Specific context
Quach et al [39], 2021	Vietnam–Hanoi	First wave	Travelers entering Vietnam	Flight	Government
Reid et al [31], 2021	United States–City of San Francisco	First wave	General population	City territory	Government
Wong et al [34], 2020	China–Hong Kong	First wave	Patients and health care workers	Queen Elizabeth Hospital	Specific context

[a] MSFAC: Military Support Facility.

[b] PEH: people experiencing homelessness.

[c] The articles refer to the same study but with 2 different focuses: Koetter et al [27] described the organizational model of contact tracing (CT), whereas Pelton et al [30] focused on key performance indicators.

[d] CT: contact tracing.

General Population

All studies targeting the general population have described CT models implemented at the local level (regional territories, counties or cities). Two studies focused on cases diagnosed within a university hospital, the Penn State College of Medicine [27,30], while 1 study described CT activities carried out within Yale University's community, in addition to those targeting the city of New Haven's general population [29].

Not all studies provided details on case notifications. Where described, case notification envisaged the communication of new COVID-19 cases from test laboratories or test centers to CT teams [27,28,30] or the use of infectious disease notification systems, either with automatic notification [26] or through an active search of new cases conducted by an epidemiologist [29].

All studies reported the identification of close contacts by telephone interviews with cases, except for the model described by Mueller et al [28] in the Lagos area, where contacts were line-listed for possible follow-up at the point of sample collection. A total of 3 studies specified that the interviews with cases were conducted using defined questionnaires or forms [25,27,29] developed by epidemiologists. In all cases, the contact list was entered into an electronic database or software.

Contacts were notified of their exposure to a COVID-19 case via telephone in all models. In 2 cases [26,31], the phone call was accompanied by a letter, email, or SMS text messaging notifying the exposure. Koetter et al [27] reported that the CT team from the Penn State College of Medicine used a premade phone script designed with assistance from epidemiologists treating infectious diseases to provide information on exposure and quarantine.

The management and monitoring of contacts during quarantine (14 days in all studies) was carried out mainly using telephone [25-28]. As an alternative to telephone monitoring, the model implemented in the Lagos area also provides home visits by nurses to assess symptoms and take swabs of symptomatic contacts [28]. The students of Penn State College of Medicine [27,30] monitored the symptoms of the cases contacted through a questionnaire sent by email from the CT management software (REDCap [Research Electronic Data Capture], Vanderbilt University) with automatic feedback to the CT team. In the model described by Reid et al [31], screening of symptoms during quarantine occurred via SMS text messaging sent automatically from the COVID-19 tracking application CommCare (Dimagi Inc) and subsequent feedback to the CT team.

The CT models retrieved from the literature used different types of human resources. In some cases, only health workers were involved [25,26], providing different roles depending on their professional background. In the model implemented in the Accra Region [25], clinicians based at the regional level informed contacts of exposure and supervised the work of community nurses engaged in contact monitoring, whereas case investigations were conducted by epidemiologists and disease control officers at the local level. The model described by Kalyanaraman et al [26] involved CT teams composed of nurses responsible for investigating cases and informing contacts, as well as health assistants and runners responsible for monitoring contacts, under the supervision of an epidemiologist. Some studies have reported the involvement of medical and health profession students in CT activities. At the Penn State College of Medicine, medical students were involved in the CT of cases diagnosed within the hospital, being employed either in the management of cases (case teams) or contacts (contact teams) [27]. Yale University health care professional students were involved on a voluntary basis in a CT program aimed at both campus and off-campus populations in collaboration with the local health department, which provided web-based training for volunteers [29]. The University of California San Francisco also involved medical students in a CT program developed with the San Francisco Department of Public Health, and public health experts from the 2 bodies coordinated the activities and trained the CT team, which also included retired doctors, librarians, and other civil servants [31].

All the models described used software or web platforms for case and contact management. Most studies used open-source platforms (eg, Surveillance Outbreak Response Management and Analysis System, SORMAS Foundation [25], and Open Data Kit, Jekyll and Minimal Mistakes [28]) or relied on existing platforms such as such as RedCap (Vanderblit University) [27,30] or Veoci Inc (Virtual Emergency Operations Center Software) [29]. The CT model developed by the students of University of California San Francisco and the experts from San Francisco Department of Health was initially partnered with Dimagi Inc to make use of their web-based COVID-19 tracking application, CommCare, and then transitioned to the digital platform, CalConnnect, to align San Francisco with most other jurisdictions in California [31].

Only 2 models provided the development of indicators that allowed for the measurement of the effectiveness of the interventions [30,31]. In both cases, the development of a CT model based on the rapid mobilization of human resources (including university students), team organization, and the use of digital platforms led to a reduction in the time required to complete CT activities. The study conducted at the Penn State College of Medicine showed a reduction in the test turnaround time from 21.8 to 2.3 days, also due to improvements in the testing capacity [30]. The study by Reid et al [31] showed a reduction in the time between contact registration and the first attempted contact from 5 days to 1 day over a 2-month period.

Special Populations

Studies describing CT models not addressed in the general population targeted the following population groups: workers, including health care workers (HCWs), military workers, and civilians working in military areas [32-37]; travelers [38,39]; and vulnerable populations, including inmates and homeless people [40,41]

Workers

Among studies carried out on workers, 4 studies focused on CT models developed in the health care setting [32-35] and 2 studies reported CT strategies addressed to civilians and military workers.

HCWs and Patients

Studies describing CT models addressing HCWs also reported CT activities in patients and contacts; 1 study focused on hospital patients only [35]. One study was carried out in the Mayo Clinic campuses, United States [32]; 1 was carried out in the University Hospital of Marburg, Germany [33]; and all the other studies were conducted in Hong Kong public health service hospitals.

Where indicated, the structure responsible for notifying cases among HCWs was the Occupational Health Services (OHS) [32] or the Infection Control and Prevention (ICP) service [33]. The procedure for case notification was not described in all studies. In the model described by Wong et al [34], a positive health worker was notified by the hospital's in-house laboratory, while in the model described by Breeher et al [32], case notification was made by multiple parties (infectious disease control teams, public health bodies, or self-reporting).

Contacts identification was carried out mainly by hospital internal teams: in the model described by Breeher et al [32] it was carried out by a designated exposure triage provider (ETP) composed of doctor and nurses, in collaboration with the OHS [32], while in other models, contact identification was conducted by the ICP service [33,35], sometimes in collaboration with the local health department [35]. Different approaches have been described for contact listing: some models relied on cases filling standard forms available on the web on the hospital intranet [32,33] and telephone interviews [32]; other models relied on information provided by the ward manager [34] or collected through a hospital software tracking the movement of patients within the hospital (UQ Web) [35]. Patients' contacts were identified through different digital information systems (the electronic medical record, EMR [32]; health information systems [33]; patient administration CT systems [34]; and UQ Web software [35]. All studies classified contacts according to the levels of exposure, risk, and subsequent definition of isolation measures.

Information on contacts was managed internally in all models as well: it was carried out either by hospital staff (eg, by the ETP, the exposure investigation team, and the nursing exposure investigation team in the model described by Breeher et al [32] or by the ICP in the model described by Zirbes et al [33]) or directly by cases using an intranet platform [33].

In the Mayo Clinic model, cases self-filled an internet form and were then interviewed by telephone to assess the level of risk, define isolation measures and prescribe diagnostic tests [32]. In the Marburg Hospital model, the ICP automatically notified HCWs identified as close contacts to define work restrictions and patients to begin isolation through the intranet platform. HCWs were sent to the clinic's testing centers, and results were available on the intranet, while the patients were cared by the local health authorities [33]. In the Hong Kong model described by Wong et al [34], quarantine for close contacts was arranged at a designated camp (staff) or in isolation rooms for patients with airway-transmitted infections, whereas casual contacts were subjected to medical surveillance.

Management of contacts included monitoring of symptoms, in some cases self-reported by the HCWs [32], and testing. Surveillance of symptoms duration ranged from 14 [33] to 28 [34] days from the last contact with the index case. The Marburg University Hospital model envisaged repeating antigenic tests (for health professionals) and polymerase chain reaction (PCR) tests (for patients) 3 times every 48 hours since the last contact with the index case [33], while Wong et al [34] reported that all contacts were monitored daily for temperature and symptoms for a 28 days (including the quarantine of 14 days).

The human resources used and their functions were not always clearly reported. The Mayo Clinic model detailed the inclusion of different professionals at the central level in Richmond and at the local campuses: at the central level, nurses and doctors—as part of the ETP—conducted case investigation, the exposure investigation team (composed of clinicians reallocated from other departments) conducted contacts' risk assessment, and administrative or relocated laboratory staff supported data collection; at the local level, nurses exposure investigation team established work restrictions and arranged testing for symptomatic cases [32]. In the model described by Zirbes et al [33], the ICP worker was the key figure in all the CT workflow (in December 2020, 3 ICP workers managed to monitor up to 1201 contacts).

Data on cases and contacts were collected and managed using ad hoc software [32,33,35]. In addition, software solutions were used to track cases and' movement of contacts within the hospital [35] or to allow cases and contacts to fill in standard forms, for contact listing, collecting information on exposure and symptoms [32,33].

Military Area Workers

Two studies addressing CT in the workplace described activities conducted in military areas: 1 at the headquarters of the US Navy Medicine in Virginia [36] and the other at the Creil Air Base in France [37]. Both the studies describe CT activities implemented further to notification of a COVID-19 case within the workplace: in the model described by Hall et al [36], the hospitalized index case self-notified SARS-CoV-2 infection to the office manager, whereas in the French study, the index cases (whose number is not reported) were diagnosed within the military base. In both studies, cases were notified to the local health authorities.

Military personnel [37] or the public health officer (PHO) embedded within the US Navy Medicine headquarters [36] were responsible for investigating the contact, drawing up the contact list, and identifying the possible source of infection. The local health department investigated contacts outside the workplace [36].

Information to contacts was based on their risk level [36,37]. In the study by de Laval [37], all personnel at the air base were classified as close contacts and the model focused on prompt testing of all new symptomatic people. In the US Navy study, the PHO sent information to contacts via mass email with confirmation of receipt, prescribing self-observation, or home quarantine for 14 days for low- and medium-risk contacts, respectively [36]. All personnel were instructed to contact the base health center [37] or their doctor upon onset of symptoms [36]. In the study performed by de Laval et al [37], tests were carried out directly in the base, in a specially set up field-sampling unit.

Surveillance of all identified contacts was performed daily via telephone [36,37], and in case of development of symptoms, PCR testing was required [37].

Human resources used were not specified in the study by de Laval et al [37]. In the US Navy Medicine model, all CT activities within the office were conducted by the PHO, who arranged and coordinated workspace sanitation and was responsible for investigating the case, informing and monitoring contacts, and for campaigning internal information. Administrative staff were responsible for the internal information campaign and infection control policies.

In all studies, CT activities were conducted via telephone, email, and interviews with standardized questionnaires; the PHO also made use of invitation lists, meeting attendance, and carpooling data [36].

Travelers

Two studies described CT strategies used for travelers: one focused on an index case identified on a cruise ship arriving in the Northern Territory of Australia [38] and the second focused on a CT of a flight arriving in Vietnam [39].

In both studies, the index cases were confirmed by a PCR test, but the notification procedure was not described.

In the case of a confirmed positive traveler, the identification of contacts started from the passenger list of the same flight or cruise. In the study performed by Draper et al [38], the passenger list was provided by the airline or the Australian Government Department of Health National Incident Room. In Vietnam, the passenger list was provided by the immigration office and the Civil Aviation Administration to the competent Provincial Center for Disease Control. At the provincial level, local health personnel worked with local authorities, social security departments, and local volunteers to contact passengers and identify their contacts [39].

Draper et al [38] specified that information to contacts was provided via telephone using a standard questionnaire by the contact tracer team (CTT), which also collected data on the time, place, and duration of contact and on COVID-19 symptoms [38]. In the study performed by Quach et al [39], local health personnel interviewed, tracked, tested, and arranged quarantine (for 14 days) in centralized structures for primary and secondary contacts or suggested self-quarantine at home [39].

Contact monitoring was performed randomly by compliance officers by sending daily SMS text messages to monitor the development of fever or respiratory symptoms and compliance with quarantine measures [38]. Contacts in centralized quarantine had their symptoms and temperature checked twice daily; swabs were collected after 3 to 5 days and on day 13 before exiting quarantine [39]. Accommodation, meals, and basic hygiene needs were provided by the Ministry of Health. Any contact who tested positive during centralized or home quarantine was transferred to a referral hospital for isolation and monitoring [39]. Both studies did not provide information on the composition of the CT teams.

Tools used for CT included the Telstra Integrated Messaging platform [39] for sending SMS text messages and a web-based epidemiology database (NetEpi) to collect information on close contacts [38].

Vulnerable Populations

Two studies described CT strategies in vulnerable populations. One study addressed CT of inmates within the Irish prison system [40], and the study performed by Fields et al [41] described CT strategies of people experiencing homelessness (PEH) hosted in quarantine or isolation facilities in Salt Lake County.

The notification of index cases was only described in the prison context, where prison staff notified the internal CTT of positive cases or symptomatic (experiencing cough and fever) inmates [40].

Contacts were identified through interviews with notified inmates and analysis of closed-circuit television footage [40]. For PEH, case investigations were conducted by dedicated staff visiting isolation and quarantine facilities using a standard form, initially in person and later using prepaid mobile phones or walkie talkies at the facilities.

Only Clarke et al [40] reported details on information to contacts. In the prison system model, the CTT informed inmates' contacts, arranged for their isolation, provided indications on home self-quarantine to family members and staff, and informed the public health agency.

Inmates' contacts quarantined inside prisons received clinical monitoring daily, whereas prison staff's contacts in home quarantine were monitored by the community contact management program; however, casual contacts were instructed to self-monitor in case of any COVID-19 symptoms [40]. The PEH were monitored by nurses who filled out a spreadsheet with medical and epidemiological information for each person housed in quarantine or isolation facilities [41].

The human resources involved in CT were described in the prison model. Each prison had a CTT made up of at least 4 people, including security chiefs, assistant chief officers, prison officers, psychologists, or clerical staff, whereas doctors and nurses were responsible for informing positive results and for clinical monitoring. The involved staff followed a training program developed by the National Infection Control Team, public health agency, and National Quality Improvement team [40]. In PHE facilities, nurses were responsible for collecting information on cases and contacts and for monitoring symptoms, and no information was provided on the profile of contact tracers [41].

All models envisaged the collection of case and contact information in local and sometimes centralized databases. Irish prisons collected information on cases and contacts using an Excel (Microsoft Corporation) spreadsheet and saved data in the penitentiary's IT system, which was then sent by secure email to the National Infection Control Team and the public health agency to be archived in the Health Service Executive central database [40]. Information on PEH was collected using the existing Utah National Electronic Disease Surveillance System or EpiTrax software [41].

Discussion

Principal Findings

A systematic review of the published literature on the organizational models of CT implemented during the first wave of the COVID-19 pandemic identified a limited number of studies. Despite the fact that published literature on the topic is scarce, some elements characterizing the setup of different CT programs and some recommendations to increase the efficacy of CT activities can be drawn.

A common feature of all studies was the decentralization of CT activities at the local level: CT was delegated to regions, counties, metropolitan areas, or specific settings such as hospitals, prisons, and communities, with the involvement of local call centers or human resources, as opposed to a centralized approach where CT is usually conducted in a national or central center [11]. However, in most models all steps of CT (case identification, identification, and monitoring of contacts) were implemented locally; in others, the identification of contacts and the overall management of CT activities took place at a central level [25,32,40]. Centrally managed models were mainly described in specific settings characterized by an internal CT tracing system (eg, the Mayo Clinic model in the study by Breeher et al [32] and the Irish Penitentiary Institutes model described by Clarke et al [40]). The model described by Asiimwe et al [25], implemented in the Great Accra Region of Ghana, followed the structure of the country's health system, with activities carried out in 3 tiers: national, regional, and district tiers with a strong focus on community care [42]. Evidence from European case studies suggests that the governance and organization of CT systems follow the structure of health systems, with a greater decentralization of activities in countries with regional management of health services [8]. According to the European Centre for Disease Control and Prevention (ECDC), the decentralization of CT systems represents a challenge for the collection of comprehensive and harmonized data on the volume and effectiveness of the interventions carried out that need to be addressed [8].

Several studies have described the involvement of human resources not belonging to public health agencies as contact tracers, such as university students from health faculties [27,29-31], hospital health workers, staff of CT programs implemented within health facilities [32], or representatives of other organizations, such as United Nations agencies (eg, study conducted by Mueller et [28] in Nigeria, with the involvement of the WHO [World Health Organization] and UNFPA [United Nations Population Fund] staff). As the number of cases increased, the main international public health agencies (Centers for Disease Control and Prevention [CDC], ECDC, and WHO) recommended the mobilization of nonpublic health staff, such as students, community health workers, volunteers, and civil servants, provided that they are adequately trained and supervised by public health bodies responsible for epidemic control [3,4,43,44]. Many of the documented experiences complied with this recommendation, showing its effectiveness in reducing the time needed to complete CT activities and in increasing the number of people contacted [27-32].

A common element emerging from all studies is the need to use IT software to support CT activities, as the number of cases and contacts to be monitored increased. The use of digital technology can overcome challenges related to incomplete contact identification, delays in the identification and isolation of cases, and notification and quarantine of contacts. Available evidence has been synthetized in some reviews, suggesting the effectiveness of digital technologies in supporting the control of the epidemic, but also underlying several normative, technical, and acceptance barriers to be addressed [45-47]. The WHO stressed the need to integrate such tools into comprehensive and adequately resourced CT strategies [4].

Different CT models were based on multiagency collaboration, with partnerships between public health agencies and other actors (eg, universities, United Nations agencies, community organizations, companies, and other institutions). Collaboration across different actors was not only aimed at the mobilization of human resources but also at the exchange of information; in the CT models aimed at travelers [38,39], collaboration between public health bodies and airline companies, port or airport management, and flight control bodies was essential to help trace persons who may have been exposed to SARS-CoV-2 during flights, as also recommended by international guidelines [48].

Three studies reported the use of outreach strategies to carry CT activities through home visits to closed settings (eg, prisons, shelters for PHE) [25,38,41]. This approach was used to address susceptible communities, which are difficult to reach through usual communication channels (telephone, email). The outreach approach was also used to reach out to the general population in the 2 models developed in African Countries (Ghana and Nigeria), where community worker programs are widely implemented [25,38]. The positive role of outreach activities conducted by community health workers in improving the effectiveness of CT interventions was previously highlighted in a systematic review conducted in the context of tuberculosis control [43]. The review indicated the potential value of outreach and community health workers in conducting case investigations in specific populations, such as drug addicts or homeless people. For these populations, it also indicated that location-based strategies of CT might lead to identification of an increased number of contacts, as also described in the model developed by Fields et al [41] for PHE.

CT programs aimed at health care professionals were characterized by the direct involvement of in-hospital OHS [32] and ICPs in CT activities [32,33]. In the Marburg University Hospital model described by Zirbes et al [33], ICP workers were the pivot of the CT process, accessing all information related to cases and contacts through a web-based platform. As also suggested by ECDC guidance on infection prevention and control and preparedness for COVID-19 in health care settings, potential mitigation measures, including CT, need to be addressed in collaboration with the existing OHS or health and safety committees [49]. As stressed by Breeher et al [32], CT in hospital settings may be extremely resource intensive. The use of electronic tools and organization into functional teams were shown to have improved efficiency and integration of standardized processes and made CT scale up feasible.

The 2 studies describing CT in the workplace, both conducted in the military setting, were based on an integration of the work conducted by public health agencies and staff responsible for occupational health and safety (in the US Navy model described by Hall et al [36]), with the presence of PHOs embedded in the workplace. CT activities in the workplace and collaboration between the different bodies responsible for safety at work, also by virtue of the existing legislation in various countries, are strongly recommended to limit the spread of the SARS-CoV-2, helping to reduce the need for close work activities [50-52]. International bodies also recommend promptly testing symptomatic workers and providing for their isolation, as described in the strategy developed by de Laval et al [37].

Finally, attention was paid to some of the models for the development of strategies aimed at promoting community engagement, which is recognized as an essential element for the success of CT programs [53]. Two studies have emphasized the importance of addressing the social needs of individuals placed in isolation and quarantine (eg, food, drugs, and connection to other services), also to increase compliance with isolation measures [26,27]. Another element facilitating community engagement was the involvement of contact tracers speaking other languages to ensure compliance of linguistic minorities with isolation and quarantine [27,31].

In general, one of the main findings of our literature review was the scarcity of published studies specifically aimed at describing the organizational aspects of CT activities. This could be because of difficulties in measuring and describing the effectiveness of CT interventions, making the topic of little interest in the scientific community [15]. Conducting a proper evaluation of the effectiveness of CT, testing, and isolation interventions is a complex task, as the type of evidence required is difficult to obtain (ie, randomization of interventions is not ethically acceptable); hence, available evidence is mainly based on modeling techniques or proxy data [2,22,54]. Most published studies on CT have focused on the development of mathematical models aimed at describing the factors determining the effectiveness of CT [55]. Though these studies can be useful in estimating the effectiveness of CT under different assumptions, they cannot provide indications on the organizational aspects of CT activities. Disseminating information on how CT strategies have been developed in different contexts, including data on human and technical resources, organization, coordination, and governance of activities, could provide useful elements for future planning and contribute to "evidence making" in this field. The absence of empirical data during the COVID-19 pandemic has challenged the traditional evidence-based approach, requiring other ways of generating and synthesizing evidence, where narrative studies on CT organizational models represent examples of evidence-making interventions [56,57].

Limitations

Only a few studies included in our review attempted to provide data on the effectiveness of the intervention, by identifying and calculating some key performance indicators to detect improvements in the effectiveness of CT interventions (mainly measured by a reduction in the time needed to complete CT activities or an increase in the number of cases and contacts reached) following some adjustments in the organization of activities (eg, increase in human resources and adoption of a digital tool). As also suggested in recent systematic reviews on the effectiveness of CT strategies for infectious disease control, more evidence is needed to understand how to optimize the effectiveness of CT across a range of settings and contexts, including large-scale comparative studies [15], informing "how, where, and when" to deploy CT most effectively [15]. Few data collected were not fully comparable across different studies. As suggested by Vogt et al [22], a universally agreed set of indicators is needed to allow for cross-system comparisons and to improve the performance of CT systems.

The main limitation of this systematic review was the focus on the first phase of the epidemic (first wave, March to June 2020) only. Our primary aim was to describe how CT strategies were first developed in different settings to respond to a novel virus outbreak. Nevertheless, collecting and synthesizing information on how CT strategies were adapted to changes in the epidemiological situation would be relevant to support the future planning of CT activities in response to viruses characterized by different modes of transmission, incubation time, and virulence. Furthermore, we did not consider changes that occurred with the availability of COVID-19 vaccines at the end of 2020, when most public health efforts were directed toward the organization of vaccination campaigns, and research mainly focused on measuring vaccine effectiveness.

Therefore, further evidence is needed to evaluate the adaptation of CT models to the different phases of the epidemic, including strategies adopted to scale up interventions, integration of traditional and digital methods, and adjustments of CT with regard to vaccination status.

Conclusions

In conclusion, our systematic review provides some preliminary evidence on organizational models of CT developed across various settings and contexts during the first wave of the COVID-19 pandemic. We identified some common elements in all strategies that allowed for the effective development of CT activities in the early phase of a novel virus epidemic, including decentralization of activities (case notification, identification, and management of contacts), involvement of nonpublic health trained resources, use of digital tools for CT management, interagency collaboration, adoption of strategies to increase community engagement, and aspects peculiar to each setting (eg, outreach, involvement of OHS and ICPs). Despite the lack of data on CT effectiveness, these findings can provide some indications for future planning and development of CT strategies for infectious disease control. Further research on the organizational models of CT strategies during the COVID-19 pandemic, including data on real-world effectiveness and on strategies developed during the following phases of the epidemic, would be needed to contribute to a more robust evidence-making process.

Acknowledgments

The review was conducted under the scope of the CCM (National Centre for Disease Prevention and Control) 2020 Projects "Modelli organizzativi per l'efficientamento delle attività di contact tracing" (Organizational models to improve the efficiency of contact tracing activities) and "Potenziamento del contact tracing attraverso il rafforzamento del ruolo dei Dipartimenti di Prevenzione sul territorio, anche in relazione alle condizioni di maggiore suscettibilità alle conseguenze sfavorevoli dell'infezione (fattori di rischio comportamentali, malattie croniche e multi-morbidità, età avanzata, ecc)" (Enhancement of contact tracing by strengthening the role of local Prevention Departments) funded by the Italian Ministry of Health.

The authors wish to thank all project partners for their contributions: Dr Pio Pellegrini, Local Health Authority of Frosinone; Dr Claudia Celebrini, Local Health Authority of Frosinone; Dr Alessandro Perrella, Hospital A Cardarelli, Napoli; Dr Massimo Majolo, Hospital A Cardarelli, Napoli; Dr Federica Michieletto, Veneto Region; Dr Elena Narne, Azienda Zero, Veneto Region; Dr Gisella Pitterm, Azienda Zero, Veneto Region; Dr Giulia Capodaglio, Azienda Zero, Veneto Region; and Dr Stefania Bellio, Azienda Zero, Veneto Region. They also thank Dr Stella Lanzi (Italian Agency for Regional Healthcare services) for her support in reviewing of the English language.

Abstract

Background: HIV-1 infection continues to affect global health. Although antiretrovirals can reduce the viral load or prevent HIV-1 infection, current drugs require daily oral use with a high adherence level. Long-acting antiretrovirals (LA-ARVs) significantly improve medication adherence and are essential for HIV-1 prophylaxis and therapy.

Objective: This study aimed to investigate the safety and efficacy of long-acting cabotegravir (CAB-LA) and long-acting rilpivirine (RPV-LA) in the prevention and treatment of HIV-1 infection.

Methods: PubMed, Embase, and the Cochrane Library were searched for studies from database inception to November 12, 2022. We included studies that reported efficacy and safety data on LA-ARV intervention in people living with HIV and excluded reviews, animal studies, and articles with missing or duplicate data. Virological suppression was defined as plasma viral load <50 copies/mL 6 months after antiviral therapy initiation. We extracted outcomes for analysis and expressed dichotomous data as risk ratios (RRs) and continuous data as mean differences. Depending on the heterogeneity assessment, a fixed- or random-effects model was used for data synthesis. We performed subgroup analyses of the partial safety and efficacy outcomes of CAB-LA+RPV-LA. The protocol was registered with the Open Science Framework.

Results: We included 12 trials comprising 10,957 individuals, of which 7 were prevention trials and 5 were treatment trials. CAB-LA and RPV-LA demonstrated safety profiles comparable with those of the placebo in terms of adverse event–related withdrawal. Moreover, the efficacy data showed that CAB-LA had a better effect on HIV-1 prevention than tenofovir disoproxil fumarate–emtricitabine (17/5161, 0.33% vs 75/5129, 1.46%; RR 0.21, 95% CI 0.07-0.61; I^2=70%). Although CAB-LA+RPV-LA had more drug-related adverse events (556/681, 81.6% vs 37/598, 6.2%; RR 12.50, 95% CI 3.98-39.23; I^2=85%), a mild or moderate injection site reaction was the most common reaction, and its frequency decreased over time. The efficacy of CAB-LA+RPV-LA was comparable with that of daily oral drugs at 48 and 96 weeks (1302/1424, 91.43% vs 915/993, 92.2%; RR 0.99, 95% CI 0.97-1.02; I^2=0%), and a high level of virological suppression of 80.9% (186/230) was maintained even after 5 years of LA-ARV use. Similar efficacy outcomes were observed in both treatment-naive and treatment-experienced patients (849/911, 93.2% vs 615/654, 94%; RR 0.99, 95% CI 0.96-1.02; I^2=0%). According to the questionnaires, more than 85% of people living with HIV favored LA-ARVs.

Conclusions: LA-ARVs showed favorable safety profiles for both the prevention and treatment of HIV-1 infection and were well tolerated. CAB-LA has more satisfactory efficacy than tenofovir disoproxil fumarate–emtricitabine, significantly reducing the rate of HIV-1 infection. CAB-LA+RPV-LA maintains virological suppression for a long time and may be a viable switching strategy with enhanced public health benefits by reducing transmission. However, further trials are required to confirm the efficacy of these drugs.

KEYWORDS

long-acting cabotegravir; CAB-LA; long-acting rilpivirine; RPV-LA; pre-exposure prophylaxis; PrEP; treatment; long-term suppression

Introduction

Background

HIV-1 infection continues to affect global human health, with an estimated 38.4 million individuals living with HIV-1 by the end of 2021 and 28.7 million accessing antiretroviral therapy (ART) by the end of December 2021 [1]. Despite the enormous progress made in ART, over 5000 people are newly infected with HIV-1 worldwide every day [2]. Studies have shown that ART has demonstrated significant efficacy in limiting HIV-1 viral replication, reducing plasma viral load (VL), and strengthening the immune system. This provides people living with HIV with long-lasting virological suppression [3,4]. The use of ART has the potential to considerably reduce HIV-related morbidity and death, thereby improving the overall health status of people living with HIV and prolonging their life expectancy [5]. Pre-exposure prophylaxis (PrEP) with ART before HIV-1 exposure is a major HIV-1 prevention innovation that can effectively reduce HIV-1 infection rates and provide benefits to populations at high risk for HIV-1 infection [6]. Oral regimens comprising tenofovir disoproxil fumarate–emtricitabine (TDF-FTC) have proven to be effective in preventing HIV-1 infection in high-risk individuals in several clinical trials of HIV-1 PrEP [7,8].

Although antiretrovirals can control the symptoms of people living with HIV, there is no cure for HIV-1 infections. Currently, ART requires lifelong administration, and most antiretrovirals must be taken daily to suppress HIV-1 infection [9,10], which requires a high level of adherence to ART by users [11,12]. people living with HIV or people at high risk of HIV-1 infection face considerable challenges in maintaining the efficacy of ART in the face of the pressure to take daily drugs. In addition, prolonged daily oral medications can lead to treatment fatigue [13,14] coupled with changes in daily lifestyle, stigma associated with long-term medication use, burden of drug use, and multiple social factors [15], all of which can lead to suboptimal adherence and reduce the efficacy of medications or even lead to the emergence of drug-resistant viral variants. Long-acting antiretrovirals (LA-ARVs) have the potential to increase ART adherence, reduce HIV-1 transmission, and achieve public health benefits by decreasing the number of new HIV-1 infections.

The advent of LA-ARVs may overcome several problems associated with the daily use of oral pills and privacy of patients taking drugs. They are used once a month or every 2 months, greatly reducing the frequency and burden of daily medication, eliminating the need to take daily pills [16,17] and improving the convenience of taking medicine while protecting patients' privacy and reducing the social stigma associated with HIV-1, which is important for people living with HIV and those at high risk of HIV-1 infection. Cabotegravir is a novel integrase inhibitor with acceptable safety and tolerability when administered orally once daily [18]. The nonnucleoside reverse transcriptase inhibitor rilpivirine is administered orally once daily for HIV-1 treatment. LA-ARVs have currently been approved for the treatment and prevention of HIV-1 infection in several countries. In March 2020, ViiV Healthcare announced that Health Canada approved Cabenuva (cabotegravir and rilpivirine extended-release injectable suspensions) for the market. This was the first global approval of Cabenuva as an alternative to existing antiviral regimens for virologically suppressed people living with HIV [19]. The United States Food and Drug Administration has approved Cabenuva as a complete regimen for the treatment of HIV-1 infection in adults with virological suppression on a stable antiretroviral regimen [19] and Apretude (cabotegravir extended-release injectable suspension) for HIV-1 PrEP in high-risk adults and adolescents weighing at least 35 kg [20]. Apretude is also approved as a prophylactic drug in Europe [21], Australia, South Africa [22], Zimbabwe [23], and other countries. In light of the benefits associated with LA-ARVs, there is a growing interest in their development, as well as concerns regarding their potential adverse effects, safety, and efficacy.

Objectives

Therefore, this meta-analysis aimed to summarize existing trials on LA-ARVs, particularly long-acting cabotegravir (CAB-LA), long-acting rilpivirine (RPV-LA), and CAB-LA+RPV-LA; assess their safety and efficacy; and provide evidence for their widespread use.

Methods

Overview

We conducted a meta-analysis using version 6.2 of the Cochrane Handbook for Systematic Reviews of Intervention [24]. We followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines were followed [25] (Multimedia Appendix 1). The protocol was deposited and registered in the Open Science Framework [26].

Search Strategy

We thoroughly searched the PubMed, Embase, and Cochrane Library databases for eligible articles published from their inception to November 12, 2022. Only articles published in English were included in this study. Search terms included "HIV," "AIDS," "long-acting formulations," "cabotegravir," "gsk1265744," and "rilpivirine" (Multimedia Appendix 2). After deleting duplicates, 2 writers independently screened the titles, abstracts, and full-text papers. Disagreements were resolved through dialogue and reaching a consensus.

Study Eligibility Criteria

The inclusion criteria were as follows: (1) study design, randomized trials; (2) study population, adults aged ≥18 years; (3) intervention, LA-ARVs; and (4) end points, which included safety and efficacy data. For the exclusion criteria, we excluded pregnant or lactating women. We excluded reviews, conference abstracts, case reports, letters, animal studies, irretrievable full-text articles, and studies that shared the same data set. We only included the latest or most detailed data when repeated data were encountered.

Currently, different guidelines have different definitions of HIV-1 virological suppression. According to the World Health Organization guideline [27], we defined virological suppression as a plasma VL <50 copies/mL 6 months after the start of ART.

Drug-related adverse event (AE) and AE-related withdrawals were the primary safety outcomes. The major efficacy outcomes were confirmed with HIV-1 infection for prevention and the percentage of individuals with plasma HIV-1 RNA <50 copies/mL for treatment. Secondary safety outcomes included the proportion of individuals with (1) any AE, (2) AE of grade 3 or higher, (3) injection site reaction (ISR), (4) serious AE (SAE), and (5) death, whereas secondary efficacy outcomes of treatment included (1) changes in CD4$^+$T cell counts from baseline, (2) the incidence of confirmed virological failure (VF), and (3) the proportion of resistance-associated mutations (RAMs) in patients who acquired HIV-1 infection or with confirmed virologic failure.

Data Extraction and Risk of Bias Assessment

A Microsoft Excel spreadsheet was used to extract data from each study. We extracted all relevant data: (1) general information, including the name of the first author and trial, trial number, publication year, and the number of patients; (2) study parameters, including interventions, controls, and study design; and (3) participant characteristics, including age and the proportion of the male population; and (4) outcomes, including safety and efficacy data.

As a means of assessing bias risk, the Cochrane risk-of-bias tool was used to analyze the 5 domains of random sequence generation, allocation concealment, blinding of participants and personnel and outcome assessors, incomplete outcome data, and selective outcome reporting. Findings were classified as low, unclear, or high bias. The 2 reviewers worked separately to extract the data and assess the possibility of bias. Multimedia Appendix 3 [28-42] shows details of the risk of bias assessment.

Statistical Analysis

RevMan statistical software (version 5.3; The Cochrane Collaboration) was used for statistical analyses and Adobe Illustrator (Adobe) was used for graphical editing and presentation. We used proportion and risk ratio (RR) values to express dichotomous data, whereas for continuous data, we used mean differences. A forest plot was used to estimate cumulative effects. The I^2 test revealed statistically significant heterogeneity. Four degrees of heterogeneity were distinguished: 0% to 40%, presumably insignificant; 30% to 60%, medium; 50% to 90%, substantial; and 75% to 100%, high [24]. Subgroup analysis was used to investigate the potential heterogeneity. If applicable, leave-one-out sensitivity analysis was performed to investigate the consistency of the results. If sufficient publications were available, publication bias was investigated using funnel plots and the Egger test.

Results

Study Selection and Characteristics

We obtained 5662 records through an initial literature search, including 1321 in PubMed, 3857 in Embase, and 484 in the Cochrane Library. After removal of duplicates, 4108 studies remained. A total of 72 publications remained after screening the titles and abstracts for full-text inspection. Furthermore, 15 papers comprising 10,957 individuals were ultimately enrolled for data analysis, which contained 12 trials, including 7 trials for prevention (5 on CAB-LA [28-32], 2 on RPV-LA [33,34]), and 5 trials on CAB-LA+RPV-LA [35-42] for treatment. The LATTE-2, ATLAS, and FLAIR treatment trials included one maintenance phase and one extension phase study. Figure 1 illustrates the procedure for conducting the literature search.

CAB-LA was injected intramuscularly and subcutaneously at intervals between 4 and 12 weeks, at dosages ranging from 100 to 800 mg. RPV-LA was injected intramuscularly at doses between 300 and 1200 mg every 4 to 8 weeks. Two doses of CAB-LAs and RPV-LAs were administered intramuscularly. In one case, 400 mg CAB-LA and 600 mg RPV-LA were administered every 4 weeks; in the other case, 600 mg CAB-LA and 900 mg RPV-LA were administered every 8 weeks. Only one CAB-LA trial used both injection methods (intramuscular and subcutaneous). Only intramuscular injection was selected for combined analysis of the data. Table 1 summarizes the characteristics of the included studies.

The bias risk assessment showed that 8 studies [28,29,31-34,36,40] had a low bias risk, whereas 7 open-label trials [30,35,37-39,41,42] with unclear allocation concealment had a high risk of bias (Figures S1 and S2 in Multimedia Appendix 3).

[e] Q8W: every 8 weeks.

[f] I: intervention group.

[g] C: control group.

[h] Q12W: every 12 weeks.

[i] TDF: tenofovir.

[j] FTC: emtricitabine.

[k] QD: daily.

[l] RPV: rilpivirine.

[m] Q4W: every 4 week.

[n] PO: per os.

[q] DTG: dolutegravir.

[o] ABC: abacavir.

[p] 3TC: lamivudine.

[q] VL: viral load.

[r] Not available.

PrEP Medication

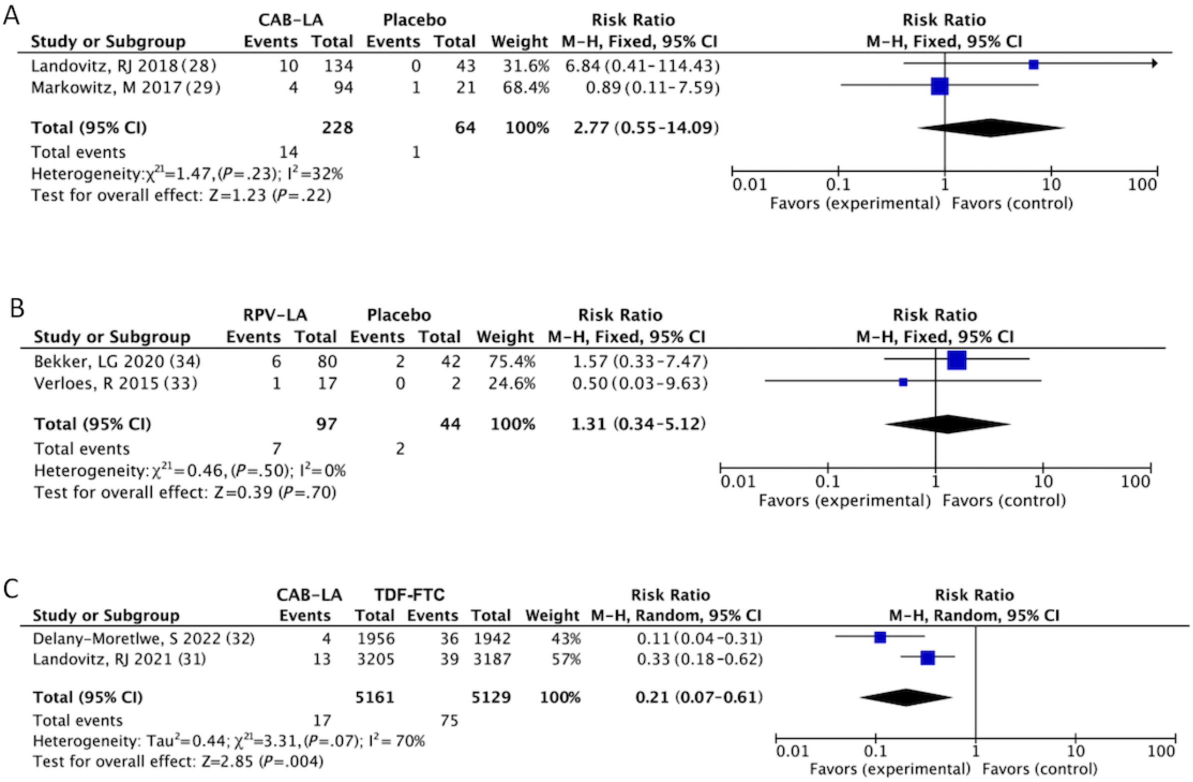
Safety

For CAB-LA, 3 of the 5 trials were placebo controls and 2 were TDF-FTC controls. Compared with the placebo, the frequency of AE-related withdrawals (14/228, 6.1% vs 1/64, 2%; RR 2.77, 95% CI 0.55-14.09; I^2=32%; Figure 2A) was similar, as was any AE or SAE (Figures S1A and S1B in Multimedia Appendix 4 [28-40,42]). In contrast, there was high heterogeneity for ISR (165/268, 61.6% vs 15/72, 21%; RR 3.38, 95% CI 0.79-14.44; I^2=80%; Figure S1C in Multimedia Appendix 4). Because of the lack of studies, we could not determine the origin of heterogeneity.

Compared with daily oral TDF-FTC, there was no apparent difference in AE of grade 3 or higher (1003/3894, 25.76% vs 1047/3892, 26.9%; RR 0.96, 95% CI 0.89-1.03; I^2=0%; Figure S1D in Multimedia Appendix 4) and SAE (153/3894, 3.93% vs 154/3892, 3.96%; RR 0.99, 95% CI 0.80-1.24; I^2=0%; Figure S1E in Multimedia Appendix 4). In comparison, CAB-LA had more ISRs (2301/3799, 60.57% vs 815/3798, 21.46%; RR 3.03, 95% CI 2.27-4.04; I^2=91%; Figure S1F in Multimedia Appendix 4) than TDF-FTC. Although ISR was more frequent in the intervention group, the most frequently reported side effect was injection site pain. ISR is often mild to moderate in severity and its frequency gradually diminishes.

Similarly, RPV-LA was well tolerated. For the primary outcome, the occurrence of AE-related withdrawal (7/97, 7% vs 2/44, 5%; RR 1.31, 95% CI 0.34-5.12; I^2=0%; Figure 2B) did not differ between the 2 groups. Analyses of the SAE and ISR (Figures S1G and S1H in Multimedia Appendix 4) showed no obvious differences.

Figure 2. Meta-analyses on safety and efficacy profiles of CAB-LA and RPV-LA: (A) AE-related withdrawals: CAB-LA versus placebo [28,29], (B) AE-related withdrawal: RPV-LA versus placebo [33,34], and (C) confirmed HIV-1 infection: CAB-LA versus TDF-FTC [31,32]. AE: adverse event; CAB-LA: long-acting cabotegravir; RPV-LA: long-acting rilpivirine; TDF-FTC: tenofovir disoproxil fumarate–emtricitabine.



Efficacy

The ECLAIR trial [29] revealed 1 proven HIV-1 infection in the cabotegravir group throughout the follow-up period and 1 confirmed HIV-1 infection in the placebo group within the injection phase. In addition to TDF-FTC's reduction in HIV-1 infection by TDF-FTC, CAB-LA also reduced the rate by 76% (17/5161, 0.33% vs 75/5129, 1.46%; RR 0.21, 95% CI 0.07-0.61; I^2=70%; Figure 2C). One of the 13 participants who acquired HIV-1 infection after enrollment in the CAB-LA group of the HIV Prevention Trials Network (HPTN) 083 trial [31] was reclassified as having a baseline infection. Only 4 infections occurred with regular CAB-LA injections and 2 had drug-resistant mutations.

In HPTN 083 trial [31], 86% of the TDF-FTC group participants maintained plasma concentrations over the lower limit of quantification (0.31 ng/mL), which showed high adherence to oral drugs. In the HPTN 084 trial [32], 2 of the 4 patients with infections in the CAB-LA group had undetectable plasma cabotegravir concentrations, one had delayed cabotegravir injections, and one had baseline infection. None of the infections occurred with on-time injections. The TDF-FTC group documented poor or nonadherence in 35 of the 36 infections, and TDF concentrations greater than 0.31 ng per mL were observed in 55.91% (1084/1939) of participants.

For RPV-LA, the HPTN 076 trial [34] reported that one placebo participant developed HIV-1 infection during the injection period. A total of 67.9% (76/112) of the participants strongly agreed to use RPV-LA at the time of their last injection visit, and 88% stated that they would use it in the future. The efficacy and safety results of the prophylactic drugs are detailed in Multimedia Appendix 5 [28-34]. The RAMs in the people living with HIV are detailed in Multimedia Appendix 6 [28-42].

Treatment

Safety

Table 2 presents the results for the CAB-LA+RPV-LA. Data analysis revealed that the AE rate of CAB-LA+RPV-LA was higher than that of the daily oral drugs. The incidence of drug-related AE (556/681, 81.6% vs 37/598, 6.2%; RR 12.50, 95% CI 3.98-39.23; I^2=85%; Figure 3A) at 48 weeks in CAB-LA+RPV-LA group was higher than that in the daily oral group, so were the AE-related withdrawal (48/1194, 4.02% vs 14/937, 1.5%; RR 2.65, 95% CI 1.48-4.74; I^2=0%; Figure 3B) at 48 weeks and 96 weeks, any AE (647/681, 95% vs 448/598, 74.9%; RR 1.27, 95% CI 1.12-1.44; I^2=74%; Figure S2A in Multimedia Appendix 4), and AE of grade 3 or higher (75/681, 11% vs 34/598, 5.7%; RR 1.93, 95% CI 1.30-2.87; I^2=5%; Figure S2B in Multimedia Appendix 4).

When ISR was excluded, drug-related AE after excluding ISR (167/591, 28.3% vs 36/591, 6.1%; RR 5.41, 95% CI 1.35-21.64; I^2=91%; Figure S2C in Multimedia Appendix 4) and AE of grade 3 or higher after excluding ISR (47/591, 8% vs 34/591, 5.8%; RR 1.38, 95% CI 0.90-2.12; I^2=45%; Figure S2D in Multimedia Appendix 4) were reanalyzed. There was no obvious difference in the SAE (Figure S2E in Multimedia Appendix 4). No deaths occurred because of the drugs used.

When patients in the LATTE-2, ATLAS, and FLAIR trials entered the extension phase [31,32,35], people on daily oral medication switched to CAB-LA+RPV-LA, and the long-acting group continued their previous treatment. No statistically significant differences were observed between the groups. The incidence of AE-related withdrawal (14/513, 2.7% vs 5/276, 1.8%; RR 0.76, 95% CI 0.24-2.41; I^2=19%; Figure 3C), any AE (506/513, 98.6% vs 246/276, 89.1%; RR 1.06, 95% CI 0.89-1.25; I^2=97%; Figure S3A in Multimedia Appendix 4), and SAE (39/513, 7.6% vs 16/276, 5.8%; RR 0.82, 95% CI 0.46-1.47; I^2=0%; Figure S3B in Multimedia Appendix 4) in extension phase did not differ significantly between the long-acting arm and the switch arm.

Table 2. Safety and efficacy results of CAB[a]-LA[b]+RPV[c]-LA (all results are expressed in terms of frequency (n/N) unless otherwise stated).

Trial name	Design	Safety							Efficacy

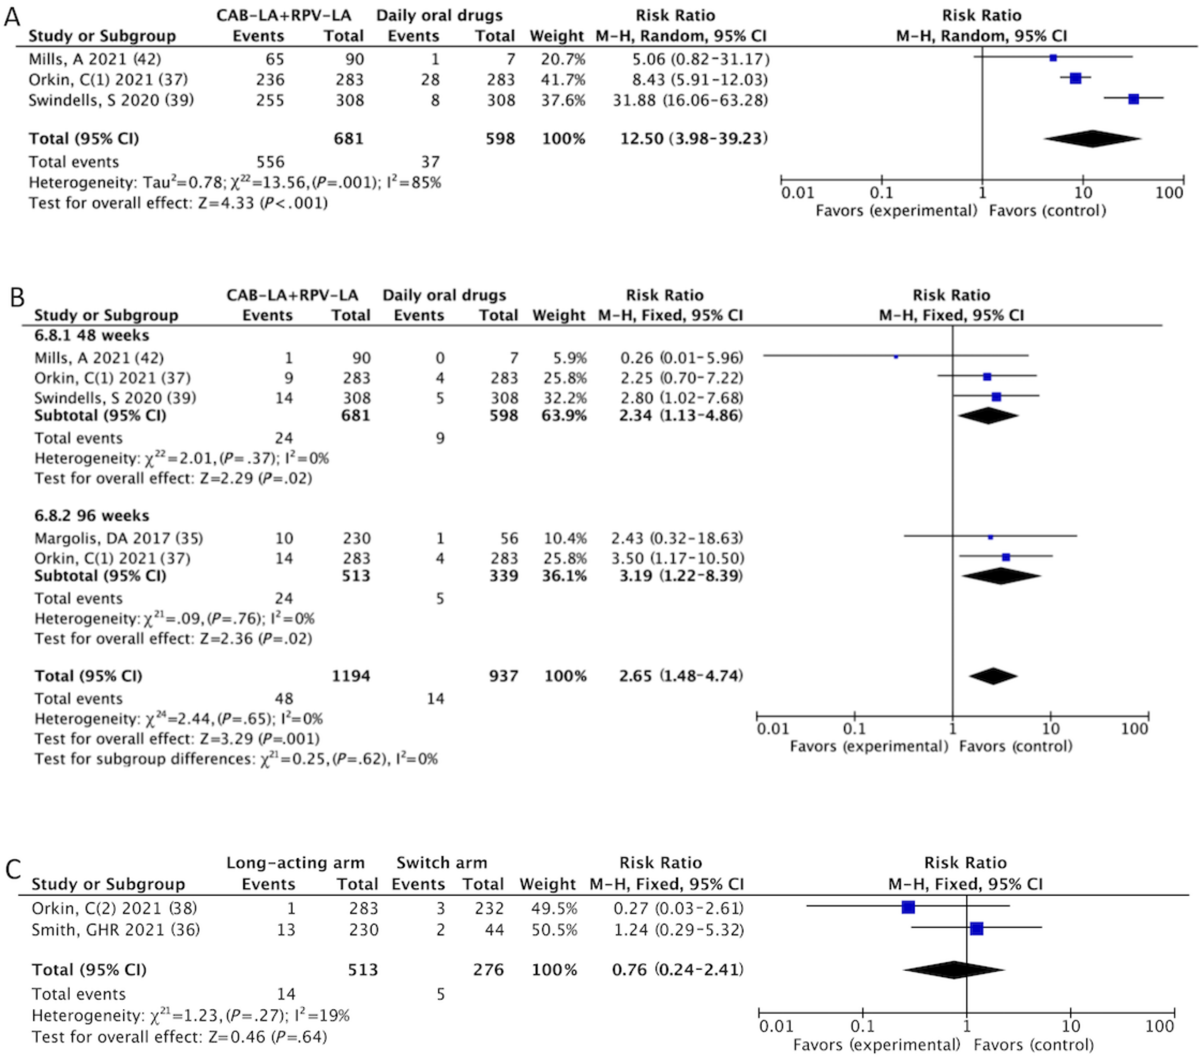
Figure 3. Meta-analyses on safety profiles of CAB-LA+RPV-LA: (A) drug-related AE: CAB-LA+RPV-LA versus daily oral drugs [37,39,42], (B) AE-related withdrawal: CAB-LA+RPV-LA versus daily oral drugs [35,37,39,42], and (C) AE-related withdrawal: long-acting arm versus switch arm [36,38]. AE: adverse event; CAB-LA: long-acting cabotegravir; RPV-LA: long-acting rilpivirine.



Efficacy

In terms of efficacy, we performed a subgroup analysis of the percentage of individuals with plasma HIV-1 RNA levels <50 copies/mL (1302/1424, 91.43% vs 915/993, 92.2%; RR 0.99, 95% CI 0.97-1.02; I^2=0%; Figure 4A) and the incidence of confirmed VF (13/1104, 1.18% vs 12/930, 1.3%; RR 0.93, 95% CI 0.43-2.04; I^2=0%; Figure S2F in Multimedia Appendix 4) at 48 weeks and 96 weeks. Similarly, when we grouped the treatment-naive patients in the study with treatment-experienced patients (849/911, 93.2% vs 615/654, 94%; RR 0.99, 95% CI 0.96-1.02; I^2=0%; Figure 4B), there were no statistically significant differences in the efficacy outcomes.

We summarized and analyzed the results of RAMs in patients with VF during treatment. The results showed no statistical difference between the CAB-LA+RPV-LA group and the daily oral drug group in terms of RAMs associated with integrase inhibitors (6/9, 67% vs 0/9, 0%; RR 4.64, 95% CI 1.00-21.62; I^2=0%; Figure S1A in Multimedia Appendix 6) or nonnucleoside reverse transcriptase inhibitors (7/9, 78% vs 3/9, 34%; RR 2.12, 95% CI 0.90-4.97; I^2=0%; Figure S2B in Multimedia Appendix 6). In addition, a bar chart of the number of RAMs occurring between groups is presented in Figure S3 in Multimedia Appendix 6.

For patients in the extension phase, there was no significant difference in the percentage of infected people with plasma HIV-1 RNA less than 50 copies/mL (436/536, 81.3% vs 292/305, 95.7%; RR 0.90, 95% CI 0.79-1.03; I^2=85%; Figure 4C) between those who continued LA-ARVs and those who switched to LA-ARVs. This was the change from the baseline in CD4$^+$ T cell counts (Figure S3C in Multimedia Appendix 4). Only one participant in the switch arm reported confirmed VF during the extension phase of the FLAIR trial. The 96-week results of the ATLAS-2M [41] corroborated that 90.62% (947/1045) of individuals maintained plasma HIV-1 RNA levels of less than 50 copies/mL. Compared with daily oral ART, patient satisfaction levels with CAB-LA+RPV-LA were high.

Most participants preferred the long-acting regimen; after all injections, 99% (206/208) of the long-acting group in the LATTE-2 trial [35] expressed satisfaction with their current ongoing therapy. In the ATLAS and POLAR trials [39,42], 97.4% (266/273) and 87.5% (77/88) of respondents in the long-acting group, who filled out the questionnaires, said they were inclined to use CAB-LA+RPV-LA instead of daily oral drugs. In the FLAIR extension phase [38], we found that 4 people living with HIV using CAB-LA+RPV-LA for 124 weeks had RAMs, 3 of which had been detected at 96 weeks of the FLAIR trial. The detailed resistance data are provided in Multimedia Appendix 6.

Figure 4. Meta-analyses on efficacy profiles of CAB-LA+RPV-LA: (A) plasma HIV-1 RNA less than 50 copies/mL: CAB-LA+RPV-LA versus daily oral drugs [35,37,39,42], (B) plasma HIV-1 RNA less than 50 copies/mL: CAB-LA+RPV-LA versus daily oral drugs [35,37,39,42], and (C) plasma HIV-1 RNA less than 50 copies/mL: long-acting arm versus switch arm [36,38,40]. CAB-LA: long-acting cabotegravir; RPV-LA: long-acting rilpivirine.

Discussion

Principal Findings

To the best of our knowledge, this meta-analysis is the first to assess the safety and efficacy of LA-ARVs in people living with HIV, as well as the advantages of LA-ARVs as a switching strategy. We found a previously published article on LA-ARVs that focused on exploring the safety and pharmacokinetic profiles of 2 drugs, CAB-LA and RPV-LA, for use as PrEP in the prevention of HIV-1 infection [43]. We added newly updated articles on this premise, including data from the HPTN 083 [31] and HPTN 084 [32] trials. The CAB-LA was examined and described in greater detail. In addition, we not only focused on prophylactic drugs but also compared the existing daily antiretrovirals with all existing trials of the combination of LA-ARVs for treating HIV-1 infection. We collected study data with a long follow-up period, and in addition to the results from the maintenance phase of treatment, we collected data within the extension phase for CAB-LA+RPV-LA, providing information on the efficacy beyond 96 weeks and even up to 5 years. To provide more comprehensive evidence for the use of LA-ARVs, we extracted and analyzed the safety and efficacy data, adherence, and patient satisfaction. The availability of LA-ARVs is important for HIV-1 prevention and treatment and for reducing HIV-1 transmission. LA-ARVs with longer dose intervals significantly improve medication adherence by reducing the burden of daily dosing [44], protecting patient privacy, and reducing the stigma associated with HIV-1 infection.

This analysis suggests that participants have a favorable safety profile for LA-ARVs in terms of either prevention or treatment. LA-ARVs have also shown better efficacy than daily oral drugs; however, fewer trials and more studies are required to validate their efficacy. First of all, all participants tolerated the prophylactic drugs, CAB-LA and RPV-LA. Although we observed differences in drug-related AE between the 2 groups in the ECLAIR trial [29], the majority were classified as grade 1 or 2, had little effect on the participant, and were not life-threatening. CAB-LA had more ISRs than oral TDF-FTC owing to the injection of CAB-LA placebo in the control group, which had less of an effect on the organism. Most ISRs in the long-acting group were mild or moderate with a low frequency, and a few patients dropped out of the trial due to ISR. Therefore, CAB-LAs have a good safety profile as a prophylactic agent. CAB-LA is more effective than TDF-FTC in preventing HIV-1 infection and can effectively lower the incidence of HIV-1 infection. Adherence has been shown to have a substantial effect on drug efficacy. The efficacy results from the HPTN 084 trial were comparable with those of the HPTN 083 trial; however, participants in the HPTN 084 trial had lower adherence to the drug, resulting in a higher infection rate in the oral drug group. Second, most infections that occurred in the CAB-LA group in both trials [31,32] were due to low or undetectable plasma concentrations, which were the result of participants not injecting the dose on time or the infection was occurring during the oral induction phase. A combined analysis of the efficacy results from the 2 trials revealed a high degree of heterogeneity, which may be attributable to the variance in the enrolled populations. The statistically significant difference in efficacy in the HPTN 083 trial also demonstrated the superiority of CAB-LA over TDF-FTC. Therefore, cabotegravir is superior to TDF-FTC in preventing HIV-1 infection and has adherence advantages.

However, we observed 4 breakthrough infections in the CAB-LA group in the HPTN 083 trial. Researchers believe that this could be due to several factors, such as low concentrations of cabotegravir in the plasma or rectal tissue, delayed detection of HIV-1 infection, and drug resistance [45]. As mentioned in the package inserts of Apretude, drugs that might significantly reduce cabotegravir's plasma concentration should be avoided. Therefore, to conduct a more thorough investigation of the efficacy of CAB-LA as PrEP, additional data, including pharmacokinetics and other characteristics, are needed, and in the future, additional trials will be done in multiple enrollment populations.

CAB-LA+RPV-LA also had a better safety profile in treating people living with HIV, although patients experienced more AEs (any AE, drug-related AE, AE-related withdrawals, and AE of grade 3 or higher) at the primary end point time of 48 or 96 weeks than those on daily oral drugs. Firstly, similar to CAB-LA, ISR was the most prevalent AE, predominantly mild or moderate, and its frequency decreased as the study progressed. A few patients dropped out of the trials because of ISR, and most participants generally accepted the overall ISR. We reanalyzed the results of drug-related AE and AE of grade ≥3 after excluding ISR. The results demonstrated no statistically significant difference between the 2 groups in terms of AE of grade 3 or higher after excluding ISR. In contrast, most drug-related AEs, excluding ISR, were fever, which is a subjective symptom of patients and may affect the experimental results. In addition, we observed a lower incidence of ISR in the extension phase than in the maintenance phase, which could be attributed to tolerance to long-term injections.

Second, most control groups might have continued their current daily oral drugs, whereas the intervention groups underwent the oral induction phase or switching therapy, which could have led to more AE in the long-acting group. This possibility was consistent with the findings of a previous switch study [46] that the consequences of starting a new treatment instead of continuing the same treatment may lead to an increase in AE. Although patients who received LA-ARVs experienced more AEs, cabotegravir plus rilpivirine was the most popular regimen. Even in participants who switched from daily oral drugs to CAB+RPV, the safety results were not significantly different from those who used CAB-LA+RPV-LA for a long time. Most participants preferred the cabotegravir plus rilpivirine therapy and presented higher levels of satisfaction.

There was no significant difference between CAB-LA+RPV-LA and daily oral drugs in terms of the primary efficacy end point, and CAB-LA+RPV-LA maintained virological suppression in patients well, even in the extension phase, with the advantage of a long injection interval, which proved that CAB-LA+RPV-LA was superior to daily oral agents. In addition, analysis of data from patients treated with CAB-LA+RPV-LA for more than 2 years revealed that the

HIV-1 viral suppression rate was maintained at a high level, even in patients who received LA-ARVs for 5 years [36], indicating that CAB-LA+RPV-LA had the capacity to suppress VL for a long time. This finding lays the foundation for the long-lasting effects of LA-ARVs. However, subgroup analysis of the efficacy outcomes of treatment-naive and treatment-experienced patients who participated in the study revealed heterogeneity between subgroups, indicating that variances in the enrolled population may have influenced the trial results. We observed that the enrolled studies maintained virological suppression before receiving LA-ARVs or after the oral induction phase. According to the guidelines [47], if patients achieve virological suppression of their current ART, arbitrary regimen adjustments are not recommended but may be considered in certain specific situations, such as simplifying the regimen by reducing the number of pills and frequency of administration to facilitate a smooth drug switch. In these trials [36,38,40], patients who smoothly switched from daily oral drugs to LA-ARVs were able to maintain high levels of virological suppression, with no statistically significant differences in efficacy compared with patients on LA-ARVs, which provides support for individuals who are currently receiving oral therapy and wish to switch to LA-ARVs. If LA-ARVs are popularized in the future, CAB-LA + RPV-LA may be a good switching strategy for individuals who use daily oral drugs for long periods and maintain virological suppression.

We observed VFs in both the long-acting arm and daily oral drug arm and analyzed their RAMs. There were no statistically significant differences between the groups; however, because of the limited number of studies and participants, no definitive conclusions could be drawn. Most patients in the long-acting group continued to receive LA-ARVs and had a higher predilection for LA-ARVs than daily oral drugs. Thus, CAB-LA+RPV-LA, which greatly improved patient adherence, provided a more convenient dosing regimen and optimized the daily oral regimen in people living with HIV, who achieved and effectively maintained virological suppression. It performed well in terms of safety and tolerance of drug use in infected patients and could be an effective and promising treatment or switching strategy. However, additional trials are required to confirm the results of our study.

Our study is significant for the promotion of LA-ARVs. The emergence of LA-ARVs has made the prevention and treatment of AIDS easier. It reduces the burden on people living with HIV of different genders, avoids stigmatization associated with daily oral drug treatment, and improves the correct use and compliance of doses. This is particularly important to ensure the effectiveness of pre-exposure prevention measures. Improving the prevention and treatment of HIV-1 will reduce its transmission and contribute to reducing the prevalence of new HIV-1 infections. The United Nations Programme on HIV/AIDS has called for these life-changing injectable drugs to be quickly available, affordable, and fairly distributed to those who need them the most worldwide [48]. This requires more regional and national regulators to quickly approve and adopt a series of measures to reduce sales prices. National HIV-1 prevention programs need to develop LA-ARVs promotion plans and help health systems and communities to prepare for the use of this new drug.

Limitations

This review had several limitations. First, because the results are presented in several formats, it is impossible to integrate data for analysis such as the median form. Second, owing to the relatively low number of trials, we could not perform a publication bias analysis, and the lack of trials on RPV-LA and efficacy data may lead to potential bias. Third, so far, LA-ARVs have been studied mainly in high-income countries, and the cost of cabotegravir and rilpivirine may also be a major obstacle to their supply in low- and middle-income countries. Therefore, more research is needed to determine the efficacy, acceptability, and economic burden of LA-ARVs in different income groups, particularly in low-income and middle-income countries. Finally, we retained only the original articles and trials, discarded conferences, and the resulting data that appeared at the conference. This could have led to the omission of valid data and weakened the persuasiveness of the results.

Conclusions

In conclusion, our findings support the safety and efficacy of CAB-LA, RPV-LA, and CAB-LA+RPV-LA, which are effective and well-tolerated monthly or bimonthly injections that can provide PrEP to people at risk of HIV-1 infection, reduce the rate of HIV-1 infection, and provide a more convenient treatment option for people living with HIV. CAB-LA+RPV-LA maintained virological suppression of HIV-1 for approximately 2 years, with good efficacy even after 5 years of treatment. Similarly, effective virological suppression was maintained after switching from daily oral drugs to LA-ARVs in people living with HIV who successfully achieved virological suppression. In summary, LA-ARVs have shown good safety and tolerability in dosing, can effectively improve patient adherence, protect patient privacy, and can be a promising treatment or an alternative to oral ART. Currently, multiple LA-ARVs have been evaluated in clinical trials, including injectables, rings, and implants, such as PrEP and subcutaneous injections, for treating HIV-1 infection [49]. For example, a phase 2/3 CAPELLA study on lenacapavir confirmed a high rate of virological suppression in patients with multidrug resistance [50], and islatravir has also been confirmed for drug safety in a phase I trial [51]. Therefore, research and development of LA-ARVs is tremendously advantageous for HIV-1 prevention and treatment. Given the lack of such studies, further investigation of the efficacy of RPV-LAs is required.

Abstract

Background: Screening adherence is important in reducing colorectal cancer (CRC) incidence and mortality. Disparity in CRC screening adherence was observed in populations of different socioeconomic status (SES), but the direction and strength of the association remained unclear.

Objective: We aimed to systematically review all the observational studies that have analyzed the association between SES and adherence to organized CRC screening based on fecal occult blood tests.

Methods: We systematically reviewed the studies in PubMed, Embase, and Web of Science and reference lists of relevant reviews from the inception of the database up until June 7, 2023. Individual SES, neighborhood SES, and small-area SES were included, while any SES aggregated by geographic areas larger than neighbors were excluded. Studies assessing SES with any index or score combining indicators of income, education, deprivation, poverty, occupation, employment, marital status, cohabitation, and others were included. A random effect model meta-analysis was carried out for pooled odds ratios (ORs) and relative risks for adherence related to SES.

Results: Overall, 10 studies, with a total of 3,542,379 participants and an overall adherence rate of 64.9%, were included. Compared with low SES, high SES was associated with higher adherence (unadjusted OR 1.73, 95% CI 1.42-2.10; adjusted OR 1.53, 95% CI 1.28-1.82). In the subgroup of nonindividual-level SES, the adjusted association was significant (OR 1.57, 95% CI 1.26-1.95). However, the adjusted association was insignificant in the subgroup of individual-level SES (OR 1.46, 95% CI 0.98-2.17). As for subgroups of the year of print, not only was the unadjusted association significantly stronger in the subgroup of early studies (OR 1.97, 95% CI 1.59-2.44) than in the subgroup of late studies (OR 1.43, 95% CI 1.31-1.56), but also the adjusted one was significantly stronger in the early group (OR 1.86, 95% CI 1.43-2.42) than in the late group (OR 1.26, 95% CI 1.14-1.39), which was consistent and robust. Despite being statistically insignificant, the strength of the association seemed lower in studies that did not adjust for race and ethnicity (OR 1.31, 95% CI 1.21-1.43) than the overall estimate (OR 1.53, 95% CI 1.28-1.82).

Conclusions: The higher-SES population had higher adherence to fecal occult blood test–based organized CRC screening. Neighborhood SES, or small-area SES, was more competent than individual SES to be used to assess the association between SES and adherence. The disparity in adherence between the high SES and the low SES narrowed along with the development of interventions and the improvement of organized programs. Race and ethnicity were probably important confounding factors for the association.

KEYWORDS

adherence; colorectal cancer; fecal occult blood test; screening; socioeconomic status

Introduction

Worldwide, colorectal cancer (CRC) ranks third in cancer incidence and second in cancer mortality [1]. It has been confirmed that screening with fecal occult blood tests (FOBT) is effective in lowering CRC mortality in randomized controlled trials [2-4] and in the real world [5-7]. Unlike opportunistic screening programs, organized projects actively invite all individuals within a given age range in a specific geographic area to participate in protocol-based screening programs [8,9]. International academic organizations highly recommend the implementation of organized screening programs to reduce the burden of CRC [10-13].

The benefits of screening depend highly on screening compliance [14]. What is more, extensive research showed that the lower–socioeconomic status (SES) population had a higher incidence of CRC and even higher mortality due to poorer treatment [15-18], which meant there was a greater need for high screening adherence in the low SES to reduce health inequity. Although previous evidence suggested that inequities of income observed in opportunistic programs could largely be eliminated in organized programs [19], the association between SES and organized CRC screening adherence was inconsistent across studies [9].

A review conducted by de Klerk et al [9] qualitatively assessed the association of SES and individuals' adherence to FOBT-based organized CRC screening programs. This review found that among 11 programs, 90% (28/31) of publications reported lower adherence in the lower socioeconomic population. However, there were distinct differences in how SES was measured. Most used some types of indexes of deprivation, while some studies used more than one indicator to assess SES [9]. Currently, there were no data on the direction and strength of the association between SES and FOBT-based organized CRC screening adherence. In addition, although differences in adherence by SES and race and ethnicity had received much attention and racial disparities were partially explained by differences in SES [20], the role of race in the association of SES with adherence was controversial [21-23]. What is more, with socioeconomic disparity coming under the spotlight, efforts should be made to narrow it, and its changing trend deserves continued attention [9].

There is no conclusive evidence on the association between SES and adherence in FOBT-based organized screening. It is warranted to examine the association between SES and adherence, contributing to the improvement of screening adherence and equity to promote health equity in screening programs. Thus, the study aimed to perform a meta-analysis focusing on the association between SES and FOBT-based organized CRC screening adherence.

Methods

Search Strategy and Selection

We conducted the systematic review and meta-analysis under the direction of the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement [24]. We searched PubMed, Embase, and Web of Science from the inception date to June 7, 2023, using the search strategy: (socioeconomic OR "socioeconomic status" OR SES OR income OR education OR occupation OR insurance OR "social status") AND (colorecta* OR bowel) AND cancer* AND (screen* OR "early diagnosis" OR "early detection") AND (organized OR program*) AND (uptake OR adherence OR nonadherence OR compliance OR noncompliance OR participation OR participating OR nonparticipation OR attendance OR nonattendance OR engagement OR determine* OR factor* OR associate*). The integrated search strategy is shown in Table S1 in Multimedia Appendix 1, and references cited in review articles that were on similar topics were also checked.

Inclusion and Exclusion Criteria

First, titles and abstracts, and then full-text articles, were screened for inclusion by 2 investigators (ZL and CW) independently. We included studies that measure the association between SES and adherence to organized CRC screening programs. Inclusion and exclusion criteria are shown in Textbox 1.

Textbox 1. Inclusion and exclusion criteria of studies.

Inclusion criteria

- Original articles
- Observational studies conducted in organized colorectal cancer (CRC) screening programs
- Used fecal occult blood tests (FOBT) as the only primary screening test
- Average-risk population
- Assessed socioeconomic status (SES), including individual SES, neighborhood SES, and small-area SES
- Assessed SES with any index or score combining indicators of income, education, deprivation, poverty, occupation, employment, marital status, cohabitation, and others, and the SES index or score was defined as categorical variables
- Provided data to obtain related either unadjusted effect sizes (including odds ratios and relative risks) or adjusted ones
- Assessed adherence or nonadherence to FOBT-based CRC screening, which was objectively recorded
- Assessed adherence rate with the percentage of individuals invited to participate in screening that participate
- English language

Exclusion criteria

- Lacked enough data to calculate either unadjusted or adjusted effect sizes, including qualitative studies, reviews, commentaries, letters, and guidelines
- Conference abstracts that did not contain enough information for quality assessment
- Assessed adherence to colonoscopy or other screening tests
- Focused on only low-SES population or high-SES population, for example, focusing on only low-income population
- If several studies were conducted in the same program, participants should be counted only once. Duplicated samples were excluded, and the study with the biggest sample that offered the most information was included.
- Assessed country-level SES, province-level SES, or any SES aggregated by geographic areas larger than neighbors
- Assessed self-reported adherence
- Any language other than English

Data Extraction and Statistical Analysis

Sample data were extracted by 2 investigators (ZL and CW) independently, with disagreements solved by discussion and consensus. The standardized form consists of (1) the first author; (2) publication year; (3) study design; (4) country; (5) program name; (6) sample size; (7) adherence rate; (8) name of the SES index or score; (9) SES measures involved; (10) focusing on SES or not; (11) SES level; (12) original adjusted effect size; (13) available unadjusted and adjusted effect sizes (relative risks were transformed into odds ratios [ORs]) [25]; (14) covariates of adjusted effect sizes; (15) single-level or multilevel multivariate model; and (16) age range of screening. If effect sizes of an SES index or score with more than 2 levels were reported (usually), the effect sizes between the 2 extremes were extracted (eg, most vs least deprivation). The lowest SES was used as the reference group, and if the highest SES was used as the reference group, the reference group of the OR would be converted. When the unadjusted effect sizes were absent, they were calculated with the present cross-table data.

The Newcastle-Ottawa Quality Assessment Scale (NOS) for cohort studies and the Agency for Healthcare Research and Quality (AHRQ) methodology checklist were separately used to assess the quality of cohort and cross-sectional studies, which categorized the studies as high, middle, and low-quality [26-28]. The pair of investigators rated the quality independently, and discrepancies were solved through discussion and consensus. The Kappa coefficient was used to evaluate the consistency of the results.

Data Synthesis

ORs with corresponding 95% CIs were used for analysis, and an inverse variance method was used. We used Stata (version 17.0; StataCorp) to analyze data. The “flocci” command was used to convert the reference group of original estimates. “mean,” “meta bias,” and “meaning” were used to perform analysis. The Cochrane Q statistics and I^2 estimations were used to assess study heterogeneity. With considerable heterogeneity, a random effect model using the Daimonian and Laird method was used to conduct the meta-analysis.

We first assessed the unadjusted bivariate correlations between SES and adherence. Then we used the effect sizes of multivariate models with the most adjustment factors to assess the adjusted association. Tables and forest plots were used to display the results.

We examined heterogeneity using the Cochrane Q statistic and the I^2 statistic. Subgroup analysis was conducted to probe the potential source of heterogeneity across studies according to some characteristics of the studies: year of print (before or after the median year of print of the studies), adherence rate (lower or higher than 45%, which was the acceptable threshold set by the European guidelines [14]), SES focus (whether focusing on SES or other factors), SES level (individual level or nonindividual level, which includes neighborhood and small-area SES), and adjustment (adjusting for race and ethnicity or not, only for adjusted effect sizes) with at least 3 studies in a group. Publication bias was assessed using Egger and Begg tests [29,30]. Sensitivity analysis investigated the influence of each study (including the only cross-sectional study) on the overall meta-analysis summary estimate through a random effect model using the method of Daimonian and Laird.

Results

Systematic Review

The initial search yielded 1819 articles, and 9 articles were identified from reference lists. Of the 1819 articles, 910 remained after removing 909 duplicates by EndNote X8.1 (Thompson Reuters) automatically (Figure 1) [24,31]. In total, 102 full-text articles were assessed, and 10 met the inclusion and exclusion criteria.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram. CRC: colorectal cancer; FOBT: fecal occult blood test; SES: socioeconomic status.

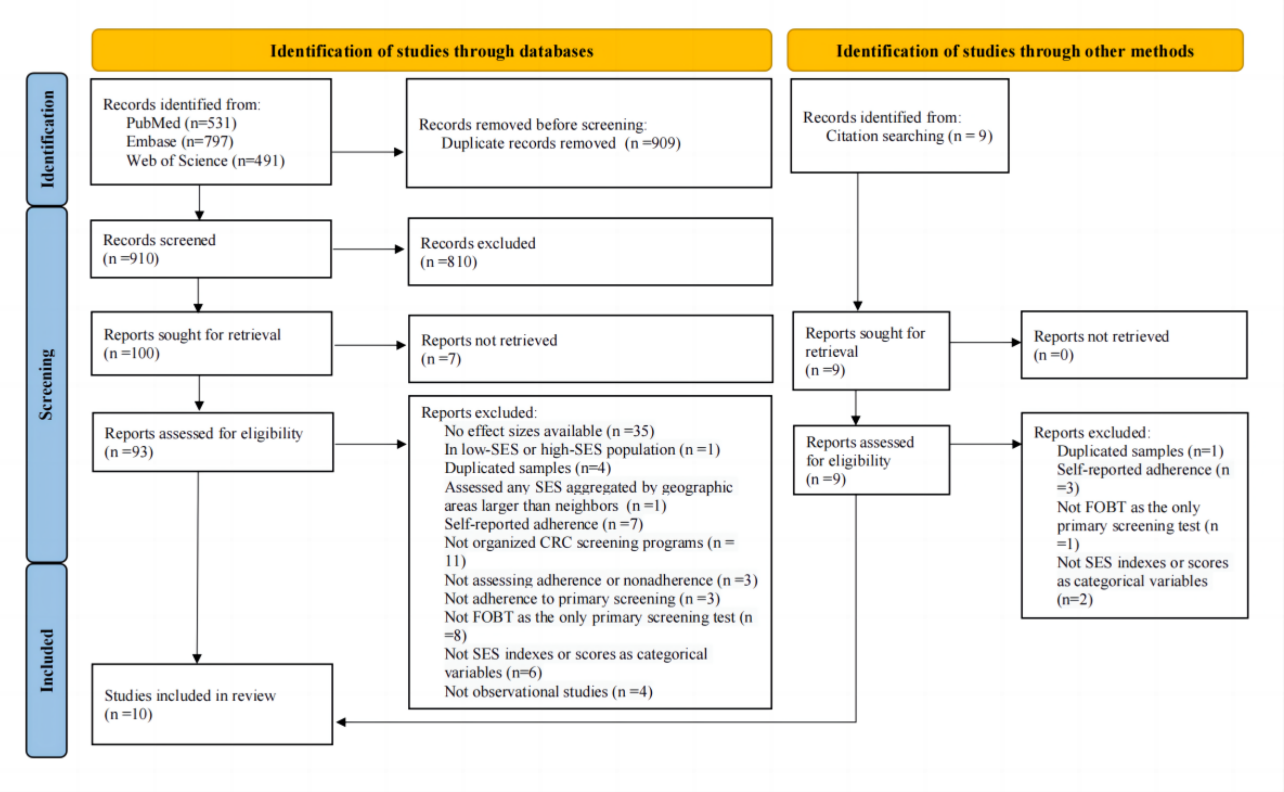

Table 1 shows an overview of the included studies, and Table S2 in Multimedia Appendix 1 lists other characteristics. A total of 9 of them were cohort studies, while 1 (515,388 participants) was cross-sectional. All studies included were carried out in developed European countries. All of the studies were of high quality, and the consistency of the literature quality evaluation results was 1.00 (Tables S3 and S4 in Multimedia Appendix 1). There was no uniform adjustment, and the potential confounders, including age, sex, race, ethnicity, cohabitation, marriage, and employment, were included and adjusted in different ways. Surprisingly, all ORs included were significantly larger than 1.00; in other words, all the studies agreed that SES was positively associated with adherence. Therefore, the results of the comparison of unadjusted and adjusted pooled estimates between subgroups were more important.

Table 1. Overview of the studies included in the meta-analysis.

[a] SES: socioeconomic status.

[b] SES focus: whether focusing on socioeconomic status or other factors.

[c] Not available.

[d] CRC: colorectal cancer.

Meta-Analysis With Unadjusted and Adjusted Effect Sizes

A total of 9 studies provided unadjusted effect sizes, with 1,927,075 (63.7%) participants in 3,026,991 targeted individuals. And 8 studies reported adjusted effect sizes, involving 3,220,822 targeted individuals and 2,117,839 (65.8%) participants.

A positive and strong association was observed between SES and adherence (unadjusted OR 1.73, 95% CI 1.42-2.10; adjusted OR 1.53, 95% CI 1.28-1.82). The forest plots are shown in Figures 2 [32,33,35-41] and 3 [32-34,36,37,39-41]. There was no evidence of publication bias. Sensitivity analysis showed robust results (Figures S1 and S2 in Multimedia Appendix 1). A fair degree of heterogeneity was found.

Figure 2. Forest plot of total unadjusted effect sizes for the association between socioeconomic status and adherence. OR: odds ratio.

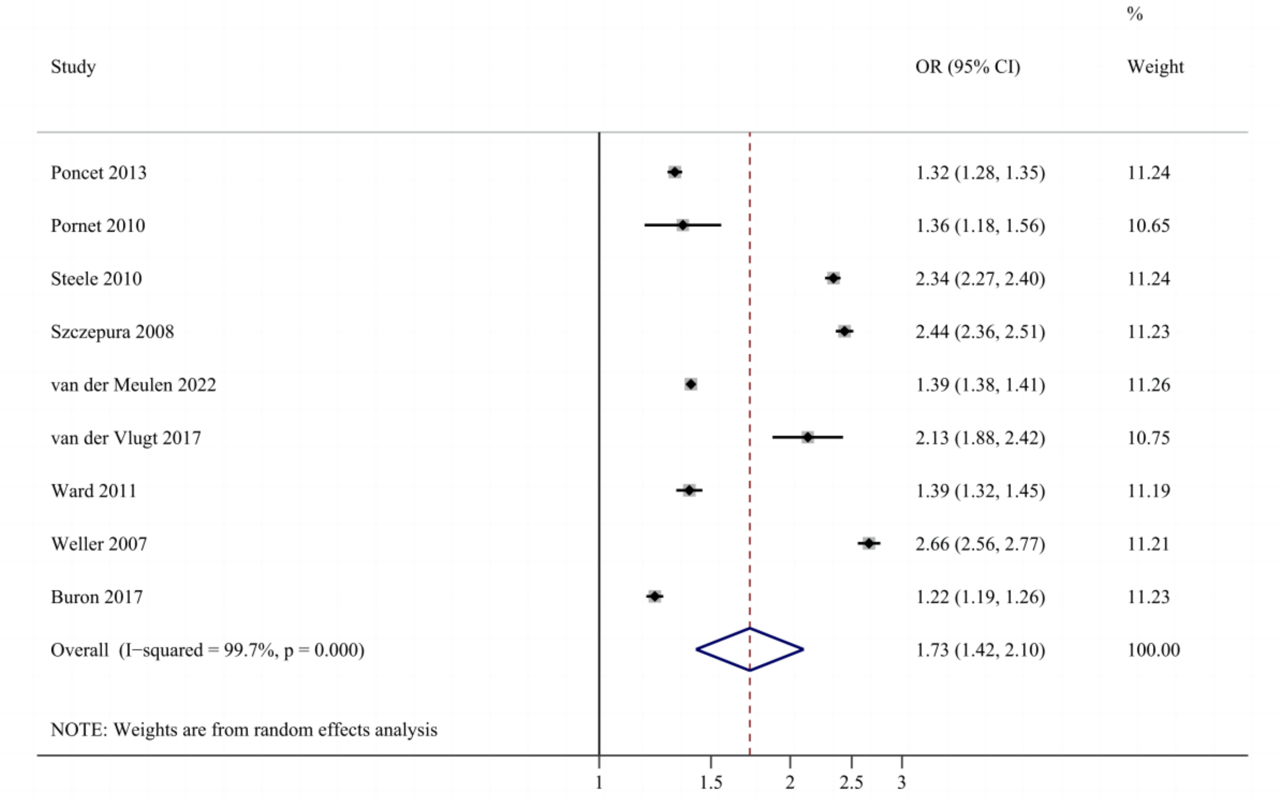

Figure 3. Forest plot of total adjusted effect sizes for the association between socioeconomic status and adherence. OR: odds ratio.

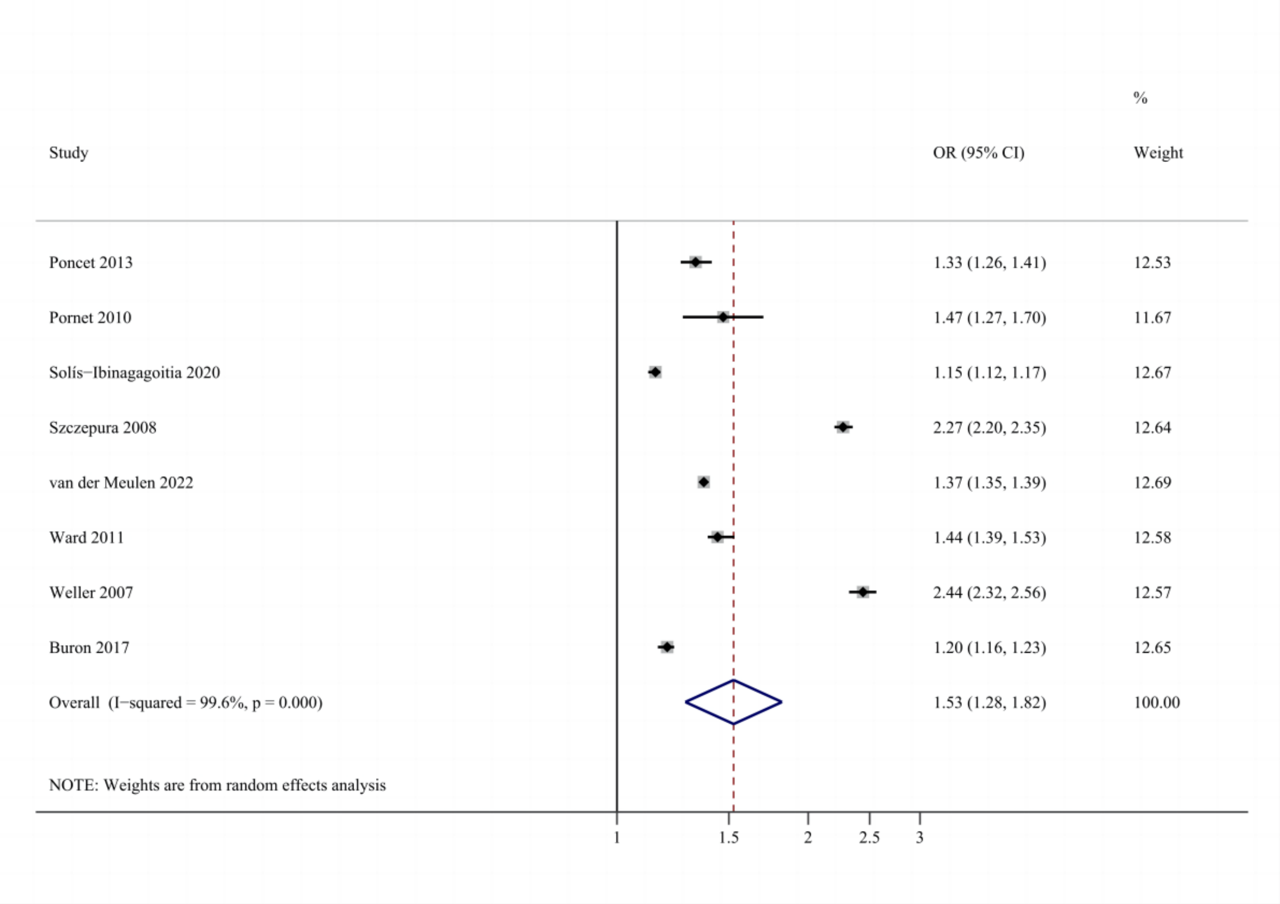

Subgroup Analyses With Unadjusted and Adjusted Effect Sizes

The positive association between SES and adherence remained significant in all feasible subgroup analyses (with at least three studies in a group), except for the adjusted association in the subgroup of individual-level SES (adjusted OR 1.46, 95% CI 0.98-2.17; Figures 4 and 5; Figure S3 in Multimedia Appendix 1). On the contrary, in subgroups of nonindividual-level SES, the adjusted association was significant. In other words, high nonindividual SES increased adherence, but individual SES did not influence adherence.

Figure 4. Forest plot of subgroup analysis using unadjusted effect sizes. There were only 2 studies in the subgroup of individual-level socioeconomic status (SES), which were not included in the subgroup analysis. *P* values less than .05 were considered statistically significant. OR: odds ratio; SES focus: whether focusing on socioeconomic status or other factors.

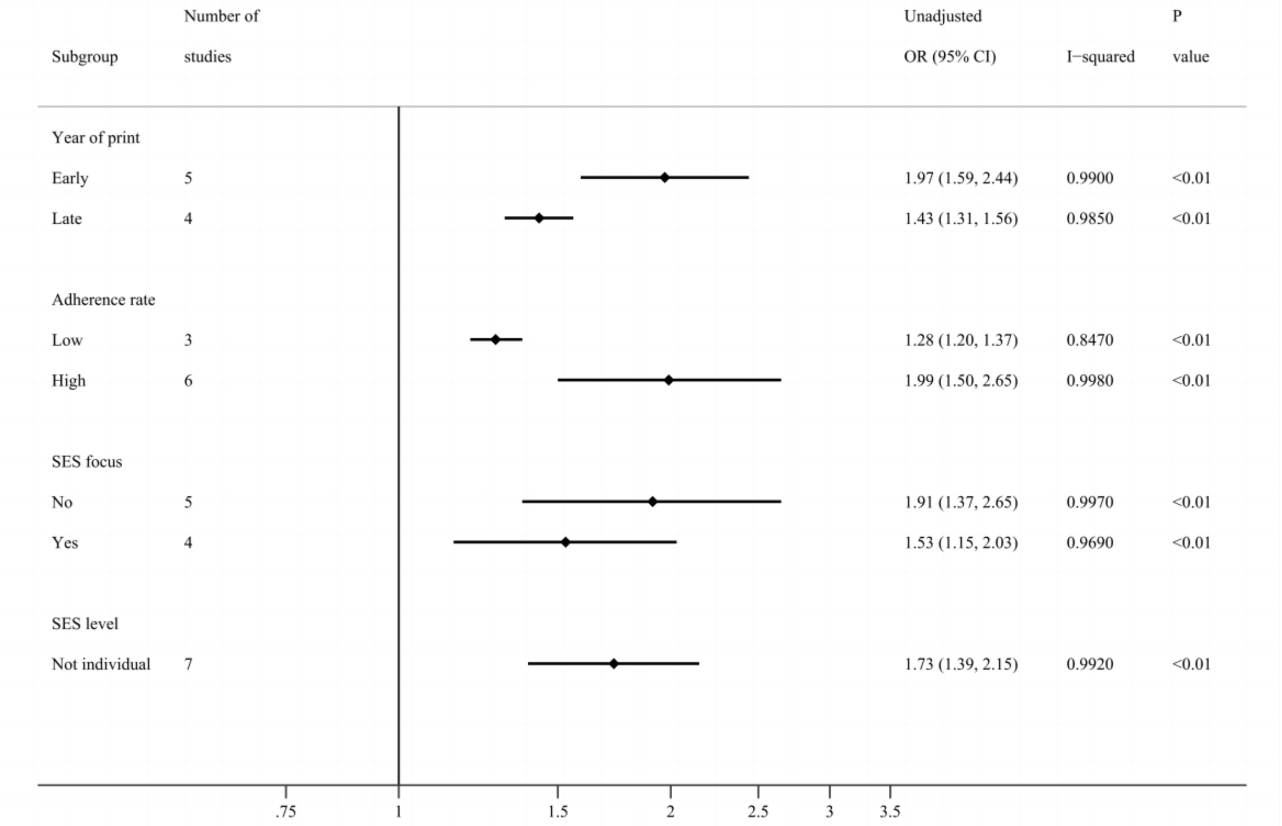

Figure 5. Forest plot of subgroup analysis using adjusted effect sizes. There were only 2 studies that adjusted for race and ethnicity, which were not included in the subgroup analysis. OR: odds ratio; SES focus: whether focusing on socioeconomic status or other factors.

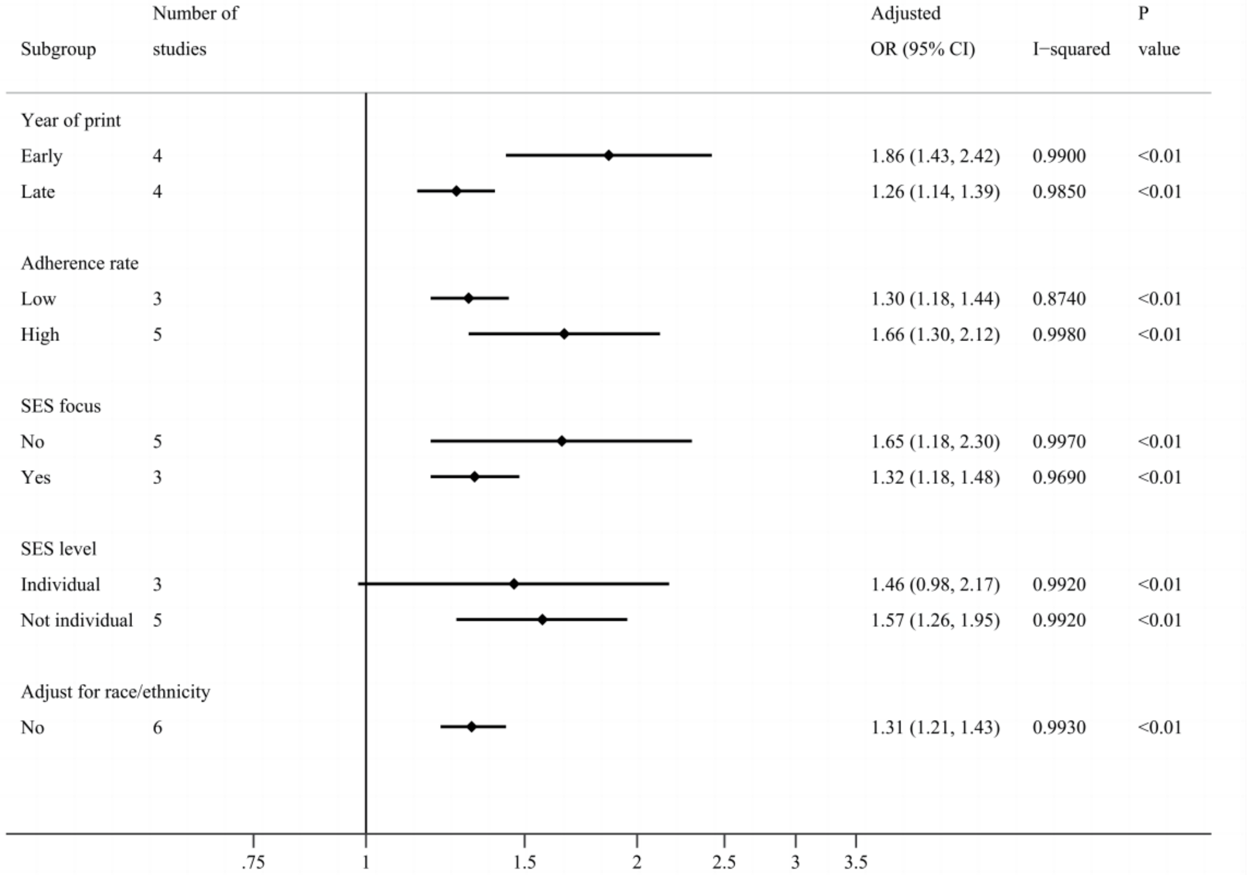

As for subgroups of the year of print, not only was the unadjusted association significantly stronger in the subgroup of early studies (OR 1.97, 95% CI 1.59-2.44) than in late studies (OR 1.43, 95% CI 1.31-1.56; Figure S4 in Multimedia Appendix 1), but also the adjusted one was significantly stronger in the early group (OR 1.86, 95% CI 1.43-2.42) than the late group (OR 1.26, 95% CI 1.14-1.39; Figure S5 in Multimedia Appendix 1), which was consistent and robust. In addition, the overall adherence rate of the late studies was higher than the early ones, which were 67.2% versus 52.1% in unadjusted associations and 68.1% versus 50.1% in adjusted associations.

The other results were not statistically significant, but they provided some insights. For multivariate analysis, the pooled estimate of the subgroup of studies that did not adjust for race and ethnicity (OR 1.31, 95% CI 1.21-1.43) seemed smaller than the overall pooled estimate (OR 1.53, 95% CI 1.28-1.82). The adjustment for race and ethnicity better showed a positive association. In addition, the strength of the association between SES and adherence seemed lower when the adherence rate was low or when SES was the focus of the studies (unadjusted OR 1.53, 95% CI 1.15-2.03; adjusted OR 1.32, 95% CI 1.18-1.48) than not (unadjusted OR 1.91, 95% CI 1.37-2.65; adjusted OR 1.65, 95% CI 1.18-1.48).

Discussion

Meta-Analytic Findings

To our knowledge, this is the first systematic review and meta-analysis assessing the strength of the association between SES and FOBT-based organized CRC screening adherence. It indicated considerably higher adherence among the highest SES compared with the lowest. The positive association was significant in both unadjusted and adjusted analyses, while being consistent across most possible sets of pooled estimates and all possible subgroup analyses, including the year of print, adherence rate, SES focus, SES level, and adjustment for race and ethnicity.

The association between high SES and high adherence was similar to those reported in 4 previous reviews investigating the participation of multiple modalities of CRC screening in both organized and opportunistic screening programs [42-45]. Furthermore, the disparity in adherence would lead to disparity in CRC incidence and mortality. In a modeling study estimating the disparity between African American and White individuals in the United States, the disparities in uptake of screening were able to account for 42% of the disparity in incidence and 19% of the disparity in mortality [46]. It thus seemed urgent to decrease the disparity in adherence to reduce health inequity driven by SES.

Differences in Subgroup Analysis

Subgroup analysis of different SES levels indicated that individual-level SES was not associated with adherence, which suggested that different SES levels could be the source of heterogeneity between studies. A systematic review by Mosquera et al [47] indicated that different indicators of individual SES showed various associations with adherence, separately. While individual educational level was positively associated with screening participation and higher deprivation was associated with lower participation, studies differed in the results of the association between individual income and participation [47]. In this meta-analysis that assessed SES index and scores rather than single indicators, individual SES was not associated with adherence after adjustment.

Nevertheless, country-level SES, which was not involved in this meta-analysis, was confirmed to not be associated with adherence either. In 2009, Pruitt et al [48] conducted a systematic review of the association between area SES and adherence. They found that 3 of 5 studies had at least one positive association and noted that country-level SES variables were not associated with any type of CRC screening adherence. Therefore, adherence might be associated with neighborhood or small area–level SES rather than individual- or country-level [48].

Due to the difficulty and trouble of collecting individual-level data, commonly used measures of SES were based on geography, at different levels of aggregation from countries to neighborhoods [49]. And it was proven that the agreement between area- and individual-level SES was low [50]. As a result, neighborhood SES or small-area SES was more competent to be used to assess the association between SES and adherence, and in this case, SES was significantly associated with adherence.

Although socioeconomic and racial and ethnic disparities in organized CRC screening were noted [9,51], the effect of race and ethnicity on the association has not been concluded yet. Another important finding of this analysis was that race and ethnicity might be important confounding factors for the association between SES and adherence. In accordance with the present results, a previous study in the United States using income level as the measure of SES reported that in the hierarchical analysis by race and ethnicity, there was no significant association between SES and adherence among the non-White population. Especially for adherence to a screening colonoscopy, a significant interaction between race and ethnicity and income level was identified [52]. Although O'Malley et al [21] declared that racial differences in adherence could be fully explained by differences in SES, most studies of other conditions found independent associations with both SES and race and ethnicity [22,23]. Consequently, in order to improve adherence and address inequity, future research should consider strategies to improve the adherence of the low-SES population regarding ethnic composition.

The results of this meta-analysis showed that the disparity between the high and low-SES populations in adherence decreased. Since the adherence rate of the subgroup with a later year of print was higher than that of the other subgroup, a probable explanation was that adherence of the low-SES population increased more than the high as organizational screening programs developed with more and more interventions to promote adherence. Actually, a large-sample randomized controlled trial proved that certain interventions could not only improve overall participation but also particularly enhance the adherence of the low-SES population [53]. In this context, future studies should focus on cost-effective strategies that are suitable to be integrated into large-scale organized programs and further address the disparity in the near future. Our ideal goal is not equal adherence but to eliminate the health inequity of the CRC.

Strengths and Limitations

This is the first meta-analysis assessing the association between SES and adherence, especially with the first focus on FOBT-based organized CRC screening adherence. Previous reviews merely focused on the qualitative association between SES and adherence and did not deal with the influence of confounding factors. However, this study confirmed, quantified, and further explored the positive association between SES and adherence by performing meta-analysis and subgroup analysis and comprehensively interpreting the results of both the unadjusted association and the adjusted one.

A few limitations should be considered when interpreting the results. First, considerable heterogeneity existed and although we performed subgroup analysis and sensitivity analysis, it remained. The probable explanation of the heterogeneity was that in the absence of a widely recognized SES index, we observed different kinds of indexes and scores, which combined different indicators at different levels and used different weights to indicate SES. However, most indexes and scores incorporate the 3 SES indicators of income, education, and employment. The different start ages and stop ages used by the different programs resulted in differences in the mean age of the population, leading to differences in sample characteristics. Second, we recognized that all the studies included were carried out in the high-income setting even though we did not make a restriction on the inclusion criteria and actively supplement the literature collection from the reference lists. It might be caused by a limited number of studies that quantitatively assessed the association between SES and adherence to organized screening programs, especially in low-income countries where organized screening was not widespread. Therefore, whether the results can be generalized to low- and middle-income countries remains unknown. Finally, different adjustments might cause residual confounders in the included studies. To minimize this effect, we took both unadjusted and adjusted effect sizes into account and were more confident to draw a conclusion when the results of them were consistent.

Conclusions

To conclude, we found the high-SES population had higher adherence to FOBT-based organized CRC screening. Neighborhood SES or small-area SES was more competent than individual- and country-level SES to be used to assess the association between SES and adherence. Race and ethnicity were probably important confounding factors for the association. The good news was that the disparity of adherence between the high SES and the low SES narrowed with the development of interventions and the improvement of organized programs. Future research should focus on digging into the causation of the association and creating targeted interventions and strategies to improve the adherence of the low-SES population, which aims at overcoming the inequality in the chances of benefiting from organized screening programs.

Acknowledgments

This study is funded by the CAMS Innovation Fund for Medical Science (grants 2021-I2M-1-067 and 2021-I2M-1-011), Sanming Project of Medicine in Shenzhen (grant SZSM201911015), and the Hope Star of Talent Program of National Cancer Center/ Cancer Hospital of the Chinese Academy of Medical Sciences.

Data Availability

The data sets generated during and/or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

ZL, XD, CW, and NL conceived and designed the study; WC, YZ, and ZW provided study materials and tools; ZL, XD, and CW were responsible for the collection and assembly of data; LZ and FW were responsible for data analysis; JL, JR, and JS were responsible for interpretation; ZL and CW were involved in writing the manuscript; YX, WC, and NL revised the manuscript. All the work was performed under NL’s instructions. All authors read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Culturally and linguistically diverse groups are often underrepresented in population-based research and surveillance efforts, leading to biased study results and limited generalizability. These groups, often termed “hard-to-reach,” commonly encounter language barriers in the public health (PH) outreach material and information campaigns, reducing their involvement with the information. As a result, these groups are challenged by 2 effects: the medical and health knowledge is less tailored to their needs, and at the same time, it is less accessible for to them. Modern machine translation (MT) tools might offer a cost-effective solution to PH material language accessibility problems.

Objective: This scoping review aims to systematically investigate current use cases of MT specific to the fields of PH and epidemiology, with a particular interest in its use for population-based recruitment methods.

Methods: PubMed, PubMed Central, Scopus, ACM Digital Library, and IEEE Xplore were searched to identify articles reporting on the use of MT in PH and epidemiological research for this PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews)–compliant scoping review. Information on communication scenarios, study designs and the principal findings of each article were mapped according to a settings approach, the *World Health Organization monitoring and evaluation* framework and the *service readiness level* framework, respectively.

Results: Of the 7186 articles identified, 46 (0.64%) were included in this review, with the earliest study dating from 2009. Most of the studies (17/46, 37%) discussed the application of MT to existing PH materials, limited to one-way communication between PH officials and addressed audiences. No specific article investigated the use of MT for recruiting linguistically diverse participants to population-based studies. Regarding study designs, nearly three-quarters (34/46, 74%) of the articles provided technical assessments of MT from 1 language (mainly English) to a few others (eg, Spanish, Chinese, or French). Only a few (12/46, 26%) explored end-user attitudes (mainly of PH employees), whereas none examined the legal or ethical implications of using MT. The experiments primarily involved PH experts with language proficiencies. Overall, more than half (38/70, 54% statements) of the summarizing results presented mixed and inconclusive views on the technical readiness of MT for PH information.

Conclusions: Using MT in epidemiology and PH can enhance outreach to linguistically diverse populations. The translation quality of current commercial MT solutions (eg, Google Translate and DeepL Translator) is sufficient if postediting is a mandatory step in the translation workflow. Postediting of legally or ethically sensitive material requires staff with adequate content knowledge in addition to sufficient language skills. Unsupervised MT is generally not recommended. Research on whether machine-translated texts are received differently by addressees is lacking, as well as research on MT in communication scenarios that warrant a response from the addressees.

Introduction

Background

Public health (PH) and epidemiology are increasingly challenged by decreasing response proportions, in general, and an underrepresentation of culturally and linguistically diverse (CALD) communities, in particular [1]. Such underrepresentation increases the risk of biased estimates and, therefore, might limit the generalizability of findings in population-based research [2-7]. Ultimately, it might hinder the inclusion and involvement of these communities in disease prevention, surveillance efforts, and emergency response. In PH outreach and information campaigns, reaching CALD populations often poses greater difficulties than reaching other groups. As a result, these groups are challenged by 2 effects: the medical and health knowledge is less tailored to their needs, and at the same time, it is less accessible to them. These effects will only increase in importance as migration owing to globalization, global conflict, and economic inequalities increasingly shapes our societies toward multiculturality.

Using personalized recruitment material is an effective approach to engage individuals from CALD groups in population-based studies [8]. The choice of language matters because language barriers often result in their disengagement with PH initiatives [9-11]. If recipients are not able to comprehend transmitted information in the first place, they cannot react to it or provide an informed response [12]. Inclusive outreach approaches in PH study material, such as simplifying technical language or using multilingual cover letters, have been proven to improve access to information, foster meaningful participation, and reduce study nonresponse [13-15].

PH officials and researchers often struggle to effectively reach and engage all target audiences evenly. Although sufficient knowledge about the cultural composition of the target populations may be available (ie, the necessity to use particular languages), budget limitations usually restrict how many professional translations can be prepared and used for PH communication and outreach efforts to start with. A further complication with printed outreach material is that the number of different language versions that can be sent out in a single letter is physically limited, but the preferred language of an individual often is not known; therefore, it is difficult to conduct targeted outreach with specific language versions tailored to each recipient.

The use of machine translation (MT) technology poses a potential solution to overcome language hurdles in multilingual populations and improve effective material dissemination. As a computerized system, MT is able to automatically translate text or speech from 1 source language to multiple output languages [16]. In clinical settings, the technology has already been used to lower language barriers and facilitate services independently of the spoken language of the physician [17]. In the context of PH and epidemiology, MT could also be used to increase outreach by providing cross-lingual access to information and supporting PH staff to optimize material translation workflows.

Prior Work

To our knowledge, there are 4 recent systematic reviews that cover aspects of the use of translation technologies in medical and clinical settings. In 2018, Dew et al [18] published a review on how the development of MT technology could be useful to assist one-way communication among individual stakeholders. In 2020, Frampton et al [19] systematically mapped digital tools for the recruitment and retention of participants in randomized controlled trials. Although the authors did not specifically address MT or similar language technologies, one of their main takeaways was that few studies address its use to support underserved groups. A year later, Thonon et al [20] published a review on the use of mobile apps to facilitate dialogue between health care professionals and CALD individuals with low language proficiency levels. In 2022, Vieira [21] published a review with a focus on the use of MT in medical and legal settings as 2 separate cases of translations of highly specialized vocabulary. The paragraphs devoted to medical settings mostly focused on one-to-one communication examples, mainly corroborating the findings of Dew et al [18].

In addition to these systematic reviews, other studies have assessed the use of MT in different health settings. Panayiotou et al [22] provided a methodical evaluation of 15 Apple iPad-compatible language translation apps to facilitate conversations between health care providers and patients in Australia; aside from its geographically bounded context, the study centers on native mobile apps for one-to-one communication. Nurminen and Koponen [23] outlined several applications of MT for increasing information accessibility in humanitarian settings (eg, an armed conflict, a natural disaster, or an epidemic), including a paragraph devoted to discussing community-based health, as well as safety and security information. Although relevant to PH, the overview neither specifically reviews other contexts nor identifies patterns in the literature regarding the state of readiness of MT for PH settings.

These earlier publications are mostly confined to reporting literature on the use of MT for real-time bilingual person-to-person communication. The technology is mainly studied as an on-premise solution to support medical service provision in spoken interactions between specific groups of patients (eg, tourists, refugees, or expatriates) and health care staff (eg, general practitioners, caregivers, or paramedics) [24-28]. Only a few of the articles explore the use of multilingual translation tools for disseminating PH information to specific target audiences [29] or for population-wide health initiatives [30].

The Goal of This Study

The objective of this scoping review was to systematically map the use of MT for conducting PH outreach, with a particular focus on population-based recruitment methods. As a first step, we identify the information exchange scenarios in which MT technology is used to facilitate essential PH operations in different health and care settings. Second, we provide an overview of the types of study designs and research instruments for monitoring and evaluating the use of MT in these cases. Third and last, we synthesize the reported findings, benefits, and risks in relation to technical, socioeconomic, and ethicolegal technology readiness levels.

Methods

Search Strategy and Selection Criteria

This scoping review was preregistered on the Open Science Framework on February 11, 2022 [31], and conducted in accordance with the updated guidance on scoping reviews of the JBI Manual for Evidence Synthesis [32] as well as the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist (Multimedia Appendix 1 [33]) [34,35].

This scoping review exclusively includes peer-reviewed original research describing and assessing the use and suitability of MT for written texts for the purpose of improving collective outreach as well as the response and involvement of participants in the fields of epidemiology and PH, regardless of the specific target interventions or health areas involved. Given the technical nature of the research topic, peer-reviewed conference papers were also included. In addition, articles reporting guidelines or consensus statements concerning the use of MT in PH settings were included. The scoping review considers only studies written in English and published from 2007 onward, a year after the launch of the first fully web-based MT system and the publication of the first reference framework for MT quality assurance (the EN15038 standard) [36]. Studies of individual care or counseling settings (eg, practitioner and patient) were excluded because, in these settings, MT is used for spoken two-way communication. Textbox 1 presents the eligibility criteria.

Textbox 1. Eligibility criteria for the scoping review.

Inclusion criteria

- Article type
  - Peer-reviewed original research
  - Peer-reviewed conference papers
  - Consensus statements concerning the use of machine translation in public health settings
- Language
  - Studies published in English
- Time span
  - Studies published after January 2007
- Study design
  - Empirical studies

Exclusion criteria

- Article type
  - Non–peer-reviewed research or gray literature
- Language
  - Studies not published in English
- Time span
  - Studies published before 2007
- Study design
  - Nonempirical studies
  - Studies of individual care or counseling settings

Search Strategy

Searches were conducted in PubMed (MEDLINE), PubMed Central, Scopus, ACM Digital Library, and IEEE Xplore.

As recommended by JBI, the search string was constructed according to the population or participants, concept, and context (PPC) framework [32]. No specific restrictions were used to define the study populations. The concept was defined by terms related to automatic translation technology and the context by defining settings for population-based communication in PH, epidemiology, and community-based health care (Multimedia Appendix 2).

Initially, the search string was created to query the PubMed search engine and thereafter adapted to PubMed Central, Scopus, IEEE Xplore, and ACM Digital Library (the search terms are listed in Multimedia Appendix 2). Where available, database-specific index terms were added (eg, Medical Subject Headings [MeSH] terms for PubMed). The search was restricted to abstracts and titles. The search strategy was refined with the assistance of a professional librarian. All searches were executed on January 31, 2022, and updated on March 3, 2023.

After deduplication and the application of the exclusion criteria (ie, language not English, publication before 2007, and non–peer-reviewed articles), both authors (PSH-E and SR) independently screened the titles and abstracts of all remaining records using the R packages *revtools* [37] and *metagear* [38], which provide tools for semiautomatic deduplication and title or abstract screening. Disagreements were discussed and resolved by reaching a consensus. If necessary, full texts were consulted.

Data Extraction, Synthesis, and Analysis

Data extraction was conducted using a standardized data extraction template to extract bibliographic characteristics, health information exchange scenarios, research objectives and corresponding study designs, and technical characteristics of the MT tools used, as well as to identify the principal findings in the selected articles.

Health information exchange scenarios were assessed using a settings approach to health promotion [39]. We extracted and classified data regarding the (1) transmitters and recipients of translated materials, (2) types of translated materials, (3) types of MT systems and the source and target languages studied, and (4) nature of the use of MT in PH procedures as unsupervised (ie, without editing efforts) or supervised (ie, combined with editing efforts).

Research objectives were assessed according to the World Health Organization (WHO) monitoring and evaluation (M&E) framework [40], which is useful to map the research and development of digital health technologies according to their stage in the innovation maturity life cycle. We then classified the articles as either monitoring studies or evaluation studies. We considered monitoring studies to be those involving research on the technical quality and stability of MT (eg, technology assessments and comparative experiments) and evaluation studies to be those reporting on the appraisals of the technology-based interventions over time (eg, usability, affordability, and economic cost-effectiveness studies), as well as implementation research for integrating developed systems within broader PH workflows.

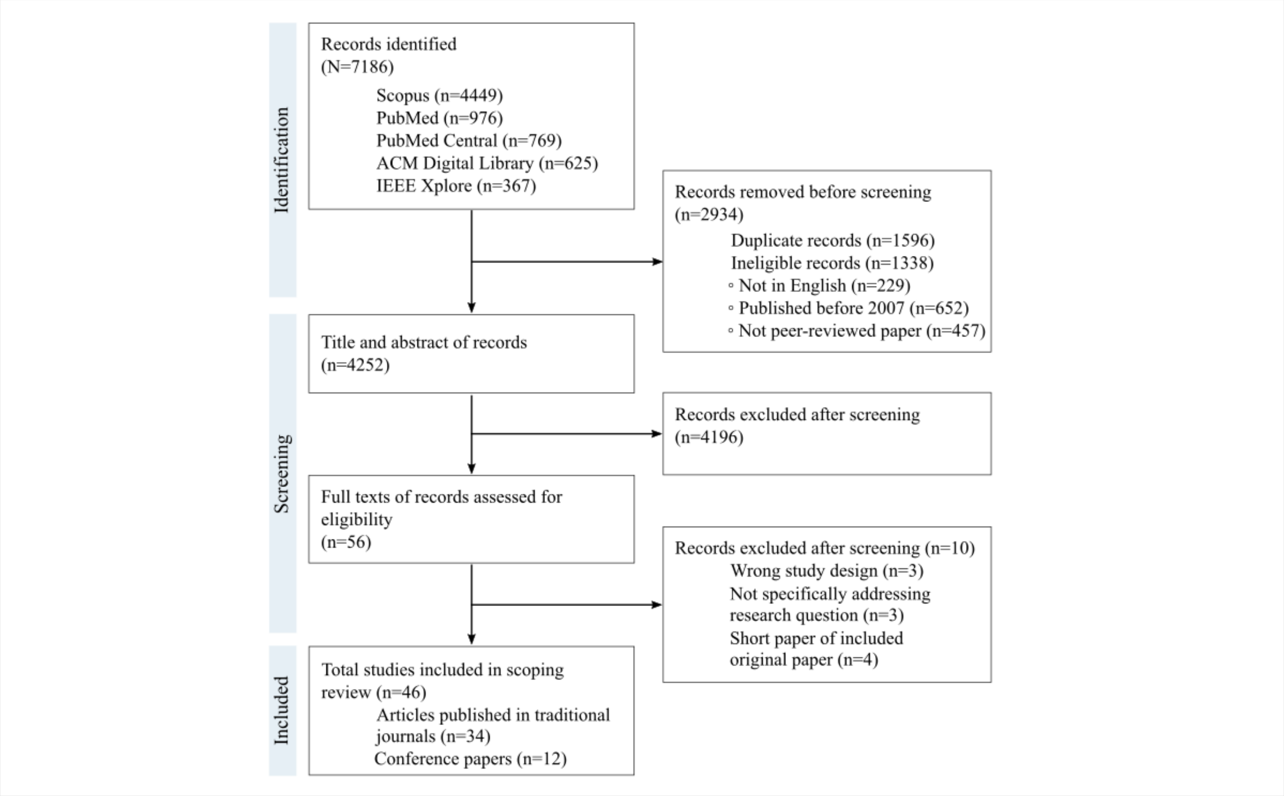
To assess the principal findings, we extracted sentences reporting quantitative and qualitative outcomes from the results sections. Following the *service readiness level* framework of evidence proposed by Hughes et al [41], we organized the statements as concerning technical, socioeconomic, or ethicolegal readiness levels of MT technology. On the basis of a manual sentiment analysis, we then detected the tonality of each text and classified them as positive, negative, or neutral.

Results

Search Outcomes

Conducted on January 31, 2022, and updated on March 3, 2023, the search yielded a total of 7186 records, of which 2934 (40.83%) were removed (1596/2934, 54.4% duplicates and 1338/2934, 45.6% not meeting the eligibility criteria). A review of the titles and abstracts of the remaining 4252 records resulted in 56 (1.32%) being selected for a full-text screening. From these 56 articles, 10 (18%) were removed for not meeting the study design criteria, not specifically addressing the research question, or for providing duplicate information from another included paper (Multimedia Appendix 3), and 46 (82%) were included in the systematic scoping review (Figure 1; Multimedia Appendix 4 [29,42-86]).

Figure 1. Flow diagram of the search and study selection process following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines.



The records were published between 2009 and 2023 as either conference papers (12/46, 26%) [48,53,55,60,61,63,65,71,78,80,82,84] or articles in traditional journals (34/46, 74%) [29,42-47,49-52,54,56-59,62,64,66-70,72-77,79,81,83,85,86] (Multimedia Appendix 4).

PH Information Exchange Scenarios

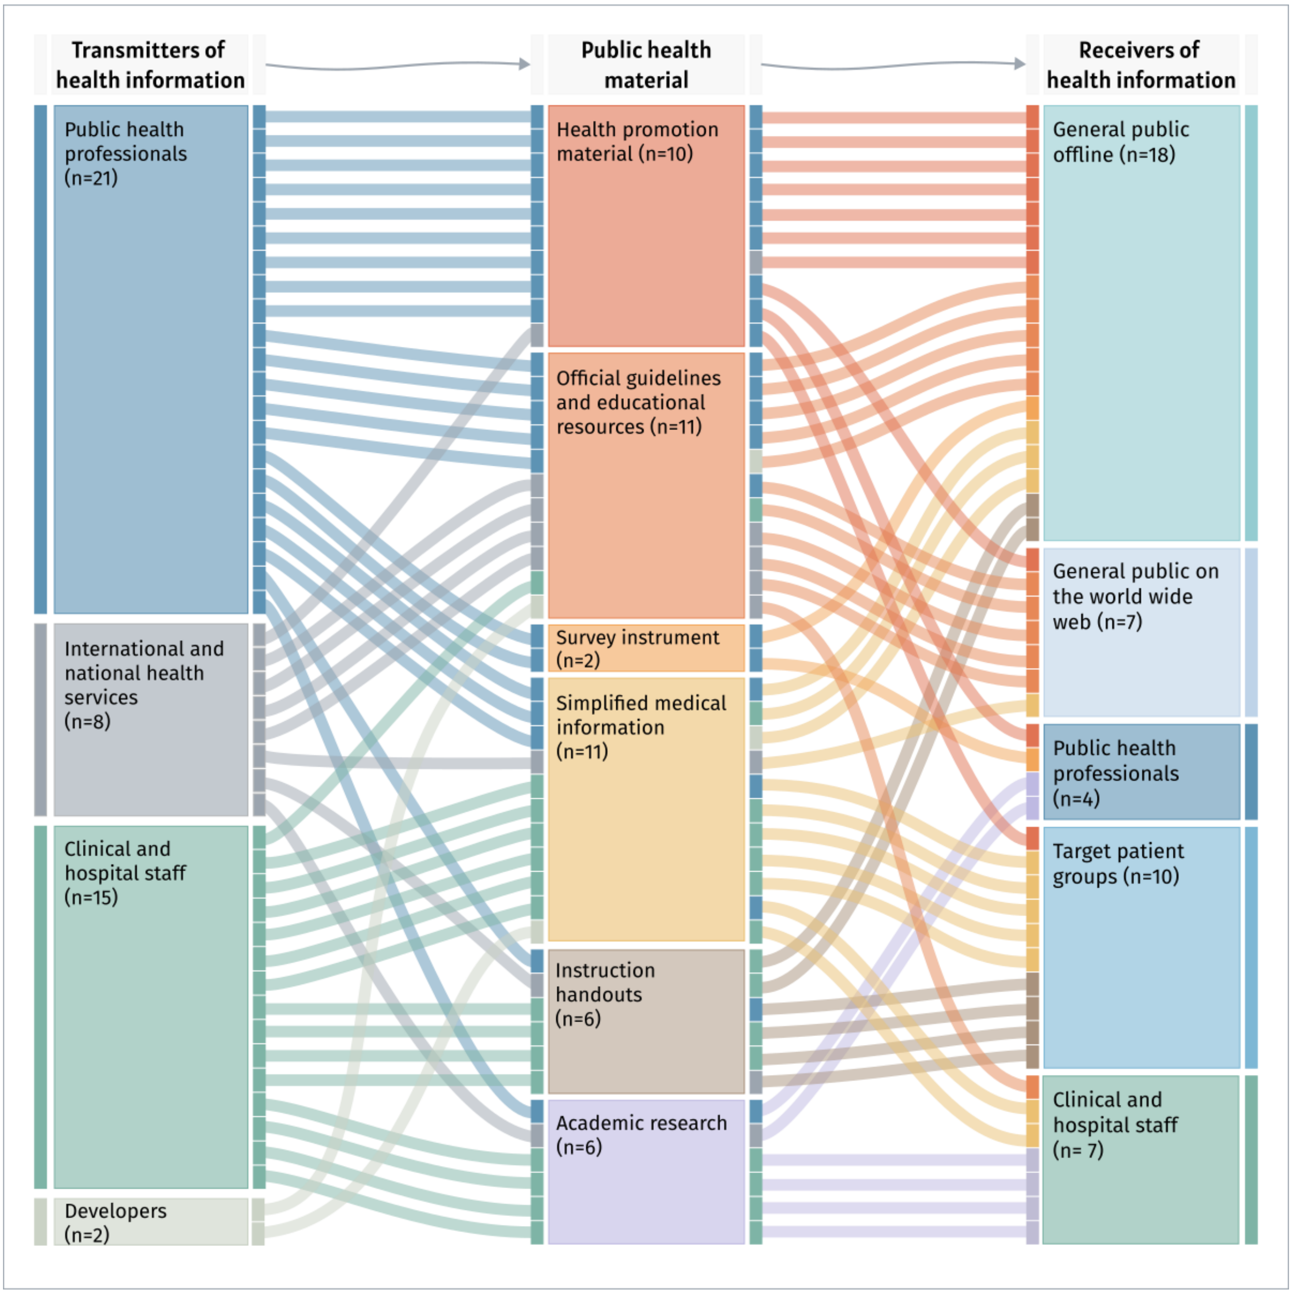
Four types of information transmitters (ie, the end users of MT) could be identified: PH departments and research institutions (21/46, 46%) [29,49,50,52-54,56,59,60,62,63,65,70,73-78,80,86]; clinical and hospital staff (15/46, 33%) [44-47,51,58,61,66,68,69,71,72,79,81,85]; international and national health organizations, such as the WHO, the US Centers for Disease Control and Prevention, and the UK National Health Service (8/46, 17%) [42,43,55,57,64,82-84]; and developers of web-based health information platforms (eg, Cochrane) or social media outlets (eg, Facebook; 2/46, 4%) [48,67].

The types of PH materials translated with MT fell into 6 broad categories: official guidelines and educational resources (11/46, 24%) [42,43,53,62,67,70,75,79,80,82,83], simplified medical information and lexica (11/46, 24%) [48,54,55,61,63,68,69,71,81,85,86], PH promotional material (10/46, 22%) [29,49,50,59,60,64,65,76-78], instruction handouts (6/46, 13%) [51,52,57,58,66,72], academic research (6/46, 13%) [44-47,73,84], and survey instruments (2/46, 4%) [56,74].

The information receivers (ie, the end users of translated material) could be categorized into 5 types: the wider population as targets of PH material offline (18/46, 39%) [29,48,51,53,55,58,59,62,64,65,67,68,74,76-78,80,86] or on the world wide web (7/46, 15%) [42,43,49,70,75,79,82], patient groups or communities (10/46, 22%) [50,52,57,61,63,66,69,72,81,85], clinical and hospital staff (7/46, 15%) [44-47,54,71,83], and PH professionals (4/46, 9%) [56,60,73,84].

Figure 2 provides a Sankey diagram visualizing PH information exchanges supported with the use of MT technology between groups of transmitters and receivers across the selected articles (Multimedia Appendix 5 [29,42-86]).

Figure 2. Public health information exchange scenarios: transmitters and receivers of public health information and the types of public health materials.



Overall, the most frequent use case of MT for collective communication in a PH setting is between PH staff and the public receiving paper-based health information (ie, offline; 14/46, 30%) [29,53,56,59,60,62,65,73,74,76-78,80,86] such as health promotion material (6/14, 43%) [29,59,65,76-78] or educational resources (3/14, 21%) [53,62,80]. The second most frequent use cases were exchanges involving clinical and hospital staff (10/46, 22%) [51,58,61,66,68,69,72,79,81,85] such as nurses or emergency wards disseminating simplified medical information (5/10, 50%) [61,68,69,81,85] or preparing instruction handouts for targeted audiences (4/10, 40%) [51,58,66,72].

Most of the articles (40/46, 87%) [29,42-48,50-63,66-69,71-74,77,79-86] specified the type of procedure for the use of MT as either unsupervised (30/40, 75%) [42-48,50-52,54-58,63,67-69,71-73,79-85] or supervised (10/39, 26%) [29,53,59-62,66,74,77,86] (Multimedia Appendix 5). Unsupervised MT was used for enabling translation plug-ins on PH websites (9/30, 30%) [42,43,48,67,69,79,81-83], translating PH material via web-based MT services (8/30, 27%) [50-52,56-58,68,72], and translating English content into the researchers' language (7/30, 23%) [44-47,73,80,84], as well as to investigate the risks of mistranslation and translation quality (5/30, 17%) [54,55,63,71,85]. Supervised MT procedures included postediting (6/10, 60%) [29,53,59,60,77,86] or pre-editing of source language (2/10, 20%) [61,62], as well as back translations (2/10, 20%) [66,74] of sample texts on the web and paper-based material.

The tested MT software tools were either freely available on the web from commercial technology vendors or were in-house built systems created by the research teams themselves (Multimedia Appendix 5). Regarding commercial vendors, Google Translate was the most used translation engine (28/46, 61%) [29,43-45,48,50-52,54-59,62,63,66,69,72,74,76-83,86], followed by Microsoft Bing (5/46, 11%) [44,47,61,69,79] and DeepL Translator (2/46, 4%) [73,86], among others. All these systems were used as domain-agnostic systems and not pretrained on specific language corpora. All articles regarding in-house built systems (9/46, 20%) [61,63,69,71,76,79,80,82,84] presented a prototype demonstration of domain-specific MT systems specifically trained on PH-related and medical vocabulary. The studies comparing these systems against each other (4/9, 44%) [71,79,80,84] advocate for using in-house built systems for shorter text with medical terminologies in long-term projects, whereas off-the-shelf systems may be used for more general information. In relation to each other, the evidence does not clearly favor 1 translation engine over another. Instead, it suggests that the choice among systems depends on the language pairs and the vocabulary domain used in the material. Provided that the texts are not exclusively reliant on specific terminologies, domain-agnostic solutions are equally suited for handling short-text translations.

Of the 46 articles, 40 (87%) [29,42-48,50-63,66-69,71-74,77,79-86] studied the use of MT to translate from 1 source language into 1 or several target languages (Multimedia Appendix 5). Of these 40 articles, 37 (93%) [29,42-45,48,50-63,66-69,71-74,77,79-85] specified the source language, whereas 35 (88%) [29,42-45,48,50-52,54-63,66,67,69,71-74,77,79-86] specified the target language. Of the 12 source languages, English was the most commonly evaluated (32/37, 86%) [29,42-45,48,50-60,62,66-68,71,72,74,77,79-85], followed by French (4/37, 11%) [48,69,79,80,84], German (3/37, 8%) [69,79,80], and Spanish (3/37, 8%) [79,80,84]. MT was tested in translating texts from English into at least 44 other languages, with Spanish (17/35, 49%) [29,48,50-52,57-60,66,72,74,79,80,83-85], Chinese (13/35, 37%) [50-52,56,58,62,72,74,77,81-83,85], and French (7/35, 20%) [52,71,74,79,80,83,84] being the most frequent target languages. Within this subset of 35 articles, 25 (71%) [29,42-45,50-52,54,56,57,59-63,66,69,72-74,77,79,80,85] conducted studies in specific geographies targeting populations and communities with limited language proficiency. Of these 25 articles, 19 (76%) [29,50-52,56,57,59-63,66,69,72,74,77,79,80,85] targeted individuals with limited English proficiency, mainly residing in the United States (17/19, 89%) [29,50-52,56,57,59-61,63,66,69,72,77,79,80,85].

Study Designs According to the WHO M&E Framework

In accordance with the WHO M&E framework [40], we identified 6 types of research designs across the selected articles (Table 1; Multimedia Appendix 6 [29,42-86]): MT technology assessments (study type 1; 23/46, 50%) [29,43-46,48,50-52,54-59,62,68,72-74,77,85,86], technology stability standards (study type 2; 3/46, 7%) [66,71,81], prototype demonstrations (study type 3; 8/46, 17%) [61,63,69,79,80,82-84], usability studies (study type 4; 4/46, 9%) [42,47,64,65], economic evaluations (study type 5; 4/46, 9%) [49,70,75,78], and implementation research (study type 6; 4/46, 9%) [53,60,67,76]. Nearly three-quarters (34/46, 74%) of the articles [43-46,48,50-52,54-59,61-63,66,68,69,71-74,76,79-86] conducted monitoring studies (ie, study types 1, 2, and 3), whereas more than a quarter (12/46, 26%) [42,47,49,53,60,64,65,67,70,75,76,78] conducted evaluation studies (ie, study types 4, 5, and 6).

Table 1. Categorization of studies according to the World Health Organization monitoring and evaluation framework (n=46).

Study type and research design	Studies, n (%)
Monitoring studies: functionality and stability of MT[a] at predefined levels of quality	
1. MT technology assessments: studies assessing MT quality, functionality, and performance	23 (50)
2. Technology stability standards: studies proposing standards or criteria for MT quality assurance	3 (7)
3. Prototype demonstrations: studies reporting on the development and design of an in-house built MT-based system	8 (17)
Evaluation studies: MT technology in health-related settings	
4. Usability studies: studies addressing end-user attitudes, perceptions, and responses when using the prototype system and assessing how easily end users can interact with the system	4 (9)
5. Economic evaluations: studies addressing accessibility, availability, or affordability of the system	4 (9)
6. Implementation research: studies around the implementation of MT technology within a broader (public) health system architecture	4 (9)

[a] MT: machine translation.

The monitoring studies adopted standard MT evaluation methods to measure the quality of MT output across various samples of health information material. Most of these studies focused on studying MT quality in terms of structural accuracy (28/34, 82%) [29,43,45,46,48,50-52,54-58,61,63,68,69,72-74,77,79-84,86] and fluency in unsupervised MT procedures (17/34, 50%) [44-46,50,51,54,56,57,59,62,66,71,72,77,80,81,85]. A quarter (8/28, 29%) of the articles [61,62,69,71,79,80,82,84] assessing structural accuracy supplemented their findings with standard automatic evaluation methods to verify the quality of MT output in comparison with the output of professional human translators. Flesch-Kincaid grade level scores and content analysis techniques were used to measure the readability levels and meaning preservation of the translated sentences. In a few of the articles (6/34, 18%) [50,51,57,58,66,72], MT was also evaluated in terms of the risk severity of mistranslation (ie, the degree of negative impact on the patient's health outcome because of a wrong translation). Studies investigating postediting (4/34, 12%) [29,59,77,86] or back translation (2/34, 6%) [66,74] focused on identifying error patterns or measuring the amount of time saved, whereas pre-editing (2/34, 6%) [61,62] was investigated to understand the ability of MT to handle PH jargon and medical terminologies.

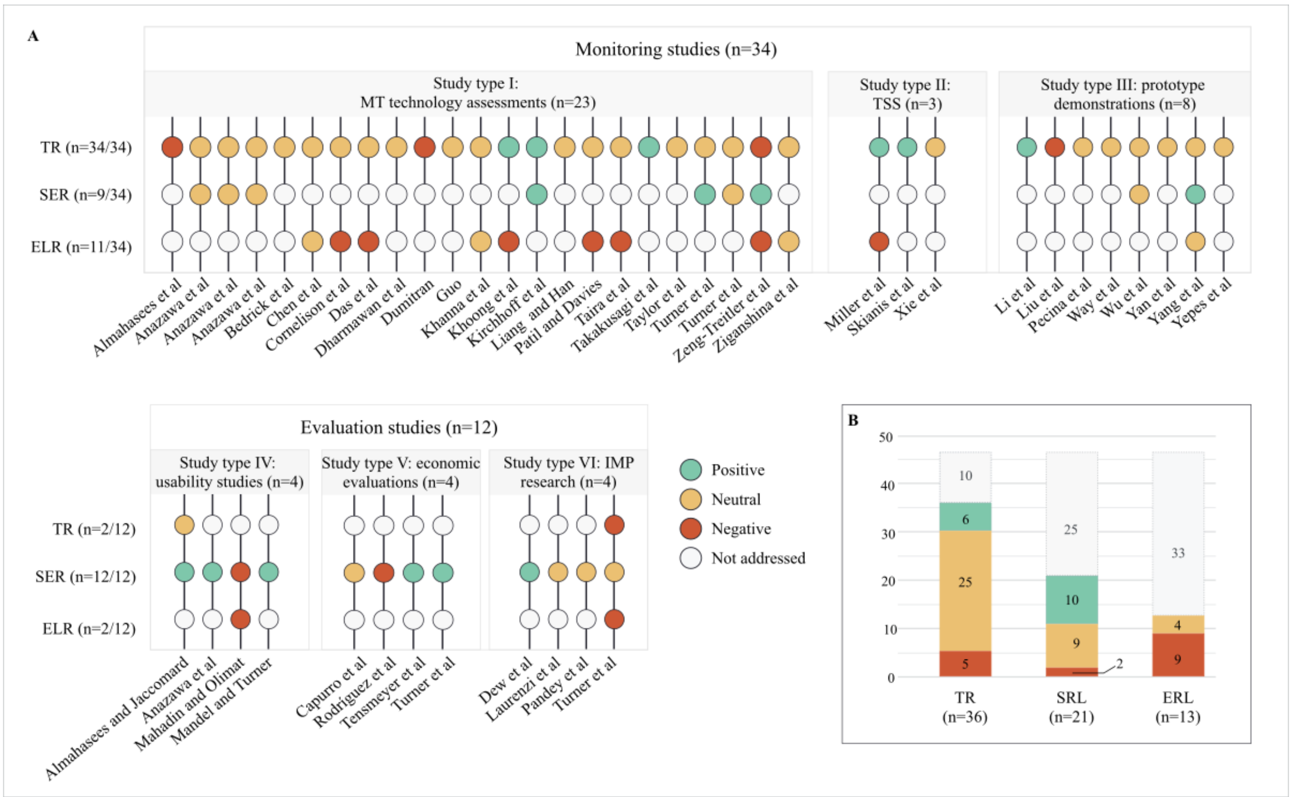
In their experiments, some of the studies (4/34, 12%) [29,43,59,81] extracted sentences from global PH (2/4, 50%) [43,81] and local PH promotion documents (2/4, 50%) [29,59]. Others (7/34, 21%) [48,51,58,61,66,68,72] carried out their experiments with general patient care instructions (2/7, 29%) [66,68], with side effects lists and directions for the use of prescribed drugs (3/7, 43%) [48,51,61], and from free-text or commonly used sentences in discharge instructions (2/7, 29%) [58,72]. A few of the articles (5/34, 15%) [44-47,54] used sentences from nursing abstracts (4/5, 80%) [44-47] and technical glossaries and dictionaries (1/5, 20%) [54]. Most of these experiments (27/34, 79%) [29,43-46,48,50-52, 54-59,61,63,66,68,74,77,80-82,85,86] recruited participants among PH professionals and certified translators with high proficiency in target and source languages or some experience with PH vocabulary. In general, discussions on ethical issues and quality inefficiencies across different languages did not address the impact of MT on possible information divides.

The evaluation studies deployed qualitative research instruments to understand how different types of end users view the adoption of MT technology in their information communication processes. Along with semistructured interviews, cognitive workflow analyses were used to understand current practices and the actual use of MT for multilingual document production workflows by PH departments. In addition, many of the studies (8/12, 67%) [42,47,49,53,64,65,67,78] used structured questionnaires and semistructured interviews to assess the perceived usefulness of MT (4/8, 50%) [42,47,64,67] and attitudes toward its adoption (4/8, 50%) [49,53,65,78] in such cases. Some of the articles (3/12, 25%) [53,60,76] sought to determine the practicality of implementing MT in combination with postediting efforts into local PH department workflows by timing and measuring the translation error rate of different translation procedures. Of the 12 studies, 4 (33%) [47,60,65,78] interviewed PH personnel and experts, and 2 (17%) [49,70] analyzed the availability of languages in PH web pages. Only 1 (8%) [42] of the 12 studies surveyed individuals in a real-world setting (ie, Facebook posts) to understand intelligibility or comprehension problems produced by MT in daily life situations on the web.

Technical, Socioeconomic, and Ethicolegal Readiness Levels

A total of 70 statements were identified as principal findings in the discussion and conclusions sections within the 46 articles (Multimedia Appendix 7 [29,42-86]). The majority (36/46, 78%) of the articles under review [29,42-46,48, 50-52,54-59,61-63,66,68,69,71-74,76,77,79-84,86] drew conclusions regarding the level of technical readiness of MT, nearly half (21/46, 46%) [29,42,44-47,49,53,59,60, 64,65,67,70,75-78,80,83,85] considered MT's socioeconomic readiness, and more than a quarter (13/46, 28%) [50-52,57,58,64,66,68,72,76,83,85,86] discussed the ethicolegal readiness of the translation outcomes for PH operations. Overall, one-fifth (16/70, 23%) of the statements within the articles expressed optimism about the use of MT for PH purposes [29,42,47,53,58,59,61,65,66,71,73,75,78,83,85], whereas another one-fifth (16/70, 23%) was pessimistic [43,51,52,55,58,63,64,66,68,70,72,76,85], and the remainder (38/70, 54%) presented mixed or inconclusive results [29,42,44-52,54,56,57,60,62,67-69,72,74,76,77,79-84,86]. Optimistic, pessimistic, and neutral statements are accounted for by green, red, and yellow circles, respectively, in Figure 3 [29,42-86].

Figure 3. Appraisal of study results. (A) Positive, negative, and mixed findings on the use of machine translation (MT) in public health settings by type of study and technology readiness dimensions. (B) Aggregate of final statements (N=70) by technological readiness levels across the 46 selected articles. IMP: implementation research; ELR: ethicolegal readiness; SER: socioeconomic readiness; TR: technical readiness; TSS: technology stability standards.



Concerning final statements on the technical readiness of MT, three-quarters (25/36, 69%) [29,42,44-46,48,50-52,54,56,57,62,68,69,72,74,77,79-84,86] of the articles were inconclusive and expressed cautionary optimism for translating PH material. Some of these articles (5/25, 20%) [29,62,74,77,86] recommended using a combination of MT and postediting efforts to improve translation quality and productivity. Of the 25 articles, 2 (8%) [61,62] also recommended using pre-editing efforts, such as controlled language and vocabularies, to reduce the need for postediting efforts. Articles addressing the socioeconomic readiness of automatic translations (21/46, 46%) [29,42,44-47,49,53,59,60,64,65,67,70,75-78,80,83,85] concluded either with optimistic (10/21, 48%) [29,42,47,53,59,65,75,78,83,85] or mixed results (9/21, 43%) [44-46,49,60,67,76,77,80], whereas a couple presented pessimistic results (2/21, 10%) [64,70]. On the one hand, these articles confirmed the enthusiasm of PH workers to adopt MT to increase cost-effectiveness as well as provide diverse material to wider audiences. On the other hand, they also stressed the importance of preparing the workforce to use the technology and ensuring that standard processes are created in light of PH equity goals. Regarding ethical and legal readiness, none of the articles mentioning the topics (n=13) concluded with optimistic statements; the findings were mostly negative (9/13, 69%) [51,52,58,64,66,68,72,76,85] and a few were mixed (4/13, 31%) [50,57,83,86]. In general, the articles stressed that the technology represents noteworthy communication risks, namely owing to a varying translation accuracy across languages. A few studies (4/13, 31%) [52,66,72,86] also pointed out that the commercial vendors' algorithms are not verifiable by the researchers or staff, resulting in a loss of control when not combined with editing efforts.

Discussion

Principal Findings

In our scoping review, we sought to systematically identify and map existing peer-reviewed literature on the use of MT for population-based outreach, with a particular interest in its use for recruiting participants for PH and epidemiological research. None of the included articles (n=46), published between 2009 and 2023, tested MT for recruiting participants to population-based studies or in scenarios where a response from addressees is expected. Research on the use of MT for PH activities is still in its early stages, primarily concentrating on assessing the technical readiness for one-way written communication between PH officials and addressed audiences. The majority of information transmitters (ie, the end users of MT) were PH professionals in PH departments and research, clinical and hospital staff, or staff at international and national health organizations. PH materials translated with MT were predominantly official guidelines and educational resources, simplified medical information, or PH promotional material. The intended target audiences (ie, the receivers of translated material) were the wider population (both offline and seeking information on the world wide web), patient groups, or professionals in PH and clinical settings. Nearly three-quarters (34/46, 74%) of the articles reported monitoring studies, with the remaining quarter (12/46, 26%) reporting evaluation studies.

Research on the Use of MT for PH Activities Is Still Nascent

The current focus of research is mostly concentrated on understanding the extent to which machine-translated output is reliable and stable enough for translating specific sample texts, while placing less emphasis on the feasibility of its use in real-world settings. Published study types mostly provided technical maturity assessments of MT (eg, in exploratory research, experimental proofs of concept, and implementation research studies).

The majority of the studies (28/46, 61%) [29,43,45,46,48,50-52,54-58,61,63,68,69,72-74,77,79-84,86] solely focused on MT accuracy errors and how to drive error rates down. Most of the articles (23/46, 50%) [29,43-46,48,50-52,54-59,62,68,72-74,77,85,86] provided technical assessments, and in most of the cases (14/23, 61%) [29,43-46,48,54-56,59,62,73,74,77], they studied neither the reliability of the technology for specific target audiences nor the potential risks of mistranslation. Although articles often specified the type of MT algorithm as either statistical MT or neural MT (Multimedia Appendix 5), none systematically compared the algorithms or reported on specific advantages or disadvantages. Therefore, it is not clear whether the type of algorithm has any relevance for using MT in PH scenarios.

A handful of studies (9/46, 20%) [61,63,69,71,76,79,80,82,84] reported ongoing research in the development of in-house software, pretrained on specific vocabulary. These systems were reported to outperform off-the-shelf models (eg, Google Translate and DeepL Translator), namely when translating shorter text with specialized terminologies, such as those used in medical guidelines or prescriptions. The fact that the technology is evolving and can now be trained in PH and biomedical vocabulary sheds light on future possibilities to meet the needs of staff working with more complex PH material. However, the current state of evaluations on the advantages and disadvantages of the off-the-shelf systems over internally developed models does not yet allow PH researchers to model the best use of both systems during specific stages of material production. Provided that PH material does not heavily rely on domain-specific vocabulary, off-the-shelf MT solutions are sufficiently reliable in terms of translating shorter text. Given that these systems are predominantly free to use and easily adaptable to a translation workflow, proprietary models are relatively costly to develop and maintain, as well as scale to new vocabularies.

The literature tends to focus on evaluating the accuracy of supervised translations from the language of the working staff or researchers (typically English) to 1 or a few languages (in most cases, Spanish, Chinese, or French). The observed inclination to study English as a source can be attributed to the origin of the selected articles in this review. For most of the studies (19/46, 41%) [29,50-52,56,57,59-63,66,69,72,74,77,79,80,85], the target audiences of interest were large linguistically diverse communities residing in predominantly English-speaking countries (eg, the United States, the United Kingdom, and Australia). Future studies could also aim to cover underrepresented languages beyond that of the largest linguistically diverse groups and continue exploring cases to support linguistically diverse PH staff. For now, a few of these studies (6/46, 13%) [29,59,66,74,77,86] tested MT in light of postediting efforts. As user-friendly MT applications become more accessible to the public and professionals, we can reasonably assume that the focus of MT research in PH might shift from generating texts with MT to generating texts that are optimized for MT, that is, the emphasis might shift from technical accuracy and postediting efforts to pre-editing of texts.

A limited number of articles (21/46, 46%) [29,42,44-47,49,53,59,60,64,65,67,70,75-78,80,83,85] investigated the societal acceptance of MT, mainly by surveying the attitudes of PH staff toward its adoption, formulating new concepts, and studying current practices and standards. The selected studies point to the conclusion that PH staff are enthusiastic and open to adopting MT in their workflows. Almost half (10/21, 48%) of the studies held positive attitudes toward the potential cost-effectiveness of using MT to increase public access to PH information. However, the technology has not been routinely adopted by PH departments owing to safety concerns, the loss of control over content, and the unquantified variability of the quality of translation between languages. There is a need to further identify relevant stakeholders for implementing and deploying MT, as well as to test proposed solutions in controlled environments with the end users of translated material.

Most of the experiments (31/46, 67%) were based on expert focus groups and surveying PH professionals, whereas only a few (3/46, 7%) explored end-user interactions, preferences, and perspectives in real-world settings. However, without real-world studies conducted outside laboratory settings and in field experiments, the user experience of the technology remains largely unknown. Only a few studies (8/46, 17%) [42,47,49,53,64,65,67,78] tested the usability and acceptability of MT in community settings. Future studies could explore, for example, end-user interactions with machine-translated text in daily life settings, while also continuing to survey PH professionals in digital environments and capturing their attitudes toward use and adoption, as well as measuring the actual information uptake by groups targeted with machine-translated materials compared with nontranslated materials alone.

Moreover, no article focused solely on the legal or ethical aspects of the use of MT for PH purposes. However, some of the studies (13/46, 28%) [50-52,57,58,64,66,68,72,76,83,85,86] did provide a generic consideration of ethical compliance aspects as part of their discussions. To the extent that these concerns were addressed, 2 (4%) of the 46 studies called attention to the fact that the commercial vendors' algorithms are not transparent to researchers and staff. Investigating MT from an ethical perspective, such as its impact on the digital divide, and establishing standards for its adoption also remain pending in light of PH equity goals and the risk of harmful errors.

No Current Research on MT in Two-Way Communication Scenarios

None of the reviewed studies specifically tested MT for the recruitment of participants in population-based research. The literature only covers the use of MT for communicating in PH settings that do not warrant a response from addressees. Most of the studies (27/46, 59%) [29,42,43,49-53,57-60,62,64-67,70,72,75-80,82,83] focused on the use of MT for translating simple text in flyers, instructions, and general information sheets from 1 language into a selected few. Hardly any of the articles (44/46, 96%) [29,42-74,80-86] discussed cases where the technology was used to communicate with several linguistically diverse populations at once. Only 2 (4%) [75,79] of the 46 studies introduced the use of MT for emergency preparedness and outreach prompted by the COVID-19 pandemic. These cases remain examples of unidirectional communication between PH staff and addressed audiences who are not expected to provide a response in return.

One possible reason why MT has not been used for recruitment in population-based research may be that there is limited utility in providing translations of PH material into languages that are not spoken or read by researchers or field staff or in recruiting participants who cannot interact with the languages in which the study is offered. On the contrary, if studies are offered in multiple languages, they are usually prepared with research instruments and personnel pre-equipped with the skills to meet the language diversity of the study population. It is therefore rather unlikely that MT would be necessary for translating recruitment materials in the first place.

However, there are scenarios in which MT may prove beneficial in population-based recruitment; for example, in studies on children and adolescents, the actual study participants often speak the language of the country fluently, but their legal guardians, who have to consent to their children's participation, might not be proficient in the language. Providing them with study information and consent forms in their preferred language might help them to understand what is asked from them and their children and, therefore, increase the probability that they will provide consent. However, for such purposes, ensuring a certain translation quality is crucial to meet ethical and legal requirements, but, as mentioned before, this review did not find much evidence of research regarding this problem.

Furthermore, providing multilingual invitations could also help PH employees to understand the demand for different languages at the population level. If addressees could be enabled to report their preferred languages back to PH staff, the collected data might be used to adapt ongoing or future studies to provide additional language support. Alternatively, addressees could be informed that participation is possible, contingent on being accompanied by a translator.

Finally, even if it is not possible to add each language preferred by potential study participants, using MT tools for PH study invitations would ensure that more addressees understand the content of the invitation letters, which, given their official appearance, might otherwise leave them uncertain regarding missing out on something important or even undermine trust in PH departments and reduce participation in future studies or initiatives.

Limitations

Our findings should be considered with limitations. First, this review is limited to publications addressing the use of MT either as part of the research question or as a key point of discussion in the publications. It cannot be ruled out that MT might already be used as a routine tool, and therefore, its use is not reported in peer-reviewed papers. Second, we used an interpretative sentiment analysis to classify the principal findings for each article based on the extraction of selected statements. This exercise, although systematic and with the intention of objectivity, is prone to the authors' interpretation of enthusiasm regarding the specific dimensions of digital technology maturity. Finally, the search was limited to articles published only in English, which might bias the results toward studies examining MT from or into English. There is also a possibility that articles published before 2007 could contain information relevant to the research question. However, because the technology has evolved exponentially in the last 2 decades, prior information is likely to be outdated and no longer applicable to current standards.

Conclusions

Using MT in epidemiology and PH can enhance outreach to linguistically diverse populations. The translation quality of current off-the-shelf systems, such as Google Translate or DeepL Translator, is sufficient if postediting is a mandatory step in the translation workflow. Postediting of legally or ethically sensitive material requires staff with adequate content knowledge in addition to sufficient language skills. When preparing texts for translation, it is advisable to use shorter sentences and specifically mark domain-specific vocabulary for possible postediting. Unsupervised MT is generally not recommended. Research on whether machine-translated texts are received differently by addressees is lacking, as well as research on MT in communication scenarios that warrant a response from the addressees.

Acknowledgments

The authors gratefully acknowledge Lara Christianson's counsel and her contribution to refining the search strategy, as well as Sara E. Cooper's final proofreading and language editing. This study was partially supported by Leibniz ScienceCampus Bremen Digital Public Health [87], which is jointly funded by the Leibniz Association (W4/2018), the federal state of Bremen, and the Leibniz Institute for Prevention Research and Epidemiology–BIPS. The funding source had no role in the design, data collection, data analysis, or decision to submit the manuscript for publication.

Data Availability

The complete list of included studies and all data generated or analyzed during this study are included in this published article and the multimedia appendices.

Authors' Contributions

PSH-E and SR conceptualized and guided the research project, established methodology, conducted the literature search, and contributed to the data interpretation. PSH-E curated and analyzed the data and designed and visualized the figures. PSH-E wrote the original draft of the manuscript. PSH-E and SR revised and edited the manuscript. SR was in charge of supervision and the initial funding acquisition. Both authors reviewed and validated the results and approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The global burden of lung cancer (LC) is increasing. Quantitative projections of the future LC burden in different world regions could help optimize the allocation of resources and provide a benchmark for evaluating LC prevention and control interventions.

Objective: We aimed to predict the future incidence of LC in 40 countries by 2035, with an emphasis on country- and sex-specific disparities.

Methods: Data on LC incidence from 1978 to 2012 were extracted from 126 cancer registries of 40 countries in *Cancer Incidence in Five Continents Volumes V-XI* and used for the projection. Age-standardized incidence rates (ASRs) per 100,000 person-years and the number of incident cases were predicted through 2035, using the NORDPRED age-period-cohort model.

Results: Global ASRs of the 40 studied countries were predicted to decrease by 23% (8.2/35.8) among males, from 35.8 per 100,000 person-years in 2010 to 27.6 in 2035, and increase by 2% (0.3/16.8) among females, from 16.8 in 2010 to 17.1 in 2035. The ASRs of LC among females are projected to continue increasing dramatically in most countries by 2035, with peaks after the 2020s in most European, Eastern Asian, and Oceanian countries, whereas the ASRs among males will continue to decline in almost all countries. The ASRs among females are predicted to almost reach those among males in Ireland, Norway, the United Kingdom, the Netherlands, Canada, the United States, and New Zealand in 2025 and in Slovenia in 2035 and even surpass those among males in Denmark in 2020 and in Brazil and Colombia in 2025. In 2035, the highest ASRs are projected to occur among males in Belarus (49.3) and among females in Denmark (36.8). The number of new cases in 40 countries is predicted to increase by 65.32% (858,000/1,314,000), from 1.31 million in 2010 to 2.17 million in 2035. China will have the largest number of new cases.

Conclusions: LC incidence is expected to continue to increase through 2035 in most countries, making LC a major public health challenge worldwide. The ongoing transition in the epidemiology of LC highlights the need for resource redistribution and improved LC control measures to reduce future LC burden worldwide.

KEYWORDS

lung cancer; incidence; projections; temporal trends; worldwide

Introduction

Background

Globally, lung cancer (LC) represents the first and third most commonly diagnosed cancer among males and females in 2020, respectively [1]. In 2020, an estimated 2.2 million new LC cases occurred worldwide, representing 14.3% (1.4 million) and 8.4% (0.8 million) of all new cancer diagnoses among males and females, respectively [1]. LC incidence rates have been steadily decreasing among males in most high-income countries (eg, European and Oceanian countries) in recent decades, whereas they have been rapidly increasing among females [2-4].

Research Significance

However, the global LC burden continues to increase owing to population growth, population aging, and changes in the prevalence of risk factors (eg, smoking and air pollution), which will further exert tremendous strain on populations and health systems worldwide [2-4]. Quantitative projections of the future LC burden in different world regions, in terms of expected number of new cases and incidence rates in both absolute size and trends, can help optimize the allocation of resources for screening, diagnosis, and therapy and provide a benchmark for evaluating LC prevention and control interventions worldwide, with the aim of reducing the LC burden and promoting health equity [5].

Objective

Historical LC incidence trends have been comprehensively evaluated worldwide [2-4,6]. However, to our knowledge, no previous study has predicted the future burden of LC incidence on a global scale. We aimed to quantify the future LC incidence in 40 countries by 2035 using long-standing and high-quality population-based data, with an emphasis on country- and sex-specific disparities.

Methods

Data Sources

Data on LC incidence (International Classification of Diseases 10th Revision C33-34) stratified by a 5-year period of diagnosis (1978-1982, ... , 2008-2012), sex, and 5-year age group were extracted from national and regional population-based cancer registries available in *Cancer Incidence in Five Continents* volumes V to XI [7,8]. The specific requirements for the inclusion of a registry were at least 15 consecutive years of data and compilation in the latest volume (XI) of the *Cancer Incidence in Five Continents* series [2,9,10]. These criteria are indicative of each registry's data quality over time, given that the editorial process involves a detailed assessment of the comparability, completeness, and validity of the incidence data [2,9,10]. A total of 126 cancer registries from 40 countries in 10 world regions (Northern Europe, Western Europe, Southern Europe, Central and Eastern Europe, North America, Central and South America, Eastern Asia, Southeastern Asia, Southwestern Asia, and Oceania) were included. Of these, 19 countries contributed national data for the analysis (Denmark, Estonia, Iceland, Ireland, Lithuania, Norway, Austria, the Netherlands, Croatia, Cyprus, Malta, Slovenia, Belarus, Bulgaria, the Czech Republic, Slovakia, Costa Rica, Israel, and New Zealand). For the remaining 21 countries (the United Kingdom, France, Germany, Switzerland, Italy, Spain, Poland, Canada, the United States, Brazil, Chile, Colombia, Ecuador, China, Japan, Republic of Korea, Philippines, Thailand, India, Turkey, and Australia), data from multiple regional registries in a given country were aggregated to obtain a proxy for the national incidence. Population predictions (medium-fertility variant) were obtained from the United Nations World Population Prospects 2022 Revision up to 2035 by country, year, sex, and age [11].

Statistical Analysis

Incidence rates per 5-year period of diagnosis and 5-year age group by sex were calculated based on the corresponding incident cases and population data from population-based cancer registries. Age-standardized incidence rates (ASRs) per 100,000 person-years were calculated based on the world standard population [12]. The number of cases by age group at the national scale were estimated by applying regional age-specific incidence rates to the national populations [9,10]. Lifetime cumulative risks were calculated for those aged 0 to 74 years and are expressed as percentages, which can be interpreted as the probability that an individual will develop LC before the age of 75 years in the absence of competing causes of death [13].

In this study, the well-known NORDPRED age-period-cohort model [9,10,14,15] was used to predict the number of new LC cases and incidence rates from 2013 to 2017 to 2033 to 2037 by country, sex, and age. Let us assume that, conditional on rates, the number of incident LC cases follows a Poisson distribution:

Where y_{ap} and n_{ap} represent the number of incident cases and person-years at risk, respectively, in the age group a=0−4, ... , 85+ and in the period P=1978-1982, ... , 2008-2012.

Then, the NORDPRED age-period-cohort model using a power-5 link function is defined as follows:

In this expression, A_a is the age component of age group a; D is the common linear drift parameter of both calendar period p and birth cohort c; is the nonlinear period component of period ; and is the nonlinear cohort component of cohort c. Birth cohort c was extracted by subtracting the midpoint of the 5-year age group a from the corresponding midpoint of the 5-year calendar period P [2]. The 3 to 7 recent 5-year observed periods (depending on data availability) were extrapolated using a power-5 link function to level off growth, with a projection of drift parameter *D* that was attenuated by 25%, 50%, 75%, and 75% in the second, third, fourth, and fifth prediction periods, respectively [14]. Furthermore, we assessed the prediction performance of the NORDPRED age-period-cohort model, with detailed information and the corresponding findings presented in Multimedia Appendix 1 [15-20].

The projected number of new cases in 2035 were calculated by applying the predicted age-specific rates for 2033 to 2037 using the United Nations national population forecasts for 2035 for each country [14]. Mean annual differences in the number of predicted cases in 2035 (the midpoint of calendar period 2033-2037) relative to 2010 (the midpoint of calendar period 2008-2012) are partitioned into changes in risk (rates) and changes in demographics (population size and age structure) [15]; the detailed information is presented in Multimedia Appendix 1. The number of predicted cases and ASR in 2035 are presented and compared with those in 2010. A percentage change of ≥5% was defined as an increase or decrease; otherwise, the number and rates were considered stable [21]. Throughout the paper, the number of cases has been rounded to avoid spurious precision. In some cases, this creates small discrepancies with the displayed totals and percentages, which are based on the data before rounding.

Data management and modeling analyses were performed using R software (version 4.0.2; R Foundation for Statistical Computing) [22] and the NORDPRED package.

Ethical Considerations

This study does not involve human participants and animal subjects. Ethics approval was not required for this study as the study used existing nonidentifiable data that were aggregated and population level.

Results

Changes in LC Incidence Rates: 2010 to 2035

Global ASRs of the 40 studied countries are predicted to decrease by 23% (8.2/35.8) among males, from 35.8 per 100,000 person-years in 2010 to 27.6 in 2035, and increase by 2% (0.3/16.8) among females, from 16.8 in 2010 to 17.1 in 2035. Among the 40 studied countries, the ASRs are predicted to decline among males in 37 countries and among females in 17 countries between 2010 and 2035 (Figures 1-3; Multimedia Appendices 2 and 3). The largest decreases in ASRs are projected in the Philippines (−21.5/36.9, −58%; ASR 36.9 per 100,000 person-years in 2010 vs 15.4 in 2035), Colombia (−7.7/13.9, −55%; 13.9 vs 6.2), and Slovenia (−25.3/48.2, −53%; 48.2 vs 22.9) among males and in the Philippines (−5.3/12.2, −44%; 12.2 vs 6.9), Israel (−5/11.4, −43%; 11.4 vs 6.4), and Turkey (−3.3/8.1, −40%; 8.1 vs 4.8) among females. For each region, the largest reductions in ASRs are projected in Estonia (−26.3/57, −46%; ASR 57.0 per 100,000 person-years in 2010 vs 30.7 in 2035) for males and in Iceland (−9.2/33.0, −28%; 33.0 vs 23.8) for females in Northern Europe; in Switzerland for both sexes (−13.5/37.2, −36%; 37.2 vs 23.7 for males; −2.4/20.4, −12%; 20.4 vs 18.0 for females) in Western Europe; in Slovenia (−25.3/48.2, −53%; 48.2 vs 22.9) for males in Southern Europe; in the Czech Republic (−25.7/51.2, −50%; 51.2 vs 25.5) for males and in Poland (−2.7/13.4, −20%; 13.4 vs 10.7) for females in Central and Eastern Europe; in the United States for both males (−13.7/39.4, −35% 39.4 vs 25.7) and females (−10.6/30.2, −35%; 30.2 vs 19.6) in North America; in Colombia (−7.7/13.9, −55%; 13.9 vs 6.2) for males and in Costa Rica (−1.0/4.3, −24%; 4.3 vs 3.3) for females in Central and South America; in the Republic of Korea (−8.0/42.8, −19%; 42.8 vs 34.8) for males in Eastern Asia; in the Philippines for both sexes (−21.5/36.9, −58%; 36.9 vs 15.4 for males; −5.3/12.2, −44%; 12.2 vs 6.9 for females) in Southeastern Asia; in Turkey (−33.0/69.3, −48%; 69.3 vs 36.3) for males and in Israel (−5.0/11.4, −43%; 11.4 vs 6.4) for females in Southwestern Asia; and in New Zealand for both sexes (−6.8/29.5, −23%; 29.5 vs 22.7 for males; −3.4/24.2, −14%; 24.2 vs 20.8 for females) in Oceania.

However, the ASRs will increase in 2 countries for males and in 20 countries for females from 2010 to 2035.

Among males, percentage increases in ASRs are predicted in Cyprus (14.6/33.4, 44%; ASR 33.4 per 100,000 person-years in 2010 vs 48.0 in 2035) and Ecuador (0.7/8.0, 9%; 8.0 vs 8.7). among females, the largest increases in ASRs were predicted in Estonia (7.3/10.7, 68%; ASR 10.7 per 100,000 person-years in 2010 vs 18.0 in 2035), Malta (6.5/10.9, 60%; 10.9 vs 17.4), and Cyprus (4.8/8.7, 54%; 8.7 vs 13.5). As for each region, the steepest increases in ASRs are predicted in Estonia (7.3/10.7, 68%; ASR 10.7 per 100,000 person-years in 2010 vs 18.0 in 2035) in Northern Europe; France (3.3/15.8, 20%; 15.8 vs 19.1) in Western Europe; Malta (6.5/10.9, 60%; 10.9 vs 17.4) in Southern Europe; Slovakia (4.8/13.1, 37%; 13.1 vs 17.9) in Central and Eastern Europe; Chile (1.6/4.7, 33%; 4.7 vs 6.3) in Central and South America; Japan (6.5/16.8, 38%; 16.8 vs 23.3) in Eastern Asia; and India (0.8/4.1, 19%; 4.1 vs 4.9) in Southwestern Asia. The ASRs among females are predicted to peak after the 2020s in 27 countries (most European, Eastern Asian, and Oceanian countries), whereas those among males have already peaked in the historical period in almost all countries (except for Cyprus, Ecuador, and Japan).

Although the ASRs among males have been historically higher than those among females in all countries (except for Iceland), the sex gaps are gradually narrowing (Figures 4 and 5). The male to female ASR ratios are projected to decline in 33 countries from 2010 to 2035. The largest reductions in male to female ratios are predicted for Estonia (−3.6/5.3, −68%; sex ratio 5.3 in 2010 vs 1.7 in 2035), Brazil (−1.1/1.8, −62%; 1.8 vs 0.7), Slovenia (−1.6/2.8, −58%; 2.8 vs 1.2), Spain (−2.2/4.4, −50%; 4.4 vs 2.2), and Slovakia (−2.0/4.1, 48%; 4.1 vs 2.1). ASRs among females are predicted to almost reach those among males in Ireland, Norway, the United Kingdom, the Netherlands, Canada, the United States, and New Zealand in 2025; in Slovenia in 2035; and even surpass those among males in Denmark in 2020 and in Brazil and Colombia in 2025.

In 2035, LC incidence is projected to vary 8-fold among males and 10-fold among females across countries (Figure 3; Multimedia Appendices 2 and 3). The highest ASRs were projected in Belarus (49.3 per 100,000 person-years), Cyprus (48.0), Japan (45.3), France (42.0), and Bulgaria (40.1) among males and in Denmark (32.9), the Netherlands (28.7), the United Kingdom (28.0), Ireland (27.1), and China (24.7) among females. The male to female ratio is projected to vary 11-fold across countries, ranging from 0.7 in Brazil to 7.5 in Turkey.

Figure 1. Trends in age-standardized (world) incidence rates of lung cancer in European countries, 1980 to 2035: observed rates (solid line) and projected rates (dashed line). The blue line stands for males, and the red line stands for females. Age-standardized (world) rates per 100,000 person-years.

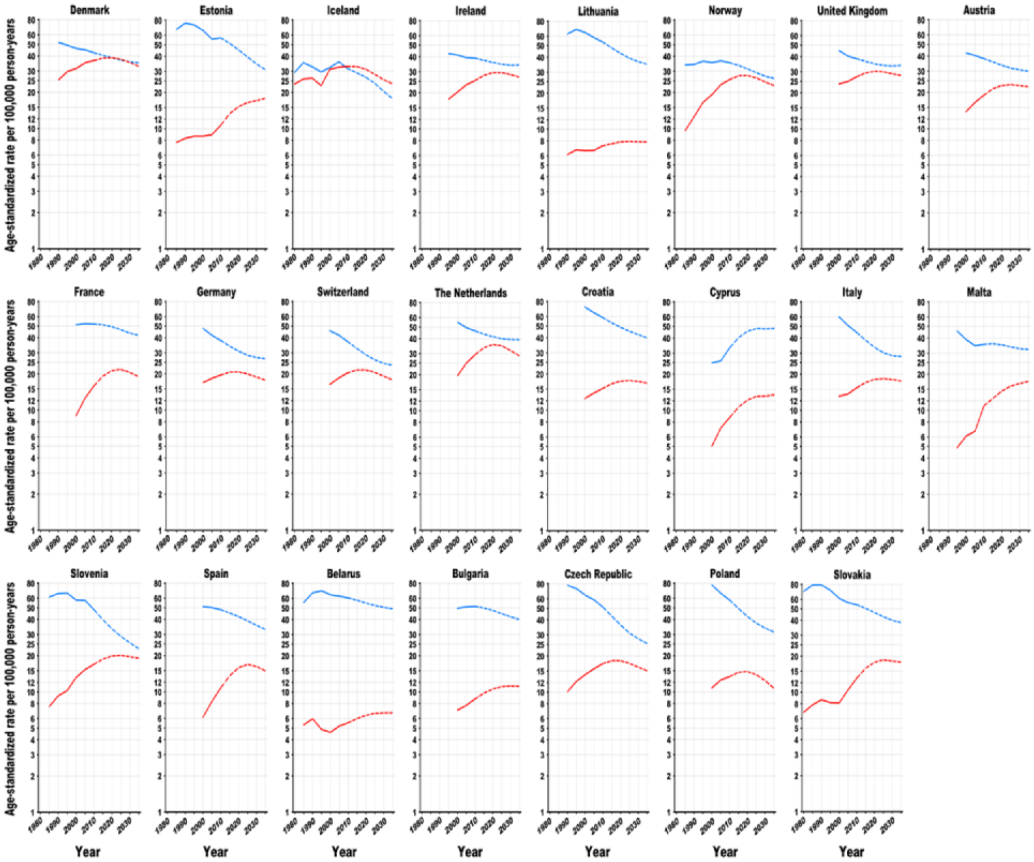

Figure 2. Trends in age-standardized (world) incidence rates of lung cancer in American, Asian, and Oceanian countries, 1980 to 2035: observed rates (solid line) and projected rates (dashed line). The blue line stands for males, and the red line stands for females. Age-standardized (world) rates per 100,000 person-years.

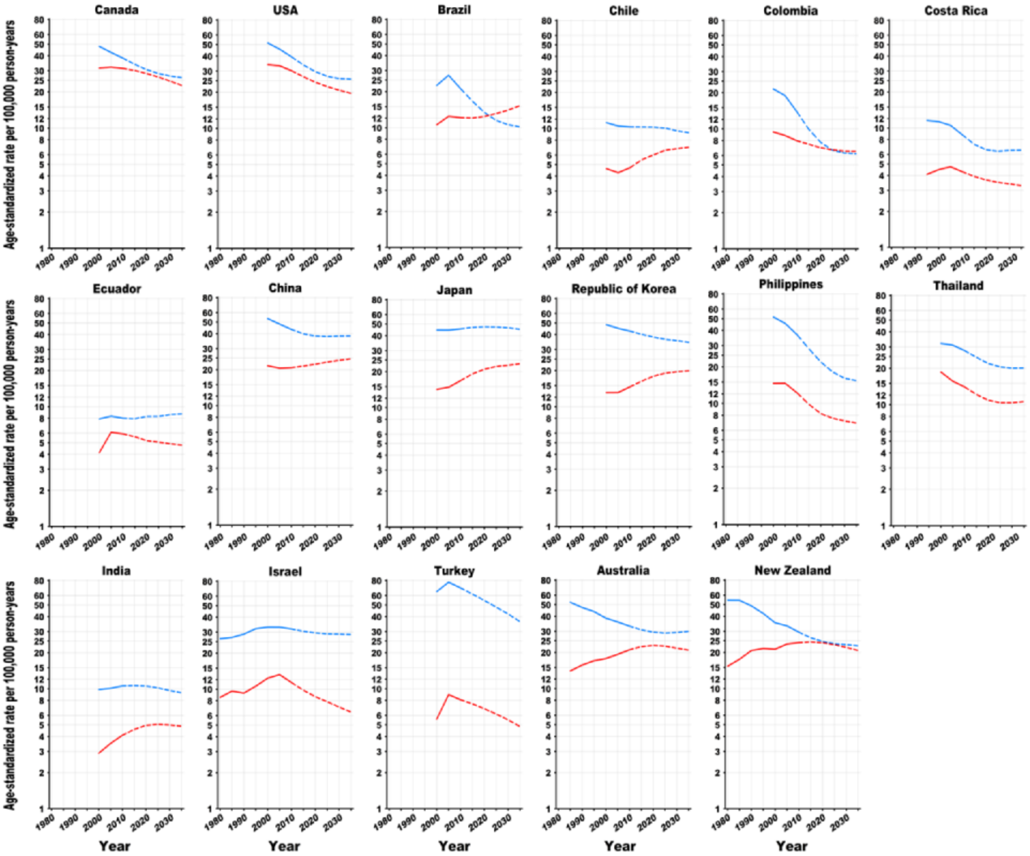

Figure 3. Lung cancer age-standardized incidence rates in 2010 and projected rates in 2035 in 40 countries. Rates for 2010 and 2035 represent average rates for the 5-year period centered on the respective year. Blue color stands for males, and red color stands for females. Age-standardized (world) rates per 100,000 person-years.

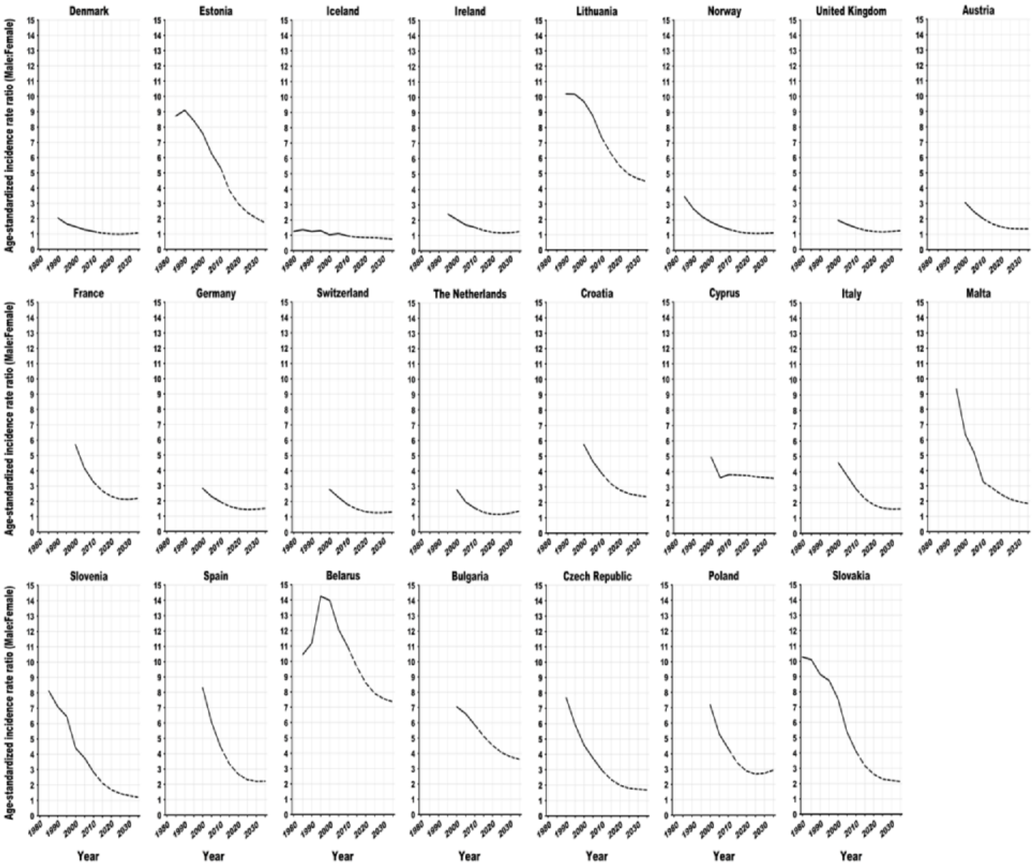

Figure 5. Trends in the male to female age-standardized (world) incidence rate ratios of lung cancer in American, Asian, and Oceanian countries, 1980 to 2035: observed rate ratios (solid line) and projected rate ratios (dashed line).

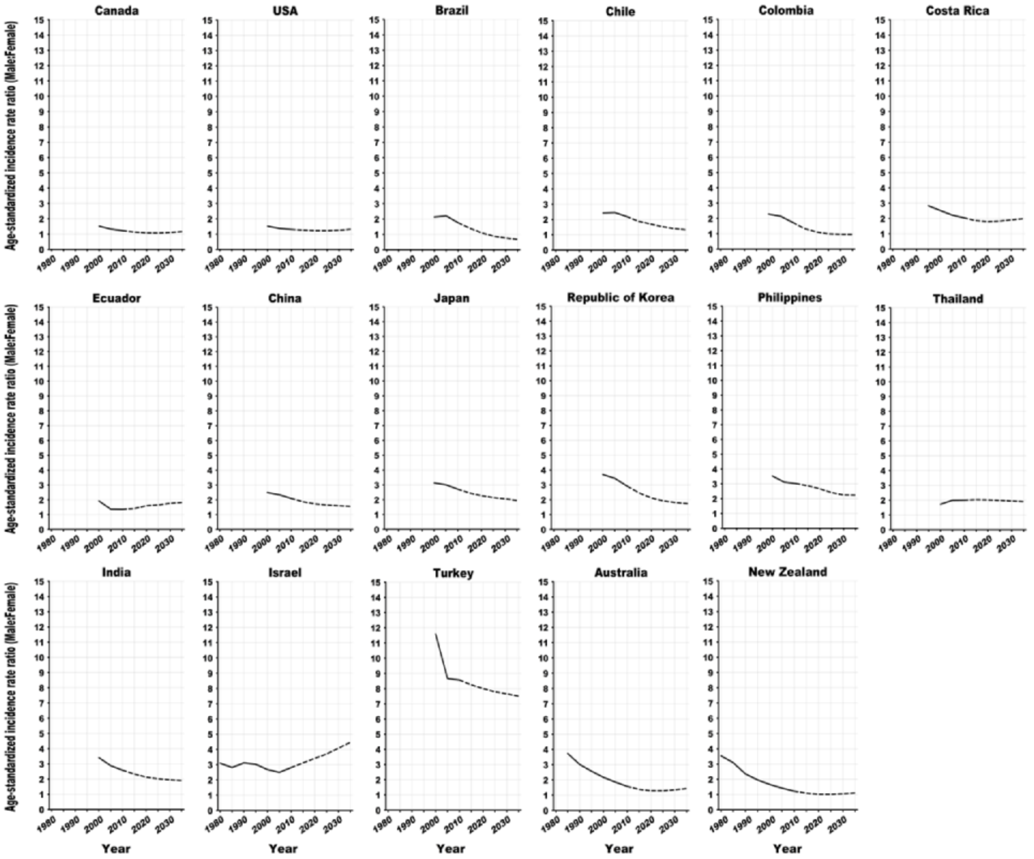

Changes in the Number of New LC Cases: 2010 to 2035

Overall, the number of new cases in the 40 included countries is predicted to increase by 50.19% (429,000/854,000), from approximately 0.85 million in 2010 to approximately 1.28 in 2035, among males and is set to nearly double, from approximately 0.46 million to approximately 0.89, among females (Multimedia Appendices 2 and 3). When stratified by geographic region, the most rapid increases were predicted in Eastern Asia (342,000/433,000, 79.00% for males and 303,000/216,000, 140.05% for females).

When analyzed by country, the number of new cases is expected to increase in 32 countries among males and in all 40 countries among females between 2010 and 2035 (Multimedia Appendices 2 and 3). The predicted increases among males in most of these 32 countries are mainly due to population growth and aging, regardless of marked decreases in LC risk, whereas those among females in most countries in Southern, Western, and Central and Eastern Europe are largely due to marked increases in LC risk (Figures 6 and 7). The most rapid increases were predicted in Cyprus (459/257, 178.3%) among males and Chile (1253/620, 202.2%) among females (Multimedia Appendices 2 and 3). In 2035, the largest number of new cases was projected in China (655,000), Japan (112,000), and the United States (105,000) among males and China (451,000), the United States (95,000), and Japan (61,000) among females.

Figure 6. Projected changes in the number of new lung cancer cases between 2010 and 2035 in 40 countries among males, partitioned into population and risk change. Numbers for 2010 and 2035 represent average numbers for the 5-year period centered on the respective year. Due to population change: projected change in the number of cases due to population growth and aging. Due to risk change: projected change in the number of cases due to changes in incidence rates. Blue color stands for population change, and red color stands for risk change.

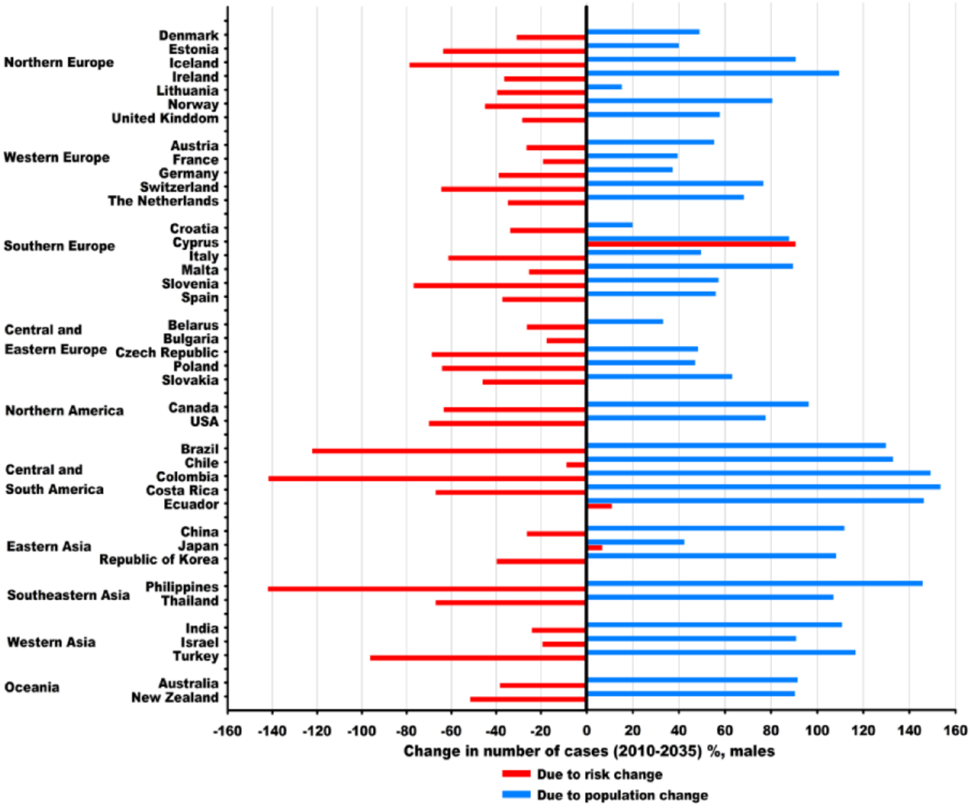

Figure 7. Projected changes in the number of new lung cancer cases between 2010 and 2035 in 40 countries among females, partitioned into population and risk change. Numbers for 2010 and 2035 represent average numbers for the 5-year period centered on the respective year. Due to population change: projected change in the number of cases due to population growth and aging. Due to risk change: projected change in the number of cases due to changes in incidence rates. Blue color stands for population change, and red color stands for risk change.

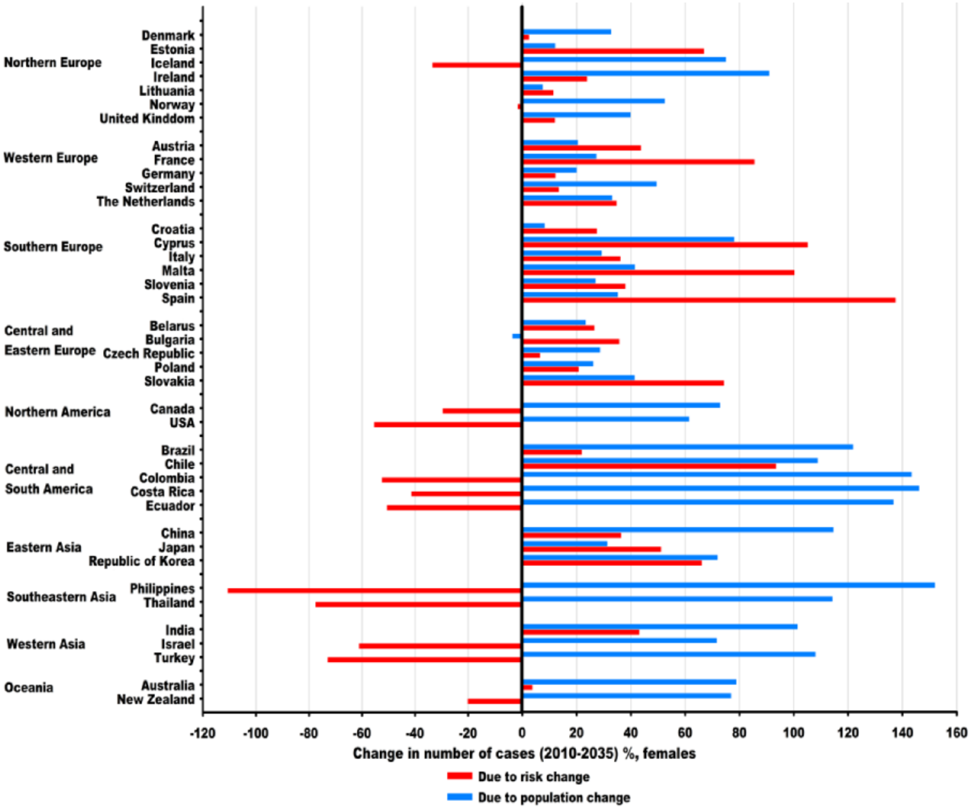
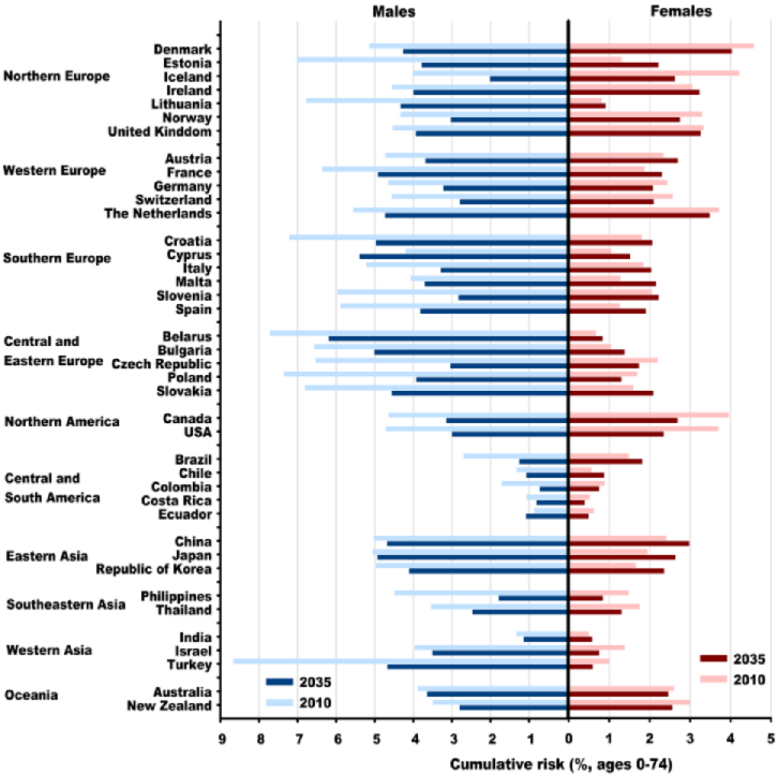


Cumulative Risk of LC Incidence in 2035

The cumulative risks among males are expected to decrease in almost all countries (except Cyprus and Ecuador) between 2010 and 2035, whereas those among females are expected to increase in 20 countries (especially in Eastern Asian and Southern European countries; Figure 8; Multimedia Appendices 2 and 3). In 2035, the highest cumulative risk among males is expected in Belarus (6.2/100, 6.2%), Cyprus (5.4/100, 5.4%), Bulgaria (5/100, 5%), Croatia (5/100, 5%), and Japan (4.9/100, 4.9%), which indicates that approximately 5 to 6 of 100 males will be diagnosed with LC before the age of 75 years in the aforementioned countries. Among females, the highest cumulative risks are expected in Denmark (4/100, 4%), the Netherlands (3.5/100, 3.5%), the United Kingdom (3.3/100, 3.3%), Ireland (3.2/100, 3.2%), and China (3/100, 3%).

Figure 8. Cumulative risk (in percent, ages 0-74 years) of lung cancer in 2010 and 2035 in 40 countries. Blue color stands for males, and red color stands for females.



Discussion

Principal Findings

In our study, the ASRs of LC among females are predicted to increase in half of the countries between 2010 and 2035, while those among males are expected to decrease in almost all studied countries. The ASRs among females are expected to peak after the 2020s in most European, Eastern Asian, and Oceanian countries and will reach and surpass those among males in 11 countries after the 2020s. In 2035, high rates are predicted to mainly occur among males in Central and Eastern European countries and among females in Northern European countries. The largest increases in the number of new cases in both sexes between 2010 and 2035 are predicted in Eastern Asia. China will have the largest number of new cases in both sexes by 2035.

Interpretation of Changes in LC Incidence Rates

Tobacco smoking is the leading risk factor for LC, with 76.2% (74.6 to 77.8) of LC-related deaths among males and 38.9% (36.7 to 40.9) of LC-related deaths among females attributed to smoking in 2019 [3]. Temporal trends in LC incidence are largely affected by smoking patterns in the past 30 to 40 years [23,24], and the future LC burden will depend on historic smoking patterns at the population level [25]. Smoking prevalence among males in most European countries (eg, the United Kingdom and Spain) peaked during the 1950s and 1960s, whereas that among females peaked in the 1980s and 1990s [23,26-32]. For example, the smoking prevalence among Spanish females increased from 5.8% in 1970 to 26.5% in 1990 and then decreased after the 2000s [23,30]; this could largely explain the predicted increase in the LC incidence rate and the peak LC rate in 2025 among females. Similarly, the lag duration of 30 to 40 years combined with the maximum smoking prevalence during the 1980s and 1990s [26,27,31,32] could indicate that LC incidence rates among females will peak after the 2020s in many European countries. In addition, a recent study showed that the smoking-attributable fractions of LC mortality among males are predicted to decline in Denmark and the Netherlands from 2009 to 2050, whereas those among females will increase until it peaks in 2028 in Denmark and 2033 in the Netherlands [33], similar to our projections of changes in LC rates from 2010 to 2035. Notably, smoking patterns in younger birth cohorts may directly indicate future LC incidence rates [32,34,35]. The predicted increase in LC incidence rates among females in most European countries could be largely explained by the cohort effect because of the increased smoking prevalence in cohorts born after the 1950s [32,36]. The predicted decreases in LC incidence rates in the United States in both sexes might largely result from changes in smoking habits in cohorts born after the 1940s, who mainly smoked low-tar and filter-tipped cigarettes [2,37,38].

Interpretation of the Discrepancy of Changes in LC Incidence Rates Between Sexes

The convergence of decreasing male and increasing female incidence rates of LC in our study could be largely explained by the changes in smoking prevalence. Globally, females started smoking later than males (the 1950s), but the smoking prevalence increased rapidly until the 1990s and then remained relatively stable [23,26-32,39]. For example, in France, tobacco smoking increased from 0.4 daily smoked cigarettes per woman in 1953 to 3.7 in 1991 and thereafter remained stable, whereas males smoked approximately 8.6 cigarettes per day in 1953 until a peak in 1980 (9.6 cigarettes per day) and declined steadily

(5.2 cigarettes per day in 2003) [39]. Notably, smoking behavior and smoking prevalence among males and females have become increasingly similar in the younger generation worldwide [40,41], indicating the convergence of decreasing male and increasing female incidence rates of LC.

Interpretation of Geographic Distributions in Predicted LC Incidence Rates and Cumulative Risks

In 2035, the incidence rates of LC are projected to vary significantly across regions for both sexes. The highest predicted rate and cumulative risk among males in Central and Eastern European countries could be largely attributable to the historically higher smoking prevalence than that of Western countries and delays in the implementation of smoking prevention and cessation measures [42-44]. LC mortality rates attributable to smoking were also estimated to be the highest in Central and Eastern European countries in 2019 [3]. Among females, the highest predicted LC rate and cumulative risk in Northern European countries could be largely explained by the historically high LC rate and the fact that smoking prevalence among females only began to decrease after the late 1980s [31,32].

Interpretation of Changes in New LC Cases

Worldwide, the reduction in LC risk among males will only partially offset the expected increase in the number of new LC cases because of population growth and aging. However, the increasing future LC burden among females will be driven by increasing LC risks, and thus mainly tobacco smoking patterns and trends, in most countries in Southern, Western, and Central and Eastern Europe. In addition, the largest number of new LC cases is predicted in China, accounting for nearly half (45%) of the total number of new cases among all studied countries in 2035, and more than half (60%) of the total increase in the number of new cases between 2010 and 2035. A recent study showed that the LC mortality rates attributed to smoking and ambient particulate matter pollution in China were estimated to be 80.8% and 20.8% among males and 23.4% and 19.7% among females in 2017, respectively [45]. China has the largest smoking population in the world, with an estimated 301 million smokers, and the smoking proportions of males and females in the Chinese population are 52.9% and 2.4% in 2010 [46]. More than half of the LC cases attributed to exposure to ambient particulate matter pollution have been reported in China and other East Asian countries [47,48]. In addition, China has experienced rapid population growth and a transition to an aging society in recent decades [49]. Thus, the substantial future burden of LC in China might largely result from the large smoking population, deteriorating air pollution, and changing demographics, and will, to some extent, hinder the realization of global noncommunicable disease control goals with a reduction of one-third in premature mortality from noncommunicable diseases by 2030 [50]. Tobacco control programs and clean air legislation should be strengthened and additional resources should be allocated to reduce the LC burden in China.

Comparison With Prior Work

The Global Cancer Observatory of the International Agency for Research on Cancer provides the future LC incidence worldwide by 2040, based on demographic projections estimated by the United Nations Development Programme and scenarios of stable rates from the baseline year 2020 [51]. However, projections of future LC incidence by 2040 in the Global Cancer Observatory did not consider changes in the incidence rates of LC. Our predictions have accounted for historical changes in LC incidence rates using the NORDPRED age-period-cohort model, which could largely reflect the real situation of LC incidence. To the best of our knowledge, this is the first study to predict the future burden of LC incidence from a global perspective based on incidence data from high-quality population-based cancer registries, enabling direct comparisons of findings between countries. The well-known modern method based on the NORDPRED age-period-cohort model was applied to provide estimates of future LC burden in our study.

Limitations

However, this study has some limitations. First, the trend-based predictions in our study might have a certain degree of uncertainty because we assumed that the historical trends in LC incidence will continue into the future in the model [5]. However, when comparing our predicted ASRs with those already observed in, for example, Australia, Norway, and the Netherlands, these figures seem fairly close (eg, observed ASR 30.7 in Australian males in 2015 [52] vs 30.9 predicted in 2015, 21.8 in Australian females [52] vs 22.4; observed ASR 31.3 in Norwegian males in 2015 [53] vs 33.6 predicted in 2015, 28.0 in Norwegian females [53] vs 27.6; and observed ASR 38.6 in Dutch males in 2019 [54] vs 41.4 predicted in 2020, 33.1 in Dutch females [54] vs 35.7); these might largely indicate the accuracy of our projections. Second, for lower-risk and small populations (eg, Malta and Cyprus), random variation might exist. Third, we were unable to predict the future LC burden in many countries in Africa, Latin America, and Asia because of the lack of high-quality data. Fourth, the aggregated data from multiple regional registries in a given country might not fully represent the national level, although this method has been applied to cover the largest geographic area in many previously published papers [2,55,56]. Figures from regional cancer registries with limited resources could be underestimated and those from registries with abundant resources could be overestimated. Caution should be exercised when interpreting these findings.

Conclusions

The LC incidence rates among females are predicted to continue increasing dramatically in most countries by 2035, with peaks after the 2020s in most European, Eastern Asian, and Oceanian countries, whereas incidence rates among males are predicted to continue declining in almost all countries. The sex difference in the worldwide incidence of LC will further narrow down in the future. Geographic variations in LC incidence rates will remain high, with the highest rate in Central and Eastern Europe among males and in Northern Europe among females. The number of new LC cases are expected to continue to increase through 2035 in most countries because of population aging and growth, as well as changes in the prevalence of risk factors, making LC a major challenge to public health worldwide. These ongoing transitions in LC epidemiology are highly relevant to future cancer control and clinical practice. Clinicians can expect to observe more cases of LC in the future. The findings highlight the need for the redistribution of resources and improved LC control measures (eg, smoking prevention and cessation programs and air quality management programs) to reduce the future LC burden worldwide.

Abstract

Background: Over 90% of patients with cancer experience 1 or more symptoms caused directly by cancer or its treatment. These symptoms negatively impact on the completion of planned treatment as well as patients' health-related quality of life (HRQoL). It often results in serious complications and even life-threatening outcomes. Thus, it has been recommended that surveillance of symptom burden should be performed and managed during cancer treatment. However, differences in symptom profiles in various patients with cancer have not been fully elucidated for use in performing surveillance in the real world.

Objective: This study aims to evaluate the burden of symptoms in patients with various types of cancers during chemotherapy or radiation therapy using the PRO-CTCAE (Patient-Reported Outcome Version of the Common Terminology Criteria for Adverse Events) and its impact on quality of life.

Methods: We performed a cross-sectional study of patients undergoing outpatient-based chemotherapy, radiation therapy, or both at the National Cancer Center at Goyang or at the Samsung Medical Center in Seoul, Korea between December 2017 and January 2018. To evaluate cancer-specific symptom burden, we developed 10 subsets for using the PRO-CTCAE-Korean. To measure HRQoL, we used the European Organization for Research and Treatment of Cancer Core Quality of Life Questionnaire Core 30 (EORTC QLQ-C30). Participants answered questions prior to their clinic appointments on tablets. Multivariable linear regression was used to analyze symptoms based on cancer type and to evaluate the association between the PRO-CTCAE items and the EORTC QLQ-C30 summary score.

Results: The mean age (SD) of the patients was 55.0 (11.9) years, and 39.94% (540/1352) were male. Overall, symptoms in the gastrointestinal category were the most dominant in all cancers. Fatigue (1034/1352, 76.48%), decreased appetite (884/1352, 65.38%), and numbness and tingling (778/1352, 57.54%) were the most frequently reported. Patients reported more local symptoms caused by a specific cancer. In terms of nonsite-specific symptoms, patients commonly reported concentration (587/1352, 43.42%), anxiety (647/1352, 47.86%), and general pain (605/1352, 44.75%). More than 50% of patients with colorectal (69/127, 54.3%), gynecologic (63/112, 56.3%), breast (252/411, 61.3%), and lung cancers (121/234, 51.7%) experienced decreased libido, whereas 67/112 (59.8%) patients with gynecologic cancer and lymphoma/myeloma reported pain during sexual intercourse. Patients with breast, gastric, and liver cancers were more likely to have the hand-foot syndrome. Worsening PRO-CTCAE scores were associated with poor HRQoL (eg, fatigue: coefficient –8.15; 95% CI –9.32 to –6.97), difficulty in achieving and maintaining erection (coefficient –8.07; 95% CI –14.52 to –1.61), poor concentration (coefficient –7.54; 95% CI –9.06 to –6.01), and dizziness (coefficient –7.24; 95% CI –8.92 to –5.55).

Conclusions: The frequency and severity of symptoms differed by cancer types. Higher symptom burden was associated with poor HRQoL, which suggests the importance of appropriate surveillance of PRO symptoms during cancer treatment. Considering patients had comprehensive symptoms, it is necessary to include a holistic approach in the symptom monitoring and management strategies based on comprehensive patient-reported outcome measurements.

KEYWORDS

surveillance; patient-reported outcome; symptoms; cancer

Introduction

Over 90% of patients with cancer experience 1 or more symptoms caused directly by cancer or its treatment [1,2]. These symptoms negatively impact on the completion of planned treatment as well as their health-related quality of life (HRQoL). It often results in serious complications and even life-threatening outcomes [3]. Thus, it has been recommended that surveillance of symptom burden should be performed and managed during cancer treatment [4].

However, barriers to symptom monitoring are medical jargon and lack of trust [5]. In addition, there have been only few reliable and valid tools for this purpose [5]. Thus, there have been growing calls for developing and implementing standardized patient-reported outcome measurements for symptom surveillance in patients with cancers for both clinical care and research purposes [6]. A major advancement in this direction is the US National Cancer Institute's PRO-CTCAE (Patient-Reported Outcome Version of the Common Terminology Criteria for Adverse Events), which comprises 124 items of 15 categories, based on 78 CTCAE toxicities considered appropriate for patient reporting [7,8]. According to a qualitative study [5], although many participants appreciated the personalized approach with symptom monitoring, they do not want to use a symptom checker that asks too many questions or that takes too long to complete. As frequent administration of the complete library of the PRO-CTCAE is impractical and burdensome, the Food and Drug Administration recommends selecting a relevant item set that can provide insights into the most important toxicities for the treatments being evaluated [9].

So far, most guidelines developed for selecting symptom measures were designed for clinical trials, and there is a lack of guidance for practitioners and for performing surveillance in the real-world clinical setting [10]. In fact, when the adverse events (AEs) were collected from the real world, new side effects related to the medication use not listed on the drug label have been reported [11]. Although a subset for practice was recently suggested based on a Delphi study with stakeholder panels [12,13], they only covered common cancers in Western countries, such as breast, lung, and colorectal cancers; further, the guidelines are limited to uncommon cancers, such as lymphoma, stomach, or liver cancers. In addition, differences in symptom profiles among various patients with cancer have not been fully elucidated for use in performing surveillance in the real world [14]. Therefore, we aimed to evaluate the burden of symptoms in patients with various types of cancers during chemotherapy or radiation therapy using the PRO-CTCAE in the real world and its impact on quality of life.

Methods

Study Population

We performed a cross-sectional study of patients undergoing outpatient-based chemotherapy, radiation therapy, or both at the National Cancer Center (NCC) at Goyang or at the Samsung Medical Center (SMC) in Seoul, Korea between December 2017 and January 2018. Eligible participants were (1) older than age 18; (2) diagnosed with cancer; (3) currently receiving chemotherapy or radiation therapy or both; and (4) those who can read, speak, and comprehend Korean. To include a more diverse sample of patients with cancer who have relatively little information about symptom burden, we aimed to recruit at least 50 patients with lymphoma, gastric, gynecologic, head and neck, and liver cancers. To simultaneously evaluate the measurement properties of all items of the PRO-CTCAE-Korean (n=124) within a single study, we aimed to recruit 1300 patients with cancer. Based on the site investigator's assessment, patients with clinically significant cognitive impairment were excluded from the study. The sampling frame was monitored to ensure that a minimum of 15% of participants had an impaired performance status (PS), defined as an Eastern Cooperative Oncology Group (ECOG) PS of 2 or higher [7].

Participants answered questions prior to their clinic appointments on tablets without assistance but could request technical assistance from the study staff if required.

Measures

For cancer-specific symptom burden surveillance, we developed 10 subsets of the PRO-CTCAE-Korean (9 for specific cancers and 1 for general purpose). The PRO-CTCAE item library has been previously translated and validated in Korean [15,16]. The PRO-CTCAE-Korean instrument has been linguistically validated for use in Korean-speaking populations [15]. In addition, the instrument has shown high construct validity (correlation [*r*] for all items >0.30 with the anchor items) and high test-retest reliability (range of intraclass correlation coefficient 0.33-0.83) [16]. To generate a subset for each type of cancer, we included common symptomatic AEs recommended by the National Cancer Institute based on their high prevalence across different cancer treatment types [17]. In addition, we included symptomatic AEs that were prevalent in specific subgroups for different cancer sites based on a literature review and recommendation by a panel of 15 medical and radiation oncologists. We performed a Delphi survey 2 times by providing the panel with the entire list of the PRO-CTCAE-Korean instrument and then asking them to choose prevalent and important symptoms to generate subsets for each cancer type. The subsets contained a minimum of 28 to a maximum of 58 symptomatic AEs.

To measure HRQoL, we used the European Organization for Research and Treatment of Cancer Core Quality of Life Questionnaire Core 30 (EORTC QLQ-C30), previously validated in Korean [18], and scored the QLQ-C30 summary score according to the scoring manual [19]. Higher scores on these indicate better function. Further, demographic information was gathered by self-reporting, and clinical variables were obtained from electronic health records.

Statistical Analysis

A composite-grade scoring algorithm was used to obtain single numerical grades for AEs based on multiple PRO-CTCAE items [20]. Following the composite grading algorithm, a single composite grade was given to the PRO-CTCAE item combinations within the range of 0-3. A higher composite grade indicates the worse symptom experience. One rule of thumb for interpreting the difference in PRO scores is 10% of the instrument range [21]. As the score ranged between 0 and 3, we considered that differences of 0.4 points (ie, 10% of the score range) were clinically meaningful.

The symptom prevalence by composite grades of the PRO-CTCAE items is shown using a tree map. The size of the rectangles in the tree map indicates the proportion of patients with symptoms, with the darker colors indicating a higher prevalence of patients who reported symptoms as severe. Linear regression was used to analyze symptoms based on cancer type. Covariates adjusted were patient's age, sex, ECOG, and treatment types. Linear regression was also performed to evaluate the association between the PRO-CTCAE items and the EORTC QLQ-C30 summary score [22].

All analyses were performed using STATA version 16 (StataCorp LP) and R 3.6.1 (R Foundation for Statistical Computing). *P* values <.05 were considered statistically significant.

Ethical Considerations

Study participants provided written informed consent. We gave the participants a US $5 gift card to thank them for their participation. The Institutional Review Board of the Samsung Medical Center (SMC 2020-04-157) and the National Cancer Center (NCC2017-0249) approved this study. All the research data were encrypted.

Results

A total of 1352 patients (breast, n=411; colorectal, n=127; gastric, n=123; gynecologic, n=112; head and neck, n=56; liver, n=67; lung, n=234; lymphoma, n=112; prostate, n=57; and others, n=53) participated in this study. The mean age (SD) of the patients was 55.0 (11.9) years; 39.94% (540/1352) were male and 79.29% (1072/1352) received chemotherapy (Table 1).

Gastrointestinal cancer (purple) was the most dominant among all cancers (Figure 1). Patients commonly reported decreased appetite (884/1352, 65.38%), taste change (764/1352, 56.51%), nausea (588/1352, 43.49%), constipation (607/1352, 44.90%), and diarrhea (459/1352, 33.95%; Figure 1 and Multimedia Appendix 1). Fatigue (1034/1352, 76.48%) was the most frequently reported symptom followed by decreased appetite (884/1352, 65.38%), numbness and tingling (778/1352, 57.54%), insomnia (773/1352, 57.17%), taste change (764/1352, 56.51%), and hair loss (691/1352, 51.11%; Multimedia Appendix 1).

When we compared the symptoms across different types of cancer, patients reported more local symptoms caused by a specific cancer (Multimedia Appendix 1). After adjusting for age, sex, ECOG status, and treatment type, patients with gastric cancer were more likely to have taste changes, decreased appetite, vomiting, diarrhea, and abdominal pain compared with those with other types of cancer. Patients with head and neck cancer had more dry mouth and difficulty in swallowing compared with those with other types of cancer (Multimedia Appendix 2).

In terms of nonsite-specific symptoms, patients commonly reported concentration (587/1352, 43.42%), anxiety (647/1352, 47.86%), sadness (638/1352, 47.19%), and general pain (605/1352, 44.75%; Multimedia Appendix 1). After adjusting for confounders, patients with liver cancer experienced relatively more fatigue and anxiety than those with other types of cancer (Multimedia Appendix 2).

More than 50% of patients with colorectal, gynecologic, breast, and lung cancers and lymphoma/myeloma experienced sexual symptoms, such as decreased libido or pain during sexual intercourse (Multimedia Appendix 1). For example, 49.6% (63/127) of patients with colorectal cancer reported problems in achieving and maintaining erection and 51.7% (121/234) of patients with lung cancer reported decreased libido. Patients with breast (265/411, 64.4%), colorectal (63/127, 49.6%), gastric (68/123, 55.3%), gynecologic (65/112, 58.0%), and lung cancers (103/234, 44.0%) and lymphoma (52/112, 46.4%) more frequently reported skin dryness (Multimedia Appendix 1). Patients with breast (coefficient 0.19; 95% CI 0.09 to 0.28), gastric (coefficient 0.17; 95% CI 0.04 to 0.30), and liver (coefficient 0.21; 95% CI 0.04 to 0.38) cancers were more likely to have the hand-foot syndrome even after adjusting for potential confounders (Multimedia Appendix 2).

We observed a significant decrease in the mean QLQ-C30 summary scores across worsening PRO-CTCAE scores (Multimedia Appendix 3). In particular, memory, all the symptoms in the mood category, fatigue, difficulty in achieving and maintaining erection, body odor, concentration, and dizziness were associated with decreasing of QLQ-C30 summary scores (Multimedia Appendix 3).

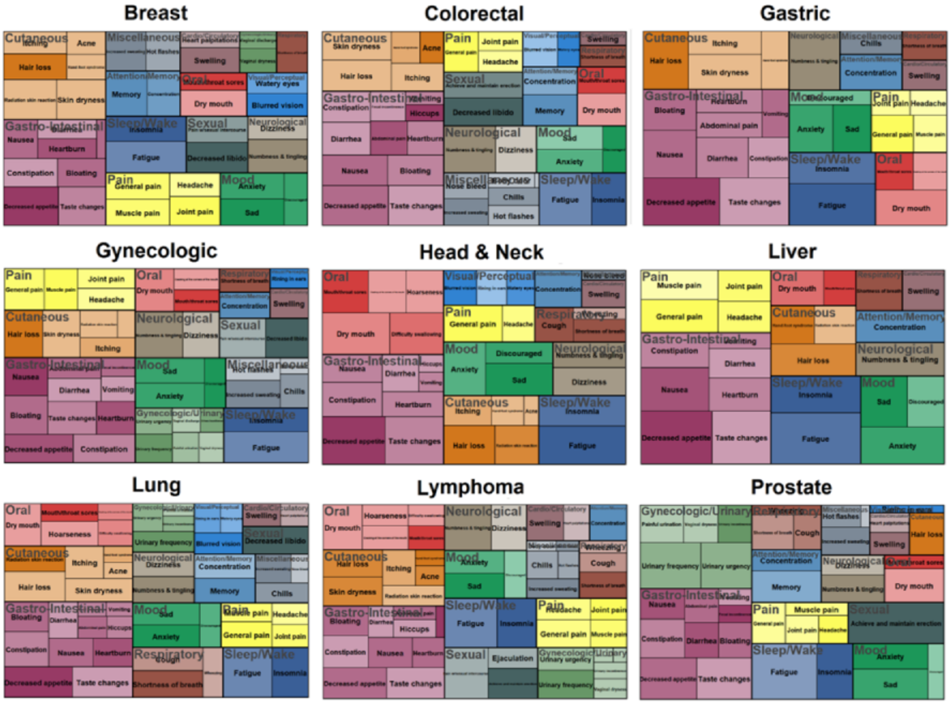
Figure 1. Tree map representing symptom severity and prevalence by type of cancer. Colors indicate the symptom summary score. Sizes of squares are proportion. Thus, the darker the color and greater the size of a square, the more severe and more prevalent the symptom.



Discussion

In this large real-world surveillance study of burden of symptoms among patients with various types of cancers undergoing chemoradiation therapy, frequency and severity of symptoms differed by cancer types. A higher symptom burden score was associated with poor quality of life, suggesting the importance of appropriate surveillance of PRO symptoms during cancer treatment.

Symptoms in the gastrointestinal category were most commonly reported among patients with different cancer types than those in other categories, and this finding is consistent with the results of a previous study [23]. Gastrointestinal cancer symptoms reportedly plagued many patients regardless of their cancer types [23] because chemotherapy can damage healthy cells in the lining of the digestive system from the mouth to the anus [24]. Therefore, chemotherapy can affect these areas and cause vomiting, diarrhea, constipation, and mouth sores. The most common side effects of chemotherapy associated with the gastrointestinal tract are taste changes, chemotherapy-induced nausea and vomiting, constipation, and diarrhea [25]. The prevention of chemotherapy-induced nausea and vomiting has been revolutionized over the past few years. Vomiting can be prevented in most cases [25]. However, other factors such as advanced age, decreased mobility, dietary errors, psychological alterations, and cancer-related complications may increase its occurrence [26]. In clinical practice, the implementation of nonpharmacological strategies plays an important role as an adjunct to pharmacological agents in alleviating chemotherapy-induced gastrointestinal symptoms.

In this study, we found that patients experienced more frequent and more severe symptoms caused by a specific cancer. For example, head and neck as well as lung and prostate cancers had relatively more oral, respiratory, and urinary tract symptoms, respectively, compared with other types of cancer. Our study findings are somewhat similar to the results of previous studies which reported that most patients (>80%) experienced symptoms related to their cancer site [27]. Although chemotherapy and related treatment regimens affect the whole body, the origin site of cancer seems to have a greater impact on patient's symptom burden. As the different types of cancer had different symptoms even when patients received the same treatment, it is necessary to provide specific care to manage the complexity of the symptoms by the cancer type [28]. Therefore, it is important to develop and use a specific subset of the assessment when evaluating chemotherapy- or radiation-induced symptoms for patients with different types of cancers or undergoing treatment options.

Using the PRO-CTCAE will help detect symptoms that were often underreported by health professionals [29], as we have shown in this study, where many patients reported problems with sexual dysfunction, which was not often assessed in previous studies [17]. In our study, more than 50% of patients with colorectal (69/127, 54.3%), gynecologic (63/112, 56.3%), breast (252/411, 61.3%), and lung cancers (121/234, 51.7%) experienced decreased libido, whereas 67/112 (59.8%) patients with gynecologic cancer and lymphoma/myeloma reported pain during sexual intercourse. However, these sexual dysfunctions are often overlooked in evaluating patients with cancers [30]. The causes of sexual dysfunction are psychological distress and endocrine dysfunction caused by the cancer itself or side effects of anticancer treatments such as surgery, radiotherapy, chemotherapy, and hormonal therapy. For example, among patients with colorectal cancer, the rates of sexual dysfunction can be even higher given the physiological changes that can result from surgery, chemotherapy, and radiation therapy [31]. Similarly, surgery for lung cancer may adversely affect the psychogenic status and sexual function in patients with lung cancer due to its invasive nature [32]. As cancer treatments and the emotional suffering from a cancer diagnosis can affect all aspects of sexuality [33], sexuality should be a routine assessment, and communication should begin early on [34].

The PRO-CTCAE includes 6 symptoms of cutaneous toxicity, which were frequently reported by our patients with lymphoma/myeloma, colorectal, gynecologic, gastric, breast, and lung cancers. Although cutaneous toxicities are the common side effects reported by patients with cancer receiving chemotherapy [35], they are often considered minor complaints compared with other side effects such as nausea or vomiting [36]. However, cutaneous toxicity is strongly associated with psychological well-being and HRQoL. Most patients with cancer reported that the impact of chemotherapy on skin irritation and dry skin was worse than they had anticipated [37]. More than two-thirds of patients that developed cutaneous side effects due to chemotherapy were significantly distressed by their altered appearance [38]. It disturbs their daily activities and personal relationships and negatively impacts their HRQoL [39]. Considering the burden of cutaneous symptoms on patients' daily activities and HRQoL [40], a multidisciplinary cancer care team, including dermatologists, oncologists, and nurses, should perform regular surveillance and appropriate interventions. Furthermore, cutaneous toxicity needs to be monitored more actively in patients with targeted agents, as dermatological toxicities are among the most common complications of targeted agents [41].

Regarding the impact of symptoms burden on HRQoL, most symptoms were associated with lower HRQoL. In particular, memory, mood, fatigue, erection, body odor, concentration, and dizziness were associated with clinically noticeable declines in HRQoL. As these symptoms were associated with daily life, they might have a greater impact on HRQoL due to their burden. In particular, fatigue was reported as one of the most common side effects of cancer that was associated with poor HRQoL, which is similar to the finding reported in a previous study [42]. Fatigue negatively impacts work, social relationships, mood, and daily activities and causes significant impairment in the overall HRQoL during and after treatment [42]. Regarding mood, all patients with cancer had a certain level of anxiety, which could be related to the fear of treatment or fear of cancer recurrence. Considering that anxiety as a symptom is dynamic and can change over time in response to cancer-related events [43], surveillance and treatment planning should incorporate factors contributing to anxiety and patient preference for psychiatric care [43]. Pain is also a frequent, nonsite-specific symptom in all patients. A more active approach may be necessary to manage pain, as it could affect many other symptoms. Patients experienced loss of confidence and restriction in physical and social activities due to chronic dizziness [44]. The burden of shortness of breath might be further compounded by fatigue, anxiety, and depression, resulting in functional limitations and compromised HRQoL [45]. Patients with cancer reported more distress when they experienced a symptom they did not anticipate [37]. Therefore, it is important to provide pretreatment information, counseling, and management resources concerning possible treatment-related side effects in these patients.

There are several limitations to our study. First, the reporting of the symptom scores was voluntary. Thus, the receipt of symptom screening may itself bias the estimates of symptom burden because the routine collection of PROs is associated with improved clinical outcomes and increased patient satisfaction. In addition, patient factors, including male sex and advanced age, were associated with lower rates of PRO-CTCAE reporting, which could reflect differential rates of participation among patient subgroups. Second, as symptom assessments are only recorded at outpatient visits, we did not capture the symptoms of patients who are admitted to the hospital or hospice, or who are otherwise too unwell to visit clinics and may probably be the most symptomatic. In addition, because of the heterogeneity in our cohort, we did not assess the influence of treatment modalities, which will differ substantially among stages, on symptom burden. Finally, although we compared symptom burden based on disease site groups, we did not describe the symptoms of unique cancers, which may mask heterogeneity in the symptom profiles of distinct cancers within larger categories, such as lymphoma/myeloma, colorectal, head and neck/esophageal, prostate/bladder, and gynecologic cancers. Despite these limitations, this study provides guidance on symptoms that should be asked about to patients in the real-world clinical setting. This study also illustrated the feasibility of linking routinely collected PROs to large population-based health care databases.

In conclusion, the frequency and severity of symptoms differed according to the type of cancer, and the symptoms were associated with poor HRQoL. Recently, there has been an emphasis on the appropriate assessment of PRO symptoms during cancer treatment [5,46]. Considering that patients would have various symptoms at different periods, and that symptoms could affect not only disease but also HRQoL, it is necessary to take a holistic approach when implementing a symptom monitoring and management strategy. The results of this study would help physicians to improve their understanding of the variations in cancer treatment–related symptoms and to use proper symptoms list by types of cancer in routine care for developing management plans and guidelines.

Acknowledgments

This study was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (2020R1I1A2074210), the National R&D Program for Cancer Control, Ministry of Health and Welfare, Republic of Korea (grant number 1520240), a grant (number 19182MFDS426) from the Ministry of Food and Drug Safety in 2019, and Future Medicine 20 × 30 Project of the Samsung Medical Center (SMX1210831).

Data Sharing

The data sets generated or analyzed during this study are available from the corresponding author (JC) on reasonable request.

Authors' Contributions

DK and JC were involved in the study design. ML, SYK, YJC, SS, and YJK were involved in data collection. DK, SK, and HK were involved in data acquisition and management. DK, SK, and HK were involved in data analysis. All authors were involved in results interpretation and manuscript writing. JC made the decision to submit this manuscript for publication.

Abstract

Background: Homicide is one of the 5 leading causes of death in the United States for persons aged 1 to 44 years. In 2019, 75% of US homicides were by gun. Chicago has a gun-homicide rate 4 times the national average, and 90% of all homicides are by gun. The public health approach to violence prevention calls for a 4-step process, beginning with defining and monitoring the problem. Insight into the characteristics of gun-homicide decedents can help frame next steps, including identifying risk and protective factors, developing prevention and intervention strategies, and scaling effective responses. Although much is known about gun homicide because it is a long-standing, entrenched public health problem, it is useful to monitor trends to update ongoing prevention efforts.

Objective: This study aimed to use public health surveillance data and methods to describe changes in the race/ethnicity, sex, and age of Chicago gun-homicide decedents from 2015-2021, in the context of year-to-year variation and an overall increase in the city’s gun-homicide rate.

Methods: We calculated the distribution of gun-related homicide deaths by 6 race/ethnicity and sex groups (non-Hispanic Black female, non-Hispanic White female, Hispanic female, non-Hispanic Black male, non-Hispanic White male, and Hispanic male), age in years, and age by age group. We used counts, percentages, and rates per 100,000 persons to describe the distribution of deaths among these demographic groups. Comparisons of means and column proportions with tests of significance set at $P \leq .05$ were used to describe changes in the distribution of gun-homicide decedents over time by race-ethnicity-sex and age groups. The comparison of mean age by race-ethnicity-sex group is done using 1-way ANOVA with significance set at $P \leq .05$.

Results: The distribution of gun-homicide decedents in Chicago by race/ethnicity and sex groups had been relatively stable from 2015 to 2021 with 2 notable exceptions: a more than doubling of the proportion of gun-homicide decedents who were non-Hispanic Black female (3.6% in 2015 to 8.2% in 2021) and an increase of 3.27 years in the mean age of gun-homicide decedents. The increase in mean age coincided with a decrease in the proportion of non-Hispanic Black male gun-homicide decedents between the ages of 15-19 and 20-24 years and, conversely, an increase in the proportion of non-Hispanic Black male gun-homicide decedents aged 25-34 years.

Conclusions: The annual gun-homicide rate in Chicago had been increasing since 2015 with year-to-year variation. Continued monitoring of trends in the demographic makeup of gun-homicide decedents is necessary to provide the most relevant and timely information to help shape violence prevention efforts. We detected several changes that suggest a need for increased outreach and engagement marketed toward non-Hispanic Black female and non-Hispanic Black male individuals between the ages of 25-34 years.

KEYWORDS

gun-homicide surveillance; gun-homicide decedents; demographics; age, gun violence; firearm

Introduction

The United States is an outlier among the world's 28 most populous high-income countries, with a homicide by gun rate 11.4 times that of all these countries combined [1]. Within the United States, gun homicides constitute 75% of all homicides [2] and is one of the 5 leading causes of death for persons aged 1 to 44 years [3]. The US gun homicide rate increased by 34% from 2019 to 2020 [4]. In 2020, Chicago, the third largest US city, had a gun homicide rate of 22.65 per 100,000 persons, nearly 4 times the overall US rate of 5.9 per 100,000 persons [2].

The public health approach to violence prevention calls for a 4-step process, beginning with defining and monitoring the problem [5]. Insight into the characteristics of gun-homicide decedents can help frame next steps, including identifying risk and protective factors, developing prevention and intervention strategies, and scaling effective responses. Although much is known about gun homicide because it is a long-standing, entrenched public health problem, it is useful to monitor trends to update ongoing prevention efforts.

In Chicago, as is the case nationally, the risk for gun-related homicide is not evenly distributed. Adolescents and young adults, males, and Black persons have elevated gun-related homicide rates compared to other population segments [6-8]. Historically, persons between the ages of 15 and 24 years have had the highest gun-related homicide rates [7].

Chicago's annual rate of gun-related homicides has varied year to year [5,8], but the overall trend has increased since 2015 [9]. In 2021, the number of gun-related homicides in Chicago hit a 40-year high, surpassing the most recent high in 2020 [9]. We wondered if the distribution of gun-homicide decedent demographic characteristics in Chicago had changed with year-to-year variation in Chicago's gun-homicide rates and in the context of the overall increase in gun-homicide rates.

Understanding changes in decedent characteristics can help advance knowledge of drivers of increases in gun-homicide rates and inform prevention and intervention efforts, including the allocation of resources to prevent future gun homicides. Since prevention settings and content are usually based on intent to reach the populations most at risk, knowledge of changes in the demographics of at-risk populations may help shape more efficacious responses. Consideration of demographic factors such as age and sex in relationship to race/ethnicity is paramount because, as Feld and Bauldry [10] note, gun homicides are unevenly distributed by race/ethnicity and overall summary conclusions may obfuscate important variations.

Our objective was to use public health surveillance data and methods to describe changes in the race/ethnicity, sex, and age of Chicago gun-homicide decedents from 2015-2021, in the context of year-to-year variation and an overall increase in the city's gun-homicide rate.

Methods

Ethical Considerations

This study was determined to be exempt from institutional review board review by the Northwestern University institutional review board because research involving deceased persons is not considered human subjects research, and the data are publicly available and deidentified. The study data source was deidentified retrospective case-level surveillance data from the Cook County Medical Examiner Case Archive [9]. These data were collected after death was declared; therefore, no informed consent was possible or required. To protect against possible identification of individuals in the data set, we suppress counts for cells with fewer than 5 in table presentations.

Data Sources

Gun-homicide decedent data were from Cook County Medical Examiner Case Archive data [9]. The archive includes data on decedent characteristics and fatal incident date and location. Population data came from American Community Survey [11].

Inclusion Criteria

This study included all homicides in which the fatal injury occurred in the city of Chicago with the death occurring between January 1, 2015, and December 31, 2021, where the manner of death was ruled "homicide" and the "gun-related" variable was endorsed by the Cook County Coroner's Office. The start date is January 1, 2015, because that is the first year that electronic surveillance of these deaths had complete case ascertainment.

For our analyses, we used a continuous variable for age in years, as well as a categorical variable where we collapsed the decedent age in years into the following age groups: <15, 15-19, 20-24, 25-34, 35-44, 45-54, 55-64, and 65+ years. Age groups were based on standard age groups generated from the US Census. We also created a race-ethnicity-sex group variable by assigning decedents into 1 of the following 6 race/ethnicity and sex groups: non-Hispanic Black female, non-Hispanic White female, Hispanic female, non-Hispanic Black male, non-Hispanic White male, and Hispanic male. We did not include data on Asian, Native Hawaiian or Other Pacific Islander, or American Indian or Alaska Native racial groups due to the low numbers of decedents, which makes comparisons of distributions unreliable.

Statistical Analysis

We calculate the overall Chicago annual gun-homicide rate per 100,000 persons as the annual number of gun-homicides divided by the 2020 Chicago population. For analyses, we assigned decedents to 1 of 6 race-ethnicity-sex groups (non-Hispanic Black female, non-Hispanic White female, Hispanic female, non-Hispanic Black male, non-Hispanic White male, and Hispanic male). We graphed the mean age of gun homicide decedents by the year of death and used Pearson *r* to evaluate the association between mean age and the year of death. We described the proportion of decedents by race-ethnicity-sex and age groups over time and tested for statistically significant change over time using comparisons of column proportions with significance set at $P \leq .05$. The comparison of mean age by race-ethnicity-sex group was done using 1-way ANOVA with significance set at $P \leq .05$. We also examined changes in annual gun-homicide rates per 100,000 persons by age group using the annual number of gun-homicide deaths by age group divided by the annual Chicago population for that age. Analyses were done in IBM Statistics 27. We used graphing procedures in Microsoft Excel 2016, IBM Statistics 27, and Tableau (Salesforce Inc) for data visualizations.

Results

Between 2015 and 2021, there were 3723 gun-homicides among Chicago residents recorded by the Cook County Medical Examiner's Office. Decedents were 92% (n=3425/3723) male, 82% (n=3054/3723) Black, and 15.2% (n=566/3723) Hispanic with a mean age of 28.99 (SD 11.18) years. The overall Chicago gun homicide rate increased 58% from 14.46 to 22.92 per 100,000 persons during this time frame (see Figure 1).

Figure 1. Chicago gun-homicide rate per 100,000 persons: 2015-2021.

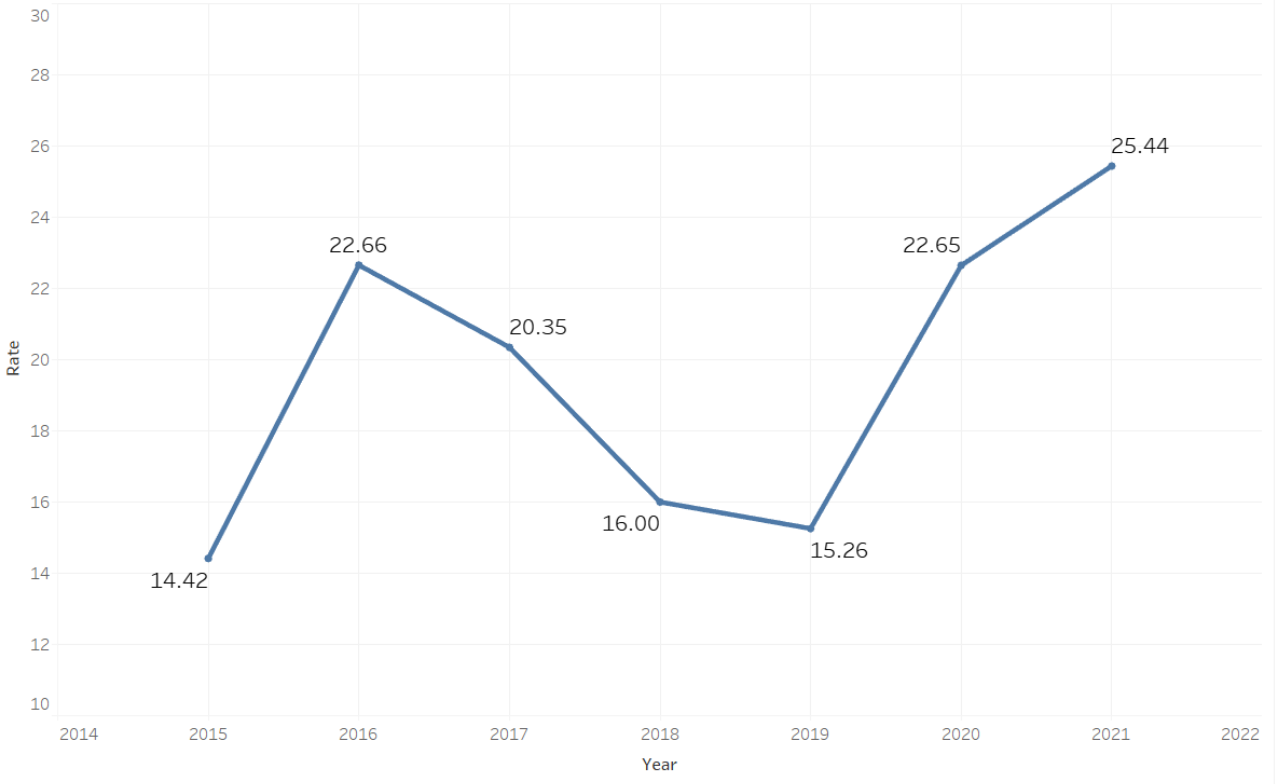

Table 1 reports the annual percentage of gun-homicide deaths by 6 race-ethnicity-sex group combinations. Each row represents the proportion of gun-homicide decedents by race-ethnicity-sex group. Across all years, non-Hispanic Black male individuals consistently made up the largest proportion of gun-homicide decedents in Chicago (≥72.5%). The proportion of gun-homicide deaths among non-Hispanic Black female individuals had more than doubled from 2015 (n=14/391, 3.6%) to 2021 (n=56/685, 8.2%); however, this increase was not statistically significant ($P > .05$).

From 2015 to 2021, the mean age of gun-related homicide decedents increased by 3.27 years (Figure 2). The largest increase (+1.94 years) occurred between 2017 and 2018.

The mean age among Chicago gun-homicide decedents differed by race-ethnicity-sex group ($F_5 = 9.39$; $P < .001$; Table 2). Non-Hispanic White male and female groups had higher mean ages compared to other groups.

Table 1. Proportion of Chicago gun-homicide deaths by race-ethnicity-sex groups from 2015-2021.

Race-ethnicity-sex group	Year of death and the proportion of gun-homicide death[a]						
	2015, n (%)	2016, n (%)	2017, n (%)	2018, n (%)	2019, n (%)	2020, n (%)	2021, n (%)
Non-Hispanic Black female	14 (3.6)	27 (4.4)	33 (6)	30 (6.9)	33 (8)	45 (7.3)	56 (8.2)
Non-Hispanic White female	0 (0)	<5 (0.5)	<5 (0.4)	<5 (0.7)	<5 (0.7)	<5 (0.3)	<5 (0.6)
Hispanic female	<5 (0.8)	<5 (1)	6 (1.1)	6 (1.4)	6 (1.5)	<5 (0.6)	10 (1.5)
Non-Hispanic Black male	313 (80.1)	467 (75.9)	409 (74.4)	336 (77.6)	308 (75.1)	448 (72.5)	521 (76.1)
Non-Hispanic White male	8 (2)	14 (2.3)	11 (2)	10 (2.3)	9 (2.2)	16 (2.6)	11 (1.6)
Hispanic male	53 (13.6)	98 (15.9)	89 (16.2)	48 (11.1)	51 (12.4)	103 (16.7)	83 (12.1)

[a] Denominators are not reported due to the suppression of cell counts to protect against possible identification of individuals.

Figure 2. Chicago gun-homicide decedent mean age by year of death: 2015-2021.

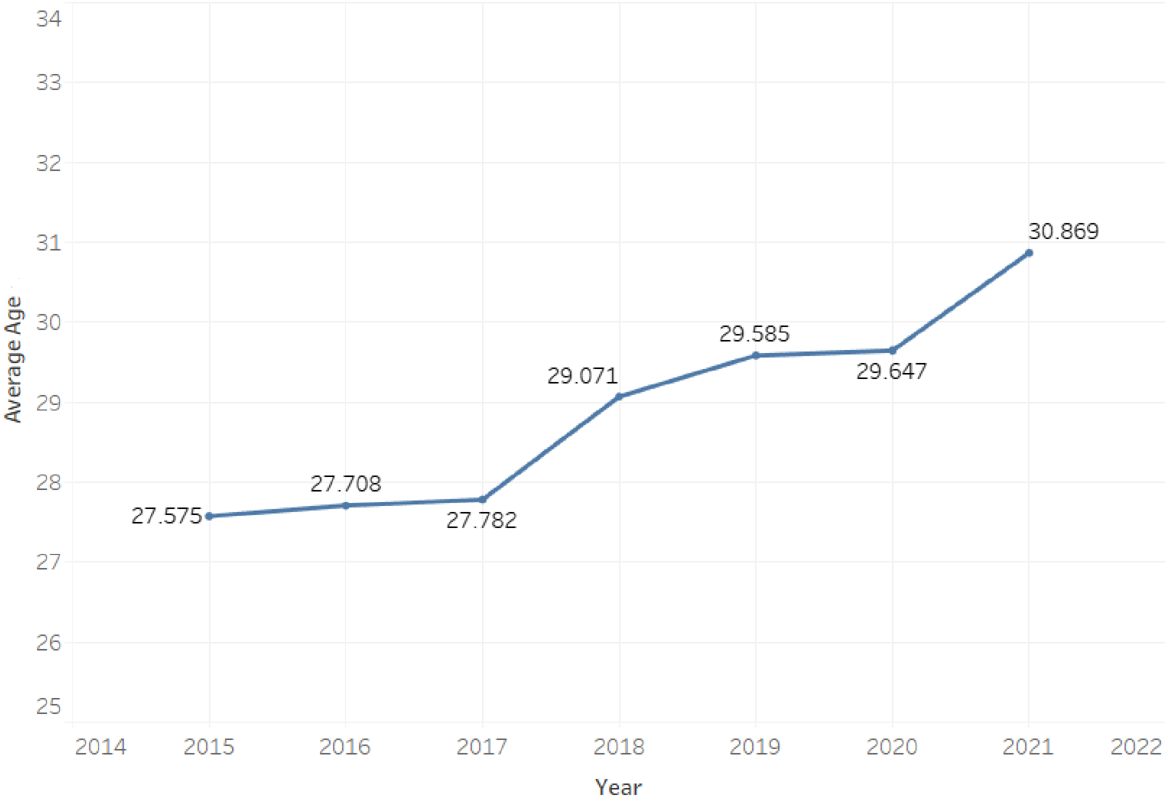

Table 2. Chicago gun-homicide decedents' mean age in years by race-ethnicity-sex group from 2015-2021.

Race-ethnicity-sex group	Year of death and mean age (years)						
	2015	2016	2017	2018	2019	2020	2021
Non-Hispanic Black female	27	28	24	38	28	27	31
Non-Hispanic White female	—[a]	53	60	28	48	31	37
Hispanic female	29	22	24	28	34	24	28
Non-Hispanic Black male	28	28	28	29	29	30	31
Non-Hispanic White male	31	34	34	41	34	30	39
Hispanic male	27	27	27	27	29	30	30

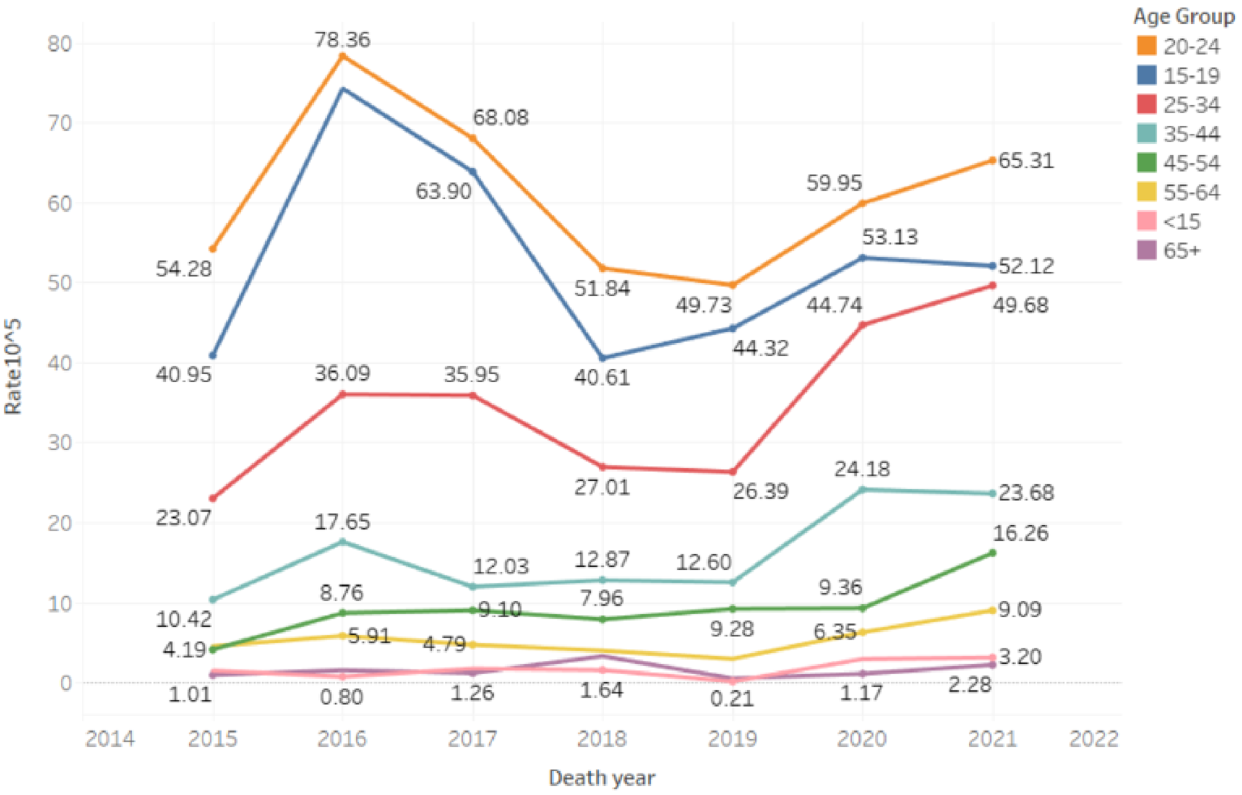
[a] Not applicable.

We also examined the annual distribution of decedents by age group across each of the 6 race-ethnicity-sex groups using tests of column proportions to evaluate statistical significance of differences (data not shown). Only 2 of the 6 race-ethnicity-sex groups examined had statistically significant changes in the annual distribution of decedents. The non-Hispanic Black female group had a statistically significant decrease in the proportion of gun-homicide deaths among those aged 65+ years, dropping from 16.7% (n=5/30) of gun-homicide deaths among non-Hispanic Black female individuals in 2018 to 2.2% (n<5/45) in 2020 (*P*=.02). However, the total number of non-Hispanic Black female deaths among those aged 65+ years during the study period was low (n=6/3702).

Among the non-Hispanic Black male group, there were statistically significant drops in the proportion of 15–19-year old gun-homicide decedents from 2016 (n=94/615, 20.1%) to 2020 (n=53/618, 11.8%; *P*=.01), from 2016 (n=94/615, 20.1%) to 2021 (n=54/685, 10.4%; *P*<.001), and from 2017 (n=78/550, 19.1%) to 2021 (n=54/685, 10.4%; *P*=.003). Among the non-Hispanic Black male group, there were statistically significant drops in the proportion of 20–24-year-old gun-homicide decedents from 2015 (n=95/391, 30.4%) to 2020 (n=81/618, 18.1%; *P*=.002), from 2015 (n=95/391, 30.4%) to 2021 (n=104/685, 20%; *P*=.01), and from 2016 (n=125/615, 26.8%) to 2020 (n=81/618, 18.1%; *P*=.04). Meanwhile, there were statistically significant increases in the proportion of 25–34-year-old non-Hispanic Black male gun-homicide decedents from 2015 (n=99/391, 31.6%) to 2020 (n=191/618, 42.6%; *P*=.04) and from 2016 (n=146/615, 31.3%) to 2020 (n=191/618, 42.6%; *P*=.008).

We also examined gun-homicide rates per 100,000 persons for each age group (see Figure 3). Rates offer important information about the relative risk to groups based on their proportion of the total population. The highest gun-homicide rates were consistently among the 15-19, 20-24, and 25-34 years age groups. From 2020 to 2021, the 15-19 and 35-44 years age groups saw slight declines. Most other groups increased, although the magnitude of increase differed by age group.

Figure 3. Chicago gun-homicide rate by age group from 2015-2021.



Discussion

Principal Findings

The annual distribution of gun-homicide decedents by race-ethnicity-sex group had been relatively stable over time, even in the context of year-to-year changes in gun-homicide rates and the 2015-2021 increase in gun-homicide rates in Chicago. There was a large but nonstatistically significant increase in the proportion of non-Hispanic Black female gun-homicide decedents from 2015 (3.6%) to 2021 (8.2%). The lack of statistical significance may be due to a relatively small (238/3723, 6.4%) number of non-Hispanic Black female individuals among gun-homicide decedents. The mean age of Chicago gun-homicide decedents increased by 3.27 years from 2015-2021. This increase in mean age coincided with a decrease in the proportion of non-Hispanic Black male gun-homicide decedents between the ages of 15-19 and 20-24 years and, conversely, an increase in the proportion of non-Hispanic Black male gun-homicide decedents between the ages of 25-34 years.

Although there is much discussion of firearm violence in Chicago in news publications [12] and, less often, research literature [13,14], there is little detailed information available on the demographics of gun-homicide decedents in the face of changes in violence other than to note broad populations at the highest risk at one point in time. This study examined the intersection of race/ethnicity, sex, and age among of Chicago gun-homicide decedents over a 7-year period in which there were year-to-year changes in overall gun-homicide rates. It provides key information on group representation in gun homicide during periods of escalation and periods of retraction. The changes in the makeup of gun-homicide decedents we detected signal a need for expanded prevention outreach and intervention engagement marketed toward non-Hispanic Black female individuals of all ages and non-Hispanic Black male individuals between the ages of 25-34 years, while at the same time, efforts are needed to expand outreach to and engagement of younger non-Hispanic Black male individuals, who consistently have the highest gun-homicide rates in Chicago.

This study has several strengths and limitations. In terms of strengths, the study incorporated very recent and reliable surveillance data from the Cook County Medical Examiner's Office, a nonpartisan office led by an appointed chief medical examiner. However, it is well known that death certificate reporting of race and ethnicity underreports certain subgroups [15], and so, it is likely that certain race/ethnicity groups, especially Alaska Native or American Indian individuals, those with more than one race/ethnicity affiliation, and Hispanic individuals may be underreported in the Medical Examiner data used in this study. Regarding other limitations, our reliance on US Census age groups as denominators for calculating homicide rates prevents a more nuanced analysis of single-year age risks. Further, although we report on demographics of gun-homicide decedents, ideally, more information on the circumstances surrounding these gun-related homicide deaths is needed to inform intervention approaches.

Conclusions

The findings from this modest study provide a basis for informing firearm violence prevention and intervention strategies and can inform a research agenda going forward. Further research could address the following questions: Will this shift toward increased non-Hispanic Black female and non-Hispanic Black male gun-homicide decedents between the ages of 25-34 year endure over time? What are the drivers associated with this increase in the proportion of non-Hispanic Black female gun-homicide decedents? and Are these age and gender shifts accompanied by changes in the precipitators and features of gun-homicide events? Because gun-homicide is a leading public health problem in the United States and, even more so, locally in Chicago, understanding the stability of and changes within decedent demographic subgroups is part of a required first step to inform targeted prevention responses.

Acknowledgments

We would like to acknowledge the Cook County Medical Examiner's Office for making archive data publicly available for this project.

Data Availability

Gun-homicide decedent data are available from the Cook County Medical Examiner Case Archive [9]. Population data came from the 2020 US Census [11].

Conflicts of Interest

None declared.

Abstract

Background: The COVID-19 pandemic has challenged public health efforts globally. Timely population-based surveillance is crucial to support public health programs and policies to limit the spread of COVID-19. The South Carolina (SC) Sampling and Testing Representative Outreach for Novel Coronavirus Guidance (SC STRONG) statewide initiative was established to estimate population-level prevalence and immunity and characterize the transmission dynamics of SARS-CoV-2 using community testing and online surveys.

Objective: This paper aimed to leverage the survey data collected as part of the initiative to understand risk perceptions, testing practices, and preventive behaviors and identify risk factors for COVID-19 test positivity in SC over time.

Methods: Probability proportionate to size cluster random sampling was used to select SC residents to participate in testing for COVID-19 infection and antibodies and to complete an online survey. This paper focuses on data from the online surveys completed between November 2020 and June 2021. Descriptive statistics were used to describe risk perceptions, attitudes and behaviors, and associated changes over time. Univariate and multivariate logistic regression models were used to identify factors associated with self-reported COVID-19 test positivity.

Results: Among the 7170 online survey respondents, 58.7% (4213/7170) self-reported ever testing for COVID-19. The most commonly cited barriers to testing were inconvenient dates, time, and location, as well as discomfort. Overall, 18.7% (790/7170) of respondents reported a history of COVID-19 test positivity. Multivariate logistic regression results indicated that individuals who were aged 50 years or older, self-identified as Black/African American, were obese, and were employed as frontline health care workers or nursing home staff were more likely to self-report COVID-19 test positivity. By contrast, there was a decreased likelihood of test positivity among respondents who were concerned about the burden of COVID-19 in their community and about being infected.

Conclusions: Strategies to remove testing barriers should be implemented to improve access. Our findings provide insights on statewide testing patterns, adoption of prevention behaviors, and risk factors for infection and may inform public health strategies to curb transmission.

Introduction

The year 2020 brought new public health challenges and highlighted the need for data to inform ongoing public health response efforts. In South Carolina (SC), the first case of COVID-19 was detected on March 4, 2020 [1]. As of July 2021, the cumulative numbers of confirmed COVID-19 cases and associated deaths in SC were over 700,000 and 11,500, respectively [1]. Mitigation measures in the state have included face mask ordinances, closure of nonessential businesses, isolation of COVID-19 cases, tracing and quarantining of close contacts of cases, and promotion of personal protective behaviors, such as routine testing, face coverings, hand hygiene, and social distancing. These measures were implemented to reduce disease spread and remain crucial to prevent overcrowding hospitals and emergency rooms with patients with severe disease during local outbreaks [2]. Even as COVID-19 vaccines are rolled out, preventive behaviors remain crucial components in the arsenal to address the pandemic. To effectively minimize COVID-19 transmission risk and prevent the loss of life, achieving and sustaining high uptake of preventive behaviors needs to be prioritized [3,4].

The adoption of preventive behaviors in part depends on the perceived severity of disease, perceived susceptibility to disease, benefits of compliance, and removal of barriers to the adoption of protective behaviors [5]. Knowledge and attitudes partially influence the adoption of these behaviors [6]. While several studies have assessed COVID-19 attitudes and behaviors, most were at the national scale or based on convenience sampling [7-11]. Some of these studies discuss the role of information exposure and knowledge in health behavior, and national-level estimates are likely to differ from state-level estimates. There is a paucity of research at the state level, particularly in SC, a state primarily defined by conservative ideology; thus, a description of the population’s perceptions is warranted for a locally tailored public health response [12-14]. Given the continuing incidence of COVID-19, the overwhelming public health burden, and the rapidly changing epidemiology of COVID-19, there is an urgent need for timely population-based surveillance data to support state-specific, targeted policies and public health efforts to address the pandemic.

The objectives of this analysis were 2-fold: first, to understand SC respondents’ testing patterns, risk perceptions, and preventive behaviors and associated temporal changes and second, to identify risk factors for COVID-19 test positivity to inform public health policies and programs in SC. Understanding the population’s perceived risk allows for the targeting of public health interventions to reduce the burden of COVID-19 while addressing health inequities [15]. This paper reports on results from 3 rounds of surveys conducted from November 2020 to June 2021 among 7170 SC residents participating in the SC Sampling and Testing Representative Outreach for Novel Coronavirus Guidance (SC STRONG) project. The SC STRONG project was established in October 2020 across all 4 public health regions in the state with the goal of estimating population-level seropositivity and immunity and characterizing population-specific transmission dynamics [16]. This ongoing initiative is led by the SC Department of Health and Environmental Control (SC DHEC) together with multidisciplinary academic collaborators, local health clinics, and health care providers across the state. The project consists of multi-round cross-sectional community testing and surveys, and to date, 3 rounds of community testing and surveys have been completed. The project complements reportable disease surveillance for COVID-19 by characterizing attitudes and behaviors toward public health measures to limit COVID-19 transmission among a large random sample of SC residents.

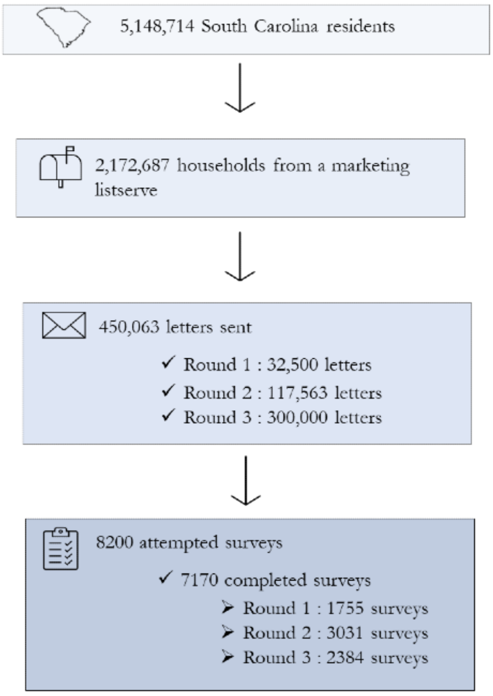
Methods

Setting and Study Design

SC has a population of approximately 4.86 million inhabitants aged 5 years and older [17]. The state has 46 counties distributed across 4 public health regions, all of which were included in the SC STRONG project. A description of the SC STRONG project has been published elsewhere [18]. Briefly, a direct mailer marketing list with 2,172,687 unique physical addresses was purchased from Mailers Haven and used to establish a sampling frame (Figure 1). Multi-stage cluster sampling with probability proportionate to size was used to select clusters and 30 residents from each selected cluster. Invitation letters to participate in testing for active COVID-19 infection and antibodies and to complete an online survey were mailed to selected residents. The invitation letters included an explanation of the project, instructions on how to participate in free community testing, and a QR code and URL for the online electronic survey. The number of invitations mailed each round varied depending on the anticipated response rate. To improve response rates, at least two reminders were sent to selected residents. Additionally, to accommodate participants with no internet access and allow them to complete the online survey, the testing site provided the option to fill out the survey on site.

The online survey was administered via REDCap (Research Electronic Data Capture) and hosted by Health Sciences South Carolina. REDCap is a secure web-based software platform designed to support data capture for research studies [19]. A standardized survey questionnaire available in English and Spanish was used to collect data on sociodemographic characteristics, testing behaviors, daily behaviors, and risk perceptions. The questionnaire consisted of questions from existing COVID-19 surveys and new questions developed by the SC STRONG team [20]. Additional survey questions regarding acceptance, motivations, and barriers to getting the COVID-19 vaccine were added in January 2021.

Figure 1. Flow diagram of study participation.



Statistical Analysis

Descriptive statistics and visualizations were used to describe the sample population and chi-square statistics were used to compare sociodemographic characteristics of the SC general population, survey respondents, and respondents who reported ever testing for COVID-19. Data on the SC general population were obtained from the 2019 American Community Survey [17]. Testing behaviors and barriers, attitudes and barriers toward the vaccine, and uptake of preventive behaviors were summarized. The preventive behaviors considered included practicing social distancing, wearing a mask, and self-isolation or quarantining. Respondents were considered adherent to preventive behaviors if they reported practicing these behaviors “sometimes,” “most of the time,” or “all the time” during the previous 2 weeks. Univariate logistic regression models with “week” as an independent variable were used to assess temporal changes in behaviors and attitudes. Changes in behaviors and attitudes per week were expressed as maximum likelihood estimates with 95% CIs.

History of testing was derived from 2 survey questions: “Have you ever been tested for active coronavirus infection (nasal or saliva test)?” and “Have you ever been tested for coronavirus antibodies (blood test)?” As the goal was to identify risk factors for a positive COVID-19 test among those with history of testing, individuals with no prior testing for active coronavirus infection or antibodies were excluded from this analysis. The outcome of interest was based on self-reported diagnosis of coronavirus antibodies or active coronavirus infection derived from the following survey questions: “Have you ever tested positive for active coronavirus infection?” and “Have you ever tested positive for coronavirus antibodies?” Respondents who answered yes to either question were categorized as having ever tested positive for COVID-19. The likelihood of COVID-19 test positivity was assessed with univariate multivariable logistic regression. Explanatory variables of interest were selected based on previous studies assessing risk factors for COVID-19. To account for likely racial inequalities, “Black” and “Hispanic” were added as indicator variables. Household income was added as a proxy for socioeconomic status. Other explanatory variables considered were preexisting medical conditions, number of household members, living or working in congregate settings, testing behaviors, risk perceptions, and knowledge of COVID-19 preventive measures. To account for differences in risk of COVID-19 over time, models adjusted for time in weeks since recruitment for SC STRONG began. In addition to age, gender, income, and race or ethnicity, which were specified a priori, variables with a *P* value less than 0.1 in the univariate logistic regression models were included in the initial multivariable regression model. A stepwise backwards elimination procedure was used to obtain the final multivariable model. Crude and adjusted odds ratios (aORs) from the logistic regression analyses are reported. Checks for multicollinearity were performed using variance inflation factors (VIFs). Covariates with a VIF greater than 8 were dropped. A *P* value less than .05 was considered statistically significant. Analyses were conducted using STATA/SE (version 16.1; StataCorp) and SAS Studio (version 3.8; SAS Institute).

Ethical Considerations

Human-subjects ethics approval was sought for the SC STRONG project. The institutional review boards at the University of South Carolina and the SC DHEC both determined that SC STRONG project activities did not constitute human-subjects research under the auspices of public health surveillance (102072). Participation in testing and survey completion was voluntary.

Results

Overview

From October 26, 2020, to June 16, 2021, 3 rounds of data collection were conducted, and 450,063 invitation letters were mailed out (Figure 1). The first round of data collection took place from October 26, 2020, to January 22, 2021, and 32,500 invitation letters were mailed. This round coincided with the second wave, when daily COVID-19 cases peaked to over 5500 (Figure 2). The second round of data collection took place from January 25, 2021, to March 31, 2021, and 117,563 letters were mailed (Figure 1). This round was toward the end of the second wave of COVID-19, when the daily number of cases fell to less than 1200 per day and COVID-19 vaccines became available under phase 1b to populations living and working in shared settings with increased risk and to frontline essential workers (Figure 2). The third round of data collection ran from April 2, 2021, to June 16, 2021, and 300,000 letters were mailed (Figure 1). At the time of this round, COVID-19 vaccines were available to individuals aged 16 years or older (Figure 3).

A total of 8200 surveys were attempted across the 3 rounds, and 1030 surveys were excluded due to incomplete or inconsistent responses; therefore, a total of 7170 completed surveys was used for the present analysis (Figure 1). The response rate for all 3 rounds was 1.6% (7170/450,063). The response rate decreased with each round, from 5.4% (1755/32,500) in the first round to 0.8% (2384/300,000) in the third round. There was also variation in the percentage of responses by county of residence (Figure 3). More survey respondents lived in the upstate region (eg, Greenville County at 950/7091, 13.4%), in coastal areas (eg, Charleston County at 726/7091, 10.3%, and Horry County at 639/7091, 9%), and in areas surrounding the capital city (eg, Lexington County at 500/7091, 7.1%, and Richland County at 667/7091, 9.4%).

Most survey respondents were aged 60 years or older (4087/7170, 57%), female (4151/7170, 57.9%), and Caucasian (6087/7170, 84.9%; Table 1). Survey respondents were fairly representative of the general SC population in terms of gender and income. However, Hispanic/Latino Americans and African Americans were underrepresented in the survey. Whereas 5.8% and 26.3% of the general SC population are Hispanic/Latino Americans and African Americans, only 2.2% (158/7170) and 8.9% (683/7170) of survey respondents identified as Hispanic/Latino Americans and African Americans, respectively. Moreover, older age groups were overrepresented in the study population. There were also differences among survey respondents by COVID-19 testing status. Respondents who were previously tested for COVID-19 tended to be younger, female, and have higher income than the overall sample of survey respondents (Table 1).

[c] *P* values (chi square test) for differences between those ever tested for COVID-19 and those with no history of testing.

[d] Percentages may add to more than 100%, as survey respondents could give multiple answers.

Impact of the Pandemic

The COVID-19 pandemic impacted the lives of SC residents in multiple ways. In terms of employment, 3.8% (271/7170) reported becoming unemployed during the pandemic, 10.6% (760/7170) reported reductions in income or pay, and 7.8% (562/7170) reported working fewer hours than normal (Table 2). In terms of mental and emotional health, 72.1% (5173/7170) reported often feeling stressed, nervous, or on the edge, 56.7% (4063/7170) reported often feeling sad or depressed in the previous 2 weeks, and 19% (1365/7170) reported having physical reactions when thinking about the pandemic. However, only 2.6% (191/7170) reported being diagnosed with anxiety or depression during the pandemic. In terms of food security, very few respondents reported experiencing lack of food (73/7170, 1%) or going without eating (282/7170, 4%) in the previous 2 weeks due to lack of money or resources.

Table 2. Trends in behaviors and attitudes among South Carolina residents toward testing, vaccination, and preventive measures for the COVID-19 pandemic (n=7170).

Behaviors and attitudes	Respondents, n (%)	Change per week[a]	*P* value
Ever been tested	4213 (58.7)	0.03	<.001
Active infection[b]	3988 (94.6)	0.03	<.001
Antibodies[b]	862 (20.5)	0.02	<.001

Having felt some level of stress, anxiety, or being on the edge in the past 2 weeks	5173 (72.1)	–0.03	<.001
Impact of pandemic on food insecurity			
Lack of food in the past 2 weeks	73 (1)	–[f]	.1
Gone without eating in the past 2 weeks	282 (4)	–0.02	<.001

[a] Adjusted logistic regressions including time (in weeks) as a predictor to assess for trends over time.

[b] Percentages represent percentages of those ever tested.

[c] Percentage may add more to than 100%, as survey respondents could give multiple answers.

[d] Percentage of those with no history of testing (n=593).

[e] N/A: not applicable, as the variable violated the assumption for logistic regression.

[f] Point estimate for the change per week was smaller than 0.001; the – symbol indicates the direction of the change (ie, negative).

COVID-19 Testing Practices and Barriers

Of the 7170 survey respondents, 58.7% (4213/7170) reported ever testing for COVID-19 active infection or antibodies, and there was a 3% increased likelihood of testing for COVID-19 with every week that passed (Table 2). The most common barriers to testing were inconvenient times and dates (143/593, 20.3%), the discomfort of the test (141/593, 19.2%), and lack of knowledge of where to go to be tested (118/593, 16.1%). Nevertheless, the likelihood of citing these testing barriers decreased with time. On the other hand, the most common reasons for getting tested were having a close contact who had tested positive (1397/4213, 33.2%); having coronavirus-like symptoms (1314/4213, 31.2%); medical, travel, or employment requirements (834/4213, 19.8%); and being concerned about the high number of COVID-19 cases in the community (789/4213, 18.7%). A less common reason for testing was curiosity (721/4213, 17.1%). More than half of respondents received testing at a drive-through or community pop-up testing site (2746/4213, 65.2%) and reported being tested more than once (2372/4213, 56.3%). Over time, respondents were more likely to get tested and reported getting tested in a drive-through or community pop-up testing site. Of those who had ever been tested, 18.8% (790/4213) reported testing positive for antibodies or active infection at some point.

COVID-19 Preventive Behaviors

Most respondents reported social distancing (7068/7170, 98.6%) and wearing face masks (7035/7170, 98.1%) in the previous 2 weeks, and fewer reported self-isolation (676/7170, 9.4%) or quarantining (Table 2). The likelihood of engaging in these practices decreased with time (*P*<.001). Overall, 45.8% (2498/5460) of respondents reported being vaccinated against COVID-19. An assessment of attitudes toward the vaccine indicated that 72.9% (3982/5460) of respondents thought the COVID-19 vaccines were safe, and 41.6% (2270/5460) planned to get vaccinated at some point. Among those who reported not planning to get the vaccine, the main reason was discomfort with being one of the first to be vaccinated (282/571, 49.4%). Overall, there was an increased likelihood of vaccination (20%) and positive attitudes toward the vaccines per week.

Factors Associated With COVID-19 Test Positivity

In the multivariable logistic regression analysis, several factors were significantly associated with COVID-19 test positivity (Table 2). The likelihood of COVID-19 test positivity was increased among individuals who identified as Black/African American, were employed in a nursing home or as a frontline health care worker, were obese, and reported testing at the doctor's office. Furthermore, the aOR of a positive COVID-19 test was highest for individuals who decided to test because of coronavirus-like symptoms (aOR 7.37, 95% CI 6.08-8.94) and those with a family member or close friend who currently or previously had COVID-19 (aOR 4.61, 95% CI 3.41-6.24). On the other hand, the likelihood of COVID-19 test positivity was decreased among individuals who expressed concern about being infected (aOR 0.38, aOR 0.30-0.47) and who chose to test out of concern for the perceived high burden of COVID-19 in the community (aOR 0.28, 95% CI 0.20-0.40). There was no statistically significant difference in the likelihood of test positivity by gender or income.

Discussion

Principal Findings

Using serial population-based surveys conducted between November 2020 and June 2021, this paper sought to describe COVID-19 risk perceptions, testing patterns, and preventive behaviors and identify factors associated with test positivity among a large random sample of SC residents. Overall, 58.7% (4213/7170) of respondents reported ever testing for COVID-19, and over time, there was a decrease in barriers to testing. This finding is consistent with the increased availability of testing locations across the state over time. Moreover, our results suggested an increased likelihood of testing over time, an increased likelihood of positivity based on symptoms and exposure, and a decreased likelihood of positivity based on individual concern. Despite increased testing, there were decreases in practicing preventive behaviors such as mask-wearing and social distancing, indicating fatigue. Previous research has shown that states with no mask policy and low mask adherence reported high COVID-19 infection rates, while states with high mask adherence and strict mask-wearing policies showed decreased infection rates [21]. It is important to note that politics has had a drastic effect on COVID-19 epidemiology, and there has been contradictory messaging regarding infection information and uptake of mitigation policies. This is reflected in misinformation driven by aligned political beliefs that conflicts with the scientific evidence and recommendations from public health agencies [22].

Comparison With Prior Work

In this paper, 18.7% (790/7170) of respondents self-reported ever testing positive for COVID-19, which is comparable to the estimated seroprevalence of 16.4% for SC residents aged 5 years or older [18]. Our estimate could be influenced by self-selection, as our data for ever having tested positive were based on self-reports. Moreover, availability of the vaccine began in mid-January for individuals aged 70 or older, which likely also impacted testing demand. At the time of the survey, 58.7% (4213/7170) of respondents had ever been tested for COVID-19, whereas it has previously been reported that 66.7% received the vaccine, suggesting the possibility that a number of respondents did not actively seek testing due to fear of exposure [23]. Our results show the likelihood of test positivity was highest among Black/African Americans and older individuals (aged ≥50 years). Although the state does not report race or ethnicity data for testing, count data for COVID-19 deaths in SC indicate that Black/African Americans and older people are more likely to be unvaccinated, to be hospitalized for severe disease, and to die from COVID-19 [18]. The likelihood of test positivity decreased 38% in individuals who expressed concern about becoming infected, which aligns with the findings of Yildirim and Güler [24], who highlighted the direct association between perceived risk and positivity. When developing strategies to increase the adoption of preventive behaviors, understanding perceived individual risk is essential. Moreover, testing sites are often inconveniently located or open during times that are less available for people living in deep poverty due to the low flexibility of low-wage jobs and difficulty obtaining transportation. Therefore, considerable improvements should be made to accommodate the lowest socioeconomic strata, which cannot appropriately use these public health services.

Limitations

The findings presented in this paper should be interpreted in light of several limitations. First, given the cross-sectional survey design, the temporal relationship between outcome and exposures cannot be ascertained and causality cannot be determined. Second, the representativeness of the sample is limited due to the low response rate; the lack of partner clinics in some areas of the state may have hindered participation in the community testing and online survey. Third, the sampling frame was based on a purchased marketing listserve that may not be up-to-date. Fourth, COVID-19 test positivity was based on self-reports, which are prone to bias. Fifth, comparison of sociodemographic characteristics by history of testing indicated that the respondents who sought testing were more likely to be older, female, Caucasian, and have a higher income than the general population, potentially limiting the generalizability of our results. Lastly, although an electronic survey was selected to ensure respondent safety and minimize costs of survey implementation, only about 81.8% of households in SC have access to the internet [25]. Staff were available to assist with completion of the survey online, and paper surveys were also available at the pop-up events. The analysis was restricted to responses included in the survey; this approach did not represent nonrespondents and did not capture several socioeconomic and education variables that were not included in the survey. Similarly, the results need to be considered cautiously, as the distribution of respondents might only represent individuals with broadband internet access, which would underrepresent those populations that commonly suffer health disparities and inequities related to socioeconomic, educational, and racial background.

Conclusions

Population-based surveys are useful tools in understanding attitudes, behaviors, and practices and can inform public health responses and the adaptation of strategies to reach high-risk populations. Despite its limitations, the SC STRONG initiative represents a statewide outreach and partnership program with local clinics and health care providers. The findings presented here provide insights to understand risk perceptions and testing behaviors and have important implications given that Southern states have historically struggled with compliance and implementation of preventive public health measures.

Acknowledgments

We would like to thank the South Carolina residents and clinical partners who participated in this surveillance initiative. We would also like to thank our additional partners from the South Carolina Sampling and Testing Representative Outreach for Novel Coronavirus Guidance (SC STRONG) project team (listed in alphabetical order): Graham Adams (South Carolina Office of Rural Health), Roxanne Ancheta (South Carolina Department of Health and Environmental Control; SC DHEC), O’Neal Best (University of South Carolina; U of SC), Sarah Cockrell (South Carolina Primary Health Care Association), Madison Collins (U of SC), Hanson Cowan (U of SC), Megan Davis (SC DHEC), Kenneth R Deans, Jr (Health Sciences South Carolina; HSSC), Abbie Drake (College of Charleston), Joan M. Abstract

Background: Longitudinal studies characterizing the epidemic trend of respiratory syncytial virus (RSV) in Hubei Province are scarce.

Objective: We aimed to depict the dynamics of the RSV epidemic among hospitalized children with acute respiratory tract infections (ARTIs) during 2014 to 2022 in the Maternal and Child Health Hospital of Hubei Province and investigate the influence of the 2-child policy and the COVID-19 pandemic on RSV prevalence.

Methods: The medical records and testing results of hospitalized children with ARTI from January 2014 to June 2022 were extracted. Nasopharyngeal samples were tested with direct immunofluorescence assay. Detection rates of RSV were categorized according to the diagnosis of patients: (1) overall, (2) upper respiratory tract infection (URTI), and (3) lower respiratory tract infection (LRTI). Poisson regression models were used to investigate the association between RSV detection rate and age, gender, or diagnosis. The detection rates of RSV before and after the implementation of the universal 2-child policy were compared using a Poisson regression model. Multiple comparisons of RSV detection rates were conducted among 3 stages of the COVID-19 pandemic using chi-square tests. Seasonal autoregressive integrated moving average was performed to predict RSV behaviors from February 2020 to June 2020 under the assumption of a non-COVID-19 scenario.

Results: Among 75,128 hospitalized children with ARTI, 11.1% (8336/75,128) were RSV-positive. Children aged <1 year had higher detection rates than older children (4204/26,498, 15.9% vs 74/5504, 1.3%; *P*<.001), and children with LRTI had higher detection rates than children with URTI (7733/53,145, 14.6% vs 603/21,983, 2.7%; *P*<.001). Among all the children, a clear seasonal pattern of the RSV epidemic was observed before 2021. Most of the highest detection rates were concentrated between December and February. The yearly detection rate of RSV remained at a relatively low level (about 8%) from 2014 to 2017, then increased to 12% and above from 2018. The highest monthly detection rate was in December 2018 (539/1493, 36.1%), and the highest yearly rate was in 2021 (1372/9328, 14.7%). There was a moderate increase in the RSV detection rate after the 2-child policy was implemented (before: 860/10,446, 8.2% vs after: 4920/43,916, 11.2%; *P*<.001). The largest increase, by 5.83%, occurred in children aged <1 year. The RSV epidemic level decreased sharply in the short term after the COVID-19 outbreak (detection rate before: 1600/17,010, 9.4% vs after: 32/1135, 2.8%; *P*<.001). The largest decrease, by 12.0%, occurred in children aged <1 year, but a rebounding epidemic occurred after 2020 (680/5744, 11.8%; *P*<.001).

Conclusions: Children have been experiencing increased prevalence of RSV since 2018 based on surveillance from a hospital in Hubei Province with a large sample size. The 2-child policy might have increased the RSV prevalence, and the COVID-19 epidemic had a temporary inhibitory effect on RSV transmission. Vaccines against RSV are urgently needed.

Introduction

Respiratory syncytial virus (RSV) is an enveloped, single-stranded, negative-strand RNA virus belonging to the genus *Orthopneumovirus* within the family *Pneumoviridae* [1]. RSV is one of the most common pathogens leading to acute lower respiratory tract infections (LRTIs) among infants [2]. It has been reported that approximately 70% of children are infected in the first year after birth, and almost 100% are infected in their first 2 years [3]. In adults and older children, RSV usually causes mild clinical cold-like signs and symptoms such as congested or runny nose, cough, fever, sore throat, sneezing, and headache, which can disappear in 1 week to 2 weeks [4]. In contrast, RSV can cause much more severe outcomes including pneumonia, bronchiolitis, and even death in young children, especially in infants with underlying diseases or a weak immune system [4]. Recent research estimated that 33.0 million episodes, 3.6 million hospital admissions, 26,300 in-hospital deaths, and 101,400 overall deaths were attributed to RSV-associated acute LRTI in children under 5 years old in 2019 globally [5], and more than 95% of episodes and 97% of deaths happened in low and middle-income countries. RSV-attributable deaths were responsible for 1 in 50 and 1 in 28 deaths in children aged under 5 years old and children aged 28 days to 6 months, respectively. In addition, RSV infection in early life can cause an increased risk of multiple long-term adverse effects including asthma and decreased lung function [6]. RSV infection can also lower immunity and contribute to the risk of COVID-19 and the severity of COVID-19 illnesses [4]. Nevertheless, no drug has been successfully developed to specifically treat RSV-related illnesses to date.

Similar to other respiratory viruses, RSV is spread easily on infected respiratory droplets by air to people's eyes, noses, and mouths if people with RSV cough or sneeze near susceptible individuals. Common measures to prevent RSV infection include washing hands frequently, limiting children's contact with people who have cold-like symptoms, keeping a hygienic environment, and not sharing drinking glasses with others [4]. Dozens of promising vaccine candidates against RSV based on multiple technologies are being developed; however, no candidate has yet completed a phase 3 trial [1]. Some of these vaccine candidates may receive regulatory approval in the near future [1].

Previous studies revealed that the RSV epidemic has obvious seasonal patterns worldwide [7-9]. In the northern hemisphere, it usually occurs from October/November to April/May, while it occurs from May to September in the southern hemisphere [10]. In light of the regionality and seasonality of the epidemic, investigation of conducting continuous surveillance of RSV activities widely in different regions is warranted, especially in metropolitan cities with larger population movement, to enable early warning and medical preparations. During the early stage of the COVID-19 pandemic, marked decreases in non-COVID-19 respiratory infections including RSV that were observed in previous epidemic seasons as multiple mitigation measures were adopted to cope with COVID-19 [11-17]. The strictest nonpharmaceutical interventions (NPIs) including city lockdown, social distancing, nucleic acid testing, wearing masks, and suspension of work and school were implemented in Wuhan to contain the COVID-19 outbreak in the first half of 2020. After the control of the first wave of COVID-19, most NPIs were lifted or relaxed, and nucleic acid testing was regarded as the leading component of measures to control COVID-19. It was a typical example of assessing the impact of interventions against COVID-19 on the epidemic regularity of RSV. In addition, the universal 2-child policy was implemented in Hubei Province in 2016 and lifted the 1-child limit and allowed all couples, regardless of residence in urban or rural areas and regions and ethnic groups, to have 2 children. The potential increased number of newborns in Hubei Province after the policy shift might have influenced the epidemiological characteristics of diseases in young children. Based on data from the largest maternal and child health hospital in Hubei Province of China from 2014 to 2022, we aimed to depict the dynamics of the RSV epidemic in the past 8 years and investigate the influence of the 2-child policy and the COVID-19 pandemic on RSV prevalence.

Methods

Design, Setting, and Population

This study retrospectively reviewed RSV detection results among hospitalized children with acute respiratory tract infection (ARTI) from January 2014 to June 2022 in the Maternal and Child Health Hospital of Hubei Province. The Maternal and Child Health Hospital of Hubei Province is the largest tertiary hospital specializing in maternal and child health service and academic research in Hubei Province, with 1900 inpatient beds and more than 2.77 million outpatient visits in 2019 [18]. Hospitalized children were included if they met the following criteria: (1) diagnosed with ARTI and (2) aged less than 18 years. Specifically, ARTI consisted of upper respiratory tract infection (URTI) and LRTI. LRTI included bronchiolitis and pneumonia [19]. Children were divided into 4 age groups: <1 year, 1-2 years, 3-5 years, and 3-17 years. Basic information about the patients including demographics, symptoms, diagnosis, and examination results was extracted from the hospital case information database.

Samples and Laboratory Testing

Respiratory tract samples were collected within 24 hours after admission using nasopharyngeal swabs, which were stored in centrifuge tubes containing 3 mL saline. RSV was detected through direct immunofluorescence assay with a D^3 Ultra DFA Respiratory Virus Screening and ID Kit (Diagnostic Hybrids Inc). Detailed laboratory operations under the guidance of the kit instructions were as follows: (1) fluid containing samples was blended fully using a vortex oscillator; (2) tubes were centrifuged at 500×g for 10 minutes, then only 150 μL supernatant and sediment were kept; (3) supernatant and sediment were mixed for cell suspension, and 150 μL cell suspension was added to a glass slide, dried, immersed in cold acetone solution for 10 minutes, and dried again; (4) a drop of fluorescein isothiocyanate–labeled monoclonal antibody (about 25 μL) was added to the glass slide to cover the sample and incubated for 30 minutes in a wet box at 37 °C and rinsed and covered by a glass cover; (5) the glass slide containing samples was observed under a fluorescent microscope (Olympus BX53). A sample was regarded as positive for RSV when at least 2 positive cells with apple green fluorescence were observed in the field of view at a 200-fold magnification of the microscope.

Statistical Analysis

The detection rate was calculated as the number of RSV-positive samples divided by the total number of samples, with the 95% CI of the detection rate determined using the Clopper-Pearson method. In all analyses, detection rates are presented in 3 categories according to the diagnosis of patients: overall, URTI, and LRTI. In each category, detection rates were further described according to age group and gender. An adjusted risk ratio (RR) and 95% CI were obtained using a Poisson regression model to show the relative risk of getting RSV at 1 level compared with the reference level in 1 variable, after adjusting for the other 2 variables. For example, the risk of RSV infection in male children versus female children was assessed by adjusting the impact of age and diagnosis. Line plots and bar plots were generated to delineate the detection rate and the number of samples, respectively. A heat map was generated to compare the seasonal distribution of the RSV epidemic across different years, in which a detection rate of 8% was assumed to be an RSV epidemic. Considering the 2-child policy was implemented in 2016 in Hubei Province, the difference in the pooled RSV detection rates between the 2014-2015 and 2017-2019 periods was illustrated by calculating an adjusted RR in the Poisson regression model. These statistical comparisons were considered significant at *P*<.05. According to the COVID-19 status in Hubei Province, 3 stages were determined: stage 1 (prior to the COVID-19 pandemic: February to June in each year from 2017 to 2019), stage 2 (early COVID-19 outbreak: February 2020 to June 2020), and stage 3 (COVID-19 normalization period: February to June in each year from 2021 and 2022). The change in the RSV epidemic in the 2 periods after the COVID-19 outbreak in contrast to the period prior to COVID-19 was investigated. The chi-square test was used in multiple comparisons with statistical significance set at *P*<.025 in the Bonferroni method. Seasonal autoregressive integrated moving average (SARIMA) was used to present the difference between the predicted epidemic level of RSV from February 2020 to June 2020 in a non-COVID-19 scenario and the true detection rate of RSV in Hubei Province. Time series data of URTI cases were not analyzed with a SARIMA model as they were not stationary in the unit root test. Microsoft Excel, Stata 17 (StataCorp), and R 4.1.2 (R Core Team) were used for data processing and visualization.

Ethical Considerations

This study was approved by the clinical research ethics committee of the Maternal and Child Health Hospital of Hubei Province (2022IEC052). Informed consent was exempted due to the retrospective nature of our study. Data used in this study were anonymized and deidentified.

Results

Basic Characteristics of the Overall Sample

A total of 75,128 children from January 2014 to June 2022 met the inclusion criteria of this study (Table 1). These participants primarily consisted of children aged <2 years (50,417/75,128, 67.1%), who were male (44,959/75,128, 59.8%), and who were diagnosed with LRTI (53,145/75,128, 70.7%). Among all the children, 11.1% (8336/75,128) were RSV-positive. The children aged <1 year had the highest RSV detection rate (4204/26,498, 15.9%), followed by children aged 1 year to 2 years (2777/23,919, 11.6%), and rates in both age groups were significantly higher than that for older children (*P*<.001). No significant difference in the RSV detection rate existed between male children and female children (*P*=.54). In addition, the children with LRTI were more likely to be RSV-positive than those with URTI (7773/53,145, 14.6% vs 603/21,983, 2.7%; adjusted RR 4.88, 95% CI 4.50-5.30; *P*<.001). Among 986 children requiring care in the intensive care unit, 256 (26.0%) were positive for RSV.

Table 1. Basic characteristics of the overall sample (n=75,128).

Variables	Positive tests, n	Tests, n	Detection rate, % (95% CI)	Adjusted RR[a] (95% CI)	*P* value
Overall	8336	75,128	11.1 (10.9-11.3)	—[b]	—
Age (years)					
<1	4204	26,498	15.9 (15.4-16.3)	9.84 (7.83-12.36)	<.001[c]
1-2	2777	23,919	11.6 (11.2–12.0)	8.15 (6.48-10.25)	<.001[c]

[e] Adjusted for age and gender.

[f] URTI: upper respiratory tract infection.

[g] LRTI: lower respiratory tract infection.

Time Trend and Seasonal Pattern of RSV

Among all the children, a clear seasonal pattern of the RSV epidemic was observed before 2021. Most top detection rates were concentrated between December and February, except for March in 2018 (Figure 1). The yearly detection rate of RSV remained at a relatively low level (about 8%) from 2014 to 2017, then increased to 12% and above from 2018. The highest monthly detection rate was in December 2018 (539/1493, 36.1%), and the highest yearly rate was in 2021 (1372/9328, 14.7%). Notably, from May to September in the years before 2021, the RSV detection rate was maintained at an extremely low level, close to zero, while a wave of a moderate epidemic (about 10%) arose in the same period in 2021. From the perspective of age, obvious differences in the RSV detection rate across 3 age groups were seen. Younger children had a higher RSV detection rate. However, RSV detection rates were hard to distinguish between children <1 year old and children 1 year to 2 years old after January 2021. The detection rates between the male and female children almost coincided.

Among the children with URTI, a seasonal peak also existed in December or January (Figure 2). Monthly detection rates of more than 10% were only seen in 2021 and 2022. From 2015 to 2021, the yearly RSV detection rate in URTI cases increased continuously from 0.5% (8/1521) to 5.6% (220/3929). Children aged 1 year to 2 years had a higher positive RSV detection rate than those aged 6 years to 17 years (258/8017, 3.2% vs 26/2136, 1.2%, *P*<.001; Table S1 in Multimedia Appendix 1). No significant difference in RSV detection rate was found between genders (*P*=.37). Among the children with LRTI, the trend and seasonal pattern of RSV detection rate were similar to that in all the children (Figure 3). The monthly RSV detection rate peaked in December 2018 (521/1294, 40.3%), and the yearly detection rate peaked in 2021 (1152/5399, 21.3%). Children aged <1 year (4055//20,849, 19.5%) or 1 year to 2 years (2519/15,902, 15.8%) had obviously higher RSV-positive rates than the oldest age group (48/3368, 1.4%; all *P*<.001; Table S2 in Multimedia Appendix 1). No difference was observed between genders (*P*=.57).

The heat maps show the beginning and end weeks of the RSV epidemic in each year (Figure 4 and Multimedia Appendix 2). A similar distribution of the RSV epidemic was observed between all the children and those with LRTI. The earliest beginning of the epidemic (about the 40th week) happened in 2017 and 2021, and the latest end of the epidemic (the 15th and 20th weeks) happened in 2018 and 2021, respectively. Particularly in 2021, RSV had the longest epidemic period lasting 40 weeks (about 77% of the whole year). In contrast, the shortest epidemic period of only 15 weeks occurred in 2020. Things were quite different in children with URTI. The RSV epidemic lasted a short number of weeks (<5 weeks) in the years before 2020. However, a long RSV epidemic period occurred in 2021 (16 weeks). Heat maps of the 2 younger age groups and the 2 genders did not provide different information from that of all the children. A much shorter epidemic period was seen for children aged 3 years to 5 years or 6 years to 17 years.

Figure 1. Monthly distribution of tests for (bars) and detection rate of (lines) respiratory syncytial virus from 75,128 hospitalized children with acute respiratory tract infection during 2014 to 2022: (A) overall sample, (B) by age group, (C) by gender.

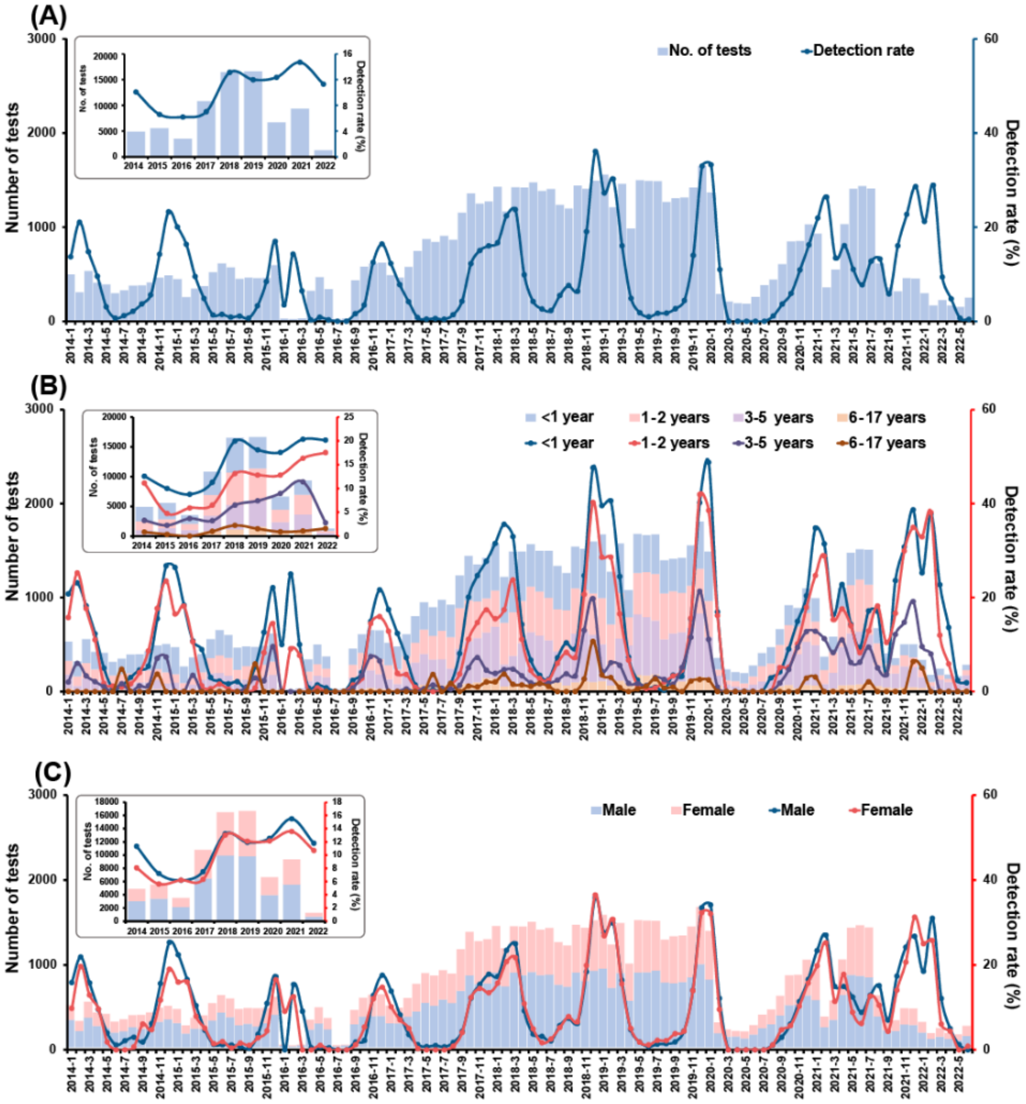

Figure 2. Monthly distribution of tests for (bars) and detection rates of (lines) respiratory syncytial virus from 21,983 hospitalized children with acute upper respiratory tract infection during 2014 to 2022: (A) overall sample, (B) by age group, (C) by gender.

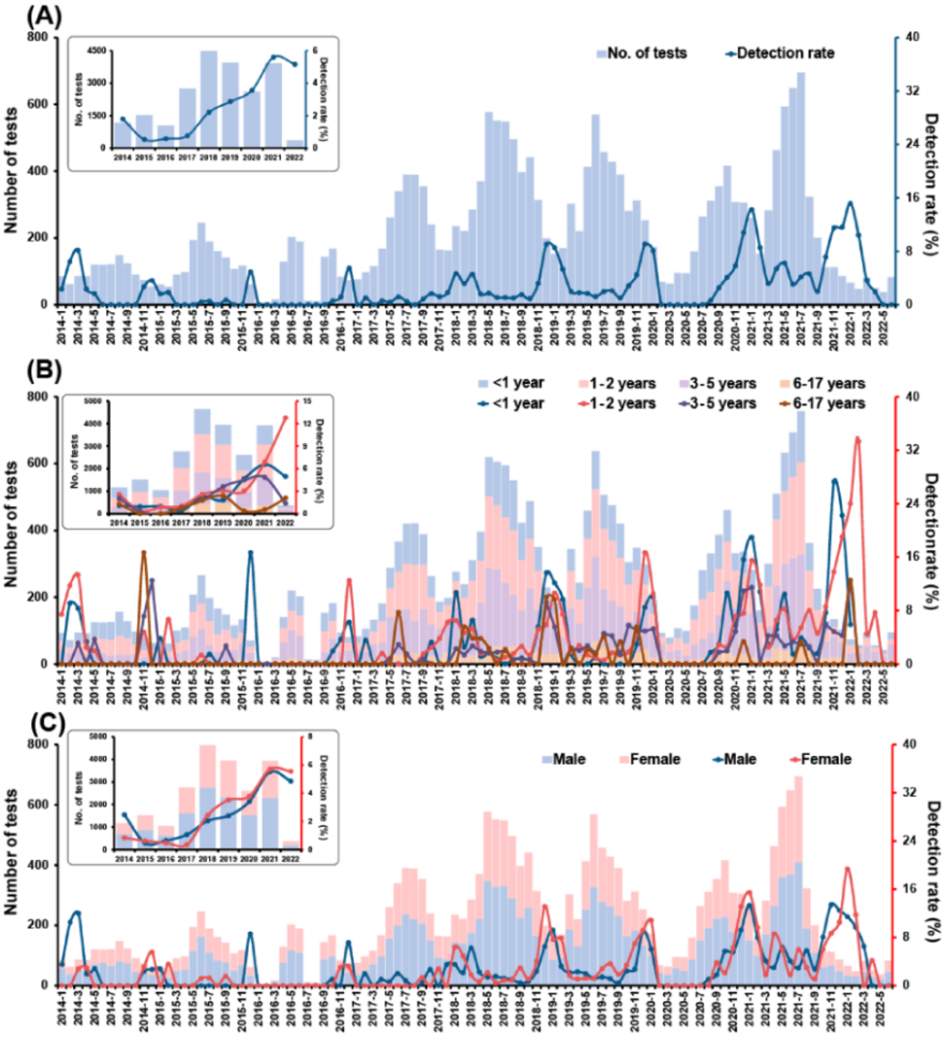

Figure 3. Monthly distribution of tests for (bars) and detection rate of (lines) respiratory syncytial virus from 53,145 hospitalized children with acute lower respiratory tract infection during 2014 to 2022: (A) overall sample, (B) by age group, (C) by gender.

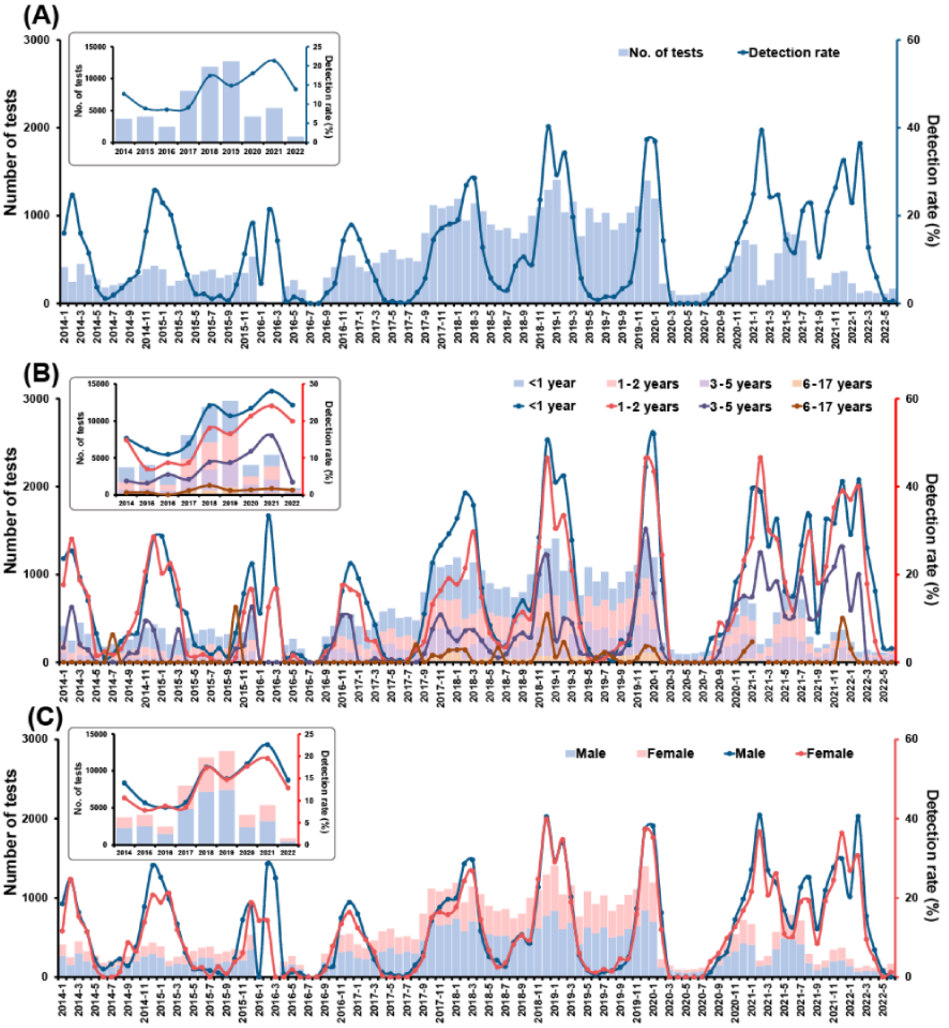

Figure 4. Heat maps of the respiratory syncytial virus detection rate by week during 2014 to 2022: (A) overall sample, (B) in those with upper respiratory tract infection, (C) in those with lower respiratory tract infection, (D) in those <1 year old, (E) in those 1 year to 2 years old, (F) in those 3 years to 5 years old, (G) in those 6 years to 17 years old, (H) in male children, (I) in female children.

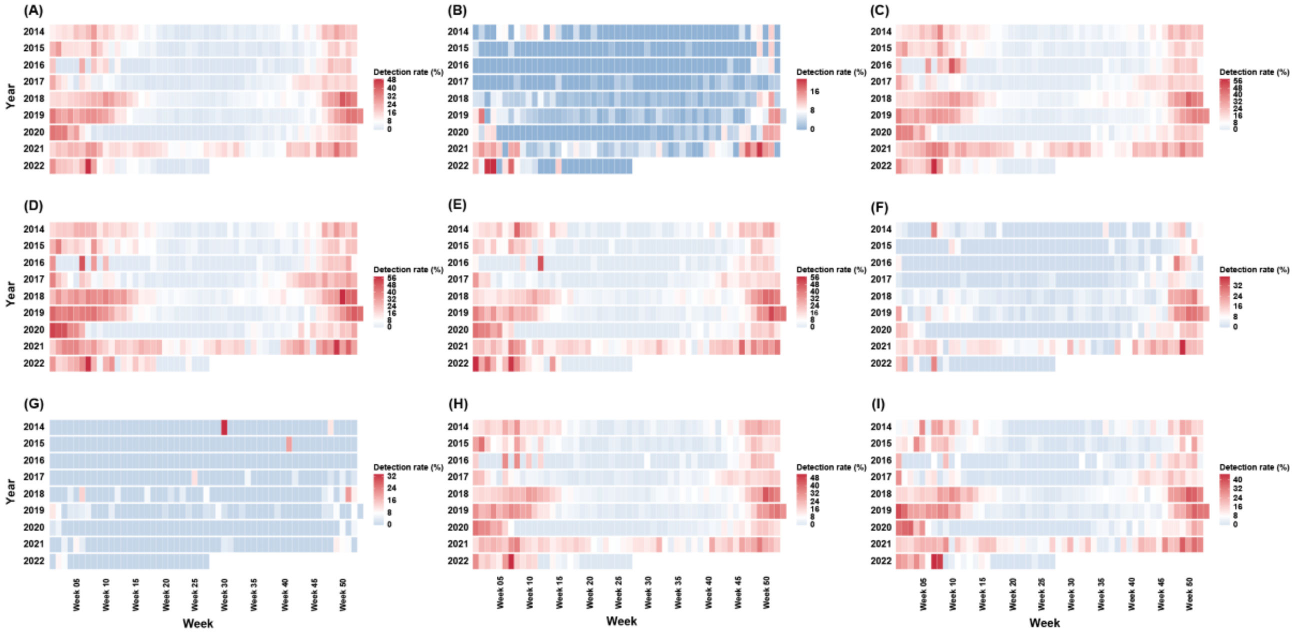

Impact of the 2-Child Policy on the RSV Epidemic

Among all the children, there was a moderate increase in the RSV detection rate in most subgroups, except for children aged 6 years to 17 years, after the 2-child policy was implemented (all *P*<.001; Table 2). The largest increase, by 5.83%, occurred in children aged <1 year. Children aged 6 years to 17 years had the highest risk of being infected after the implementation of the policy (adjusted RR 2.80, 95% CI 0.88-8.90). Similar results were found with children with LRTI. Among the children with URTI, the increased RSV detection rates in only the entire group of children and female children were significant (*P*=.001 and *P*=.002, respectively). Though female children had a high risk of RSV infection after the implementation of the 2-child policy (adjusted RR 3.12, 95% CI 1.52-6.39), the prevalence of RSV increased slightly from 0.7% (8/1133) to 2.3% (107/4658).

Table 2. Comparison of the detection rate of respiratory syncytial virus before and after the implementation of the universal 2-child policy.

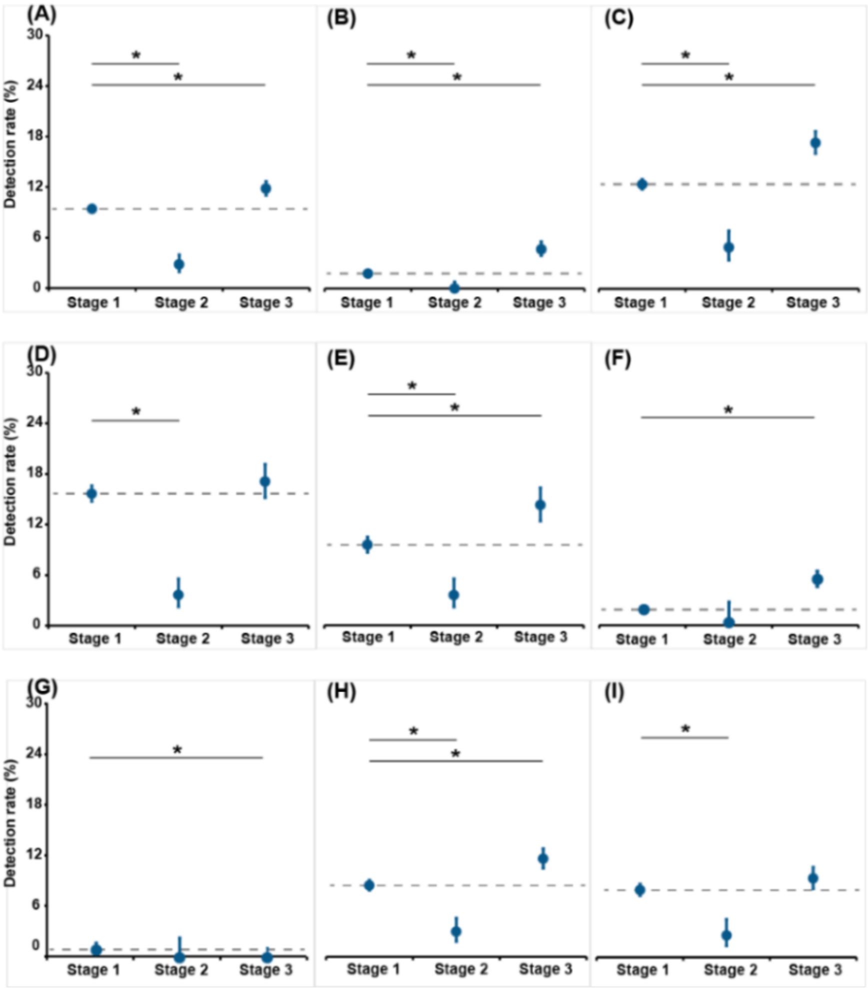
Impact of the COVID-19 Outbreak on the RSV Epidemic

Among all the children, compared with the pooled levels from February to June in each year from 2017 to 2019, all the stratifications except for the 2 older groups achieved significant reductions in the RSV detection rate during the earliest months of the COVID-19 pandemic (February 2020 to June 2020; Figure 5, Multimedia Appendix 3, and Table S3 in Multimedia Appendix 1). Of these, the sharpest decline, by 12.0%, occurred in children aged <1 year. Among the children with URTI, only the overall sample and male children showed declines of statistical significance. Among the children with LRTI, only the children aged 1 year to 2 years, 3 years to 5 years, or 6 years to 17 years did not have significantly decreased RSV detection rates. The largest decrease (13.8%) was observed in children aged <1 year.

Among all the children, compared with the pooled levels during February to June in each of 2017 to 2019, the overall RSV detection rate increased from 9.4% (1600/17,010) to 11.8% (680/5744) during the same periods in 2021 and 2022 (Figure 5, Multimedia Appendix 3, and Table S3 in Multimedia Appendix 1). All the stratifications, except for children aged <1 year and female children, had significant increases in the RSV detection rate. Of these, children aged 1 year to 2 years had the largest increase, by 4.7%. Among the children with URTI, all the stratifications, except for children aged 6 years to 17 years, had significant increases. The children aged 1 year to 2 years had the largest increase, by 4.3%. Among the children with LRTI, all the stratifications, except for children aged 6 years to 17 years, had significant increases, with the largest increase in children aged 1 year to 2 years, by 7.7%.

Multimedia Appendix 4 compares the observed rates with the predicted rates of RSV detection from February 2020 to June 2020 based on the SARIMA model. Among all the children, the forecasted RSV detection rates were much higher than the actual values. The largest decrease, by 28.5%, in the RSV detection rate happened in March 2020, denoting the most significant impact of the COVID-19 outbreak. In all the stratified analyses, the observed rates were significantly lower than the lower limit of the 95% CI of the forecasted rates representing the counterfactual scenario without COVID-19.

Figure 5. Comparison of the respiratory syncytial virus detection rate among periods according to COVID-19 epidemic status (stage 1: February to June in each of 2017, 2018, and 2019; stage 2: February 2020 to June 2020; stage 3: February to June in each of 2021 and 2022): (A) overall sample, (B) those with upper respiratory tract infection, (C) those with lower respiratory tract infection, (D) in those <1 year old, (E) in those 1 year to 2 years old, (F) in those 3 years to 5 years old, (G) in those 6 years to 17 years old, (H) in male children, (I) in female children. *P<.05.



Discussion

In this study, more than 8 years of RSV surveillance including 75,128 hospitalized children with ARTI was carried out to better understand the epidemiological characteristics of RSV based on a sentinel hospital in Hubei Province. Yearly RSV epidemic peaks concentrated in the period from December to February were observed before 2021. The RSV detection rate in 2018 and later was significantly higher than that in 2017 and before. RSV was more likely to be detected among younger children and children with an LRTI. The 2-child policy implemented in 2016 was related to an increased RSV detection rate in the following 3 years. The RSV epidemic level decreased sharply from February 2020 to June 2020, but a rebounding epidemic peak in the subsequent winters and increased epidemic levels in the summer of 2021 occurred. The results about the influence of the 2-child policy and COVID-19–related NPIs on the RSV epidemic were obtained using lengthy surveillance data from the Maternal and Child Health Hospital of Hubei Province and will need more multicenter data to further confirm.

RSV was the most frequently detected in the winter and the least frequently detected in the summer in our study, which was similar to the seasonal pattern in some temperate countries [20]. The area in which the Maternal and Child Health Hospital of Hubei Province is located is in a subtropical monsoon climate, with a high temperature in the summer and a low temperature and high relative humidity in the winter. A low temperature is likely to cause vasoconstriction of the nasal mucosa and weakens the immunity of the respiratory tract against viruses [21,22]. In winter, more frequent gathering indoors and a lack of air circulation can also contribute to the transmission of RSV. In addition, relative humidity plays an essential role in respiratory virus transmission. It has been reported that RSV epidemics tend to occur in the rainy season. Wet conditions may increase the number of viruses deposited on surfaces, promote the survival of viruses in droplets on surfaces, and, in turn, encourage the contact transmission of RSV [20,23]. Therefore, prior to rainy or cold weather, knowledge about prevention measures against RSV such as hand hygiene, environmental cleaning, and indoor ventilation should be conveyed to the public, in particular to families with young children.

Limited literature has focused on the longitudinal trends of the RSV epidemic over the past decade in Hubei Province. Most studies devoted to the epidemiological characteristics of RSV in China analyzed the positive rate of RSV among ARTI cases collected during 1 or more years in a cross-sectional manner. A study including pediatric and adult patients with ARTI from 2011 to 2016 in Guangdong Province reported a less clear and unstable seasonal pattern of RSV with epidemics almost year-round [24]. The highest detection rates of RSV usually appeared from March to May and ranged from 15% to 30% in that study. The highest detection rates in that period in our study were similar to those reported in other studies, but RSV broke out earlier. Research conducted in Beijing reported that the peak months of the RSV epidemic were November to January [25]. The results of these studies suggest that earlier RSV epidemics happen with increased latitude and decreased annual average temperatures. Another surveillance study that enrolled 19,898 hospitalized children with ARTI showed an annual RSV detection rate in the range of 5.4% to 7.0% from 2014 to 2018 in China, which was significantly lower than that in our study [26]. Considering the limited sample size and representativeness in that study, we were unable to conclude that the RSV epidemic in our study was more severe than the average countrywide level. More efforts should be taken to improve the surveillance and analyses of the RSV epidemic in different areas in China to formulate tailored prevention measures. Additionally, RSV rates and time trends are totally different across countries. Our study documented an increased RSV detection rate starting in 2018 according to hospital data. In contrast, the RSV infection rate in children with LRTI remained stable, at around 50%, during 2014 to 2018 in the València region in Spain [27,28]. Compared with our results, Germany witnessed similar RSV positivity rates for children aged 0 to 4 years from 2011 to 2021, but the yearly epidemic level was more stable [29]. RSV positivity rates of children fluctuated from 7.5% to 23% during 2007 to 2016 in the Philippines [30]. However, RSV in southwest Finland (2008-2012) and Russia (2013-2018) was rarely detected, with positivity rates of 6% and 4.4%, respectively [31,32]. In general, the area served by the hospital in our study is facing higher pressure from RSV infections in recent years.

The significant increase in the RSV-positive rate since 2018 among young children in our study might be caused by multiple reasons. A potential factor associated with the RSV epidemic among young children was the implementation of the 2-child policy in 2016 in Hubei Province. Since the beginning of the policy, the total number of births rose moderately, while the number of second child births significantly increased [33]. On one hand, the increased number of susceptible infants would contribute to a higher RSV epidemic size. This is in line with a study revealing that there was a sharp increase in inpatient admission rates for infants after China's universal 2-child policy [34]. In contrast, a modeling study showed that the 1-child policy would lower the average annual influenza attack rate in China [35]. On the other hand, the younger, second child in a family could be infected by other family members, especially their elder siblings. A study in Shanghai elucidated that elder siblings might be the main route of hand, foot, and mouth disease transmission to neonates [36]. Keeping young children from people with flu-like symptoms is a key measure to protect them from RSV infection when a vaccine against RSV is unavailable. In addition, we noted that, although children aged 3 years or older were not directly influenced by the change of the policy after 2017, the RSV epidemic in this age group also increased. There might be 2 reasons. First, RSV is a communicable virus, and the increased scope of RSV infection in infants can also lead to more infections in elder children than before. Second, in addition to the impact of the policy shift, other factors including climate change and more spread of viruses from other provinces could cause an increase in RSV infection in elder children. However, the impact of other factors needs further investigation.

It is universally acknowledged that the COVID-19 pandemic effectively decreased the occurrence of an RSV epidemic due to various measures against the transmission of respiratory viruses [17,37-43]. This phenomenon was even more obvious in the several months under the strictest interventions after the COVID-19 outbreak in our study. However, RSV rebounded to a higher level in the years after strict NPIs were loosened. A delayed outbreak or a severe rebound of RSV was also found in multiple countries [44-48]. NPIs in the context of COVID-19 could prevent the transmission of respiratory viruses but also lead to a greater number of susceptible persons, which might have resulted in larger outbreaks once the transmission routes were reopened [46]. Children aged 1 year to 2 years had a larger rebound than the other age groups in our study. That might be due to the relatively weak immune system and the expanded social activities in this age group. Additionally, the continuous increase in the RSV detection rate among young children with URTI should be noted. Though URTI symptoms are mild, a URTI caused by RSV could progress to LRTI, which has a much higher disease burden [49].

There were some limitations in this study. First, though we used data from a large sample size from the largest maternal and child health hospital in Hubei Province, the conclusions drawn from only 1 hospital might not represent the overall situation at the provincial level. More surveillance studies of RSV from multiple sites are needed to better clarify the epidemiological characteristics of RSV in Hubei Province and perform comparisons among different cities. Genotyping of RSV was not performed; thus, we were unable to elucidate the detailed epidemiological characteristics of different genotypes. Moreover, missing medical records existing for several months in 2016 potentially caused an unprecise estimate of indicators of interest. Nevertheless, despite the limited sample size in February 2016, an epidemic peak was seen, which reflected the stable seasonal pattern of RSV. Only hospitalized children were included in our study, and our findings might overestimate the general level of the RSV epidemic among children. We could only identify the longitudinal trend of RSV and compare the relative levels across different years and different populations. Additionally, preterm birth is a known risk factor for RSV infection [50]. However, due to the lack of this variable in this study, we were unable to further confirm this association or manage the potential confounding effect of preterm birth in the models.

In summary, RSV was frequently detected among hospitalized children with ARTI based on surveillance of data from a large sample size at a hospital in Hubei Province. RSV positivity was more likely to happen in young children, cases diagnosed as LRTI, and wet and low-temperature seasons. Early warning of the risk of RSV infection among high-risk populations and seasons should be considered in local public health practices. A sudden rise in the RSV epidemic after 2018 might be affected by the 2-child policy implementation in 2016. Observed in our study, the RSV epidemic significantly decreased in the short term after the COVID-19 outbreak, followed by a sharp rebound in the years that followed. This implies that healthy lifestyle habits to prevent respiratory viruses should be maintained even though the COVID-19 situation has eased. A specific vaccine against RSV is urgently needed to lower the disease burden attributable to RSV.

This work was supported by the Joint Research Fund for Beijing Natural Science Foundation and Haidian Original Innovation (L202007) and Fundamental Research Funds for the Central Universities and Peking University Health Science Center (BMU2021YJ041), Peking University Medicine Fund of Fostering Young Scholars' Scientific and Technological Innovation (BMU2021PY005).

Data Availability

The data sets used and/or analyzed during the current study are available from the corresponding author upon reasonable request.

Authors' Contributions

QBL and XWH conceived and designed the experiments, analyzed the data, reviewed drafts of the paper, and approved the final draft. SY and YZ collected and analyzed the data, prepared the figures and tables, authored drafts of the paper, and approved the final draft. WXZ, XRW, and JD collected the data and reviewed the draft. All authors approved the final draft and agreed to the published version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The incidence of oropharyngeal squamous cell carcinomas (OPSCC) has increased in recent decades, and human papillomavirus (HPV) infection is the main cause of OPSCC. The data regarding causes of death (CODs) are vitally important in informing follow-up strategies and revising treatment strategies to deal with any possible preventable treatment-related COD. However, limited studies have assessed the competing COD by HPV status in patients with OPSCC.

Objective: We aimed to analyze the distribution of the competing COD according to HPV status in OPSCC.

Methods: We retrospectively included stage I-IVB patients with OPSCC from the Surveillance, Epidemiology, and End Results database between 2010 and 2015. The association between HPV status and head and neck cancer–specific mortality (HNCSM), second primary cancer mortality (SPCM), and noncancer-caused mortality (NCCM) were analyzed. The chi-square test, Kaplan-Meier analysis, and Fine and Gray model were used for statistical analysis.

Results: We included 5852 patients in this study and 73.2% (n=4283) of them had HPV-related tumors. A total of 1537 (26.3%) patients died, including 789 (51.3%), 333 (21.7%), and 415 (27%) patients who died from head and neck cancer, second cancer, and noncancer causes, respectively. The 5-year HNCSM, SPCM, NCCM, and overall mortality were 14.7%, 6.5%, 7.7%, and 26.4%, respectively. Those with HPV-positive disease had a lower cumulative incidence of HNCSM (subdistribution hazard ratio [sHR] 0.362, 95% CI 0.315-0.417; $P<.001$), SPCM (sHR 0.400, 95% CI 0.321-0.496; $P<.001$), and NCCM (sHR 0.460, 95% CI 0.378-0.560; $P<.001$) than those with HPV-negative disease. The 5-year risk of HNCSM was 26.9% and 10.7% in those with HPV-negative and HPV-positive disease, respectively ($P<.001$). The 5-year risk of SPCM was 12.4% and 4.6% in those with HPV-negative and HPV-positive disease, respectively ($P<.001$). The 5-year risk of NCCM of death was 13.7% and 5.8% in those with HPV-negative and HPV-positive disease, respectively ($P<.001$). Using the Fine and Gray competing-risks model, our results show that those with HPV-negative tumors had a significantly higher risk of HNCSM ($P<.001$), SPCM ($P<.001$), and NCCM ($P<.001$) than those with HPV-negative tumors.

Conclusions: HPV-positive OPSCC has a lower NCSM, SPCM, and NCCM as compared to those with HPV-negative OPSCC. HPV positivity is a favorable prognostic factor in the context of overcoming cancer as well as in terms of reducing the risk of other CODs in OPSCC. Our finding supports the need to tailor patient follow-up based on the HPV status of patients with OPSCC.

Introduction

Human papillomavirus (HPV) is the most prevalent sexually transmitted infection globally and is associated with both anogenital and oropharyngeal cancers. It is estimated that over 80% of individuals will be affected by HPV at some point in their lifetime [1]. Like other types of head and neck squamous cell carcinomas (HNSCCs), oropharyngeal squamous cell carcinoma (OPSCC) has been historically associated with alcohol and tobacco consumption. However, infection with carcinogenic HPV infection has emerged as an important risk factor that has driven an increase in the incidence of OPSCC. In recent decades, OPSCC has been one of the malignant tumors with rapidly rising incidences in Western countries [2-5]. In Italy, the incidence of HPV-related OPSCC increased from 16.7% in 2000-2006 to 46.1% in 2013-2018 [6]. Moreover, HPV now accounts for 71% and 51.8% of all OPSCCs in the United States and the United Kingdom, respectively [7-9]. The etiological relation with OPSCC by HPV status was also found in the Asian population [10,11]. The existing evidence shows that HPV status impacts the prognosis and treatment decision-making of OPSCC [12,13]. Patients with HPV-positive disease had a significantly better prognosis than those with HPV-negative disease [12,13]. Moreover, several studies also explored the treatment de-escalation for HPV-positive OPSCC [14,15]. These differences have a direct effect on clinical trials that will determine treatment therapeutic standards in the future clinical practice of OPSCC.

As survivorship from OPSCC continues to increase in recent decades [16-18], the main participants in the medical field should identify the patients with OPSCC with the highest risk of dying as well as the risk of their specific cause of death (COD). In addition to HPV, smoking and alcohol use are also closely related to the development of OPSCC, which may cause competing mortality in this population. In 2 studies from the Netherlands and the US cancer registry showed that the survival outcomes of head and neck cancer (HNC) were inferior to that of a healthy population of similar gender and age [19,20]. Smoking and alcohol use are the causative factors for cardiopulmonary diseases and second primary tumors. A previous Surveillance, Epidemiology, and End Result (SEER) study showed that life expectancy for patients with HNC was significantly shorter than expected after excluding the COD related to HNC [21]. The other COD may contribute to the differences in the survival of patients with HNC [22,23]. This information is vitally important in informing follow-up strategies and revising treatment strategies to deal with any possible preventable treatment-related COD.

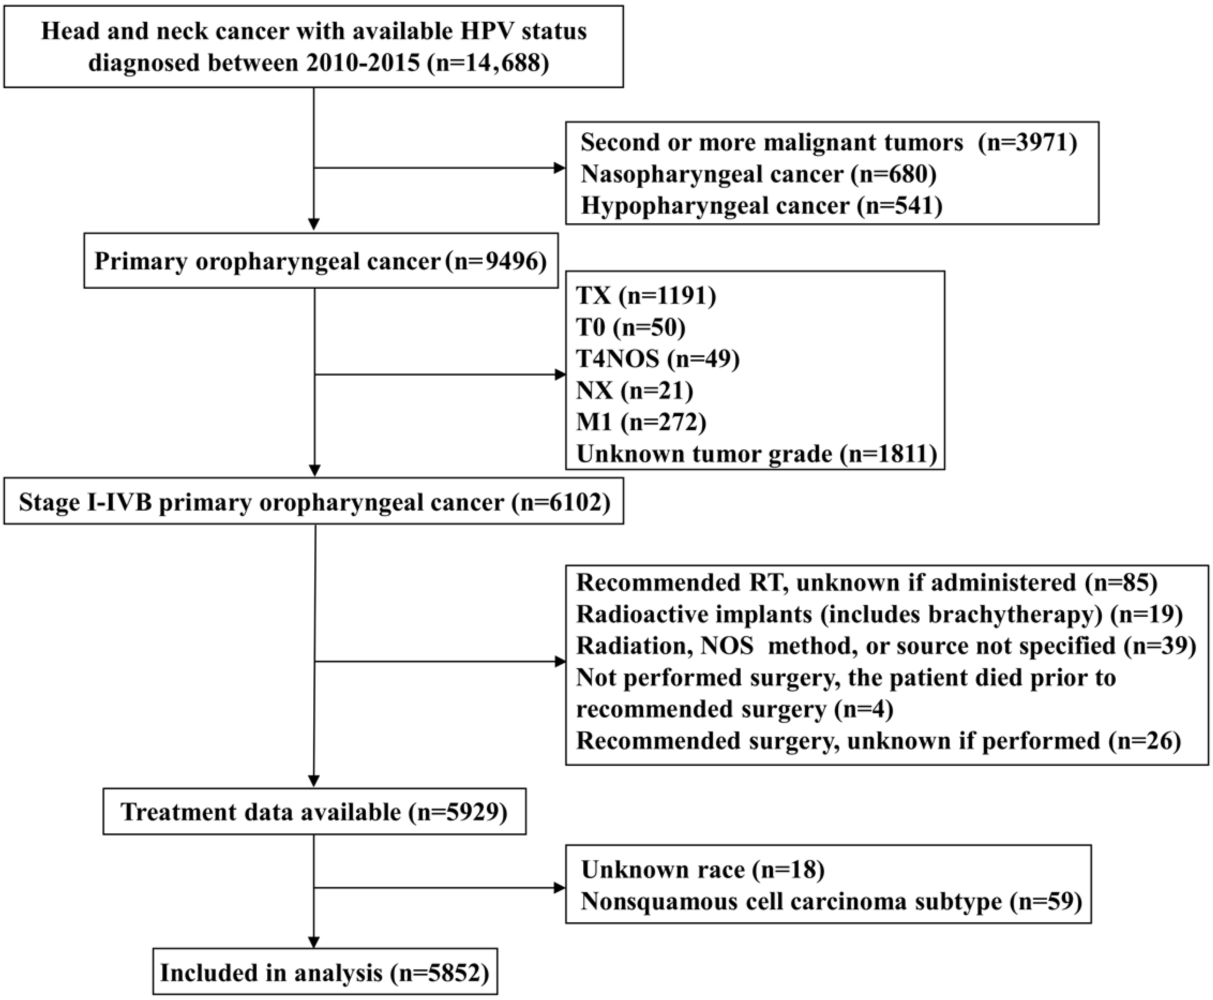
Because HPV-positive patients with OPSCC are usually younger and consume less alcohol and tobacco, the risk of cardiopulmonary disease and secondary primary tumor in this population may be lower [24,25]. The differences in survival rates for patients with HNSCC can primarily be attributed to an unequal burden of comorbidities associated with tobacco and alcohol use, treatment-related sequelae, and a high risk for the development of second primary cancer. Moreover, the surveillance for HPV-related tumors is similar to HPV-negative tumors in the current guidelines. Given the rapid rise in the incidence of potentially HPV-related OPSCC, it is crucial to provide a more comprehensive description of the COD in OPSCC. Understanding the COD by different HPV status in OPSCC could bring even more positive impact on public health, potentially impacting the follow-up strategies and revising treatment strategies while reducing treatment-related morbidity. However, limited studies have assessed the competing COD by HPV status in patients with OPSCC [26]. The objective of this study was to analyze the differences in the competing COD depending on HPV status in OPSCC.

Methods

Patient Selection

The National Cancer Institute SEER database collects population-level data on approximately 28% of the US population from 18 registries with the morbidity, mortality, and disease status of millions of patients with cancer [27]. We used the SEER databases to study patients diagnosed with OPSCC between 2010 and 2015 (International Classification of Disease for Oncology ICD-O C019, C090, C091, C098-C104, C108, C109, C142; histology codes 8073-8079 and 8083-8084). Registrars for the SEER database were required to enter HPV status beginning in 2010 and we have obtained HPV-related variables through the use of a data user agreement. The data of the retrospective cohort in the present study were obtained from the SEER HPV database, which includes the demographic data, clinicopathological characteristics, treatment, HPV status, and follow-up of patients with HNSCC [27]. We included patients who met the following criterion: (1) diagnosed between 2010 and 2015; (2) diagnosed with stage I-IVB OPSCC according to the 7th American Joint Committee on Cancer (AJCC) staging system; (3) available data regarding HPV status, race, tumor grade, AJCC staging, tumor stage, nodal stage, and metastatic stage; and (4) available data on surgery, radiotherapy, and chemotherapy. Patients with unknown HPV status, second or more malignant tumors, distant stage, and treated with radioactive implants or radioisotopes were excluded. The patient selection flowchart is listed in Figure 1.

Figure 1. Flow diagram of this study's cohort. HPV: human papillomavirus; M: metastatic stage; N: nodal stage; NOS: not otherwise specified; NX: unknown nodal stage; RT: radiotherapy; T: tumor stage; TX: unknown tumor stage.



Ethics Approval

The SEER database is a public database, and we have obtained permission to access the database (approval number 18275-Nov2021). The present study did not require ethical approval by the institutional review board of the Zhongshan Hospital, Xiamen University, because of the nonidentifying information in the SEER database. The requirement for informed consent was waived because all data used in this study were deidentified.

Data Collection

The following variables were included: age, gender, race, tumor grade, HPV status, AJCC 7th staging, and the receipt of treatment. HPV status was determined by p16 immunohistochemistry, tissue polymerase chain reaction, in situ hybridization, real-time polymerase chain reaction for E6/7 RNA, or in situ hybridization for E6/7 RNA [28]. The primary outcomes were HNC-specific mortality (HNCSM), second primary cancer mortality (SPCM), and noncancer-caused mortality (NCCM). Any COD due to HNC was encoded as HNCSM. Events for SPCM were death from the second primary cancer. Events for NCCM were death from noncancer diseases. Our secondary outcome was overall mortality (OM). OM was defined as death from all causes.

Statistical Analysis

Categorical variables were represented as absolute values with percentages, and the chi-square test was performed for the comparison between patients who were HPV-negative and HPV-positive. Kaplan-Meier analysis was used to generate the survival curves to compare differences in survival between groups over time, and the equality of these curves was compared by the log-rank test. Due to the competitive relationship among multiple outcomes in clinical survival data, the traditional Kaplan-Meier analysis will misjudge the cumulative mortality rate [29]. Therefore, competing-risks analyses using the Fine and Gray model were used to estimate the effects of covariates on HNCSM, SPCM, and NCCM. We conducted stratum-specific analyses to estimate the effects of HPV status on HNCSM, SPCM, and NCCM in accordance with gender, age, race, AJCC staging, grade, surgery, radiotherapy, and chemotherapy. All statistical analyses were conducted using SPSS (version 22.0; IBM Corp) and Stata/SE (version 14; StataCorp). A *P* value <.05 was considered statistically significant.

Results

Patient Baseline Characteristics

From 2010 to 2015, there were 14,688 cases of HNC recorded with the HPV status in the SEER HPV database; 9496 of these cases were oropharyngeal cancer and 5852 of these cases were stage I-IVB OPSCC and had treatment data available. In this cohort (n=5852; Table 1), 4283 patients (73.2%) had HPV-positive OPSCC and 1569 patients (26.8%) had HPV-negative OPSCC. Of these patients, 84.1% (n=4922), 89.2% (n=5220), and 69.9% (n=4088) were male, White, and had stage T4 disease, respectively. Regarding treatment, 89.1% (n=5216), 71.3% (n=4174), and 55% (n=2626) of patients received radiotherapy, chemotherapy, and surgery, respectively.

[a] HPV: human papillomavirus.

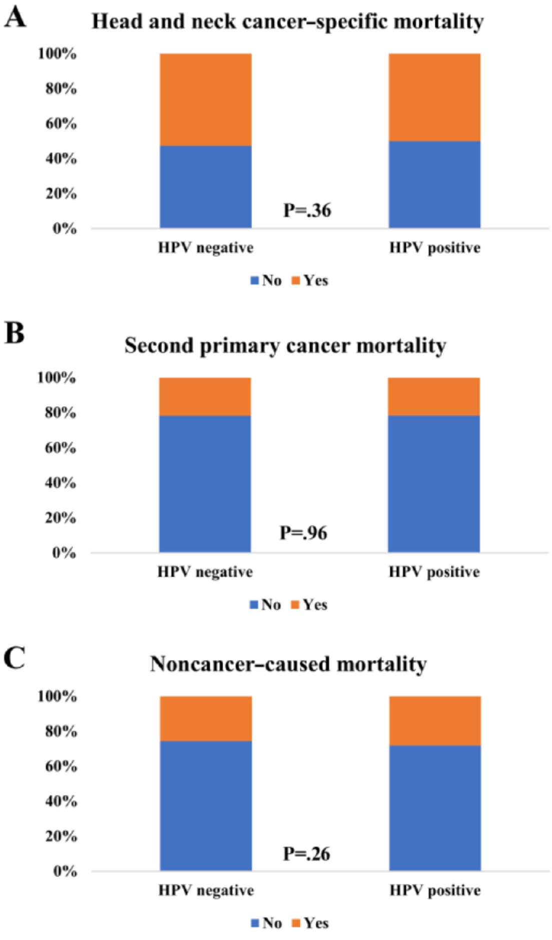
[b] AJCC: American Joint Committee on Cancer.

[c] T: tumor stage.

[d] N: nodal stage.

Patients with HPV-positive disease were more likely to be male, aged 50-64 years, White, have higher tumor grade, have early tumor stage, have advanced nodal stage, and have stage IV disease (all *P*<.001). Moreover, those with HPV-positive disease were more likely to receive surgery (*P*<.001) and radiotherapy (*P*=.015; Table 1). Similar distributions in HNCSM (*P*=.36), SPCM (*P*=.96), and NCCM (*P*=.26) were found according to HPV status (Figure 2).

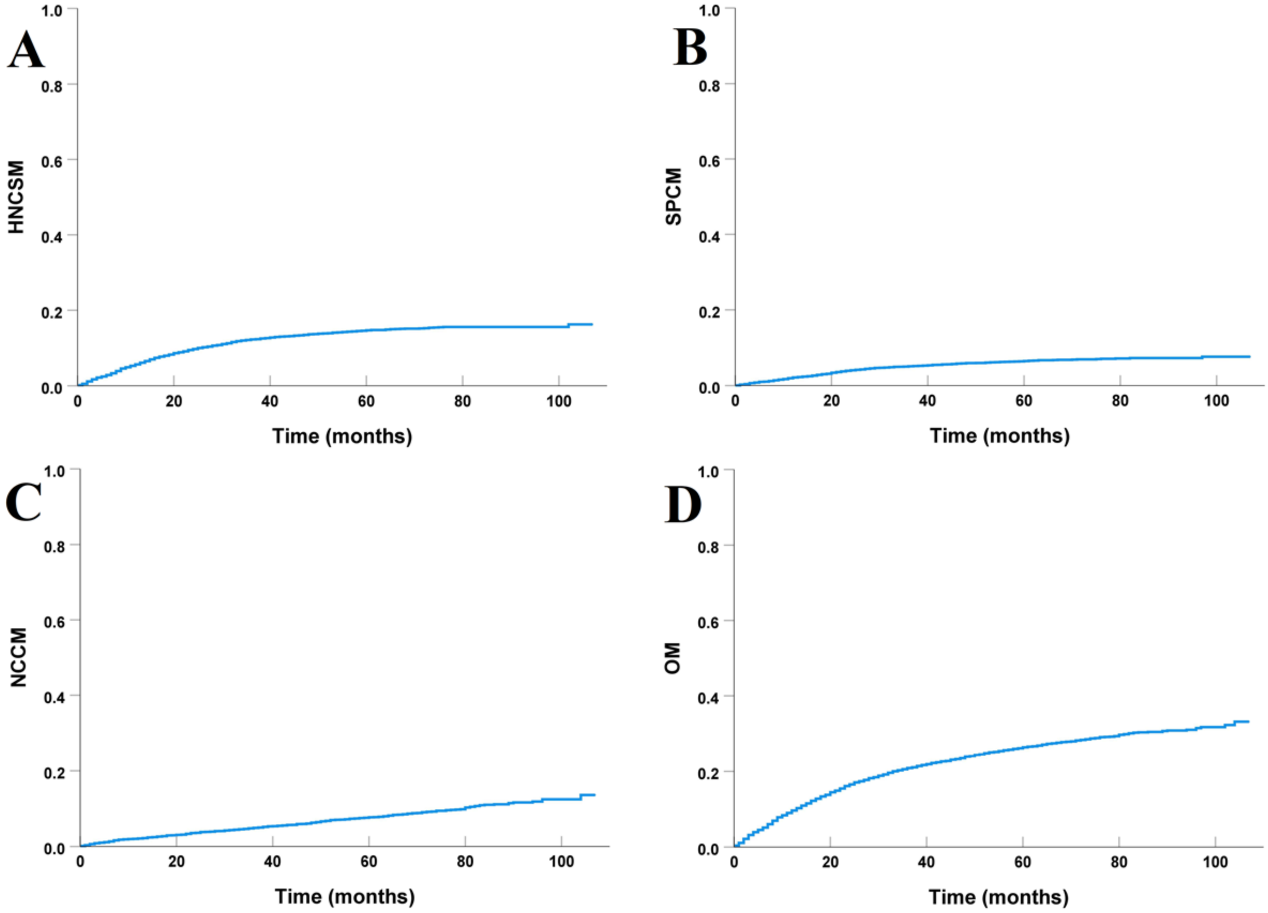
Figure 2. The distributions in (A) head and neck cancer–specific mortality, (B) second primary cancer mortality, and (C) noncancer-caused mortality according to human papillomavirus status. HPV: human papillomavirus.



Survival

With a median follow-up time of 52 months (range, 0-107 months), a total of 1537 (26.3%) patients died. There were 789 (51.3%), 333 (21.7%), and 415 (27%) patients who died from HNC, second cancer, and noncancer causes, respectively. The survival curves have been listed in Figure 3. The 5-year HNCSM, SPCM, NCCM, and OM were 14.7%, 6.5%, 7.7%, and 26.4%, respectively.

Figure 3. The curves of (A) head and neck cancer–specific mortality, (B) second primary cancer mortality, (C) noncancer-caused mortality, and (D) overall mortality in the entire cohort. HNCSM: head and neck cancer–specific mortality; NCCM: noncancer-caused mortality; OM: overall mortality; SPCM: second primary cancer mortality.



Competing Mortality

The cumulative incidence of competing CODs based on HPV status regarding HNCSM, SPCM, and NCCM are listed in Figure 4. Those with HPV-positive disease had a lower cumulative incidence of HNCSM (subdistribution hazard ratio [sHR] 0.362, 95% CI 0.315-0.417; *P*<.001; Figure 4A), SPCM (sHR 0.400; 95% CI 0.321-0.496; *P*<.001; Figure 4B), and NCCM (sHR 0.460; 95% CI 0.378-0.560; *P*<.001; Figure 4C) than those with HPV-negative disease. Using Kaplan-Meier analysis, the results showed that patients who were HPV-negative were more likely to gain experience from second cancer and noncancer causes. The 5-year risk of HNCSM was 26.9% and 10.7% in those with HPV-negative and HPV-positive disease, respectively (*P*<.001, Figure 5A). The 5-year risk of SPCM was 12.4% and 4.6% in those with HPV-negative and HPV-positive disease, respectively (*P*<.001, Figure 5B). The 5-year risk of NCCM of death was 13.7% and 5.8% in those with HPV-negative and HPV-positive disease, respectively (*P*<.001, Figure 5C). The 5-year OM was 26.1% and 10.7% in those with HPV-negative and HPV-positive, respectively (*P*<.001; Figure 5D).

Figure 4. The cumulative incidence of (A) head and neck cancer–specific mortality, (B) second primary cancer mortality, and (C) noncancer-caused mortality by human papillomavirus status using competing-risks regression. HNCSM: head and neck cancer–specific mortality; HPV: human papillomavirus; NCCM: noncancer-caused mortality; SPCM: second primary cancer mortality.

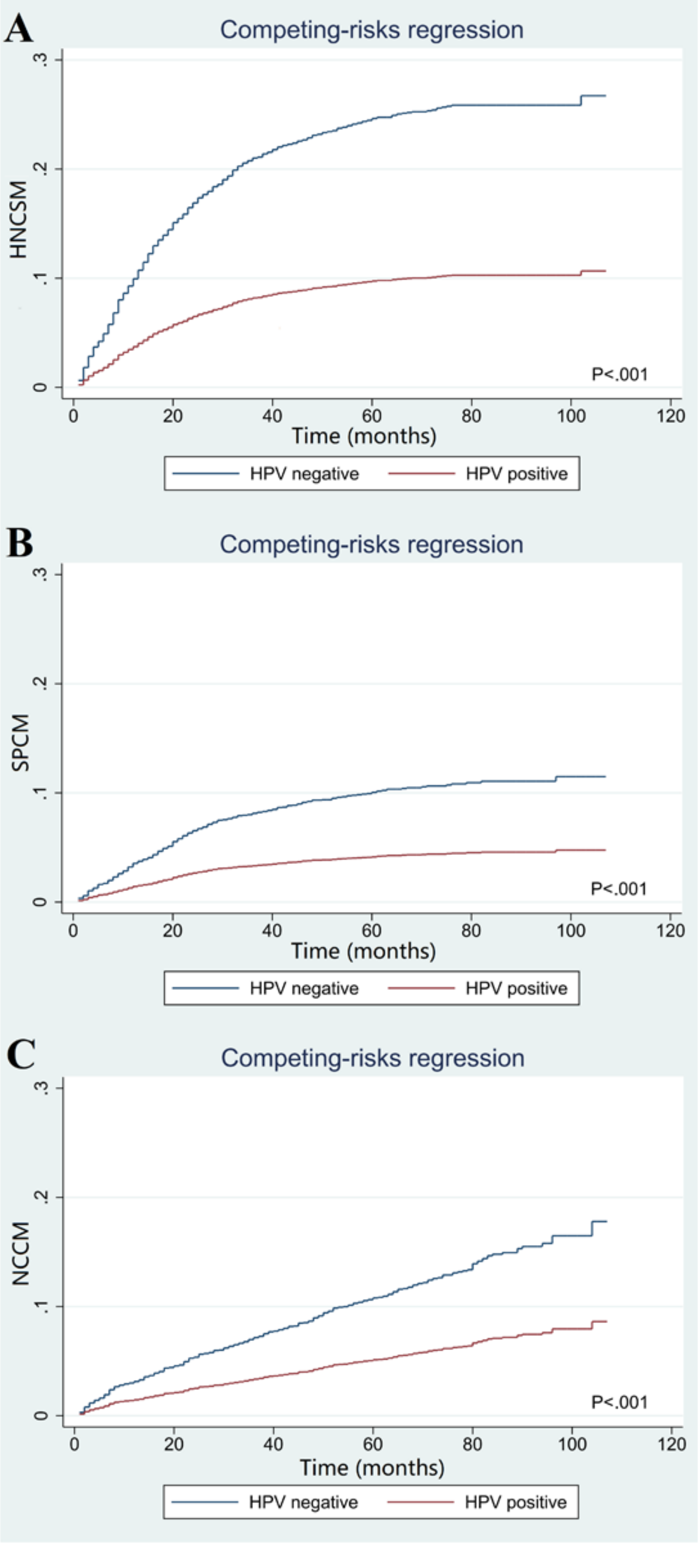


Figure 5. The effect of human papillomavirus status on (A) head and neck cancer–specific survival, (B) overall survival, (C) second primary cancer survival, and (D) noncancer-caused survival. HNCSM: head and neck cancer–specific mortality; HPV: human papillomavirus; NCCM: noncancer-caused mortality; OM: overall mortality; SPCM: second primary cancer mortality.

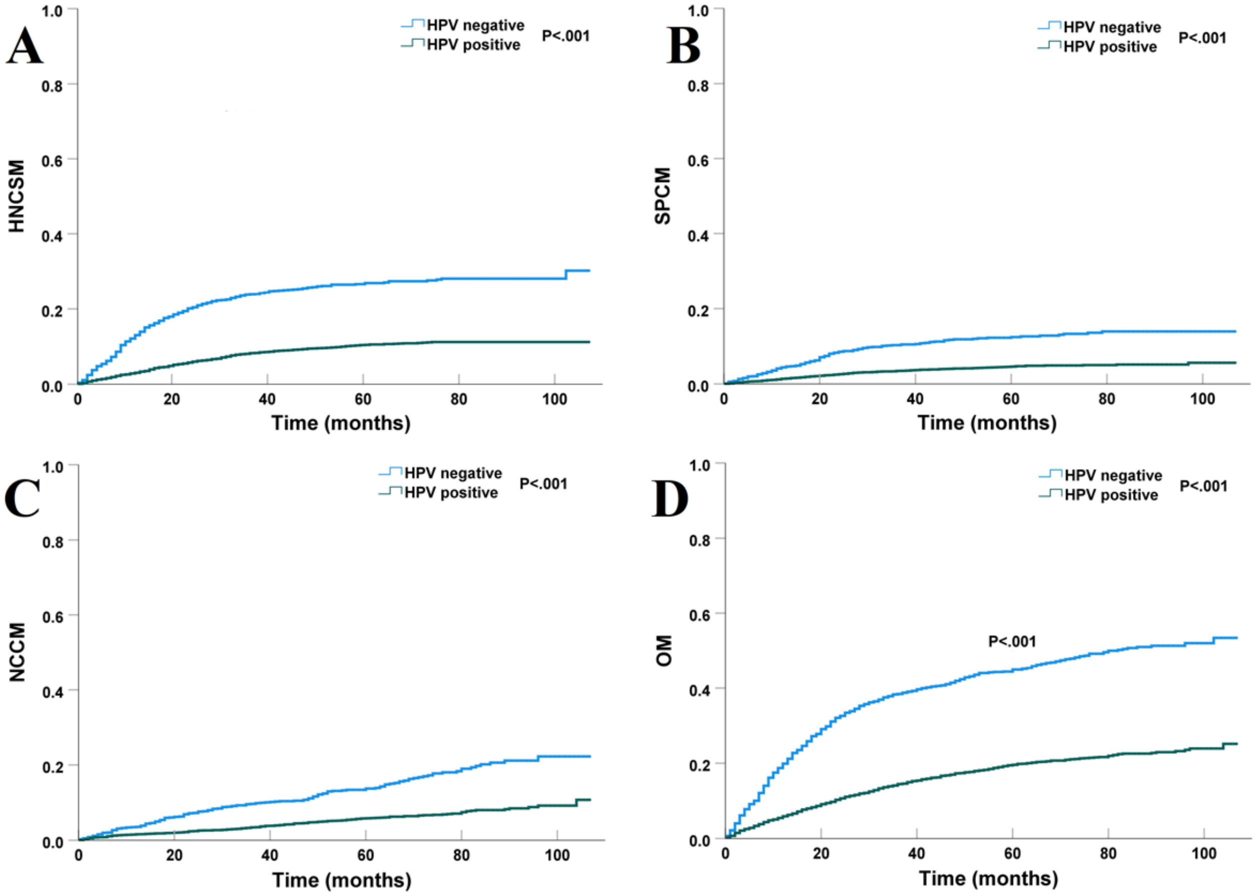

Fine and Gray Competing-Risks Model

Table 2 shows the sHR and 95% CI for selected covariates using competing-risks regression for different COD. The results of the multivariate analysis showed that the variables related to HNCSM were female, older age, Black, advanced stage, HPV-negative, receipt of surgery, and receipt of radiotherapy (all *P*<.05). Advanced stage, HPV-negative, receipt of surgery, and receipt of radiotherapy were the independent risk factors associated with SPCM (all *P*<.05). Older age, Black race, HPV-negative, receipt of surgery, and receipt of chemotherapy were the independent risk factors associated with NCCM (all *P*<.05). Stratum-specific analyses also showed that patients with HPV-positive tumor had lower HNCSM, SPCM, and NCCM than those with HPV-negative tumors after stratification by different demographic, clinicopathologic, and treatment characteristics (Table S1 in Multimedia Appendix 1).

Discussion

Principal Findings

In this study, we investigated the competing mortality in OPSCC by HPV status using a large cohort. Our results indicated that patients with HPV-negative tumors had a significantly higher risk of HNCSM, SPCM, and NCCM than those with HPV-positive tumors. The main finding of our study was that HPV-positive disease was an independent factor for better survival outcomes across all COD.

HPV status has been confirmed to be an important prognostic and predictive biomarker in OPSCC [12,13]. In recent years, several studies also have explored the relationship between HPV status and the second tumor in OPSCC. Gorphe et al [30] analyzed 888 patients with OPSCC between 2011 and 2020, they found that the 5-year competing risks of a second cancer were 16.1% and 49.9% in those patients who were HPV-positive and HPV-negative, respectively (*P*<.001). In addition, a study from Bosshart et al [31] that included 91 patients also found that HPV-positive had a lower risk of second cancer than those with HPV-negative tumors (14% vs 38.2%). Since the time of COD was only recorded in the SEER database, we could not obtain the exact time of diagnosis of the second primary tumor. However, Culié et al [32] included 340 patients with OPSCC from 14 French hospitals, and they found that patients who were HPV-positive developed low second tumors than patients who were HPV-negative (3.3% vs 11.7%, *P*=.02). However, the COD was similar in the 2 groups.

In our study, we found HNC-related death was the main COD in OPSCC (14.7%), followed by noncancer causes (7.7%), and second cancer (6.5%). Alcohol and tobacco use have been confirmed as risk factors for HNSCC. HPV-related OPSCC cannot be considered in the same field of cancerization as HPV-negative OPSCC and other HNSCCs [2-5]. However, we observed a quite similar distribution of CODs between the 2 groups, with primary cancer as the major COD. Our study suggested that the overall survival pattern of patients with OPSCC depends not only on their clinicopathological characteristics, but also significantly varies based on their age and the presence of comorbidities.

Several previous studies have assessed CODs in patients with HNSCC. They found that age, gender, race or ethnicity, presence of comorbidities, BMI, or type of treatment were the risk factors in the competing COD in patients with HNSCC [22,33-37]. In our study, we analyzed whether the HPV status would influence the COD of patients with OPSCC. A population-based cohort from Denmark was the first to investigate COD by HPV status in 1521 patients with OPSCC [26]. There were 54.3% of patients were HPV-positive and they found that HPV-positive was associated with better survival across all CODs [26]. Lop et al [38] included 423 patients with OPSCC and 12.5% were HPV-positive. They found that patients with HPV-positive disease had better OPSCC-specific survival (*P*<.001) and second primary cancer survival (*P*<.001) than those with HPV-negative tumors. However, noncancer-related causes survival was similar between the 2 groups (*P*=.13). The difference in patient characteristics may affect the distribution of CODs in the previous studies. Those with HPV-positive disease had a significantly lower cumulative incidence of death from all CODs than those with HPV-negative disease. Therefore, the inferior survival in patients with HPV-negative tumors was reflected in the higher risk of HNCSM, SPCM, and NCCM. Patients with HPV-negative OPSCC may benefit from screening for the risk to die of noncancer death or early detection of second cancers. Our study suggests that OPSCC should undergo more different effective therapies, more prevention methods to avoid noncancer deaths, and more screening tools for early detection of the second tumor according to different HPV status. They may benefit from increased research funding.

There were several studies indicating that those with HPV-positive OPSCC have a favorable survival than those with HPV-negative disease regardless of the treatment received [39,40]. In our study, 89.8% of patients were locally advanced-stage OPSCC, we also found that the receipt of treatment was associated with all CODs. The probability of treatment compliance was not recorded in the SEER database. Hess et al [41] found that treatment compliance in patients who were HPV-negative was significantly lower than in those with patients who were HPV-positive. Therefore, treatment compliance by HPV status might also have a negative effect on cancer-specific survival in OPSCC.

Screening for secondary cancer has an important effect in reducing mortality, especially for the HPV-negative population with a higher level of tobacco use [42]. Our data indicate that there were 51.3% and 21.7% patients who died from HNC and second cancer. Therefore, more frequent follow-ups should be performed to increase the detection of recurrence and secondary cancers. Moreover, our study shows an increased risk of SPCM, and NCCM in patients who were HPV-positive than in those with HPV-negative tumors. Our finding is important because it adds to the current knowledge regarding the differences in CODs among HPV status and supports the need to individualize follow-ups according to the HPV status.

In our study, 415 patients died of noncancer-related diseases, and 127 (30.6%) died from heart disease. In our study, patients with HPV-positive OPSCC tend to be younger, White, and male. Previous studies also showed that women of the Black race had a higher risk of cardiovascular disease in the general population and were cancer survivors [43,44]. According to the differences regarding epidemiological characteristics by HPV status may affect the burden of comorbidity, thus affecting the NCCM.

HPV-related tumors have a significant burden on health insurance [45]. While the HPV vaccination has been shown to prevent cervical cancer, HPV vaccination also has the potential to prevent a significant proportion of HPV-related OPSCC. We should note that 84.1% of patients in our study were male, and 85.6% were aged 50 years or older. The vaccine only prevents new HPV infections and does not treat existing infections [46]. HPV vaccination is generally not recommended for those older than age 26 years who are unvaccinated, recent guidelines have a permissive recommendation for HPV vaccination in unvaccinated adults aged 27-45 years [46]. Additionally, 47.7% of patients continued to smoke after their OPSCC diagnosis [47]. Therefore, current smoking status should be monitored throughout the treatment course of OPSCC, and smoking-cessation assistance should be provided as necessary, especially for patients with negative HPV status and a history of smoking. Therefore, further studies are needed to verify the efficacy of HPV vaccination in reducing the incidence of OPSCC and to investigate the effect of smoking cessation on various COD in patients with OPSCC.

We acknowledge certain limitations in our study. First, retrospective studies have inherent weaknesses of selection bias. Second, the lack of data regarding other sexually transmitted infections limits the interpretation of our data because behaviors that put people at risk for HPV also increase their risk for other sexually transmitted infections. Third, the lack of comorbidity data also limits the interpretation of our data. Of note, HNCSM, SPCM, and NCCM data were available and were used in this study. Fourth, the consumption of smoking and alcohol was not recorded in the SEER database. The high rates of HPV-positive OPSCC in our study could potentially be attributed to the low prevalence of smoking habits and differences in sexual behavior when compared with other geographic regions with a low incidence of HPV-positive OPSCC [37,48]. This difference in the incidence of HPV-positive tumors could limit the generalization of our findings to regions with a low incidence of HPV-positive tumors and high levels of tobacco and alcohol use. Moreover, the median follow-up time was 52 months in our study and second cancer or noncancer death is likely to develop after this delay. Finally, the SEER does not have specific records on HPV status detection methods. However, a previous study showed that the overall HPV status (positive or negative) had high degrees of accuracy in the SEER database [49]. Further research addressing these limitations could provide a more comprehensive understanding of the relationship between HPV status and competing mortality in patients with OPSCC.

Conclusions

In conclusion, our study suggests that HPV-positive OPSCC has a lower NCSM, SPCM, and NCCM as compared to those with HPV-negative OPSCC. HPV positivity is a favorable prognostic factor in the context of overcoming cancer as well as in terms of reducing the risk of other CODs in OPSCC. These disparities have direct implications on clinical trials aiming to define future therapeutic standards in clinical practice, including treatment intensification or de-escalation according to response rates, investigation of adjuvant treatment after complete response, or follow-up strategies involving imaging modalities and duration. Moreover, medical interventions tailored to the intercurrent CODs may independently provide survival benefits in addition to cancer treatments.

Abstract

Background: Avian influenza (AI) virus detections occurred frequently in 2022 and continue to pose a health, economic, and food security risk. The most recent global analysis of official reports of animal outbreaks and human infections with all reportable AI viruses was published almost a decade ago. Increased or renewed reports of AI viruses, especially high pathogenicity H5N8 and H5N1 in birds and H5N1, H5N8, and H5N6 in humans globally, have established the need for a comprehensive review of current global AI virus surveillance data to assess the pandemic risk of AI viruses.

Objective: This study aims to provide an analysis of global AI animal outbreak and human case surveillance information from the last decade by describing the circulating virus subtypes, regions and temporal trends in reporting, and country characteristics associated with AI virus outbreak reporting in animals; surveillance and reporting gaps for animals and humans are identified.

Methods: We analyzed AI virus infection reports among animals and humans submitted to animal and public health authorities from January 2013 to June 2022 and compared them with reports from January 2005 to December 2012. A multivariable regression analysis was used to evaluate associations between variables of interest and reported AI virus animal outbreaks.

Results: From 2013 to 2022, 52.2% (95/182) of World Organisation for Animal Health (WOAH) Member Countries identified 34 AI virus subtypes during 21,249 outbreaks. The most frequently reported subtypes were high pathogenicity AI H5N1 (10,079/21,249, 47.43%) and H5N8 (6722/21,249, 31.63%). A total of 10 high pathogenicity AI and 6 low pathogenicity AI virus subtypes were reported to the WOAH for the first time during 2013-2022. AI outbreaks in animals occurred in 26 more Member Countries than reported in the previous 8 years. Decreasing World Bank income classification was significantly associated with decreases in reported AI outbreaks (P<.001-.02). Between January 2013 and June 2022, 17/194 (8.8%) World Health Organization (WHO) Member States reported 2000 human AI virus infections of 10 virus subtypes. H7N9 (1568/2000, 78.40%) and H5N1 (254/2000, 12.70%) viruses accounted for the most human infections. As many as 8 of these 17 Member States did not report a human case prior to 2013. Of 1953 human cases with available information, 74.81% (n=1461) had a known animal exposure before onset of illness. The median time from illness onset to the notification posted on the WHO event information site was 15 days (IQR 9-30 days; mean 24 days). Seasonality patterns of animal outbreaks and human infections with AI viruses were very similar, occurred year-round, and peaked during November through May.

Conclusions: Our analysis suggests that AI outbreaks are more frequently reported and geographically widespread than in the past. Global surveillance gaps include inconsistent reporting from all regions and human infection reporting delays. Continued monitoring for AI virus outbreaks in animals and human infections with AI viruses is crucial for pandemic preparedness.

Introduction

Avian influenza (AI) viruses are a health, economic, and food security risk. While substantial H5, H7, and H9 virus detections in birds have occurred during the past several years, little is known about whether these detections are occurring more frequently or threatening a greater proportion of the world’s poultry, wild birds (especially threatened species), and human populations than in previous years.

AI viruses primarily affect avian species and are grouped as low pathogenicity AI (LPAI) or high pathogenicity AI (HPAI). The difference is based on the ability of the virus to cause mortality and morbidity in poultry or as assessed through genetic sequencing [1]. LPAI causes mild morbidity in poultry but lowers production and may circulate undetected in poultry populations. However, the virus can mutate (specifically H5 and H7 viruses) and become HPAI, which can cause severe disease and mortality in poultry [2]. Migration patterns of asymptomatic reservoirs such as wild waterfowl and shorebirds can lead to the transmission of AI virus to other wild birds and poultry, ultimately contributing to the global spread of AI viruses [3]. Global movement of poultry through trade can further lead to increased AI virus spread [2,4].

AI outbreaks in birds, especially HPAI in poultry, can have large economic implications. A World Bank report from 2008 estimated that global costs attributable to HPAI outbreaks could be as high as 0.7% of global gross domestic product, if AI viruses were to become enzootic throughout the world [5]. Even with control measures, outbreaks of AI viruses continue to occur globally, leading to millions of dead and culled birds, as well as increased chances of virus reassortment events in birds and nonhuman mammals such as pigs and mink [6-8]. HPAI outbreaks can lead to trade restrictions, expensive poultry products, food insecurity, and loss of livelihood [9].

Zoonotically transmitted AI viruses can cause high mortality and may recombine with human influenza A viruses to become more transmissible between humans [10,11]. Efficient and sustained transmission among humans could result in an influenza pandemic with high rates of illness and death [10]. Since 1997, there have been thousands of reports of AI virus infections in humans, most of which have been associated with the H5, H7, and H9 virus lineages [12-14].

A comprehensive review of current global AI virus surveillance information is key to assessing the pandemic risk of AI viruses. This includes reviewing the subtypes of AI viruses circulating during the past decade, their locations, what species are hosting them, and to determine if and why they are increasing in number and spread [15]. The most recent global analysis of official reports of AI outbreaks in birds and human infections with AI viruses was almost a decade ago [16]. In this investigation, contemporary AI virus reports were analyzed among animals and humans from January 2013 to June 2022 and compared with those from 2005 to 2012. AI outbreaks in animals and human AI virus infections were described, detailing the circulating virus subtypes, regions, and temporal trends in reporting animal outbreaks and human cases, and Member Country/Nation characteristics associated with animal AI outbreak reporting; additionally, surveillance and reporting gaps for animals and humans were identified.

Methods

Annual and Weekly Records of AI Outbreaks Among Animals

The World Organisation for Animal Health (WOAH) is responsible for improving animal health worldwide. During our timeframe of interest, the WOAH’s Terrestrial Animal Health Code required Member Countries to submit outbreak notifications of all HPAI viruses detected in domestic and wild birds and unusual species (such as mammals), all LPAI viruses of subtypes H5 and H7 detected in poultry, and unusual mortality events among wild birds [1]. The WOAH defines an outbreak as an occurrence of 1 or more cases in a group of animals with a defined epidemiologic relationship, such as a shared environment or common management practices. Each Member Country is responsible for reporting outbreaks to the WOAH. Immediate WOAH notification is not necessary for AI virus subtypes that Member Countries judge endemic [1]. The Food and Agriculture Organization of the United Nations (FAO) publishes monthly reports on all AI virus subtypes including outbreak information for HPAI H5N1 in endemic Member Nations and all LPAI H7N9 viruses [17].

The US Centers for Disease Control and Prevention (CDC) has monitored reports of AI virus outbreaks in animals since 2005. Information about animal outbreaks (in all nonhuman species) reported to the WOAH, FAO, and other official sources (eg, publications and local government websites) was compiled into an AI virus outbreak database that included the number of new outbreaks, by subtype, reported by each Member Country/Nation by report publication year. Starting in 2016, the weekly (based on report publication date) number of newly reported outbreaks, by subtype, from each Member Country/Nation and all animal categories in which that subtype had been reported since 2005 were also included. Animal categories were defined as wild birds (including aquatic and terrestrial waterfowl and shorebirds), zoo/captive birds (including exotic birds), birds in live bird markets, backyard/village birds (poultry such as chickens, ducks, turkeys, and geese), farm/commercial birds (poultry), and nonhuman mammals. All outbreak data are based on the number of outbreak events reported and not on the quantity of animals affected.

Outbreak data from January 1, 2013, to June 30, 2022, were used to determine annual totals for reported outbreaks; the number of Member Countries reporting, by subtype; and the predominant subtype. Subtypes that accounted for the most global outbreaks each year were considered the yearly predominant subtype. Weekly data from January 1, 2016, to June 30, 2022, were used to calculate the total number of outbreaks per subtype per month, as well as the number of newly reported animal categories. A new animal category was defined as a specific animal category, per subtype, reported by a Member Country for the first time since 2005. Results were compared with database information from 2005 to 2012. World Bank data were used to assign region categorization and income classifications to maintain consistency between animal and human health authorities [18]. WOAH data were used to assign the number of individual birds infected and culled [19]. The FAOSTAT was used to assign each Member Nation the percent of global poultry production and total number of annual live-bird imports [20]. The Wetlands International global flyway map was used to determine the number of major migratory flyways passing through each Member Country/Nation [21].

SAS (version 9.4; SAS Institute) was used to conduct univariate analyses of the relationship between independent variables of interest (World Bank income classification, yearly poultry production, total number of flyways through WOAH Member Countries, and total live-bird imports by Member Nations) and the dependent variables of interest (reported animal outbreaks). The regression analysis was restricted to 2013-2020, the years for which FAOSTAT poultry production data were available. Outbreaks from subtypes reported as endemic by a Member Country were excluded from the regression analyses. Variables of interest were assessed in the univariate model and covariates significant at an α level of .10 were included in the multivariable regression model. Relative rates were calculated using a Poisson regression and human population offset. A generalized estimating equation was used to account for correlations within Member Countries during the evaluation period. The final multivariable model was adjusted for World Bank income classification, yearly poultry production, total number of flyways, outbreak year, and total live-bird imports by WOAH Member Countries. Significance for the final model was assigned at $P \leq .05$.

AI Virus Infections Among Humans

The International Health Regulations (IHR) 2005 require Member States to report events of international public health importance to the World Health Organization (WHO) [22]. Human infections with influenza A viruses caused by subtypes that do not circulate in humans (novel) are notifiable [23]. The CDC maintains a line list of human infections caused by novel influenza virus subtypes as reported by the WHO per the IHR (2005) or other official sources (eg, ministries of health, FAO, publications); data were collected by weekly checks of these sources and include Member State of residence or diagnosis, symptom onset and report dates, outcome, exposure information, and reported human-to-human transmission (HTHT, which is defined as infection reported to have been caused by, or to have caused, an infection in another person). We analyzed all human AI virus infection notifications from January 1, 2013 to June 30, 2022.

The number of human cases was calculated by subtype, geographic location, animal exposure, age, reported HTHT, and reported case fatality proportion (rCFP). HTHT ratios (number of cases associated with HTHT divided by all reported infections) and rCFP (deaths noted at report time or in subsequent notifications divided by all reported infections) were calculated by subtype. Reporting lag was calculated as the difference in reported onset date and report date by the WHO in the event information site or other official source. United Nations data were used for population size calculations [24].

Ethical Considerations

This study was reviewed by the CDC and is consistent with federal law and CDC policy. The study was determined exempt from Institutional Review Board and Institutional Animal Care and Use Committee approval as it uses deidentified data.

Results

Annual AI Outbreaks Among Animals

Between 2013 and 2022, 95 of 182 WOAH Member Countries (52.2%), which currently produce 87.1% of the world's poultry [20], reported 21,249 AI virus outbreaks among animals associated with 34 AI virus subtypes (15 HPAI and 19 LPAI); HPAI accounted for 93.39% (n=19,844) of the reported outbreaks (Figure 1 and Table 1); 66% (39/59) of high-income and 31% (9/29) of low-income Member Countries reported an AI virus outbreak during 2013-2022 (Table 2). On average, 42 Member Countries reported AI virus outbreaks each year (65 in 2017 to 20 in 2013); 1 in 4 (26/95) Member Countries first reported AI virus outbreaks among animals in 2013-2022 (Figure 2). All but 6 reporting Member Countries were in the northern hemisphere (Table 2). High-income Member Countries reported the greatest proportion of outbreaks (14,336/21,249, 67.47%; Table 2). Overall, the European and Central Asian regions reported the greatest number of outbreaks (10,550/21,249, 49.65%), whereas Latin American and the Caribbean region reported the fewest number of outbreaks (188/21,249, 0.88%; Table 2 and Figure 2).

[b] Denominator is all WOAH Member Countries.

[c] Denominator is all WOAH Member Countries in that hemisphere/region/income classification.

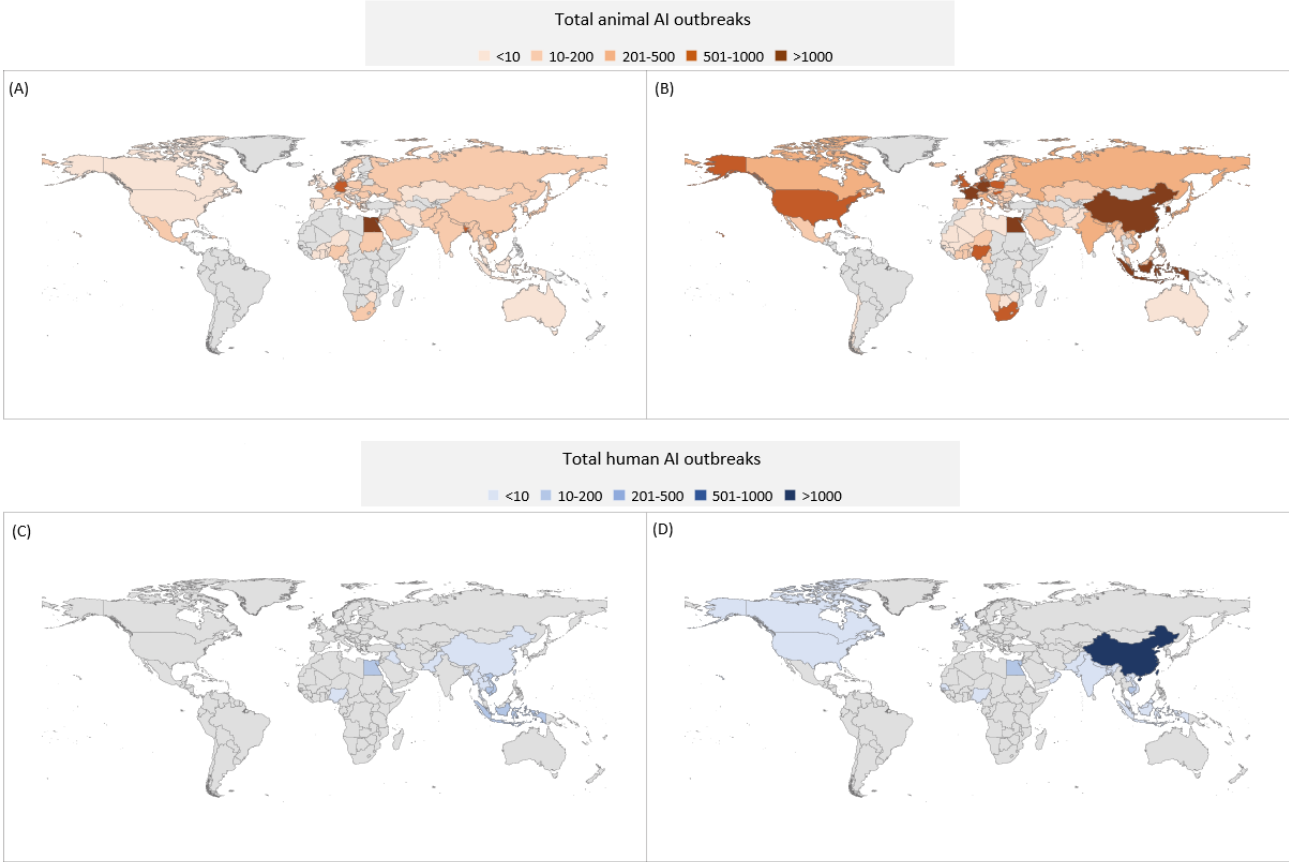
[d] Denominator is all WOAH Member Countries that reported an outbreak.

[e] Proportion of world poultry production based on most recently reported data from FAOSTAT for 2020.

[f] N/A: not applicable.

[g] Based on most recently reported data from 2021, Republic of Niue and Cook Islands are excluded from human population totals as data were not available.

Figure 2. World Organisation for Animal Health Member Countries reporting an animal avian influenza (AI) outbreak from January 2005 to December 2012 (A) and January 2013 to June 2022 (B) and World Health Organization Member States that reported human AI virus infections from January 2005 to December 2012 (C) and January 2013 to June 2022 (D).



A total of 10 HPAI and 6 LPAI virus subtypes were reported for the first time during 2013-2022. As many as 4 HPAI virus subtypes accounted for nearly 90% (n=19,068) of reported animal outbreaks: H5N1 (10,079/21,249, 47.43%), H5N8 (6722/21,249, 31.63%), H5N2 (1341/21,249, 6.31%), and H5N6 (926/21,249, 4.36%); 2 LPAI virus subtypes accounted for 5% (n=1076) of outbreaks: H7N9 (865/21,249, 4.07%) and H5N2 (211/21,249, 0.99%; Table 1). The predominant virus subtype shifted from H5N1 (767/1659, 46.23%, in 2016 to 480/3439, 13.96%, in 2017) to H5N8 (686/1659, 41.35%, in 2016 to 1924/3439, 55.95%, in 2017; Figure 1). H5N8 continued to be the predominant virus subtype in animal outbreaks each year since 2017, except during 2019 and 2022 (Figure 1). Overall, there were approximately 79,709,668 AI virus infections in birds and 323,884,584 birds were culled from 2013 to 2022 per the WOAH.

Results from the multivariable analysis for WOAH Member Countries (Table 3) that reported at least one outbreak from 2013 to 2022 indicated that decreased AI virus outbreak reporting among animals was associated with decreasing country income classification. Compared with high-income Member Countries, on average, upper-middle income countries reported 56% (adjusted relative rate 0.44, 95% CI 0.21-0.90) fewer animal outbreaks, lower-middle income countries reported 82% (adjusted relative rate 0.18, 95% CI 0.09-0.36) fewer animal outbreaks, and low-income countries reported 87% (adjusted relative rate 0.13, 95% CI 0.04-0.43) fewer animal outbreaks. Between January 2013 and June 2022, for every annual poultry production increase of 50 million head, there was a 2% decrease in reported AI outbreaks.

Table 3. Multivariable regression model[a] results for variables of interest associated with reported animal avian influenza outbreaks, January 2013-June 2022.

Independent variable	Crude relative rate	95% CI	*P* value	Adjusted relative rate	95% CI	*P* value

Weekly Reports of AI Outbreaks Among Animals

The WOAH received 2485 weekly reports from 2016 to 2022, comprising 15,240 AI virus outbreaks among animals from 91 Member Countries. On average, a median of 13 reports were submitted per week. Taiwan (208/2485, 8.37%) and Germany (176/2485, 7.08%) submitted the most weekly reports. The greatest number of reported animal outbreaks occurred during November 2021-June 2022 (6032/15,240, 39.58%) followed by November 2016-June 2017 (3423/15,240, 22.46%). While outbreaks occurred throughout the year, 87.17% (13,285/15,240) began during November-May (13,024/14,755, 88.27%, in the northern hemisphere Member Countries and 261/485, 53.8%, in the southern hemisphere Member Countries), and onset peaked in January and April in the northern hemisphere and January and November in the southern hemisphere Member Countries (Multimedia Appendix 1). The mean percentage of all outbreaks reported each month that are in a new animal category, for any given member-state, was 14% (range 0%-62%). Of the reports in new animal categories, wild bird (162/439, 36.9%), farm/commercial bird (112/439, 25.5%), and backyard/village bird (105/439, 23.9%) categories comprised most reports. Nonhuman mammals made up the least number of new reports at 1.6% (7/439) of new animal category reports.

AI Virus Infections Among Humans

During 2013-2022, 17 of WHO’s 194 Member States, which contain more than one-half (4,469,153,194/7,890,000,000, 56.64%) of the world’s population, reported 2000 AI virus infections in humans, which were associated with 10 AI virus subtypes (Figure 1). Both North American region Member States and 40% (4/10) of South Asian region Member States reported a human AI virus infection during 2013-2022 (Table 4). On average, 4 Member States reported human AI virus infections each year (range 2 in 2018 to 7 in 2014). Oman is the only Member State, with a reported human infection, that has never reported an AI outbreak among animals; 8/17 (47%) Member States first reported a human AI virus infection in 2013-2022 (Figure 2).

Table 4. WHO[a] Member States reporting human infection with avian influenza virus by region and income classification (period: January 2013-June 2022).

Region and income classification	All WHO Member States[b] (n=194)	Proportion of all WHO Member States reporting infections[c] (n=17)	Distribution of reporting Member States[d] (n=17)	Reported infections (n=2000)
Hemisphere, n (%)				
Northern	163 (84.0)	17 (10.4)	17 (100)	17 (100)

[a] WHO: World Health Organization.

[b] Denominator is all WHO Member States.

[c] Denominator is all WHO Member States in that hemisphere/region/income classification.

[d] Denominator is all WHO Member States that reported an infection.

[e] Based on most recently reported data from 2020.

[f] N/A: not applicable.

[g] Based on most recently reported data from 2021, Republic of Niue and Cook Islands are excluded from human population totals as data were not available.

H7N9 (1568/2000, 78.40%) and H5N1 (254/2000, 12.70%) viruses accounted for the most human infections (Table 5). China reported the most H7N9 virus infections (1565/1568, 99.81%). Egypt reported the majority of non-H7N9 human AI virus infection cases (194/432, 44.9%), followed by China (170/432, 39.4%). The remaining 15 Member States were responsible for 15.7% (68/432) of cases (Figure 2). Overall, the East Asia and Pacific region reported the greatest number of human cases (1786/2000, 89.30%), followed by the Middle East and North Africa region (195/2000, 9.75%; Table 4). All Member States that reported human infections were in the northern hemisphere; 24% (4/17) were classified as high income and none were classified as low income (Table 4).

Table 5. Reported case fatality proportion and known animal exposure for human infections with avian influenza virus (January 2013-June 2022).

Subtype	Cases reported (n=2000), n (%)	Deaths reported (n=446), n (%)	Reported case fatality proportion[a], (%)	Known animal exposure[b] (n=1461), n (%)
H3N8	2 (0.1)	0 (0)	0	2 (100)
H5N1	254 (12.7)	89 (20.0)	35.0	219 (86.2)
H5N6	80 (4.0)	27 (6.1)	33.8	70 (87.5)
H5Nx	3 (0.2)	0 (0)	0	3 (100.0)
H7N2	2 (0.1)	0 (0)	0	0 (0)
H7N4	1 (0.1)	0 (0)	0	1 (100.0)
H7N9	1568 (78.4)	326 (73.1)	20.8	1106 (70.5)
H9N2	86 (4.3)	2 (0.4)	2.3	58 (67.4)
H10N3	1 (0.1)	0 (0)	0	0 (0)
H10N8	3 (0.2)	2 (0.4)	66.7	2 (66.7)

[a] Deaths noted at report time or in subsequent notifications divided by all reported infections.

[b] A total of 438 cases had a missing value for the animal exposure variable.

While human AI virus infections occurred throughout the year, 89.65% (1793/2000) had illness onset dates during December-May, with the frequency of onset typically peaking in January (Multimedia Appendix 1). Of the 1953 human infections with available exposure information, 1461 (74.81%) had a known animal exposure prior to illness onset and 101 (5.17%) had no known animal exposure (Table 5). Age and sex information was available for 1989/2000 cases (99.45%); 64.30% (1286/2000) of cases were in males. Most cases were in persons aged 18-64 years (1253/2000, 62.7%). The rCFP varied by virus subtype from 0% (H3N8; 0/2) to 67% (H10N8; 2/3). The overall rCFP was 22.30% (446/2000; Table 5). There were 58/2000 reports of confirmed or possible HTHT (2.90%). The median time from illness onset to the notification posted on the IHR (2005) event information site or other official source was 15 (IQR 9-31; mean 24) days.

Discussion

Principal Results and Comparison With Prior Work

Between 2013 and 2022, more AI virus outbreaks in animals were reported by WOAH Member Countries than in the previous 8 years, with 26 Member Countries reporting their first animal AI virus outbreak. From January 2013 to June 2022, there were reports of more than 21,000 AI virus outbreaks in animals and 2000 human infections with AI viruses globally. As many as 10 new HPAI virus subtypes (new hemagglutinin/neuraminidase [HA/NA] combinations) were identified in animals, representing an almost 2-fold increase in the number of subtypes identified during our study period compared with the previous 8 years. This likely reflects broadened viral diversity, increased reporting, and enhanced surveillance. Although there were 34 subtypes reported, only 4 accounted for 89.74% (19,068/21,249) of animal outbreaks; all 4 were of the HPAI H5 lineage. During the study period, the predominant subtype causing animal outbreaks changed from H5N1 to H5N8, for all years but 1. However, in 2022, H5N1 reemerged as the predominant subtype. From 2016 to 2022, about 14% of outbreaks each month occurred in a new animal category with wild birds representing the highest percentage (36.9%, 162/439). This finding suggests that in addition to spreading geographically, AI viruses are also moving into more animal categories. Increases in geographic and animal category reporting could be attributed to increased poultry production and commercial trade [25], increased exposure to wild birds through repeated annual migrations of infected birds, changes in migration patterns because of climate change or land conversion to agricultural production [4,26,27], viral genetic evolution, and improved AI virus awareness and surveillance capacity [28].

Seasonality patterns of animal AI virus outbreaks and human infections with AI viruses were very similar and occurred year-round; the frequency of both peaked during November through May. This finding likely reflects the dominance of reporting from the northern hemisphere countries. The seasonal concurrence of animal and human infections indicates the potential for animal-to-human transmission of AI and highlights the importance of improved monitoring of AI virus subtypes in humans and animals. Animal outbreaks might rise during periods when commercial bird distribution surges in preparation for the winter holidays and lunar new year [16]. This is consistent with our quantitative results which suggest that the risk of human infection increased for those with a known exposure to animals. These epidemic patterns suggest that animal and human health authorities might consider intensifying AI virus infection prevention and control measures immediately before the onset of the November-May increase in AI animal outbreaks [16].

While AI virus outbreaks among animals and human AI virus infections had similar epidemic periods, less than one-half (921/2000, 46.1%) of human cases occurred during years when the same HPAI virus subtype was reported among animals in the same country. In our data set, H9N2 was the third most reported AI virus infection in humans. However, LPAI H9 subtypes are not required to be reported to the WOAH. As human surveillance complements animal surveillance, AI virus detections in humans may serve as signals of AI virus activity among animals. The IHR (2005) stipulates reporting of human AI virus infection within 48-72 hours of identification. Although the time from laboratory detection to reporting was not evaluated (laboratory confirmation date was not routinely reported), the median time of onset to IHR (2005) notification was 15 days with about 26.1% (517/1976) of reports lagging by 30 or more days. Delayed reporting is especially concerning for AI viruses that become capable of efficient HTHT, as significant community transmission may occur by the time of reporting. Timely identification and notification of novel influenza viruses are vital for global pandemic influenza preparedness. The most effective AI virus surveillance would include comprehensive surveillance, inclusive of all subtypes, and timely reporting in domestic and wild birds, humans and, ideally, nonhuman mammals especially swine, as pigs can play a crucial role in novel influenza virus reassortment [6,28].

In our analysis, Member Countries with World Bank income classifications other than high income were less likely to report animal AI virus outbreaks. Latin America and the Caribbean region reported the fewest number of outbreaks. There are published reports of AI virus outbreaks in the Americas, especially Latin America [29]; however, these outbreaks were not reported to the WOAH, and therefore, global surveillance systems that rely on the WOAH reporting mechanism did not capture these outbreaks. A 2022 report from the WOAH noted that HPAI is nationally notifiable in only 73.4% of Member Countries and only 67.5% of Member Countries report having surveillance in place [30]. The lack of established surveillance systems or lack of reporting from these and other Member Countries exposes a gap in global AI virus surveillance. Additionally, the WOAH does not require Member Countries to report enzootic AI [1]. This can lead to routine undercounting of AI virus activity in those Member Countries and shows that while surveillance and reporting may have improved since 2012, there is still room for improvement.

Limitations

Our study is subject to at least four limitations. First, not all Member Countries/States report AI virus outbreaks among animals or human infections with AI viruses to the WOAH or WHO, respectively, because of inadequate surveillance systems or political and economic concerns about the impact of reporting on poultry trade [28,31]. Further, our multisource data acquisition process may not have identified all cases. Therefore, these reports are likely underestimates. Second, sequencing and clade data were not consistently reported or recorded for animal outbreaks; therefore, genetic relatedness of virus subtypes was not available for this analysis. Third, data collection for the yearly and weekly outbreak and human infection databases occurred manually over the years and is therefore subject to human error. Finally, observed increases in outbreak numbers and reporting Member States/Countries may be an artifact of enhanced surveillance and not necessarily wholly because of an increase in outbreak frequency over time.

Conclusions

AI virus surveillance from 2013 to 2022 identified 10 new HA/NA combinations of HPAI virus, AI virus in novel animal categories, and 26 more Member Countries reporting animal outbreaks than in the preceding 8 years. Although we are unable to fully quantify the magnitude of each animal outbreak from our data, outbreaks from January 2013 to June 2022 have resulted in the cumulative loss of over 325 million birds. Zoonotic viral transmission from animals to humans poses a continued public health threat because efficient, sustained transmission of AI viruses in humans could trigger the next pandemic [10]. Public and animal health leaders should encourage Member Countries to adhere to international standards put forth by the WOAH and report AI virus events as indicated [1]. Timely notifications from all Member States/Countries of novel influenza virus infections in humans and AI virus outbreaks in animals are central to pandemic preparedness and prevention. It is essential for global AI virus surveillance that WHO Member State and WOAH Member Country health officials ensure that AI virus reports are submitted within the required timeline by international standards. Commonly reported AI virus subtypes in humans were not required to be reported in animals, making One Health collaboration between animal and human surveillance systems even more crucial. Further research to explore causes for AI virus increases in animals might prove beneficial, including evaluation of commercial poultry and swine farm biosecurity, mechanisms of domestic poultry and swine exposure to wild migratory bird populations, laboratory studies to investigate phenotypic characteristics of currently circulating viruses, and the effects of climate and ecological degradation on migration patterns.

Acknowledgments

This analysis was funded by the US Centers for Disease Control and Prevention (US CDC). This project uses deidentified data and is Institutional Review Board/Institutional Animal Care and Use Committee (IACUC) exempt. All authors have met all 4 International Committee of Medical Journal Editors (ICMJE) authorship criteria. We thank Ray Arthur, Joshua Mott, Young M. Yoo, Jazmin Duque, Diane Gross, Natalie Olson, Francisco Palomeque, and Katherine Roguski for helping the Division track avian influenza outbreaks during the past decade. Abstract

Background: With population aging, the prevalence of both cancer and atrial fibrillation (AF) have increased. However, there is scarce epidemiological data concerning the comorbid state of cancer and AF in low- and middle-income countries, including China.

Objective: We aimed to evaluate the site-, sex-, and age-specific profiles of cancer and AF comorbidities in Chinese populations.

Methods: Data from the Shanghai Municipal Health Commission database between 2015 and 2020 were screened, covering all medical records of Shanghai residents with medical insurance. Site-specific cancer profiles were evaluated for the population with AF relative to the age- and sex-adjusted population of residents without AF. The sex distribution and peak age of cancer diagnosis were also assessed.

Results: A total of 25,964,447 adult patients were screened. Among them, 22,185 patients presented cancers comorbid with AF (median 77, IQR 67-82 years of age; men: n=13,631, 61.44%), while 839,864 presented cancers without AF (median 67, IQR 57-72 years of age; men: n=419,020, 49.89%), thus yielding a higher cancer prevalence among residents with AF (8.27%) than among those without AF (6.05%; $P<.001$). In the population with AF, the most prevalent cancer type was lung cancer, followed by colorectal, male genital organ, stomach, breast, liver, bladder, thyroid, leukemia, and esophageal cancers. AF was associated with an average of nearly 1.4-fold (prevalence ratio [PR] 1.37, 95% CI 1.35-1.38) increased prevalence of cancer after adjusting for age and sex. For site-specific analyses, an increased prevalence of cancer in the population with AF was observed in 20 of 21 cancer sites. This increased prevalence was most prominent for nonsolid tumors, including multiple myeloma (PR 2.56, 95% CI 2.28-2.87), leukemia (PR 1.73, 95% CI 1.57-1.90), and non-Hodgkin lymphoma (PR 1.59, 95% CI 1.43-1.77); intrathoracic malignancies, including mediastinum (PR 2.34, 95% CI 1.89-2.90), lung (PR 1.64, 95% CI 1.59-1.69), and esophageal cancers (PR 1.41, 95% CI 1.28-1.56); bone and soft tissue neoplasms (PR 1.56, 95% CI 1.37-1.77); and kidney cancer (PR 1.53, 95% CI 1.36-1.72). Cancer prevalence in the population with AF relative to that in the population without AF was higher in men than in women in 14 of 18 cancer sites, and female predominance was only observed for thyroid cancer. The peak age of index cancer diagnosis was lower in the population with AF (age group: 70-74 years) than in that without AF (age group: 75-79 years), especially for specific cancer types, including thyroid, central nervous system, mediastinum, esophageal, bladder, and biliary cancers.

Conclusions: Patients with AF are associated with increased prevalence, heightened male predominance, and younger peak age of cancer. Further studies are needed to determine whether early screening of specific cancers is cost-effective and beneficial for patients with AF.

KEYWORDS

cardiovascular; malignancy; arrhythmia; cardio-oncology; prevalence; epidemiology; atrial fibrillation

Introduction

Atrial fibrillation (AF) is the most prevalent arrhythmia and affects approximately 1% of the general population [1,2]. Besides its relation to cardiovascular complications and mortality, increased risk of various noncardiovascular diseases, including cancers, was evident in a population with AF [3]. Cancer is the leading cause of noncardiovascular deaths and is associated with increased major bleeding, intracranial hemorrhage, and arguably thromboembolic events in patients with AF [4-6]. On the other hand, new-onset AF was related to a poorer prognosis in patients with cancer [7-9]. With rapid population aging and improved survival of both diseases, AF and cancer comorbidities are becoming increasingly clinically important and prevalent and should gain more attention from both cardiologists and oncologists.

Due to the asymptomatic nature of early-stage cancer and the intermittent onset of paroxysmal AF, diagnoses of both cancer and AF may experience years of latency, especially in low- and middle-income countries (LMICs) [10,11]. Wearable devices and mobile health might largely improve the screening efficiency and early detection of both cancer and AF but are not widely adopted currently [12-14]. Consequently, the time of diagnosis of AF and cancer does not reflect the true onset time of either disease, and preclinical stages, which may involve carcinoma in situ or atrial high-rate episodes, can last years. In addition, common risk factors (eg, smoking, obesity, and aging) and related molecular pathways (eg, chronic inflammation and autonomous dysregulation) might also contribute to the causality of the co-occurrence of AF and cancer [15]. Taken together, index diagnosis of AF in patients with cancer or cancer in patients with AF based on the temporal relationship between the two disorders might contain nonnegligible selection or lead-time bias [3,5,7,8]. Such potential bias was indicated by the fact that the highest diagnosis rate of new-onset AF occurred in the first 60 days after cancer diagnosis [9]. This was attributed, at least partially, to the intensive cardiovascular examinations of newly diagnosed patients with cancer.

The prevalence of both AF and cancer, as well as site-specific cancer types, varied across different regions, races, and ethnicities [16]. Consequently, the prevalence of AF-cancer comorbidities should also present with regional, racial, and ethnic differences. There is scarce epidemiological data concerning the comorbid state of cancer and AF, especially in LMICs, including China. Taking advantage of the government-issued database containing all sources of medical records from 25 million Shanghai citizens [1], this study investigated the site-, sex-, and age-specific profiles of comorbid cancer in the population with AF in Shanghai, thus providing insights regarding cancer and AF comorbidities in the Chinese population.

Methods

Database and Study Population

Data were retrieved from the Shanghai Municipal Health Commission database from 2015 to 2020 [1]. The database was administered by the Shanghai municipal government and covered all sources of medical records in Shanghai from 2346 medical institutions, including information on inpatient and outpatient visits at all hospitals and clinics and routine primary and family care. With health insurance coverage of over 96%, the local population with medical insurance largely represents the residents of Shanghai [1]. The government-instituted universal health insurance included the Urban Residents' Basic Medical Insurance scheme, the Urban Employee Basic Medical Insurance scheme, and the New Rural Cooperative Medical scheme. Patients without local medical insurance were excluded to avoid the inclusion of nonlocal patients who sought temporary medical services in Shanghai. Pediatric patients were also excluded. Adult patients (aged ≥20 years) in the database were screened for cancer and AF. Patients with cancer and AF comorbidities were defined as the patients with index diagnoses of cancer and AF between 2015 and 2020, regardless of the temporal order of the index date between the two diagnoses.

Diagnoses were recorded using the *International Statistical Classification of Diseases, Tenth Revision* (*ICD-10*). AF was identified by *ICD-10* codes I48.01-03 and O99.418. Cancers in general (*ICD-10* codes: C00-C97) and of individual systems were screened in patients with and without AF. A total of 21 types of cancer were listed as follows: esophageal cancer (C15), stomach cancer (C16), colorectal cancer (C18 to C21), liver cancer (C22), biliary cancer (C23 and C24), pancreatic cancer (C25), head and neck cancer (C00 to C14 and C30 to C32), lung cancer (C34), malignant neoplasm of mediastinum (C37 and C38), malignant neoplasm of bone and soft tissue (C40, C41, and C45 to C49), melanoma (C43), breast cancer (C50), gynecologic cancer (C51 to C58), male genital cancer (C60 to C63), renal cancer (C64), bladder cancer (C67), central nervous system (CNS) cancer (C69 to C72), thyroid cancer (C73), non-Hodgkin lymphoma (C82 to C85), multiple myeloma (C90), and leukemia (C91 to C95). Carcinoma in situ (D00 to D09) and borderline tumors (D37 to D48) were not included. The detailed *ICD-10* codes are listed in Table S1 in Multimedia Appendix 1. For analyses of sex disparities, gynecologic, breast, and male genital organ cancers were not included. China has released a nationwide regulation for cancer registration, which requires health care systems to report cancer cases since 2015 [17]. Therefore, cancer diagnosis data in this study was assumed to be reliable because the Chinese government provides financial support for patients with cancer-related *ICD-10* codes on the basis of clinical pathologic assessments.

Statistical Analysis

Data are presented as median (IQR) or as absolute values and percentages. The prevalence of comorbid cancer in the population with AF was calculated from the number of patients with cancer and AF divided by the total number of patients with AF. Due to different age and sex distributions between populations with and without AF, standardization was conducted for patients without AF according to the age and sex distributions of patients with AF (the numbers of patients before and after the adjustment are shown in Table S2 in Multimedia Appendix 1). The prevalence of cancer in patients without AF was subsequently calculated from the number of sex- and age-adjusted patients without AF who had cancer divided by the total number of sex- and age-adjusted patients without AF. The sex-specific cancer prevalence in patients with and without AF was also analyzed and compared. Pearson chi-square tests or Fisher precision probability tests were used to analyze the differences in the prevalence of various cancer types between populations with and without AF. The relative prevalence of cancer was presented as the prevalence ratio (PR) and 95% CI. *P*<.05 was considered statistically significant. All analyses were performed with SPSS 22.0 (IBM Corp).

Ethical Considerations

This study was reviewed and approved by the ethics committee of Xinhua Hospital, School of Medicine, Shanghai Jiao Tong University (XHEC-D-2022-043). Informed consent was exempted due to the retrospective design and the anonymized and deidentified patient records.

Results

Baseline Characteristics

A total of 25,964,447 adult patients (median 47, IQR 32-62 years of age; men: n=12,649,586, 48.72%) were included in the analyses (Table S3 in Multimedia Appendix 1). Among them, 22,185 patients presented with comorbid AF and cancer (median 77, IQR 67-82 years of age; men: n=13,631, 61.44%). Cancers were found in 839,864 individuals without AF (median 67, IQR 57-72 years of age; men: n=419,020, 49.89%), while AF was observed in 246,216 patients without cancer (median 77, IQR 67-87 years of age; men: n=118,063, 47.95%). As shown in Table 1, despite a uniformly higher prevalence of cancer in patients with AF, the top 10 cancers in the populations with and without AF were essentially identical, with the exceptions of leukemia in the population with AF and pancreatic cancer in the population without AF. The most prevalent cancer in the population with AF was lung cancer, followed by colorectal, male genital organ, stomach, breast, liver, bladder, thyroid, leukemia, and esophageal cancers.

Table 1. Prevalence of different cancers in patients with and without atrial fibrillation (AF).

Cancer site	Patients with AF (n=268,401), n (%)	Patients without AF (n=3,954,796[a]), n (%)
Lung	4572 (1.70)	41,168 (1.04)
Colorectum	2389 (0.89)	27,976 (0.71)
Male genital organs	1588 (0.59)	21,093 (0.53)
Stomach	1529 (0.57)	17,982 (0.45)
Breast	1032 (0.38)	12,427 (0.31)
Liver	774 (0.29)	8247 (0.21)
Bladder	593 (0.22)	7313 (0.18)
Thyroid	565 (0.21)	6927 (0.18)
Leukemia	473 (0.18)	4037 (0.10)
Esophagus	438 (0.16)	4570 (0.12)
Pancreas	424 (0.16)	5359 (0.14)

[a] Data from patients without AF were age- and sex-adjusted.

Increased Prevalence of Cancer in Patients With AF

As shown in Table 2, the prevalence of cancer in patients with AF (8.27% in total; 10.35% in men and 6.26% in women) was higher than that in patients without AF (6.05% in total; 7.21% in men and 4.89% in women; *P*<.001 for all comparisons). AF was associated with a nearly 1.4-fold higher prevalence of cancer after adjusting for age and sex (PR 1.37, 95% CI 1.35-1.38; Figure 1). A consistently increased prevalence of comorbidity with AF was observed in 20 of 21 cancer sites, with the only exception being CNS cancers (PR 0.94, 95% CI 0.71-1.25). The strongest association was observed in multiple myeloma (PR 2.56, 95% CI 2.28-2.87), followed by mediastinum cancer, leukemia, lung cancer, bone and soft tissue neoplasms, kidney cancer, and esophageal cancer.

Sex Disparities in Cancer Prevalence

The increased prevalence of various cancer types in the population with AF was further analyzed regarding sex. As shown in Table 3, the strongest association between AF and cancer was found in multiple myeloma (in men: PR 2.73, 95% CI 2.36-3.16; in women: PR 2.32, 95% CI 1.93-2.80) and mediastinum cancer (in men: PR 2.50, 95% CI 1.91-3.28; in women: PR 2.12, 95% CI 1.49-3.01) for both sexes. The increased AF prevalence in patients with lung cancer ranked third in men and seventh in women. The increased AF prevalence in patients with gynecologic cancer ranked eighth in women.

Table 3. Atrial fibrillation (AF)–related cancer prevalence in men and women.

Cancer site	Men		Women	
	PR[a] (95% CI)	*P* value	PR (95% CI)	*P* value

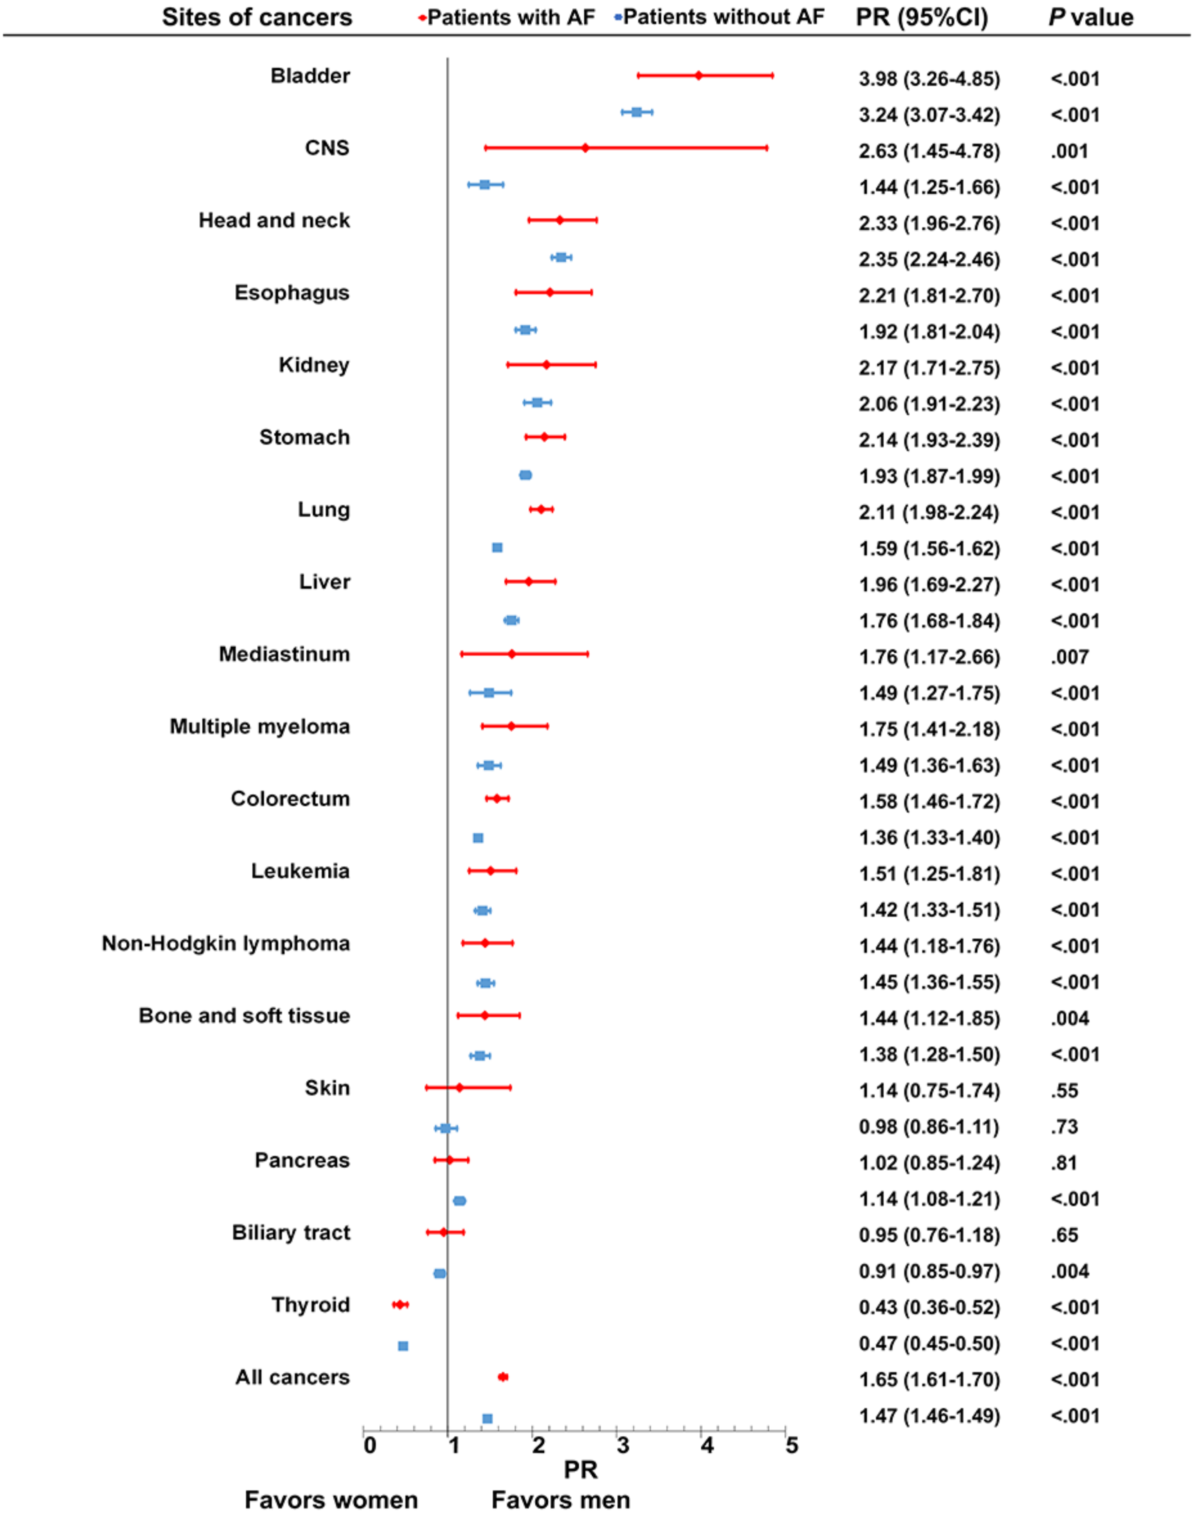
[a] PR: prevalence ratio.

As shown in Figure 2, cancer prevalence showed a male predominance in the population without AF (PR 1.47, 95% CI 1.46-1.49), which was further strengthened in the population with AF (PR 1.65, 95% CI 1.61-1.70). In the population with AF, the prevalence of cancer was higher in men than in women at 14 of 18 cancer sites (gynecologic, breast, and male genital organ cancers were excluded). Among them, a male predominance of over a 2:1 male to female ratio was found in bladder, CNS, head and neck, esophageal, kidney, stomach, and lung cancers. Cancer risk in the population with AF was similar for skin, pancreas, and biliary cancers between sexes, while a female predominance was found in thyroid cancer.

Figure 2. Sex disparities in cancer prevalence among different cancer types in patients with and without AF. Plot showing relative prevalence of site-specific cancers comparing men to women among patients with (red) and without (blue) AF. The cancer types are ranked from largest to smallest relative risk in patients with AF. A total of 18 cancer sites were analyzed. Gynecologic cancer, breast cancer, and cancer of male genital organs (mainly prostate cancer) were not included in the analyses for sex disparities. AF: atrial fibrillation; CNS: central nervous system; PR: prevalence ratio.



Sites of cancers	PR (95%CI)	*P* value

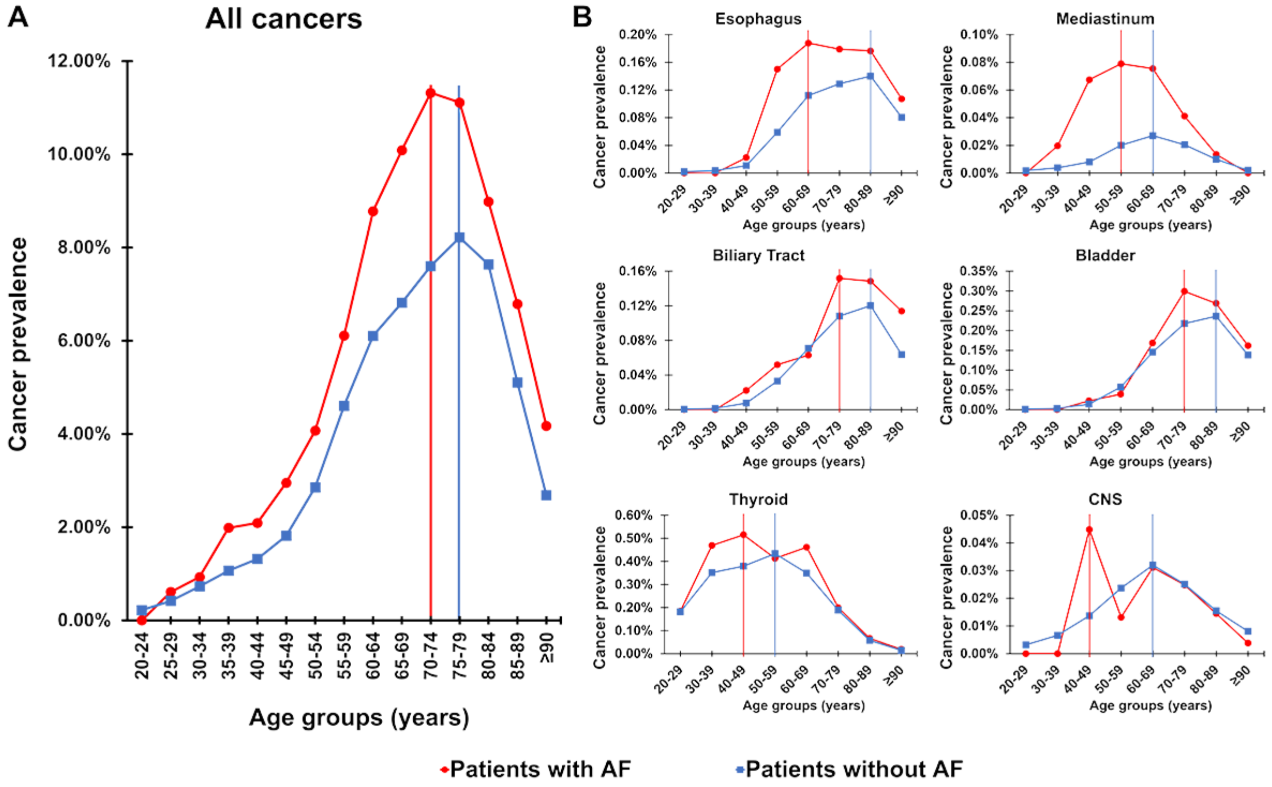
Peak Age of Cancer Diagnosis in Patients With AF

Overall, there was a younger peak age of cancer diagnosis in the population with AF (range 70-74 years) than in that without AF (range 75-79 years; Figure 3A). For specific cancer types, a younger peak age of cancer diagnosis was observed in the population with AF than in that without AF, including thyroid (with AF: range 40-49 years; without AF: range 50-59 years), CNS (with AF: range 40-49 years; without AF: range 60-69 years), mediastinum (with AF: range 50-59 years; without AF: range 60-69 years), esophageal (with AF: range 60-69 years; without AF: range 80-89 years), bladder (with AF: range 70-79 years; without AF: range 80-89 years), and biliary (with AF: range 70-79 years; without AF: range 80-89 years) cancers

(Figure 3B). In other types of cancers, the peak age of cancer diagnosis was similar between the populations with and without AF (Figure S1 in Multimedia Appendix 1).

Figure 3. Peak age of cancer in general (A) and specific cancer types (B) in patients with and without AF. AF: atrial fibrillation; CNS: central nervous system.



Discussion

Main Findings

In this whole population–based medical insurance database study, we reported the prevalence of the AF-cancer comorbid state in Shanghai, the largest city in China. The main findings were as follows: (1) the most prevalent cancer types were essentially identical between the populations with and without AF; (2) cancer prevalence was higher in 20 of 21 cancer types in patients with AF compared to those without AF; (3) prevalence of nonsolid tumors, intrathoracic malignancies, bone and soft tissue cancers, and kidney cancer were ≥1.4-fold higher in the population with AF; (4) male predominance of cancer was more prominent in the population with AF; and (5) a younger peak age of the index cancer diagnosis was observed in the population with AF, especially for esophageal, mediastinum, thyroid, bladder, biliary, and CNS cancers.

Increased Prevalence of Cancer With Comorbid AF

Increasingly, AF has been recognized as an important comorbidity in cancer. Previous studies reported that patients with cancer have an increased risk of new-onset AF compared with the general population or individuals without cancer [7,8,18]. In addition, patients with cancer and AF showed increased risks of thromboembolism, bleeding, heart failure, and mortality, which highlighted the importance of detecting and managing AF in patients with cancer [19,20]. Notably, elevated breast cancer risk was reported in patients with pre-existing AF [3,9]; however, it remained unknown if the results of these studies could be extended to other cancer types among patients with AF. This study has contributed to filling in this knowledge gap, especially in the Chinese population. Significantly increased cancer prevalence was found in the population with AF, most prominently for hematological tumors (including multiple myeloma, leukemia, and non-Hodgkin lymphoma), intrathoracic malignancies (including mediastinum, lung, and esophageal cancers), and bone, soft tissue, and kidney cancers. It is important to note that the prominent association between AF and CNS cancer, which was previously reported [8], was not observed in our study. The reason for this disparity was not clear. It is possible that the previously reported new-onset AF after CNS cancer diagnosis was mainly attributed to cardiotoxicity following cancer treatment, rather than the common pathway between oncogenesis and arrhythmogenesis.

Challenges in Establishing Temporal Relationships Between AF and Cancer

In this study, the temporal relationship between the two diseases was not differentiated for 4 reasons. First, the diagnoses of both AF and cancer commonly present latency following the development of the disease [10,11]. Years of delay in AF diagnoses have been noticed in more than 30% of patients with prior cryptogenic stroke, even under frequent electrocardiographic screening [10]. Likewise, early diagnosis of cancer relies on screening at its asymptomatic stage, which is more challenging in LMICs due to weaker health care and economic infrastructure [21]. Therefore, it would be challenging to determine the temporal order of the index diagnoses of AF and cancer.

Second, both diseases at their preclinical stage may already predispose similar pathological effects prior to their clinical stage. Atrial high-rate episodes, the precursor to AF associated with subsequent clinically documented AF, could already present AF-prone thromboembolic, cardiovascular, and mortality risks [22]. Carcinoma in situ, the precursor to invasive cancer, may have already created a tumorous microenvironment and triggered a systemic immune response during its transition [23]. Therefore, the index diagnoses might be unable to determine the potential interconnection of the two entities at their subclinical stages.

Third, various common risk factors suggested that temporal sequencing did not necessarily imply causation. Common risk factors included aging, hypertension, diabetes, obesity, smoking, consumption of alcohol, air pollution, mental and physical stress, sleep disturbances, and westernized diet and lifestyle, among others. These risk factors led to pathological processes that precipitated both diseases, such as chronic inflammation, oxidative stress, electrolyte-handling abnormalities, and autonomous dysregulation [15]. Therefore, the AF-cancer comorbid state may comprehensively reflect the true nature of the development of the two diseases.

Finally, the temporal association may result in selection bias and lead-time bias [3,5,7,8]. The highest rate of new-onset AF in the first 60 or 90 days after cancer diagnosis may partially be attributed to frequent clinical visits, electrophysiological monitoring, and comprehensive cardiovascular evaluation that may affect cancer therapy [3,9]. On the other hand, the initiation of anticoagulation after AF diagnosis may reveal occult cancers by the alerting sign of bleeding, especially at gastrointestinal and genitourinary sites [24]. Nevertheless, a definite timeline between the onset of cancer and AF did exist in several circumstances; these conditions were commonly correlated with antineoplastic therapies, including chemotherapy, targeted therapy, surgery, and radiation, as well as cancer-related pain and stress [25]. However, the effects of arrhythmogenic cardiotoxicity differed among individuals. Those with proarrhythmic atrial substrate may be more vulnerable to AF during cancer therapy.

Heightened Male Predominance of Cancer Among Patients With AF

Robust sex differences exist in almost all aspects of cancer and AF, including epidemiology, progression, treatment response, and survival [26-28]. A striking male predominance in cancers was found in the general population from over 60 countries [26]. Similarly, a 3:2 male to female ratio in AF prevalence was also present, despite a female predominance in the older population [27]. Due to the higher prevalence of both cancer and AF in men, it seemed reasonable to expect higher rates of the comorbid conditions in men than in women. Our results in the population without AF demonstrated a male predominance of cancer at 15 of 18 sites, which was consistent with a previous study [26]. Of note, the male to female ratio in cancer was further intensified in the population with AF. The extents to which sex differences among cancer types were strengthened by AF were not uniform among the different cancer types and were most prominent in lung and colorectal cancers. The varied extents suggested that mechanisms other than simple pile-up effects were at play. The response of sex differentiated cardiotoxicity to cancer therapy may also contribute to a heightened sex disparity in AF development [28].

Importance of Cancer Screening in Patients With AF

As one of the most important topics in oncology, cancer screening aims to achieve early cancer detection, improve clinical outcomes, and reduce the burden of health economics. The benefits of screening for a particular cancer must outweigh the associated costs and risks of screening. The success of a screening program also depends on the disease burden, the reliability of the test, population participation, adequate resources, and staffing. Therefore, selection of the high-risk population and the cut-off age is of high importance in cancer screening, especially in LMICs compared to countries with ample resources [29]. The current cancer screening guidelines highlighted several high-risk conditions that benefited from early screening and intensive precursor surveillance for specific cancers, such as smoking for lung cancer, human papillomavirus infection for cervix cancer, family history of malignancies, and so on [30]. The results of our study suggest not only a higher prevalence but also a younger peak age of cancer diagnosis in the population with AF. Specifically, nonsolid tumors (including multiple myeloma, leukemia, and non-Hodgkin lymphoma) and intrathoracic malignancies (including lung, esophageal, and mediastinum cancers) were characterized by higher absolute prevalence, younger peak age, and stronger associations with AF than other cancer types. Therefore, early screening of nonsolid and intrathoracic cancers via methods such as complete blood count, endoscopy, and chest computed tomography may be beneficial for patients with AF. Accordingly, more intensive heart rhythm monitoring for potential AF should also be considered in these types of cancers to optimize the risk assessment and standardize anticoagulation management.

Limitations

First, only adult patients were included in this study. AF is rare in children, and pediatric malignancies may need to be seen as a distinct subset from adult cancers due to different cancer genetics, distributions, risk factors, comorbidities, and consequently, pathophysiological mechanisms. Second, the generalizability of our findings may be limited with regard to population and time, despite the large volume of data. The profiles of both cancer and AF were undergoing a transition in China due to the constantly changing demographic structure and health economic background and were affected by other diseases and different lifestyles [31]. Shanghai, as the most industrialized region in China with the oldest population [32], may have heavier burdens of both cancer and AF than other regions in China and other LMICs [16,33]. However, the epidemiological features, medical resources, and disease management provisions in Shanghai may share a mixture of characteristics with those in LMICs and high-income countries. This may represent a future trend in other parts of China and other LMICs around the world. Third, asymptomatic AF may have gone underdiagnosed. However, thanks to the popularity of contracted family doctor services, residents in Shanghai undergo routine cardiac auscultation and intermittent handheld electrocardiogram recording, which may have largely unveiled silent AF during the 6-year inclusion period. Lastly, endogeneity bias might exist since other diseases and lifestyles also participate in the AF-cancer association.

Conclusions

This large medical insurance database study demonstrates that the comorbid state of AF and cancer is substantial in Shanghai, China. Patients with AF face increased prevalence, heightened male predominance, and a younger peak age of cancer. Physicians and patients should be aware of the cancer risks when AF is diagnosed. Screening for AF-associated cancers, such as by complete blood count for hematological tumors or thoracic computer tomography for intrathoracic malignancies, might be considered in patients with AF after a consultation with a cardio-oncologist. Likewise, more intensive heart rhythm monitoring for potential AF might be performed in specific cancers to optimize the prognosis, assessment, and prevention of cardiovascular complications. Further studies are needed to determine whether early screening of specific cancers in patients with AF is cost-effective and beneficial. Investigations regarding the value of wearable devices and mobile health in the screening and early detection of AF-cancer comorbidity are also warranted.

Abstract

Background: COVID-19 had a greater impact in the Deep South compared with other regions in the United States. While vaccination remains a top priority for all eligible individuals, data regarding the progress of booster coverage in the Deep South and how the coverage varies by county and age are sparse. Despite existing evidence of racial and ethnic disparities in COVID-19 vaccinations at the individual level, there is an urgent need for evidence at the population level. Such information could highlight vulnerable communities and guide future health care policy-making and resource allocation.

Objective: We aimed to evaluate county-level COVID-19 booster coverage by age group in the Deep South and explore its association with residential segregation.

Methods: An ecological study was conducted at the population level by integrating COVID-19 vaccine surveillance data, residential segregation index, and county-level factors across the 418 counties of 5 Deep South states from December 15, 2021, to October 19, 2022. We analyzed the cumulative percentages of county-level COVID-19 booster uptake by age group (eg, 12 to 17 years, 18 to 64 years, and at least 65 years) by the end of the study period. The longitudinal relationships were examined between residential segregation, the interaction of time and residential segregation, and COVID-19 booster coverage using the Poisson model.

Results: As of October 19, 2022, among the 418 counties, the median of booster uptake was 40% (IQR 37.8%-43%). Compared with older adults (ie, at least 65 years; median 63.1%, IQR 59.5%-66.5%), youth (ie, 12 to 17 years; median 14.1%, IQR 11.3%-17.4%) and adults (ie, 18 to 64 years; median 33.4%, IQR 30.5%-36.5%) had lower percentages of booster uptake. There was geospatial heterogeneity in the county-level COVID-19 booster coverage. We found that higher segregated counties had lower percentages of booster coverage. Such relationships attenuated as time increased. The findings were consistent across the age groups.

Conclusions: The progress of county-level COVID-19 booster coverage in the Deep South was slow and varied by age group. Residential segregation precluded the county-level COVID-19 booster coverage across age groups. Future efforts regarding vaccination strategies should focus on youth and adults. Health care facilities and resources are needed in racial and ethnic minority communities.

KEYWORDS

Deep South; COVID-19; vaccine; booster; residential segregation

Introduction

Following its approval in September 2021, the booster dose has contributed to more effective prevention and lower mortality for COVID-19 [1,2]. In the United States, the first COVID-19 booster was initially recommended to be administered at least 6 months after the completion of the primary series for individuals aged 18 years and older [2-4]. This guidance later expanded to individuals aged between 16 and 17 years [2-4]. By January 2022, the US Food and Drug Administration [5,6] extended the booster recommendation to those aged 12 to 15 years and shortened the interval to 5 months after the primary vaccination. Despite the encouraging evidence on the efficacy of the COVID-19 vaccine, as of October 19, 2022, only 50.7% of Americans aged 12 years and older had both completed the primary series and received a booster [7,8]. In the Deep South, which includes Alabama, Georgia, Louisiana, Mississippi, and South Carolina, this percentage was even lower (40%-44%) [7,8]. Although around 75% of the individuals aged 12 years and older in the United States (and approximately 63% in the Deep South) are fully vaccinated, the relatively low percentage of booster uptake is concerning as a booster dose can effectively decrease the risk of infection and severe illness [7,8]. Given that the Deep South experienced a disproportionately more severe impact from COVID-19 compared with other regions, vaccination remains a top priority for all eligible individuals [9-11]. However, there are limited data delineating booster coverage in the Deep South and how this rate varied by county and age, which is of critical importance for future vaccine planning, especially for vaccination of updated booster dose.

Racial and ethnic minority communities, including Black and Hispanic communities, are vulnerable to COVID-19 but lack a variety of health care resources. In the prevaccination period of the pandemic, these communities displayed higher incidences of infections, hospitalizations, and unfavorable treatment outcomes [9,12-14]. In the postvaccination period, both Black and Hispanic communities had a lower percentage of completing at least 1 COVID-19 vaccine dose when compared to their White counterparts [15]. This racial and ethnic disparity is also evident among children and adolescents. While the child and adolescent COVID-19 vaccination rates were low overall, Black and Hispanic children and adolescents (aged 5 to 17 years) had lower COVID-19 vaccination rates than their White and Asian peers [16]. One of the major barriers is residential segregation that restricts access to health care resources in minority communities [17]. Empirical research demonstrated that more segregated counties had more pronounced differences in COVID-19 vaccine coverage between Black and White residents [18,19]. However, the vast majority of evidence regarding racial and ethnic disparities in COVID-19 vaccination was generated from the studies at the individual level with limited population-level analyses. Of the few population-based studies, most were cross-sectional designs and did not examine the difference in COVID-19 vaccination by age groups [18,19]. Knowledge gleaned from these age-specific disparities can illuminate the progress of vaccination in racial and ethnic minority communities and facilitate the process of health care policy-making.

Well-designed ecological studies hold the potential to yield compelling evidence on racial and ethnic disparities in vaccination at the population level. Such insights can facilitate the identification of vulnerable communities and guide the optimal allocation of resources for disease control and prevention. A notable strength of ecological studies is their ability to harness comprehensive surveillance data [20,21]. Compared with individual patient data that often require rigorous ethical approvals, surveillance data are publicly accessible. Moreover, by examining racial and ethnic disparities in vaccination at aggregate levels such as communities or counties, ecological studies generate findings that are more generalizable [21]. This is a remarkable strength compared with results generated from analyses that focused on limited individuals and small geographic areas.

In this study, we evaluated the COVID-19 booster coverage by age group among the 418 counties from the 5 Deep South states and examined its relationship with racial and ethnic residential segregation using an ecological design, vaccine surveillance data, and spatiotemporal analysis.

Methods

Design, Setting, and Study Period

We conducted an ecological study at the population level by integrating COVID-19 vaccine surveillance data, residential segregation index, and county-level factors from multiple public data sets across the 418 counties of 5 Deep South states (ie, Alabama, Georgia, Louisiana, Mississippi, and South Carolina) from December 15, 2021, to October 19, 2022.

County-Level COVID-19 Booster Coverage

We retrieved variables regarding vaccine uptake from the Centers for Disease Control and Prevention (CDC) [22] COVID-19 vaccine surveillance data. This data set is representative as it reflects all vaccine partners including jurisdictional partner clinics, retail pharmacies, long-term care facilities, dialysis centers, Federal Emergency Management Agency and Health Resources and Services Administration partner sites, and federal entity facilities. The data regarding the percentage of adults who completed a primary series and have received a booster within a county (henceforth, “county-level booster coverage”) were released on December 15, 2021. The CDC also reported county-level booster coverage for people aged at least 12 years since January 27, 2022. The CDC vaccine surveillance data were updated daily until June 29, 2022, and were then updated weekly.

We retrieved the biweekly cumulative county-level booster uptake for people aged at least 18 years and those aged at least 65 years between December 15, 2021, and October 19, 2022. A total of 23 time points were included in the analyses. Since there was no existing variable for people aged between 18 and 64 years, we manually calculated the biweekly cumulative county-level booster uptake for this group by subtracting the booster uptake of people aged at least 65 years from the overall adults for each county.

For people aged between 12 and 17 years, we retrieved the biweekly cumulative booster uptake for people aged at least 12 years and at least 18 years from January 27 to October 19, 2022. A total of 20 time points were included in the analyses. We used the same method to calculate the biweekly booster uptake for this group in each county.

Residential Segregation

We defined residential segregation using the index of concentration that measures the relative amount of physical space occupied by minority groups [23,24]. Minority groups of the same relative size occupying less space were considered more concentrated and thus more segregated [23,24]. Since there is a large proportion of the Black population in the Deep South, we considered it as the main minority group and calculated the residential segregation for each county using equation (1):

where n is the number of tracts in a county, x_i is the size of the Black population in tract i, X is the size of the Black population in a county, a_i is the land area of tract i, and A is the total land area in a county [24]. The residential segregation ranged from 0 to 1, with a higher value indicating a higher degree of segregation. In each county, the higher the residential segregation score, the fewer spaces the Black population of the same relative size occupy.

Potential Confounders

Given the ecological design at the county level, we identified a list of potential county-level confounders based on prevailing literature addressing the structural and social determinants of racial and ethnic disparities of the COVID-19 pandemic in the United States [25]. Thakur et al [25] underscored that racism, social class, and social stratification shaped the risk of exposure to COVID-19 and the access to health care resources through (1) income and occupation, (2) housing and crowding, and (3) health insurance and resource distribution. Therefore, we organized the potential county-level confounders into four dimensions: (1) regional socioeconomic status (ie, the Gini index, the proportion of households with public assistance income [%], the proportion of people in low working class [%], the proportion of people with low education [%], and the proportion of noncitizen [%]); (2) housing and neighborhood environment (ie, household size); (3) health care access and susceptibility (ie, primary care provider rate [per 100,000 people] and proportion of adults who report fair or poor health [%]); and (4) transportation accessibility (ie, proportion of occupied housing units without car access [%]). These variables were validated in prior research to reflect the structural barriers to health care access and delivery [26,27]. We retrieved these variables from multiple public data sets and linked to the county level. Multimedia Appendix 1 shows the definitions and sources of all potential county-level confounders by each dimension.

Statistical Analysis

Using the geospatial mapping technique, we mapped the cumulative percentages of county-level COVID-19 booster uptake for all ages, people between 12 and 17 years, at least 18 years, between 18 and 64 years, and at least 65 years, respectively. The county-level residential segregation was also mapped. We described the median and IQR for the cumulative percentages of COVID-19 booster coverage at the county level for each of the 5 Deep South states on October 19, 2022.

We used generalized estimating equation with Poisson distribution to examine the relationship between residential segregation and COVID-19 booster coverage rate, adjusting for the repeated measures in each county and potential confounders. Since the US Food and Drug Administration [5,6] advises the first COVID-19 booster dose be administered 5 months after the completion of the primary vaccination series, to generate a robust estimate of the county-level booster coverage rate, we used the 7-day moving average of the total individuals who completed the primary series 5 months before each study time point as an offset in the Poisson model. The model can be presented using equation (2):

where $\mu_{ijt} = E(y_{ijt}|X_{ij}, V_{ijt}, t)$ is the marginal mean at time t given the covariates, and y_{ijt} denotes the total number of patients who took a booster at jth county within ith state during time t. The response (county-level COVID-19 booster coverage rate at time t) is assumed to be independent across the state but correlated within each county over time. β is a vector of regression coefficients, X_{ij} denotes the vector of county-level variables including residential segregation and other county-level covariates, γ denotes the coefficient of time, and V_{ijt} is the 7-day moving average of the total number of people who completed the primary series of COVID-19 vaccine at county j within state i at time t.

To avoid collinearity, county-level factors were standardized into the same scale with a mean of 0 and an SD of 1 before the analysis. First, we tested the main effects of time and residential segregation on the cumulative percentage of COVID-19 booster coverage. Second, given the temporal trend of COVID-19 vaccination in empirical research, we also examined the interaction between time and residential segregation and sought to understand whether the impact of residential segregation on booster coverage rate changes over time [28]. We used simple slope analysis to interpret interaction [29]. The analysis was replicated for the overall population and by age group. Finally, besides using 5 months as the interval between the primary vaccination series and booster dose as suggested by the US Food and Drug Administration, we did the sensitivity analyses, in which 6-month was used as a cutoff to calculate the offset for the Poisson model. All analyses were conducted using SAS (version 9.4; SAS Institute, Inc).

Ethical Considerations

The institutional review boards at the University of South Carolina approved the study protocol (PRO00100854). This study was an ecological analysis based on the CDC vaccine surveillance data and multiple public access data sets. No personal identification information was involved in this analysis.

Results

Overview

A total of 418 counties across 5 Deep South states were included in this study. There were 67, 159, 64, 82, and 46 counties in Alabama, Georgia, Louisiana, Mississippi, and South Carolina, respectively.

As of October 19, 2022, among the 418 counties, the median of booster uptake was 40% (IQR 37.8%-43%). In the individual states, the median of county-level booster uptake ranged from 38.4% (IQR 36.2%-40.1%) in Alabama to 43.4% (IQR 40.5%-45.4%) in South Carolina (Table 1).

Table 1. Cumulative percentages of county-level COVID-19 booster uptake for the overall sample and by age group across the 5 Deep South states, as of October 19, 2022.

States and age groups	Values (%), median (IQR)
Deep South (N=418)

At least 65 years	66.4 (64.4-69.4)

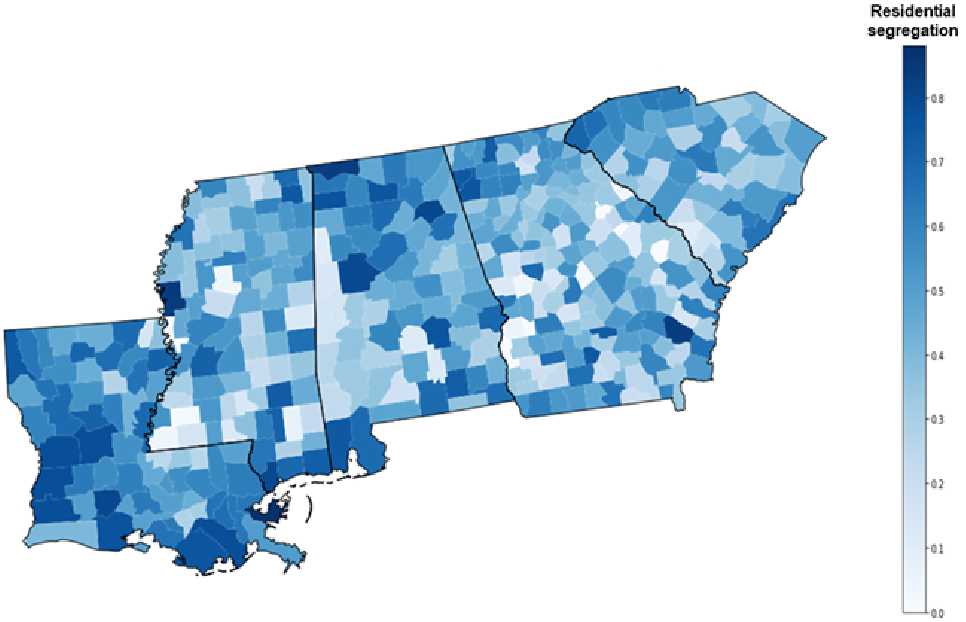
[a] The first record for the group of 12 to 17 years was available on January 27, 2022. For other groups, the first record was available on December 15, 2021.

The percentage of booster uptake for people aged at least 65 years was high with a median value of 63.1% (IQR 59.5%-66.5%) across the 418 counties. The percentage of booster uptake for people aged between 12 and 17 years was low with a median value of 14.1% (IQR 11.3%-17.4%). For people aged between 18 and 64 years, the percentage of booster coverage was 33.4% (IQR 30.5%-36.5%). Table 1 depicts the cumulative county-level percentage of COVID-19 booster uptake by age group across the 5 Deep South states, as of October 19, 2022.

Geospatial Heterogeneities in Residential Segregation and County-Level Booster Coverage

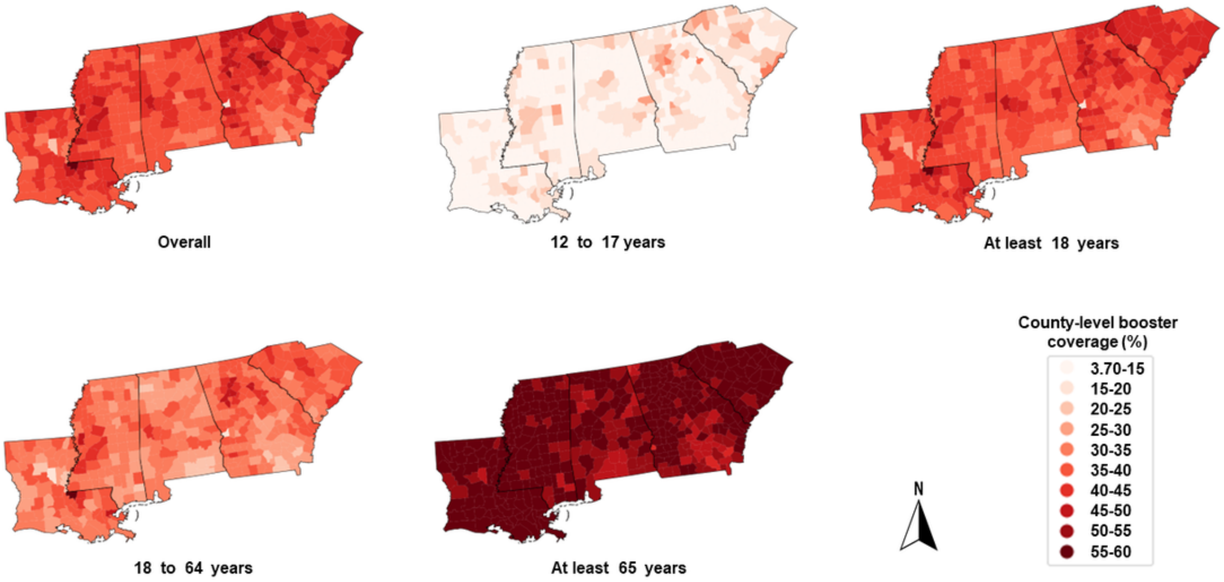
Figures 1 and 2 show the distribution of county-level residential segregation score and booster uptake, respectively. In Figure 1, counties in dark blue had higher residential segregation scores than those in light blue. There are some geospatial clusters with high levels of residential segregation within each state. For instance, Louisiana had more counties in dark blue than the other 4 states, indicating that counties in Louisiana were more segregated. These counties had high levels of residential segregation and were mainly located in the southwestern areas. In South Carolina, counties located in the northwestern and southeastern regions are more segregated compared with others.

Figure 1. County-level residential segregation in the 5 Deep South states. From left to right, the states were Louisiana, Mississippi, Alabama, Georgia, and South Carolina, respectively.



In Figure 2, counties in dark red had higher percentages of booster uptake than those in light red. In general, the percentage of completing primary series with 1 booster among people aged at least 65 years was higher than that in other age groups. In each individual state, there were some counties with low booster uptake. These counties were mainly located in southern Alabama, southeastern Georgia, southwestern and central Louisiana, southwestern and central Mississippi, and northern South Carolina. Figure 2 also shows the county-level booster uptake for other age groups.

Figure 2. County-level COVID-19 booster coverage for the overall sample and by age group in the 5 Deep South states on October 19, 2022. From left to right, the states were Louisiana, Mississippi, Alabama, Georgia, and South Carolina, respectively.



Taken Figures 1 and 2 together, there were some counties in which there was high residential segregation but low booster uptake. Some of these counties were Franklin and Coffee in Alabama, Bacon and Colquitt in Georgia, Vernon and Acadia in Louisiana, Hancock and Lauderdale in Mississippi, and Cherokee and Dorchester in South Carolina.

Relationship Between Residential Segregation and County-Level Booster Coverage

In general, as time increased, the change rate of county-level booster coverage decreased for people aged at least 18 years (β=–.051. 95% CI –0.072 to –0.031), between 18 and 64 years (β=–.053, 95% CI –0.079 to –0.027), and at least 65 years (β=–.028, 95% CI –0.044 to –0.012). For people aged between 12 and 17 years, with time increased, the change rate increased (β=.055, 95% CI 0.037 to 0.074).

Residential segregation was negatively associated with the county-level booster coverage in people aged at least 18 years (β=–.067, 95% CI –0.088 to –0.047), between 18 and 64 years (β=–.074, 95% CI –0.099 to –0.049), and at least 65 years (β=–.044, 95% CI –0.060 to –0.028). However, this negative association was not found in the analysis in people aged between 12 and 17 years (β=–.009, 95% CI –0.039 to 0.020).

In the analyses that examined the interaction between time and residential segregation on the county-level booster coverage, we consistently found a significant interaction for the overall sample (β=.054, 95% CI 0.040 to 0.069) and by age group (between 12 and 17 years: β=.031, 95% CI 0.018 to 0.044; at least 18 years: β=.057, 95% CI 0.042 to 0.072; between 18 and 64 years: β=.065, 95% CI 0.049 to 0.082; and at least 65 years: β=.047, 95% CI 0.032 to 0.062; Table 2). Simple slope analyses indicated that at a given time point, counties characterized by residential segregation above the mean (high residential segregation) experienced lower COVID-19 county-level booster coverage compared to counties where residential segregation was at or below the mean (low residential segregation). However, such difference attenuated as time increased (Figure 3).

Table 2. Residential segregation and COVID-19 booster coverage for the overall sample and by age group in the 418 counties across the 5 Deep South states from December 15, 2021, to October 19, 2022[a].

[a] Unless otherwise noted, the study period was from December 15, 2021, to October 19, 2022.

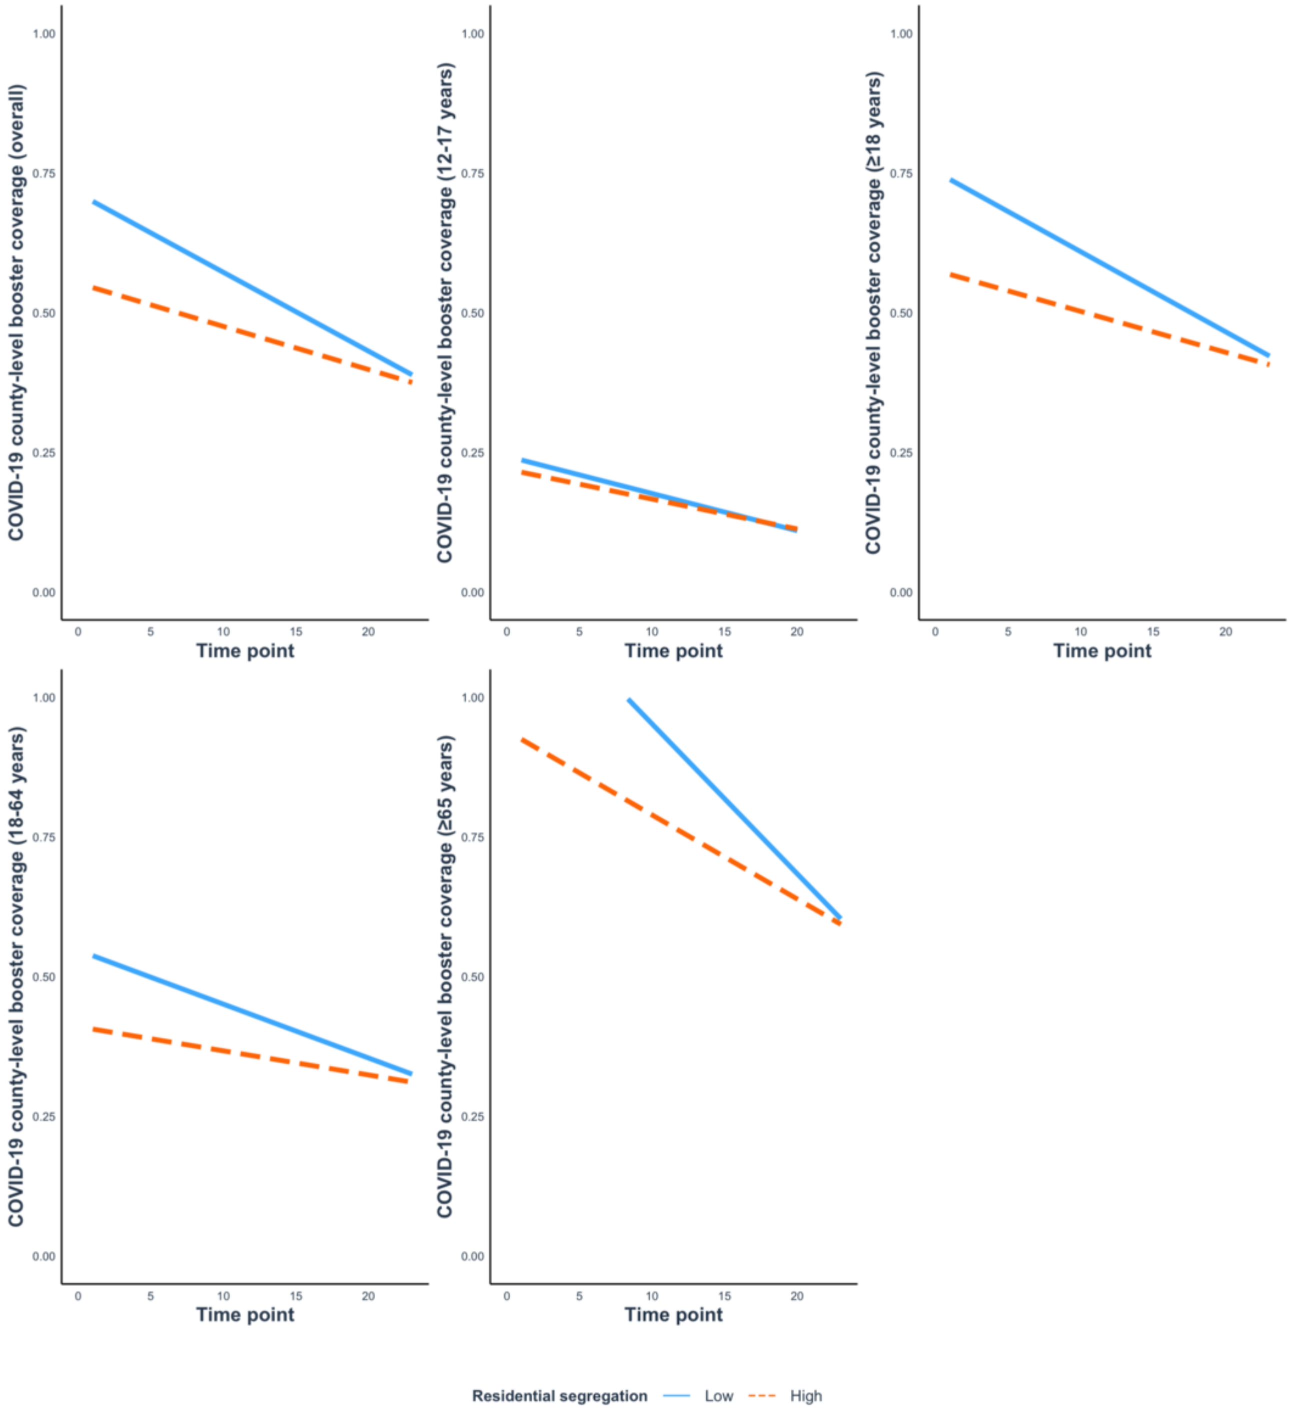
[b] From December 15, 2021 to January 26, 2022, the overall population referred to people aged at least 18 years. Since January 27, 2022, it referred to people aged at least 12 years.

[c] The first record for the group of 12 to 17 years was available on January 27, 2022. For other groups, the first record was available on December 15, 2021.

[d] Confounders: Gini index, proportion of households with public assistance income, proportion of people in low working class, proportion of people with low education, proportion of noncitizen, household size, primary care provider rate, proportion of adults who report fair or poor health, proportion of occupied housing units without access to a vehicle.

[e] $P \leq .05$.

Figure 3. Simple slope plots for interaction between time and residential segregation for the overall sample and by age group.



The sensitivity analyses using 6 months as a cutoff to derive the offset in Poisson model found that the regression coefficients for the overall population and specific age groups closely aligned with those from the primary analyses (Multimedia Appendix 2). Residential segregation was not significantly associated with county-level COVID-19 booster coverage in the subgroup analysis for people aged 12 to 17 years. The sensitivity analyses corroborated our main findings and did not change the interpretation.

Discussion

Principal Findings

In a longitudinal analysis across the 418 counties in the Deep South, we found county-level COVID-19 booster coverage was generally low and exhibited variations across different age groups. Compared with the older adult population, booster uptake was lower in youth (ie, 12 to 17 years) and adults (ie, 18 to 64 years). There was a geospatial heterogeneity in the county-level COVID-19 booster coverage, which was negatively associated with residential segregation. Specifically, counties with higher levels of segregation experienced lower booster coverage. However, this disparity decreased over time. This study was innovative as we evaluated the county-level booster coverage by age group from a longitudinal perspective, which was rare in previous research. Our findings were in line with those from the analyses at the individual level and CDC reports, which found that vaccination varied by age and racial and ethnic groups [8,22,30].

The progress of county-level COVID-19 booster coverage in the Deep South was slow and insufficient to curb the transmission of new COVID-19 variants from person to person. This slow progress was found in youth and adults. While the slow progress in these 2 age groups might be due to the low percentage of people who were fully vaccinated and eligible for a booster dose, it might also be due to the fear of long-term effects and serious side effects among the parents and the adults themselves [31,32]. Additionally, some young adults hesitated to get vaccinated against COVID-19 because they did not think it is necessary or beneficial [31,32]. Denford et al [31] found that people were unvaccinated because they considered themselves to be young, healthy, and at low risk of getting sick. However, to effectively control the pandemic in the United States, at least 70% of the population needs to get vaccinated although it is challenging.

Our findings indicated that residential segregation reflects racial and ethnic disparities at the county level and negatively impacts on the COVID-19 booster coverage, which was consistent across all age groups. Defined as the relative amount of physical space occupied by the Black population, the residential segregation in this study had consistent distributions with data from the National Institute on Minority Health and Health Disparities, demonstrating the validity of our residential segregation index [33]. There are more and more research conducted at the population level that examine the association of residential segregation with health outcomes [18,19]. Our findings add value to the existing literature by reinforcing the validity of county-level residential segregation as an indicator of racial and ethnic disparities. The negative impact of residential segregation on COVID-19 booster coverage was consistent with the empirical findings [17-19]. Racial and ethnic minority communities often experienced a scarcity of vaccine distribution sites and vaccine doses, resulting in low vaccination rates in these areas [17]. Additionally, the unequal distribution of educational resources and opportunities in highly segregated communities may preclude health education regarding the safety and effectiveness of the COVID-19 vaccine and serve as a roadblock to county-level booster coverage [34].

Our findings provide critical insights into the design of vaccine surveillance studies and the development of public health interventions to enhance booster coverage. From the research perspective, our findings demonstrated the strength of ecological study and confirmed that well-designed ecological research can yield consistent results with analyses based on individual patient data. Importantly, our conclusions had strong external validity and can be generalized to racial and ethnic minority communities in other parts of the United States. From a public health perspective, there is a pressing need to enhance vaccination initiatives in the Deep South, with a particular focus on youth, parents, and adults. Community-based health education campaigns should emphasize the safety and effectiveness of the COVID-19 vaccine. Given the disparities in health care access within racial and ethnic minority communities, to promote booster coverage, there is an urgent need to prioritize the allocation of health care facilities and resources in these areas.

Limitations

There are several limitations in this study. First, this was an ecological study focusing on county-level COVID-19 booster coverage and its contextual factors. Our findings might suffer from the ecological fallacy [20]. Caution may be needed when interpreting our findings at the individual level. Second, residential segregation was calculated based on the Black population, given the large proportion of the Black population in the Deep South. Consequently, our findings only reveal the relationship between residential segregation and booster coverage in Black communities. Third, although our analysis adjusted for a list of important county-level confounders that were selected based on a strong conceptual model and validated in prior research, other unadjusted confounders, such as political ideology and religious culture, might attenuate or enlarge the effect of residential segregation on booster coverage [15,25]. Our findings may be affected by residual confounding. We recommended future studies examine our findings with the consideration of more validated confounders. Fourth, given the nature of ecological design at the county level, we did not include individual factors in this study. Future studies incorporating both county- and individual-level factors can explore the interactions between them in predicting booster coverage. Finally, we used a proxy number of people who completed the primary series 5-month before each selected time point as an offset to model the booster coverage rate in the Poisson model, since this study was based on vaccine surveillance data, and no personal identifiers were involved. We did not have the information regarding vaccine types (eg, Pfizer-BioNTech, Moderna, and Johnson & Johnson) and the actual time interval between primary series and booster for each individual, which precluded us to model booster coverage uptake precisely. To counteract this limitation, we used the 7-day moving average of individuals who completed the primary series in our analyses. We also did sensitivity analyses using 6 months as an interval. The results were consistent with those from the analyses using 5 months. We suggest that future studies use health care administrative data to further validate our findings.

Conclusions

The progress of county-level COVID-19 booster coverage in the Deep South was slow and varied by age group. The progress was even slower in youths and adults as compared with older adults. The residential segregation precluded booster coverage across the age groups. Future efforts regarding vaccine planning and implementation should focus on the youths and adults. Health care facilities and resources are needed in racial and ethnic minority communities.

Abstract

Background: General obesity and abdominal obesity, typically measured by BMI and waist circumference (WC), respectively, are associated with an increased risk of type 2 diabetes mellitus (T2DM). However, the magnitude of the association of these two obesity indicators and their joint association with the onset of T2DM remain controversial.

Objective: The aim of this study was to investigate the associations between these two obesity indicators and T2DM among the Chinese population to contribute scientific evidence for appropriate T2DM interventions.

Methods: A cohort of 3001 eligible participants was selected from the Ningbo Adult Chronic Disease Surveillance Project running since 2015. Based on BMI, individuals were categorized into groups of underweight or normal, overweight, and obesity. Based on WC, individuals were categorized in groups of normal, precentral obesity, and central obesity. Follow-up was performed by linking data of the baseline data set with the diabetes registry data set and the vital registry data set (both from the Ningbo Municipal Integrated Noncommunicable Disease Collaborative Management System), mainly using the participants' identity numbers. Follow-up was completed when a participant was diagnosed with T2DM. The associations were estimated with multivariate Cox proportional hazard regression.

Results: In the cohort, 90 of 3001 participants developed T2DM (incidence density: 6.483/1000 person-years) with a median 4.72 years of follow-up. After controlling for age, sex, hypertension, dyslipidemia, smoking status, and family history of diabetes, the multivariate adjusted hazard ratios (HRs) across underweight/normal, overweight, and obesity BMI categories were 1.000, 1.653 (95% CI 1.030-2.654), and 2.375 (95% CI 1.261-4.473), respectively. The multivariate adjusted HRs across the normal, precentral obesity, and central obesity WC categories were 1.000, 1.215 (95% CI 0.689-2.142), and 1.663 (95% CI 1.016-2.723), respectively. Compared with the reference group (normal WC with an underweight/normal BMI), the multivariate adjusted HR for participants with both central obesity according to WC and obesity according to BMI was 2.489 (95% CI 1.284-4.825).

Conclusions: Both elevated BMI and WC at baseline increased the risk of T2DM. Compared with WC, BMI as an obesity indicator was more strongly associated with the onset of T2DM.

KEYWORDS

body mass index; waist circumference; type 2 diabetes mellitus; prospective study; data linkage; epidemiology; hazard ratio

Introduction

Diabetes mellitus is a group of metabolic disorders characterized by elevated blood glucose levels, which can lead to various health problems and severe complications with disease progression [1]. A nationwide survey in 2015-2017 reported that the prevalence of diabetes was 12.8% in China [2]. Obesity is as an important modifiable risk factor for type 2 diabetes mellitus (T2DM), and the prevalence of overweight, obesity, and abdominal obesity among the Chinese population was estimated at 28.1%, 5.2%, and 29.1%, respectively, in 2012-2015 [3,4].

BMI and waist circumference (WC) are two of the key indicators used to measure general obesity and abdominal obesity, respectively. Some studies found that compared with that of people without T2DM, the proportion of body fat distributed in the abdominal area was higher among patients who were not classified as obese according to BMI criteria, whereas some people with obesity were metabolically healthy [5,6]. Since BMI does not take the exact fat mass into account, especially the visceral adipose tissue, this indicator has a limitation in reflecting the body fat distribution [7]. It has been reported that WC might better reflect visceral obesity than BMI [8]. Recently, a growing body of studies indicated that WC was strongly associated with T2DM and is a better predictor for the onset of T2DM than BMI [9-11].

Although both general obesity and abdominal obesity have been confirmed to be associated with the risk of T2DM, the magnitude of these two obesity indicators and their joint association with T2DM remain controversial [12,13]. Moreover, the number of prospective studies addressing this issue is limited for the Chinese population. Therefore, we performed this prospective data-linkage study to investigate the independent and joint associations of these two obesity indicators with the risk of T2DM to provide better scientific evidence for T2DM interventions in Ningbo, China.

Methods

Study Design and Participants

Baseline Survey

We conducted the baseline survey (the Ningbo Adult Chronic Disease Surveillance Project) on October 26 and December 31, 2015. This was a population-based project with the aims of understanding the prevalence, awareness, treatment, and control situation, and to explore the relevant behavior risk factors of major chronic diseases (hypertension, diabetes mellitus, and dyslipidemia) among Chinese adult residents aged 15-79 years in Ningbo city.

A total of 5280 residents were selected using a multistage cluster random sampling method covering 11 districts and counties in Ningbo. In the first stage, three towns or streets were selected from each county or district using a proportionate-to-population size sampling scheme. In the second stage, two administrative villages or neighborhood communities were selected from each town or street using the same method as used in the first stage. In the third stage, one village containing at least 105 households was selected from each neighborhood community or administrative village. In the final stage, 105 randomly selected households from each village and one resident aged 15-74 years in each household whose date of birth was closest to the 15th was selected as the survey participant. Finally, a total of 5160 residents completed the survey with a response rate of 97.73% (5160/5280).

Inclusion and Exclusion Criteria for Baseline Participants

Inclusion criteria were as follows: (1) aged ≥40 years, (2) living in the current district or county for at least 6 months, and (3) capable of communicating in Mandarin or local dialects with reading skills. The exclusion criterion was having been diagnosed with diabetes by clinicians in hospitals or community health service centers at the time of the baseline survey. A total of 3001 eligible participants aged above 40 years were selected from the pool of 5160 participants. All participants signed the written informed consent form.

Ethics Approval

The research protocol was approved by the ethics committee of Ningbo Center for Disease Control and Prevention (approval number 201702).

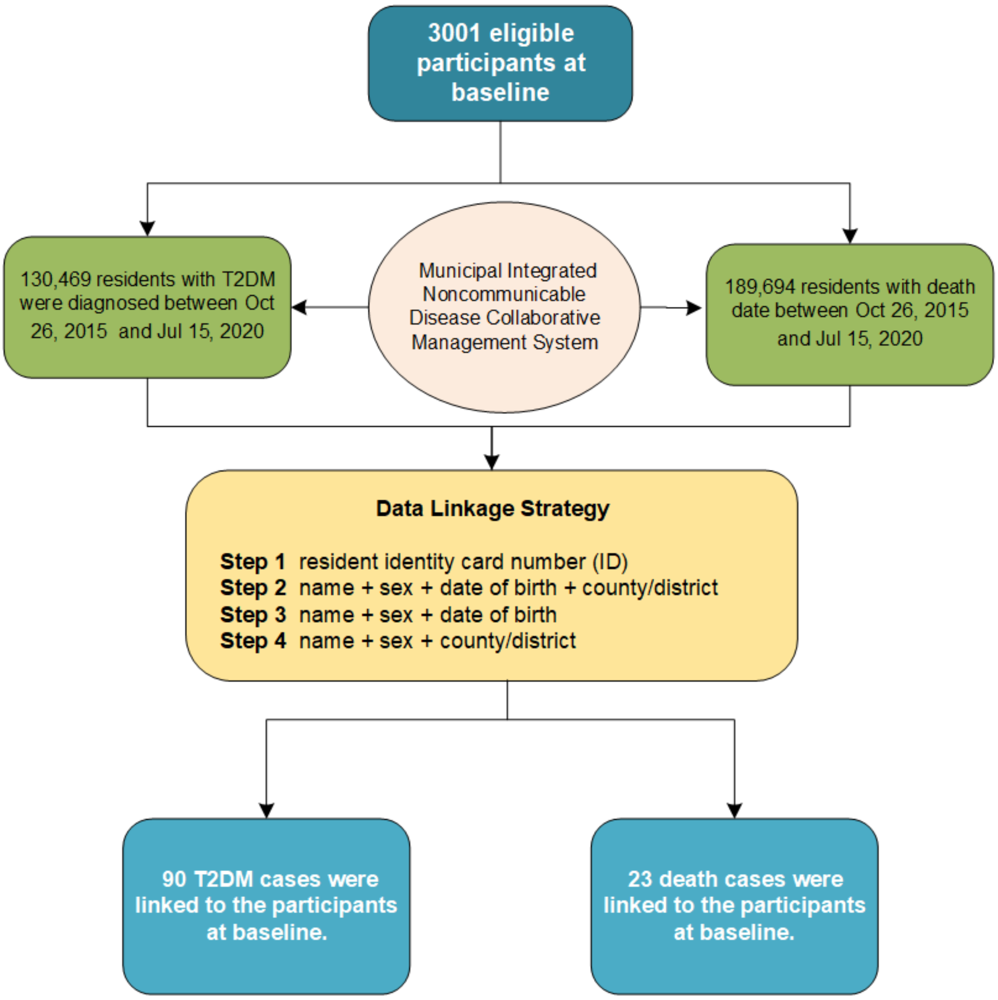
Data Collection

The data collection methods included a questionnaire survey, physical measurements, and laboratory tests. The questionnaire consisted of five components, including physical activities, environment and facilities, signs and symptoms, dietary and drinking habits, and demographic characteristics. All questionnaires were filled in face-to-face by trained staff. The completeness and accuracy of the questionnaire were double-checked by quality control personnel following the quality control requirements. We measured the height, weight, WC, blood pressure, fasting plasma glucose (FPG), glycated hemoglobin (HbA_{1c}), total cholesterol (TC), triglycerides (TG), high-density lipoprotein cholesterol (HDL-C), and low-density lipoprotein cholesterol (LDL-C) for all participants. The physical examinations were carried out by the investigators using uniform devices and methods. Participants fasted the night before measurements were taken. The height, weight, and WC were measured while the participant was wearing light clothing (shorts and T-shirt) and without shoes. The participants were required to avoid vigorous exercises, eating, and drinking beverages (especially caffeinated drinks) within 30 minutes before measuring blood pressure and to rest quietly for 5 minutes before the first measurement. The blood pressure was tested three times and the average was taken. Five milliliters of the fasting venous blood was collected from the participants to detect FPG, HbA_{1c}, TC, TG, HDL-C, and LDL-C.

Follow-up by Data Linkage

The data sources for the follow-up were obtained from the Ningbo Municipal Integrated Noncommunicable Disease Collaborative Management System (NCDCMS), which has continuously collected surveillance data since 2009 and covered the whole population of Ningbo. This system, which has been proven to obtain high-quality data and to have a low rate of underreporting (<5%), collects four types of noncommunicable disease data (diabetes mellitus, ischemic heart disease and cardiac arrest, cerebrovascular disease, malignant neoplasms) and cause of death data in a real-time manner [14]. We obtained the data from the diabetes registry with a diagnosis date from October 26, 2015, to July 15, 2020; the data of vital registration were collected according to a death date from October 26, 2015, to July 15, 2020. A total of 130,469 cases of T2DM and 189,694 cases of death were obtained from NCDCMS. The follow-up was completed by linking data of the baseline data set with the diabetes registry data set and the vital registration data set using the personal identification (ID) number. The participants who failed to link with these two data sets by ID number were linked via three combinations of identifiers in turn (ie, name+sex+date of birth+county/district; name+sex+date of birth; name+sex+county/district). A double check was performed to confirm whether the participants who successfully linked with two data sets via three identifiers were correct. Finally, 90 cases of T2DM and 23 deaths were linked to the participants at baseline through the data-linkage procedure. The flowchart of data linkage is provided in Figure 1.

Figure 1. Flowchart of data linkage. T2DM: type 2 diabetes mellitus.



Definition of Outcome (Endpoint of Follow-up)

The endpoint of follow-up was a diagnosis of T2DM. The participants who failed to be linked with the diabetes registry data set were regarded as censored. According to the Chinese Type 2 Diabetes Prevention and Control 2017 Guidelines, T2DM was defined as typical clinical manifestations (thirst, frequent urination, overeating and unexplained weight loss), and (1) random plasma glucose≥11.1 mmol/L (200 mg/dL), (2) FPG≥7.0 mmol/L (126 mg/dL), or (3) oral glucose tolerance test 2-hour plasma glucose≥11.1 mmol/L (200 mg/dL) [15].

Follow-up Time Calculation

The follow-up time was calculated as the date of diagnosis minus the start date of the baseline survey (October 26, 2015) for participants who linked with the diabetes registry data set, as the date of death minus the start date of the baseline survey (October 26, 2015) for participants who linked with the vital registration data set, and as the set end time of follow-up (July 15, 2020) minus the start date of the baseline survey (October 26, 2015) for participants who failed to link with these two data sets.

Exposure

According to the 2013 Health Industry Standards of the People's Republic of China "Criteria of Weight for Adults" and the World Health Organization report of WC and waist-to-hip ratio (WHR), BMI was categorized as underweight or normal (≤23.9 kg/m^2), overweight (24-27.9 kg/m^2), and obesity (≥28 kg/m^2). WC was divided into three groups as follows: (1) normal: WC<85 cm for men and WC<80 cm for women; (2) precentral obesity: WC of 85-89.9 cm for men, WC of 80-84.9 cm for women; and (3) central obesity: WC≥90 cm for men WC≥85 cm for women [16,17].

Covariates

Demographic and Lifestyle Factors

Demographic factors included age, sex, education level, marital status, residence place, and occupation. Lifestyle factors included smoking status, alcohol consumption, and physical activity level. Alcohol consumption was derived from the question: "Have you had any kind of alcoholic drink in the past 12 months?" Participants were divided into three groups: No; Yes, within 30 days; Yes, 30 days ago. Participants who currently smoke cigarettes or quit smoking were defined as ever smokers. Participants who never smoke cigarettes were defined as never smokers. Physical activity was classified into the following three levels in strict accordance with the Chinese guidelines for data processing and analysis of the International Physical Activity Questionnaire: low, moderate, and high. A moderate physical level was defined as (1) 3 or more days of vigorous-intensity activity of at least 20 minutes per day; (2) 5 or more days of moderate-intensity activity and/or walking at least 30 minutes per day; or (3) 5 or more days of any combination of walking, moderate-intensity activities, or vigorous-intensity activities achieving a minimum total physical activity of at least 600 metabolic equivalent (MET)-minutes/week. A high physical activity level was defined as: (1) vigorous-intensity activity at least 3 days per week achieving a minimum total physical activity of at least 1500 MET-minutes/week or (2) 7 or more days of any combination of walking, moderate-intensity activities, or vigorous-intensity activities achieving a minimum total physical activity of at least 3000 MET-minutes/week [18].

Medical Conditions

Hypertension was defined as systolic blood pressure≥140 mmHg, diastolic blood pressure≥90 mmHg, current use of antihypertensive medication, or self-reported history of hypertension [19]. Dyslipidemia was defined as TC≥5.2 mmol/L, TG≥1.7 mmol/L, HDL-C≤1.0 mmol/L, LDL-C≥3.4 mmol/L, current use of lipid-lowering medication, or self-reported history of dyslipidemia.

Statistical Analyses

The incidence density of T2DM was obtained by dividing the number of T2DM cases by the person-years of follow-up. Normally distributed continuous data are described as mean (SD) and skewed-distributed continuous data are described as median (IQR). Categorical data are described as count (percentage). Differences in the distribution of baseline characteristics between participants with and without T2DM were evaluated using the Mann-Whitney *U* test for continuous variables and with the Pearson χ^2 test for categorical variables. The strength of the association was measured using Cramer V for the χ^2 test. Tests for linear trend across categories of BMI and WC were performed by treating the categories as a continuous variable with the median value for each category.

Univariate Cox regressions were performed for each exposure (BMI categories, central obesity categories) and covariates (residence place, sex, age, education level, marital status, occupation, family history of diabetes, alcohol consumption, smoking status, physical activity, hypertension, and dyslipidemia) to calculate the unadjusted hazard ratios (HRs) with 95% CIs. Age and sex–adjusted HRs with 95% CIs were estimated with Cox proportional hazard models stratified by BMI and central obesity categories adjusting for age and sex. Multivariate Cox proportional hazard models were performed to calculate HRs with 95% CIs based on the different categories of BMI and central obesity by adjusting for potential confounders (age, sex, hypertension, dyslipidemia, smoking status, family history of diabetes).

To estimate the joint effect of general obesity according to BMI and central obesity according to WC on the risk of T2DM, the participants were classified into six groups based on the BMI and WC categories. The adjusted HRs along with potential confounders were estimated using Cox models. BMI and WC were also included in the Cox regression model as continuous variables, either separately or together. The proportionality assumption of the hazards in the Cox regression analyses was tested by Schoenfeld residuals and the assumption was satisfied for all analyses. Forest plots were used to compare the independent and joint associations of BMI and WC. All data management and statistical analyses were performed using the statistical software R version 3.4.3. *P*<.05 was considered statistically significant.

Results

Baseline Characteristics of the Participants

The final cohort included 3001 participants at baseline with a median age of 54 years. These participants were followed up for a median of 4.72 years, comprising 13,880.8 person-years of follow-up. Overall, 90 of the 3001 participants developed T2DM, with an incidence density of 6.483 per 1000 person-years by the end of follow-up. As shown in Table 1, the participants who developed T2DM were older with higher baseline BMI, WC, FBG, and HbA_{1c}, and with a greater proportion reporting a family history of diabetes compared with those who did not develop T2DM during the study period.

At baseline, 1570 (52.32%) of the participants were underweight or normal, 1159 (38.62%) were overweight, and 272 (9.06%) had obesity. Compared to the underweight or normal group, participants in the overweight and obesity groups tended to have higher WC, SBP, DBP, HbA_{1c}, LDL-C, TC, and TG; lower HDL-C; and a higher proportion of hypertension and dyslipidemia. There were 1397 (46.55%) participants with normal WC, 721 (24.03%) with precentral obesity, and 865 (28.82%) with central obesity, demonstrating similar patterns as observed for BMI categories.

Table 1. Baseline characteristics of the 3001 participants by diabetes status.

[d] N/A: not applicable.

[e] FBG: fasting blood glucose.

[f] HbA_{1c}: glycated hemoglobin.

Univariate Cox Regression Analysis

BMI categories, WC categories, age, occupation, family history of diabetes, hypertension, and dyslipidemia were significantly associated with the incidence of T2DM. Compared with participants of normal weight, the overweight (HR 2.052, 95% CI 1.293-3.258) and obesity (HR 2.924, 95% CI 1.573-5.434) categories were significantly associated with an increased risk of the development of T2DM. There was a dose-response relationship between the BMI categories and the onset of T2DM (*P* for trend <.001). Compared with participants in the normal WC group as reference, central obesity (HR 2.289, 95% CI 1.419-3.691) was significantly associated with an increased risk of the development of T2DM (*P* for trend <.001). The risk of T2DM onset was significantly increased with the increase of age. The HRs for age groups of 40-49 years, 50-59 years, 60-69 years, and ≥70 years were 1.000, 3.670, 3.423, and 5.279, respectively. The risk of T2DM in participants with hypertension and dyslipidemia was respectively 2.754 (95% CI 1.726-4.393) and 1.823 (95% CI 1.149-2.891) higher that of participants free of diseases.

Independent and Joint Associations of BMI and WC on the Risk of T2DM

The independent and joint associations of BMI and WC with T2DM development are displayed in Table 2 and Figure 2. The age and sex–adjusted HRs increased across categories of BMI and the same pattern was found after adjustment for potential confounders with a slight decrease, although the trend remained significant (*P* for trend <.001). The age and sex–adjusted HRs also increased across categories of WC (*P* for trend .003) and the trend remained significant after adjustment of potential confounders (*P* for trend .04).

Among the participants who were categorized in the central obesity group, the age and sex–adjusted HRs increased successively for those categorized in the underweight or normal, overweight, and obesity groups according to BMI compared with the reference group (normal WC with an underweight or normal BMI). Compared to the reference group, the multivariate adjusted HR for participants with both central obesity according to WC and obesity according to BMI was much higher than that for the independent association of central obesity or obesity (Table 2).

When BMI and WC were treated as continuous variables, the HR of BMI was still slightly higher than that of WC. When the BMI and WC were considered together in the regression model using mutual adjustment, BMI, but not WC, was significantly associated with the risk of T2DM (Table 3).

Table 2. Risk of type 2 diabetes mellitus stratified by categories of BMI and waist circumference (WC) in univariate, age and sex–adjusted, and multivariate-adjusted regressions.

Categories	Univariate, HR[a] (95% CI)	Age and sex–adjusted[b], HR (95% CI)	Multivariate[c], HR (95% CI)
BMI categories			
Underweight or normal (n=1570)	1	1	1
Overweight (n=1159)	2.052 (1.293-3.258)	1.941 (1.221-3.087)	1.653 (1.030-2.654)
Obesity (n=272）	2.924 (1.573-5.434)	2.918 (1.569-5.425)	2.375 (1.261-4.473)

Table 3. Risk of type 2 diabetes based on BMI and waist circumference (WC) as continuous variables.

Models	Univariate, HR[a] (95% CI)	Age and sex–adjusted[b], HR (95% CI)	Multivariate[c], HR (95% CI)
Independent effects			
BMI	1.142 (1.078-1.210)	1.141 (1.076-1.210)	1.118 (1.049-1.191)
WC	1.041 (1.019-1.063)	1.038 (1.015-1.061)	1.029 (1.004-1.054)
Joint effects[d]			
BMI	1.116 (1.021-1.221)	1.143 (1.041-1.254)	1.130 (1.027-1.243)
WC	1.011 (0.979-1.045)	1.000 (0.965-1.035)	0.995 (0.960-1.031)

[a] HR: hazard ratio.

[b] Adjusted for age and sex.

[c] Adjusted for age, sex, hypertension, dyslipidemia, smoking, and family history of diabetes.

[d] BMI and WC were considered together in the regression model.

Discussion

Principal Findings and Comparison to Previous Work

In this study, we found that both elevated BMI and WC at baseline increased the risk of T2DM. Moreover, the magnitude of association of BMI with T2DM was stronger than that of WC, regardless of treating the exposures as continuous or categorical variables, which was consistent with previous studies conducted in a Chinese population [20-22]. A prospective study performed over 7.26 years of follow-up in a southeast province of China indicated that BMI may be superior to WC in predicting the incidence of T2DM in the Chinese population [20]. A cohort study including 27,009 retirees in a central province concluded that BMI was the strongest predictor among various anthropometric indices with 4.6 years of follow-up data [22]. However, other studies reported inconsistent conclusions [23-26]. Kodama et al [23] reported that the pooled relative risk of T2DM per 1-SD increase in BMI was significantly lower than that for WC, indicating that WC was more strongly associated with diabetes risk than BMI. Lee et al [24] concluded that although WC had a stronger association with the risk of T2DM in comparison with BMI, there was no overall advantage for WC at discriminating the risk of developing T2DM compared with BMI.

The discrepancies in conclusions among studies were likely due to the differences in ethnicity of the populations. Since there is an assumption that the superiority of WC to BMI for T2DM prediction was based on the characteristics of the study population, previous studies mainly conducted in white-dominant populations or in the western sociocultural context might lead to discrepancies [23-25,27]. This study adds to this evidence for the Chinese population. Another reason for the inconsistent conclusions might be the length of follow-up. Aging is associated with progressive changes in the total and regional fat distribution [22]. As age increases, the body fat distribution changes with a decrease in lower subcutaneous fat and an increase in abdominal fat [28]. The results of previous studies might also be distorted by the increasing follow-up time as more participants tended to have abdominal obesity, which diluted the overall impact of baseline body fat distribution [23]. Differences in research methods and populations can also lead to different conclusions. Although a large-population prospective study in Chinese adults showed that WC was a better predictor than BMI for the onset of T2DM in women, this cohort study used a logistic regression model rather than a Cox regression model to predict the magnitude of associations [29]. The effect of time of follow-up was not considered in the model, which might have also affected the results. Moreover, as a cohort study carried out in an employee population, the “healthy worker effect” might have impacted these results [29]. Furthermore, the inconsistent conclusions might also be related to the different classification criteria of BMI and WC in different studies. Some studies obtained conclusions using categories of BMI or WC, whereas others used the SD.

In our study, after 4.72 years of follow-up, 90 participants developed T2DM with a total incidence density of 6.483 per 1000 person-years, similar to the study of Yang et al [21] (0.89/100 person-years). However, this incidence density was much lower than that reported in some previous longitudinal studies [30,31]. In a 10-year population-based Asian Indian cohort study, the incidence density of diabetes was 22.2 per 1000 person-years [32]. The cumulative incidence of T2DM was 14.4 and 13.7 per 1000 person-years for men and women, respectively, in an 18-year follow-up cohort study performed in Mexico [30]. The relatively low incidence density in our study may be attributed to the small number of participants at baseline, relatively young baseline population, and short follow-up time.

Limitations and Future Work

There were some limitations of this study. First, the number of participants at baseline was relatively small and the follow-up time was short. Referring to the joint associations of BMI and WC adjusting for age and sex, the HRs revealed a dose-response relationship in the overweight category. However, due to the short time of follow-up and relatively young baseline participants in this study, only 90 participants were diagnosed with T2DM. The number of newly diagnosed T2DM participants in each BMI category might not have been sufficient to detect the dose-response relationship with the increase of WC. Second, the distribution and composition of body fat might gradually change during follow-up, along with the corresponding BMI and WC. In this study, the change values of BMI and WC during follow-up were not adjusted in the models owing to the study design, which may have influenced the results. Data linkage, the key technique used in this study, has become a popular research method for generating population-level electronic cohorts, and is used as a supplement to conventional cohort studies [14,29]. Data linkage provides a convenient and cost-effective approach for collecting data from multichannel sources and investigating the causes and development in the variation of outcomes across the individual's life course [29,33]. Nevertheless, compared with a conventional cohort study, data linkage has some limitations and might introduce bias into results due to linkage errors (false matches or missed matches). Despite NCDCMS being confirmed as a platform with high data quality and a very low underreporting rate, some linkage errors are still inevitable [14]. In this study, we tried to avoid linkage errors by using three combinations of identifiers as a complement to the ID and double checking whether the cases linked via three combinations of identifiers were correct. Moreover, we controlled the proven and possible confounding factors in the models collected from the baseline survey and strictly controlled the quality of data during the investigation. Additionally, since the follow-up was completed by data linkage based on NCDCMS in Ningbo, the results might not be generalizable to other cities.

The Chinese population generally has a higher percentage of body fat and a greater propensity to central obesity compared with those of western counterparts under the same BMI [34]. Although BMI as an obesity indicator was more strongly associated with the risk of T2DM than WC in this study, we recommend that the general population and people at high risk of T2DM should focus on control of body weight as well as WC, which is consistent with the Chinese Type 2 Diabetes Prevention and Control Guideline [15]. In addition to obesity, the risk of developing T2DM was significantly higher in people who showed comorbid hypertension or dyslipidemia in comparison with participants who were free of diseases, indicating the importance of blood pressure control and maintaining a normal lipid level for the general population and especially for people at high risk of T2DM. In addition, a healthy lifestyle, including a balanced diet, regular physical activities, tobacco cessation, and alcohol control, is highly recommended, especially in the elderly population.

A study with longer-term follow-up is needed to further investigate the joint association of BMI and WC with the risk of T2DM. Although BMI, WC, and the WHR are inexpensive and easy measures to assess the adipose tissue, there is growing interest in using magnetic resonance techniques for evaluating total body fat and different fat compartments in western countries. Magnetic resonance imaging provides high accuracy in quantitatively detecting the subcutaneous and visceral adipose tissue, which could be an option to further explore the association between obesity and T2DM accurately [35]. Additionally, performing a meta-analysis for studies in the Chinese population is suggested to better detect the pooled relative risk by removing the influence of ethnicity.

Conclusion

In conclusion, both elevated BMI and WC at baseline increased the risk of T2DM. Compared with WC, BMI as an obesity indicator was more strongly associated with the onset of T2DM among Chinese adults in Ningbo. We recommend that residents of this population, especially the elderly, maintain a normal weight and a healthy lifestyle.

Acknowledgments

The authors wish to thank Dr Stacy Davlin and Dr Charlalynn Harris for providing their professional advice for this study, as well as Miss Chensheng Zhang for the abstract revision. In addition, the authors thank all investigators and study participants for their support and contributions to this study. This study was supported by the National Natural Science Foundation of China (81872721), National Key R&D Program of China (2017YFC1310902 and 2018YFC1315305), and Ningbo Medical and Health Brand Discipline (PPXK2018-10).

Abstract

Background: Disease surveillance systems capable of producing accurate real-time and short-term forecasts can help public health officials design timely public health interventions to mitigate the effects of disease outbreaks in affected populations. In France, existing clinic-based disease surveillance systems produce gastroenteritis activity information that lags real time by 1 to 3 weeks. This temporal data gap prevents public health officials from having a timely epidemiological characterization of this disease at any point in time and thus leads to the design of interventions that do not take into consideration the most recent changes in dynamics.

Objective: The goal of this study was to evaluate the feasibility of using internet search query trends and electronic health records to predict acute gastroenteritis (AG) incidence rates in near real time, at the national and regional scales, and for long-term forecasts (up to 10 weeks).

Methods: We present 2 different approaches (linear and nonlinear) that produce real-time estimates, short-term forecasts, and long-term forecasts of AG activity at 2 different spatial scales in France (national and regional). Both approaches leverage disparate data sources that include disease-related internet search activity, electronic health record data, and historical disease activity.

Results: Our results suggest that all data sources contribute to improving gastroenteritis surveillance for long-term forecasts with the prominent predictive power of historical data owing to the strong seasonal dynamics of this disease.

Conclusions: The methods we developed could help reduce the impact of the AG peak by making it possible to anticipate increased activity by up to 10 weeks.

Introduction

Background

Acute gastroenteritis (AG) is a major public health problem worldwide [1]. Commonly defined as diarrhea or vomiting in the past 24 hours [2], AG is one of the main causes of morbidity and mortality among young people and causes up to 2.5 million deaths per year in children aged <5 years around the world [3]. Although it is generally a mild disease, its morbidity and economic burden are high [4]. In France, there are >21 million episodes of AG each year [5]. Although AG episodes occur throughout the year, there is a winter peak, mainly owing to norovirus and rotavirus [6,7]. During these peaks, the increase of visits to general practitioners and emergency or pediatric departments causes health care system disruptions [8].

Disease surveillance systems capable of producing accurate real-time and short-term forecasts can help public health officials design timely public health interventions to mitigate the effects of disease outbreaks in affected populations. In France, all acute diarrhea cases seen during medical appointments are reported weekly by volunteer outpatient health care providers. An estimation of AG incidence rate is then computed, at the national or regional scale, by considering the number of sentinel physicians and the medical density of the area of interest [9]. However, data collection, processing, aggregation, and distribution processes introduce up to 3 weeks of delay in the availability of AG activity information. This temporal data gap prevents public health officials from having a timely perspective about AG activity and thus leads to the design of interventions that do not take into consideration the most recent changes in disease dynamics. Therefore, there is a growing interest in finding new ways to mitigate this information gap [10,11].

To alleviate this time lag, several studies have proposed approaches to produce accurate and reliable real-time disease activity estimates, for example, to monitor influenza [11-14]. For AG, studies have been focused on identifying the clinical characteristics of the disease. Norovirus and rotavirus are the viruses responsible for most gastroenteritis outbreaks [6,7,15-18]. This disease has a strong wintertime seasonality, but this seasonality could be affected by the climate change, which would affect norovirus transmission, host's susceptibility to norovirus infection, and resistance of norovirus to environmental conditions. This may cause large oscillations in the number of cases per year [6,7]. AG remains as a major cause of hospitalizations, especially for children, and the use of a vaccine could help to decrease the impact of the disease [16,18]. Some research teams have assessed the correlation between data sources (eg, drug reimbursement data and emergency department visits) and general practitioner visits for AG [3,19]. Other studies have shown a significant correlation between internet search query trends and AG incidence rates in different locations such as the United States, Mexico, the United Kingdom, and France [20,21]. However, none, to the best of our knowledge [22], have proposed a feasible methodology to forecast AG activity. Through this study, we investigated the challenges of achieving this and proposed a reliable forecasting approach.

State of the Art

Existing forecasting systems for other disease outbreaks, such as influenza, include statistical models that leverage information available in near real time [11-14]. One of the first and prominent studies is Google Flu Trends [23], a web-based service operated by Google. Created in 2009, the platform used the volume of selected Google search terms to estimate influenza activity in real time. However, the web service was stopped following several prediction errors owing to changes in people's search behavior as a result of the exceptional nature of the pandemic or owing to the announcement of a pandemic that finally did not appear [24]. Following this, some authors updated the Google Flu Trends algorithm to improve influenza forecasting, by including data from Google Correlate and Google Trends web services and other sources, for instance, historical influenza information [11]. Internet is not the only data source that can be used to produce information in real time. With the widespread adoption of patient electronic health records (EHRs), hospitals also generate a huge amount of data. Bouzillé et al [25] showed that EHRs are strongly correlated with influenza incidence rates. Some authors proposed statistical models using EHRs to predict influenza incidence rates in real time [12,26]. In addition, other studies showed that internet users' searches were strongly correlated with influenza epidemics and other diseases, including AG [8,21].

In this study, we evaluated the feasibility of using internet search query trends and EHR to predict AG incidence rates in near real time, at the national and regional scales, and for long-term forecasts (up to 10 weeks). We used 2 different methods—a linear approach using Elastic Net and a nonlinear approach using random forest (RF). In addition, as AG outbreaks cause disruptions in hospitals and emergency departments, we estimated AG incidence rates at the level of emergency departments and hospital stays.

Methods

Variables to Be Predicted

National Level

We obtained the national (Metropolitan France) acute diarrhea weekly incidence rates (per 100,000 inhabitants) from the French Sentinel network [27], from January 2008 to March 2018. We retrieved these data in April 2018.

Regional Level

We obtained the regional (Brittany region) acute diarrhea incidence rates (per 100,000 inhabitants) from the French Sentinel network [27], from January 2008 to March 2018. We chose the Brittany region as we used her data from a hospital in Brittany. We retrieved these data in April 2018.

Predictive Variables

Web Data

We obtained the frequency per week of the 100 most correlated French queries from Google Correlate [28]. For each signal to be predicted (national and regional levels), we retrieved Google Correlate data for the period from January 2008 to March 2018. As our prediction period is from May 2014 to February 2018, the correlation was calculated from January 2008 to April 2014. All signals were normalized to obtain mean 0 and SD 1 before calculating the correlation. The reason to correlate was to choose the most appropriate queries to predict the outbreak without previous knowledge [29]. The most correlated queries obtained for national and regional levels can differ because the weekly incidence rates for France and Brittany are different.

Clinical Data

We used data from the clinical data warehouse (CDW) of Rennes University Hospital (France), called entrepôt de données de l'HÔPital (eHOP). This CDW includes structured (laboratory test results, prescriptions, and International Statistical Classification of Diseases and Related Health Problems 10th Revision diagnoses) and unstructured (discharge letter, pathology reports, and operative reports) patients' data from 1.2 million inpatients and outpatients and 45 million documents. To identify patients with specific criteria, eHOP has its own search engine system that allows to query unstructured data with keywords or structured data with codes based on terminologies.

First, to retrieve clinical data connected with AG, we performed different full-text queries (related to gastroenteritis, its symptoms, virus, or treatments). These queries allowed to obtain all documents matching with the search criteria (often, several documents for 1 patient and 1 stay). Then, for each week, we kept the oldest document for 1 patient and 1 hospital stay, and we calculated the number of hospital stays with at least one document mentioning the keyword contained in the query. As we used 19 keywords, we obtained 19 variables from CDW eHOP.

Then, we built a database containing the time series constructed from the structured data (total n=1,335,347 time series). Regrading Google Correlate, we calculated the Pearson correlation between both national and regional incidence rates and the time series from the database. We retrieved the 100 most correlated signals. As our prediction period is from May 2014 to February 2018, we calculated the correlation between January 2008 and April 2014.

Overall, we obtained 119 variables (n=19, 15.9% of variables from the full-text queries and n=100, 84% of the most correlated variables from the structured data). The 100 most correlated variables can be different for national and regional levels. We retrieved EHR data for the period from January 2008 to March 2018 in April 2018. All these data could be extracted in real time if needed.

Historical Data

We used the incidence rates for the previous 52 weeks as predictive variables, for both national and regional levels.

Ethics Approval

This study was approved by the local ethics committee of the Rennes Academic Hospital (approval number 16.69).

Statistical Models

Linear Approach

To minimize the negative effects of using a large number of input variables, potentially including redundant information, we used Elastic Net, a regularized multivariate regression methodology that can identify parsimonious models [30]. Elastic Net combines the power of Lasso and Ridge regressions, allowing to perform a variable selection on variables that are highly correlated [31,32]. We performed the Elastic Net regression analysis using the *caret* package in R (R Foundation for Statistical Computing) and the associated function fit with the *glmnet* method [33,34]. We fixed a coefficient λ=0.5 to give the same importance to Ridge and Lasso methods.

The formulation of our model is the following:

Here, yT denotes AG incidence rate at time T=t, t+1, t+2, t+3 (for the different levels of prediction), denotes historical variables, denotes Google data, denotes EHR data, and denotes residuals.

For a given week, we needed to find the parameters, $\alpha=(\alpha_1,..\alpha_{52})$, $\beta=(\beta_1,..\beta_{100})$, and $\gamma=(\gamma_1,..\gamma_{119})$, that minimize the following:

Here, are hyperparameters of the Elastic Net regression. We used 10-block cross-validation to optimize the parameters. All parameters ($\alpha=[\alpha_1,..\alpha_{52}]$, $\beta=[\beta_1,..\beta_{100}]$, and $\gamma=[\gamma_1,..\gamma_{119}]$) were dynamically trained every week with a rolling window using all data available. In this way, the size of our training data set increased every week. For example, for the first week of January 2015, our training data set ranged from January 2008 to the last week of December 2014. To predict the first week of January 2016, our training data set ranged from January 2008 to the last week of December 2015. We obtained estimates from May 2014 to February 2018.

Nonlinear Approach

RF is a nonlinear machine learning approach based on the construction of multiple decision trees using the general bootstrap aggregating technique (known as bagging) [35]. We used this method as it showed good performance in short-term forecasting even when it is compared with other machine learning approaches such as support vector machine or neural network or a traditional approach such as autoregressive integrated moving average [36,37].

With RF, the AG incidence rates are obtained with the following:

Here, y_T denotes AG incidence rate at time T=t, t+1, t+2, t+3 (for the different levels of prediction) and denotes AG incidence rates estimate obtained with the decision tree b. We used the R package, *randomForest* [38], to create our RF models. The hyperparameters corresponding to the number of decision trees and the number of variables randomly sampled at each split were optimized on a training data set from January 2008 to May 2014. Then, regarding the Elastic Net model, RF was dynamically recalibrated for every new week of prediction by incorporating all the data available. We obtained estimates from May 2014 to February 2018.

Contribution of Each Data Source

In addition, to assess the contribution of each individual data sources or their combinations, we built Elastic Net and RF models using the following predictive variables:

1. AG incidence rates—baseline model called autoregressive model of order 52 (AR(52)) in the following sections—for the previous 52 weeks
2. Google data
3. EHR data
4. Google data and AR(52)
5. EHR data and AR(52)
6. Google data and EHR data

Evaluation

To assess the performance of our models, we compared our estimates with the real incidence rates from the Sentinel network. We calculated the root mean squared error and the Pearson correlation coefficient for our test period starting from May 2014 to February 2018. The model allowing to obtain the most accurate estimates is the one having the highest correlation and the lowest error:

1.
2.

Here, is the predicted value for the week t, is the mean of predicted values, y_t is the real value for the week t, and is the mean of real values.

Comparison With Influenza

As we used a method developed for influenza outbreaks, we compared the results obtained for AG with those obtained for influenza. The aim was to determine whether external data sources are as relevant for AG as for influenza. We started by comparing the stationarity and the seasonality of both time series by calculating the following:

1. The autocorrelation function (ACF), allowing to determine the autocorrelation between y_t and $y_{t–h}$:

where $\gamma(h)=\mathrm{cov}(y_t, y_{t–h})$

2. The partial ACF (PACF), allowing to determine the autocorrelation between y_t and $y_{t–h}$ after removing the autocorrelation between the intermediate variables $y_{t–1},\dots,y_{t–h+1}$:

$r(h)=\mathrm{corr}(y_t,y_{t–h}|y_{t–1},\dots,y_{t–h+1})$

Then, we compared the accuracy of estimates for forecast up to 10 weeks with Elastic Net and RF models using only historical data or combining Google, EHR, and historical data.

Results

Overview

First, we studied the impact of each data source for short-term forecasts with the 2 different approaches already used to predict influenza outbreaks—a linear approach with the Elastic Net model and a nonlinear approach with an RF model.

Then, we analyzed the AG and influenza time series, especially the seasonality, to better understand the differences between the 2 diseases.

Finally, we compared AG and influenza results obtained for long-term forecasts with the 2 approaches, and we assessed the impact of external data sources to increase the accuracy of our estimates.

Linear Approach

Overview

At the national and regional levels, in terms of error, the lowest values are obtained with models using historical data and external data sources (Table 1). At the national level, in terms of error, both data sources, Google and EHR produce the most accurate estimates compared with the model using only historical data—AR (52). At the regional level, the model using only historical data and EHR allows to obtain lower errors than the model using historical data and both Google and EHR data.

In terms of correlation, in most cases, at the national and regional levels, the model using only historical data allows to obtain the highest values.

Table 1. PCC[a] and RMSE[b] values obtained for the entire prediction period (May 2014 to March 2018) at the national and regional levels, with all the combinations of data sources.

Levels and data sources	Real time		1-week forecast		2-week forecast		3-week forecast

[a] PCC: Pearson correlation coefficient.

[b] RMSE: root mean squared error.

[c] AR(52): autoregressive model of order 52.

[d] Italicization highlights the 2 highest correlations and lowest errors obtained with the models for real time and 1-week, 2-week, and 3-week forecasts.

[e] EHR: electronic health record.

National Analysis

For real-time estimates, the error values range from 48.4 to 16.2 and the correlation values range from 0.83 to 0.95, with the lowest error and the highest correlation obtained with the model using only historical data—AR(52). For 1-week estimates, the error values range from 45.6 to 20, with the lowest error and the highest correlation obtained with the model using historical data and both external data sources, Google and EHR. In terms of correlation, the correlation values range from 0.51 to 0.91, with the highest value obtained with the model using only historical data. For 2-week and 3-week estimates, we have similar results, with error values ranging from 47.4 to 24.2 and 44.6 to 25.3, respectively, obtained with the model using historical data and both external data sources, Google and EHR. In terms of correlation, the values range from 0.49 to 0.90 and from 0.52 to 0.88, respectively, with the highest correlation obtained with AR(52) model.

Figure 1 illustrates the estimates obtained at the national level for forecasts up to 3 weeks with the model using only historical data and the model using historical data and both data sources, Google and EHR. For real-time estimates, the results obtained with the 2 models are comparable, but for long-term forecasts (1, 2, and 3 weeks), the estimates obtained with the AR(52) model are delayed. In addition, the model using only historical data tends to smooth estimates and overestimate between peaks.

Figure 2 is a visualization of the values of the coefficients for the model using historical data and both data sources, Google and EHR. For real-time estimates, the heat map shows that the model uses multiple variables from all data sources, such as historical data, Google data, and EHR data. Similar plots are presented in Multimedia Appendix 1 for long-term estimates.

Figure 1. National level. Predictions up to 3 weeks obtained at the national level with the model using only historical data and the model using historical data and both data sources, Google and EHR. Gold standard, French Sentinel network data. EHR: electronic health record.

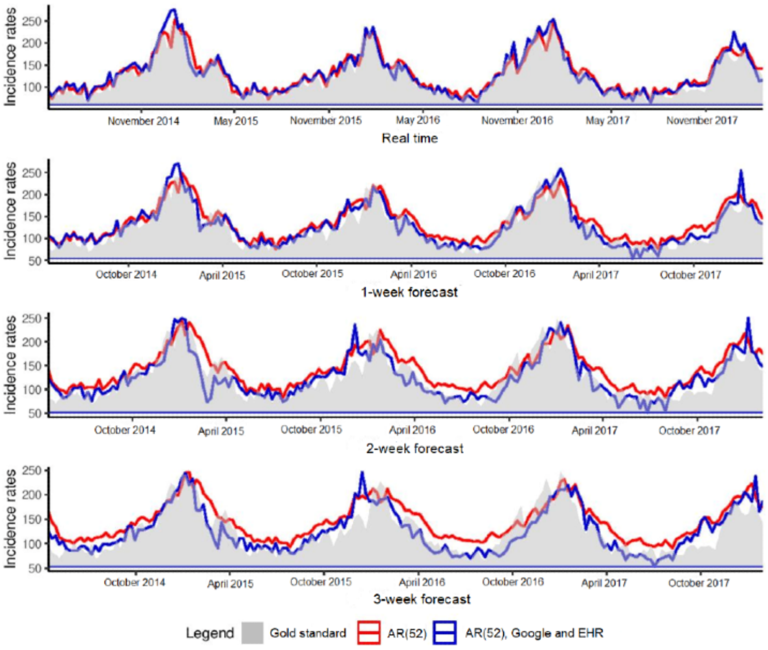

Figure 2. National level. Heatmap of the coefficients. Each line of the heatmap corresponds to one predictive variable used in the model and each point of the line corresponds to 1 week predicted. The first block of variables corresponds to electronic health record (EHR) data, the second one corresponds to Google data, and the third one to historical data. In blue, a negative coefficient is associated with the variable, whereas in red, it is a positive coefficient. The white color means that the predictive variable is not selected by the model and does not participate in forecasting the corresponding week. In yellow, highlighted variables that are kept by the model almost all the time. For EHR data, it corresponds to the predictive variables for the keywords “Autres deficits immunitaires,” “Autre virus grippal identifié,” “Streptococcus pneumoniae,” “Pneumopathie,” “Virus respiratoire syncytial.” For Google data, it is the keywords: “enero,” “enterite,” “epidemie de gastro,” “gastro entérite,” “ski massif central.” For historical data, it corresponds to the previous week as well as week 17, week 18, week 25, and week 48 before the one we want to predict.

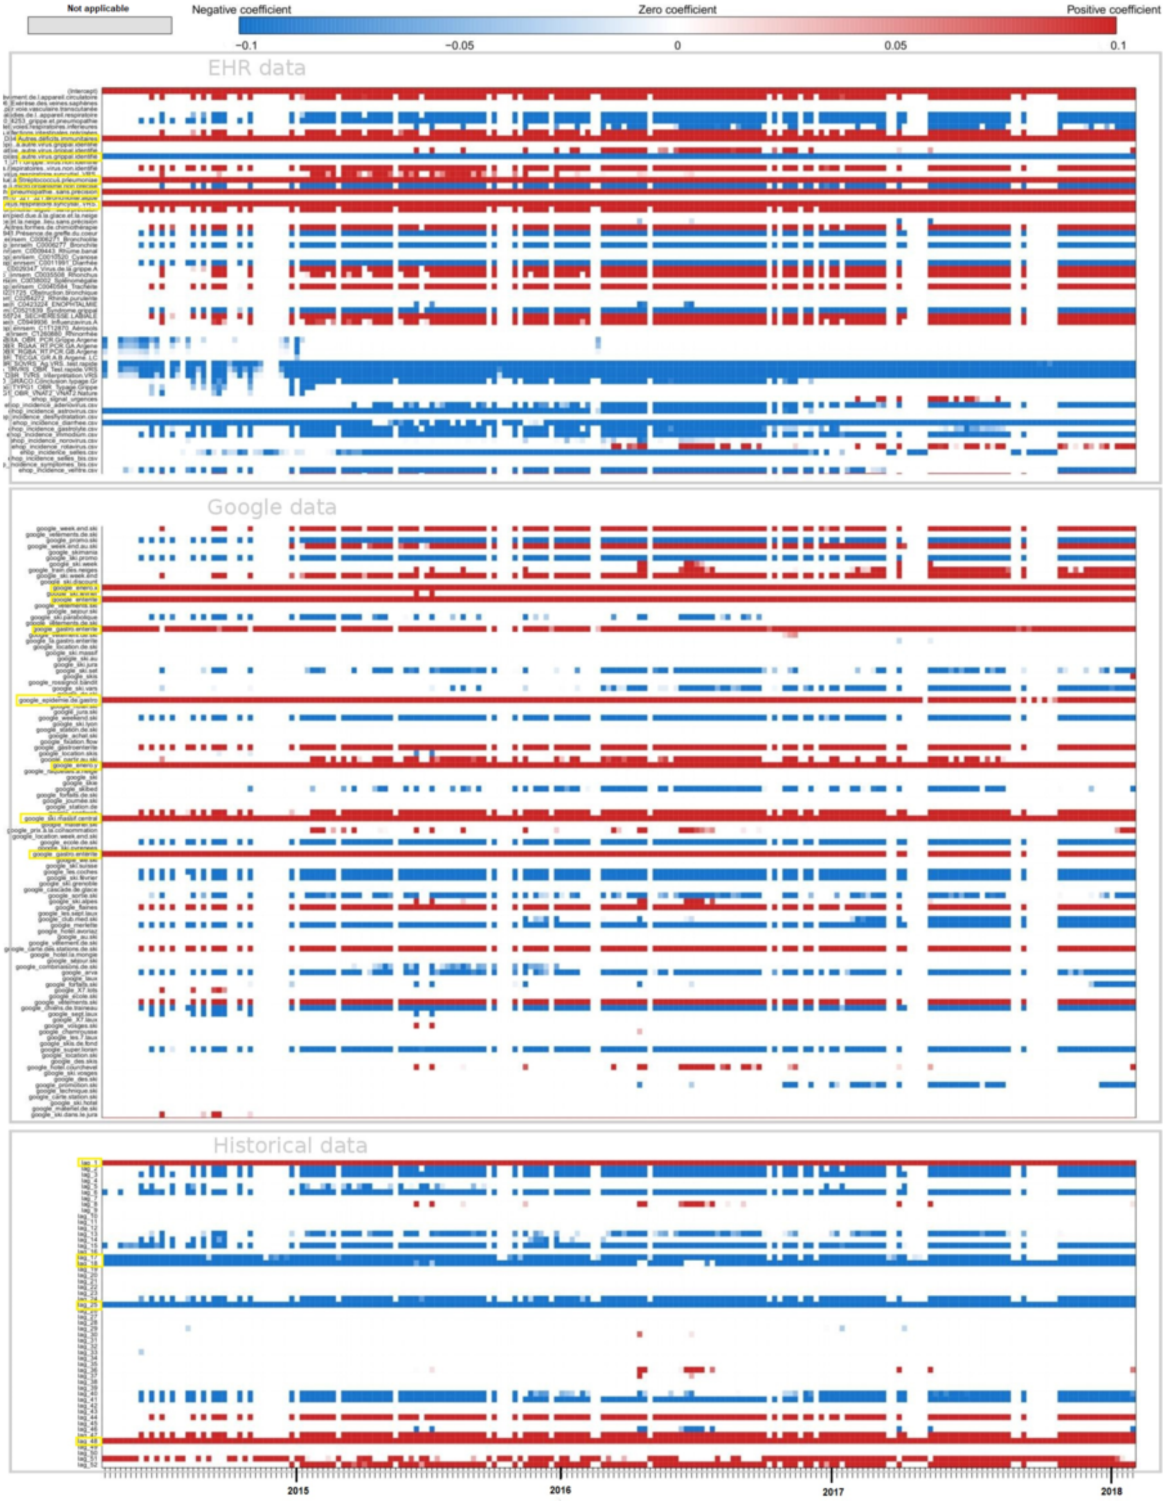

Regional Analysis

For real-time estimates, the error values range from 65.8 to 40.8 and the correlation values range from 0.46 to 0.74, with the lowest value for the error obtained with the model using only historical data and the highest value for the correlation obtained with the model using historical data and Google data. For 1-week, 2-week, and 3-week estimates, the error values range from 64.8 to 42.4, from 60.3 to 46.5, and from 61.7 to 46.3, respectively. The lowest errors values for long-term forecasts are all obtained with the model using historical data and EHR data. In terms of 1-week, 2-week, and 3-week correlation, the values range from 0.54 to 0.71, from 0.55 to 0.67, and from 0.58 to 0.68, respectively. The highest correlations for long-term forecasts are all obtained with the model using only historical data—AR(52).

Figure 3 illustrates the estimates obtained at the regional level for forecasts up to 3 weeks with the model using only historical data and the model using historical data and both data sources, Google and EHR. At the national level, for real-time estimates, the results obtained with the 2 models are comparable, but for long-term forecasts, the estimates obtained with the AR(52) model are delayed and tend to be smoothed and overestimated between peaks.

The heat map (Figure 4) shows that for real-time estimates at the regional level, the model uses multiple variables from historical data (approximately 11 variables) and low number of variables from Google data (approximately 10 variables) and EHR data (approximately 9 variables) compared with those at the national level. Similar plots are presented in Multimedia Appendix 1 for long-term estimates.

Figure 3. Regional level. Predictions up to 3 weeks obtained at the regional level with the model using only historical data and the model using historical data and both data sources, Google and EHR. Gold standard, French Sentinel network data. EHR: electronic health record.

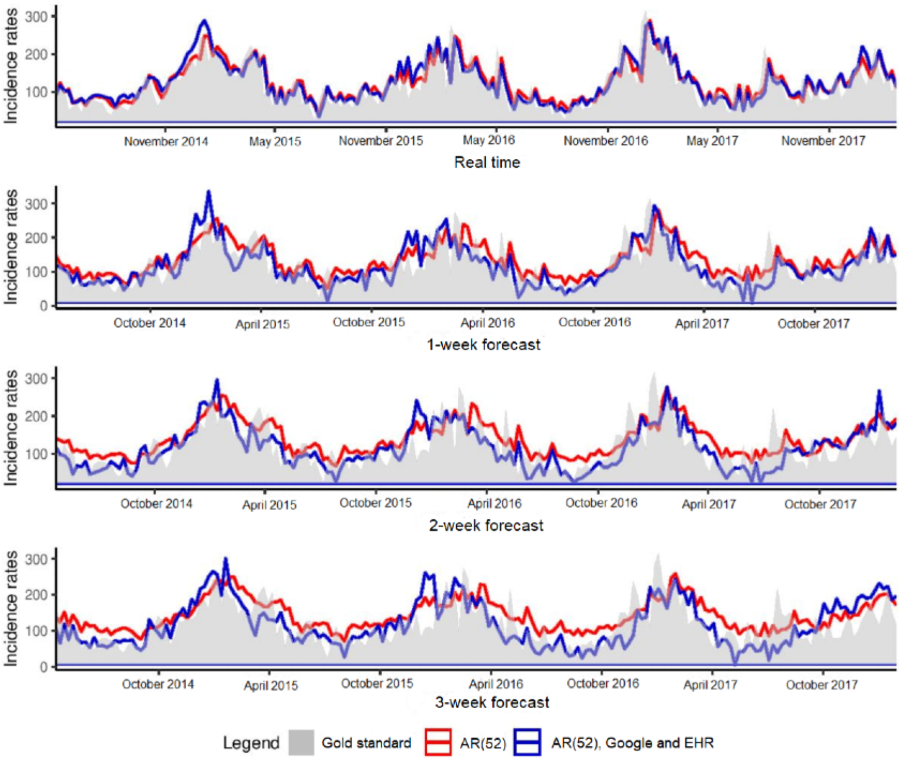

Figure 4. Regional level. Heatmap of the coefficients. Each line of the heatmap corresponds to one predictive variable used in the model and each point of the line corresponds to 1 week predicted. The first block of variables corresponds to electronic health record (EHR) data, the second one corresponds to Google data, and the third one to historical data. In blue, a negative coefficient is associated with the variable, whereas in red, it is a positive coefficient. The white color means that the predictive variable is not selected by the model and does not participate in forecasting the corresponding week. In yellow, highlighted variables that are kept by the model almost all the time. For EHR data it corresponds to the predictive variables for the keywords “Par voie sous cutannée,” “Autre virus grippal identifié,” “Voies respiratoires. Virus non identifié,” “Pneumopathie,” “Bronchiolite aigüe,” “Virus respiratoire syncytial,” “Bronchite,” “Ventre.” For Google data, it is the keywords: “enero,” “gastro enterite,” “gastro entérite,” “fixations.” For historical data, it corresponds to the two previous weeks as well as week 10, week 15, week 17, week 20, week 25, and week 48 before the one we want to predict.

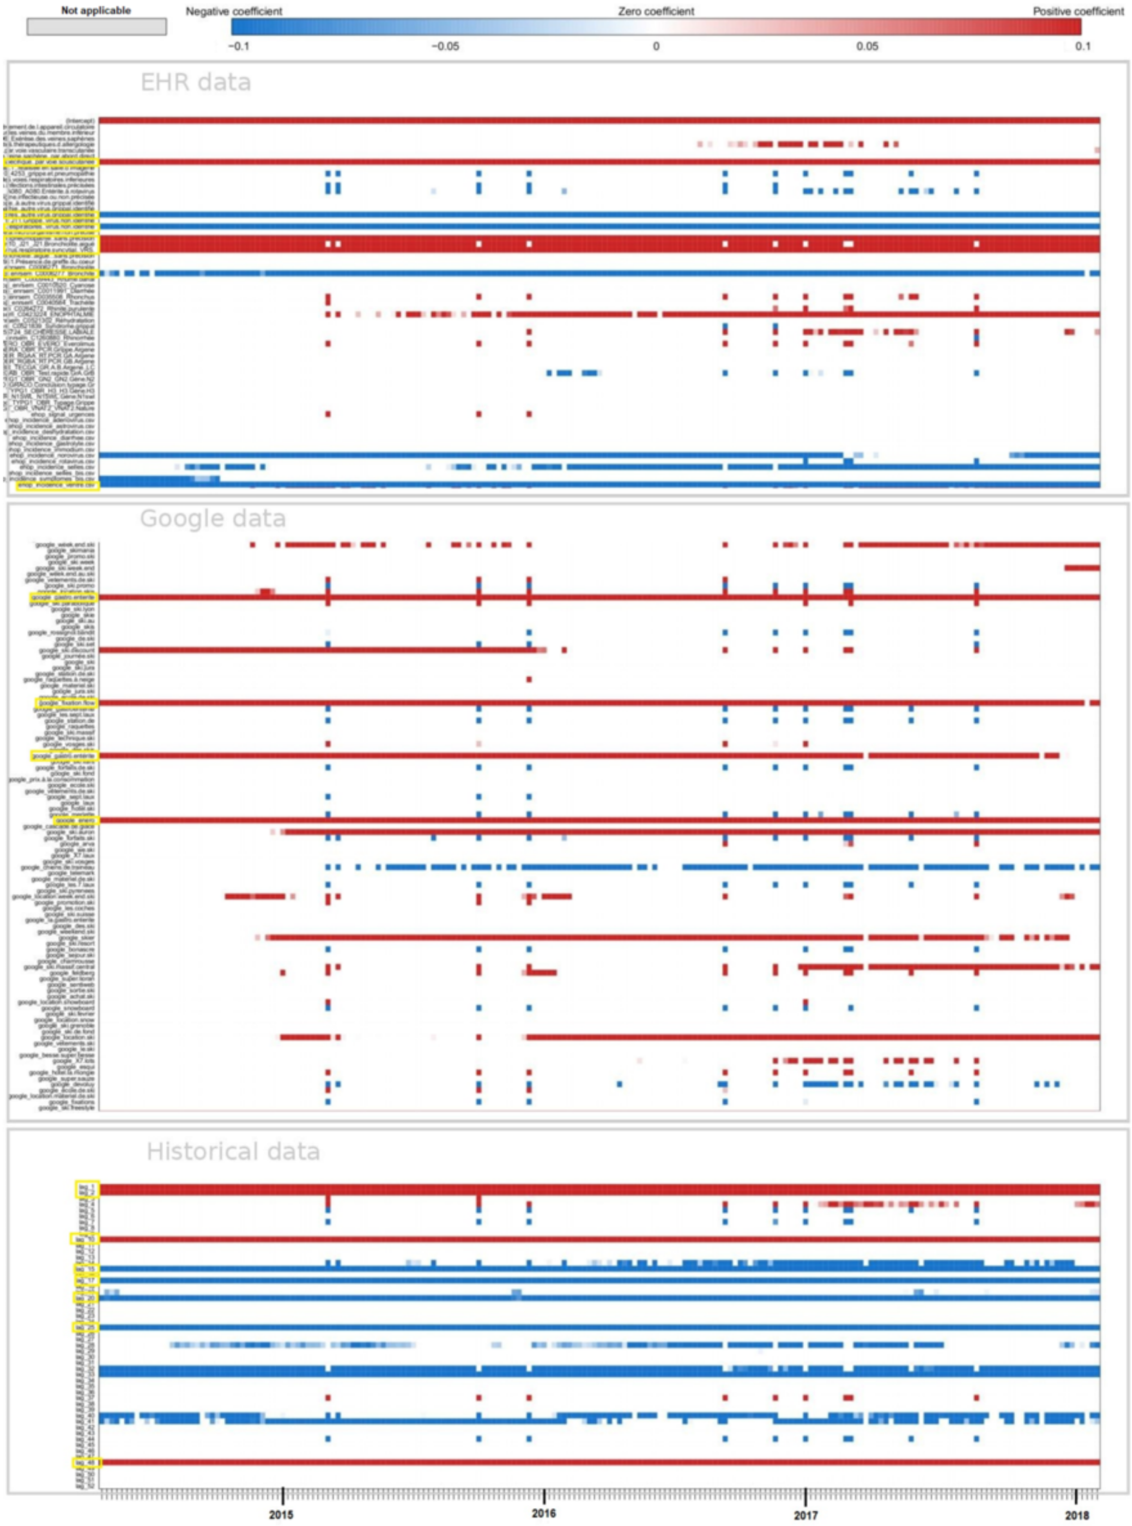

Nonlinear Approach

Overview

For the nonlinear approach, at the national level, in terms of error and correlation, results are comparable between the model using only historical data—AR(52)—and the models combining historical data and external data sources (Table 2). At the regional level, in terms of error, the lowest errors are mostly obtained with the model including historical and EHR data. In terms of correlation, the highest values are mostly obtained with the model combining historical data and both data sources, Google and EHR. For the nonlinear approach, the values for correlation are higher and the values for errors are lower than the values obtained with the linear approach.

Table 2. PCC[a] and RMSE[b] values obtained for the entire prediction period (May 2014 to March 2018) for all levels and models.

Levels and data sources	Real time		1-week forecast		2-week forecast		3-week forecast

[a] PCC: Pearson correlation coefficient.

[b] RMSE: root mean squared error.

[c] AR(52): autoregressive model of order 52.

[d] Italicization highlights the 2 highest correlations and lowest errors obtained with the models for real time and 1-week, 2-week, and 3-week forecasts.

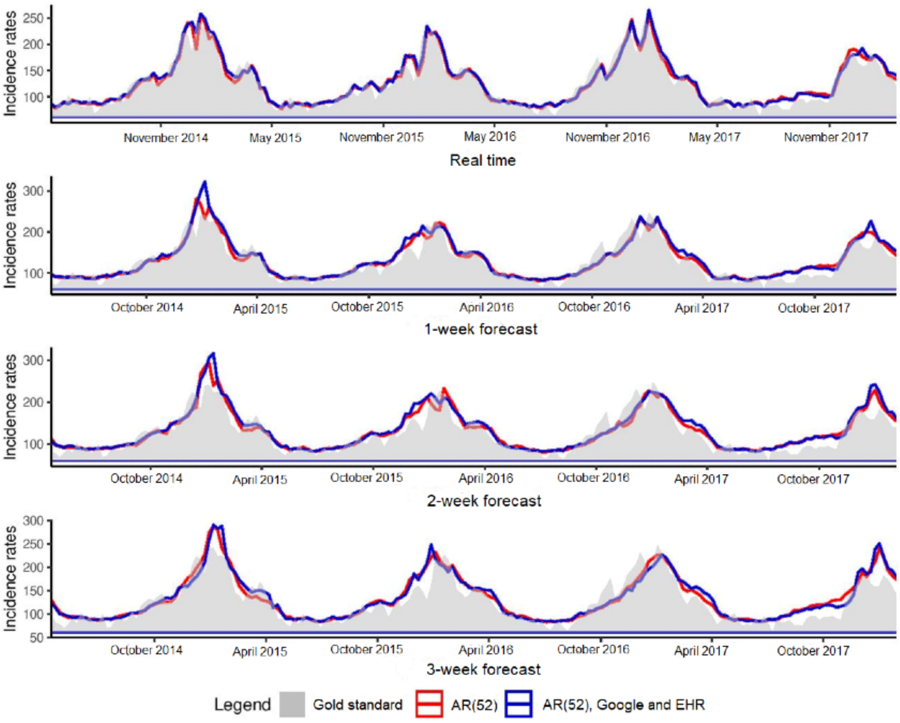
[e] EHR: electronic health record.

National Analysis

For real-time estimates, the error values range from 45.6 to 15.5 and the correlation values range from 0.80 to 0.95, with the lowest error and the highest correlation obtained with the model using only historical data—AR(52)—or the models combining historical data and external data sources. The results are similar for long-term forecasts, with error values ranging from 50.7 to 19.7 and correlation values ranging from 0.62 to 0.91 for 1-week estimates. For 2-week and 3-week estimates, the error values range from 42.6 to 22.8 and 41.9 to 22.3, respectively. In terms of 2-week and 3-week correlation, the values range from 0.74 to 0.90 and from 0.69 to 0.91, respectively.

Figure 5 illustrates the estimates obtained at the national level for forecasts up to 3 weeks with the model using only historical data and the model using historical data and both data sources, Google and EHR. For real-time estimates and long-term forecasts, the results obtained with the 2 models are comparable. In comparison with the linear approach, the nonlinear approach tends to smooth estimates.

Figure 5. National level. Predictions up to 3 weeks obtained at the national level with the model using only historical data and the model using historical data and both data sources, Google and EHR. Gold standard, French Sentinel network data. EHR: electronic health record.

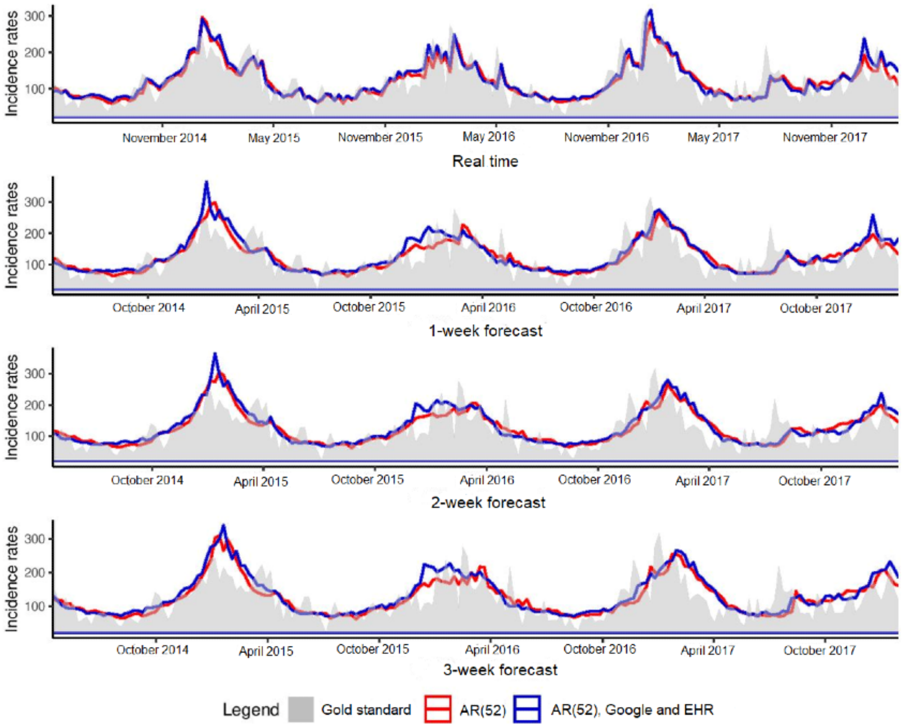


Regional Analysis

For real-time estimates, the error values range from 76.9 to 38.4 and the correlation values range from 0.54 to 0.76, with the lowest error and the highest correlation values obtained with AR(52) model and the models combining historical data and external data sources. For 1-week, 2-week, and 3-week estimates, the error values range from 69.2 to 41.1, from 60.5 to 43.8, and from 63.3 to 44.1, respectively. The lowest errors values for long-term forecasts are all obtained with the model using historical and EHR data. In terms of 1-week, 2-week, and 3-week correlation, the values range from 0.53 to 0.72, from 0.56 to 0.70, and from 0.53 to 0.70, respectively. The highest correlations for long-term forecasts are all obtained with the model using historical data and both data sources, Google and EHR.

Figure 6 illustrates the estimates obtained at the regional level for forecasts up to 3 weeks with the model using only historical data and the model using historical data and both data sources, Google and EHR. At the national level, results are comparable between the 2 models, and the nonlinear approach tends to smooth the estimates.

Figure 6. Regional level. Predictions up to 3 weeks obtained at the regional level with the model using only historical data and the model using historical data and both data sources, Google and EHR. Gold standard, French Sentinel network data. EHR: electronic health record.



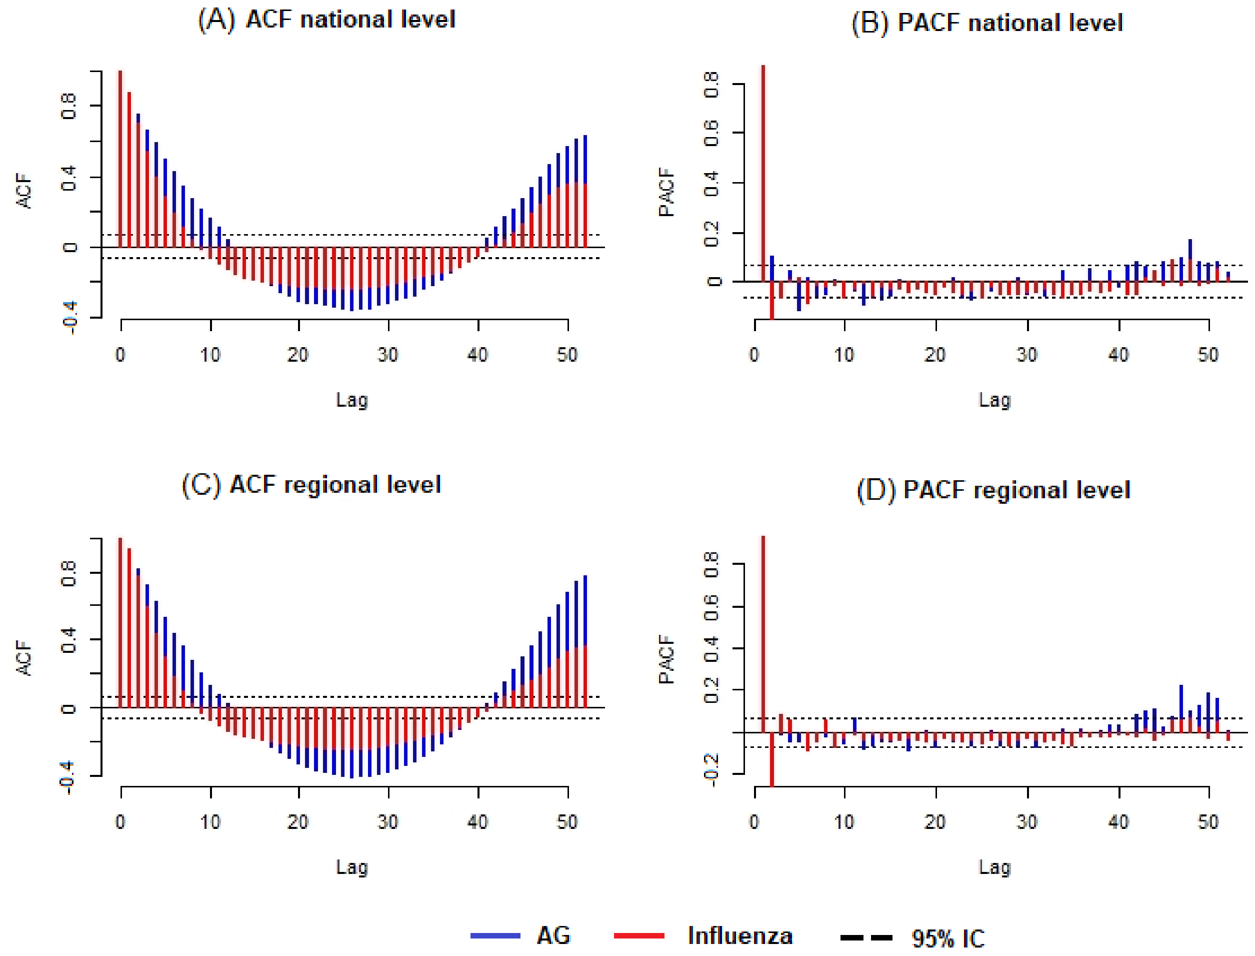
Comparison of AG and Influenza

To assess the role of external data sources in AG forecasting in comparison with influenza forecasting, we studied both time series, at the national and regional levels. As both series were stationary, we compared the seasonality. Figure 7 corresponds to ACF and PACF obtained for AG and influenza.

The ACF plot provides the correlation coefficients between a time series and its lagged values. The PACF plot provides the correlation coefficients between a time series and its lagged values after removing the effects that are already explained by the previous lags.

The ACF plots at the national and regional levels (Figures 7A and 7C) show that both time series, AG and influenza, are seasonal, but with autocorrelation more important for AG than for influenza. This result can explain why historical data are able to provide more information for AG than for influenza. We have similar results for PACF plots (Figures 7B and 7D), at the national and regional levels, where the coefficients of partial autocorrelation are larger for AG than for influenza.

Figure 7. ACF and PACF. Autocorrelation obtained for flu and AG at the national level (Figures A and B) and regional level (Figures C and D). ACF: autocorrelation function; AG: acute gastroenteritis; PACF: partial autocorrelation function.



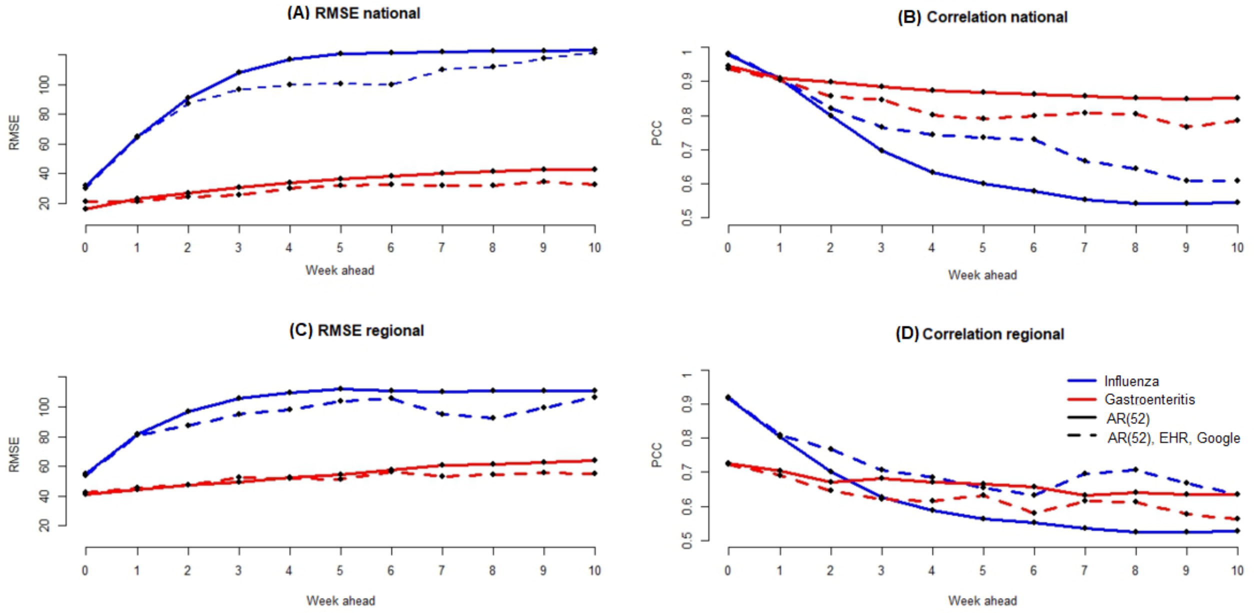
Analysis of Forecast up to 10 Weeks

Linear Approach

Figure 8 and Table S1 in Multimedia Appendix 1 show, for the linear approach, errors and correlation for AG at the national and regional levels, for forecasts up to 10 weeks. At the national level, the lowest error for real-time estimates is obtained with the linear approach using only historical data—AR(52). For long-term forecasts, from up to 1 week to up to 10 weeks, the lowest errors are obtained by using historical data and both data sources, Google and EHR. In terms of correlation, in all cases, the highest values are obtained by using only historical data. At the regional level, in terms of errors, both data sources, Google and EHR, allow to improve accuracy for forecasts from up to 4 weeks to up to 10 weeks. In terms of correlation, results are similar to those at the national level, with high values obtained by using only historical data.

Figure 8 and Table S2 in Multimedia Appendix 1 show, for the linear approach, errors and correlation for influenza at the national and regional levels, for forecasts up to 10 weeks. In contrast to AG at the national and regional levels, in terms of errors and correlation, the most accurate results are obtained by using historical data, Google data, and EHR data.

Figure 8. (A) Error values obtained at the national level for the flu and gastroenteritis for forecasts up to 10 weeks with the Elastic Net model. The solid line corresponds to the results obtained with the Elastic Net model using only historical data. The dotted line corresponds to the results obtained with the Elastic Net model using historical data and both Google and EHR data. The red color is the results for gastroenteritis disease, whereas the blue color is the results for the flu. This style line and color code are used for the 4 panels of this figure. (B) Correlation values obtained at the national level. (C) Error values obtained at the regional level. (D) Correlation values obtained at the regional level. EHR: electronic health record; RMSE: root mean squared error.

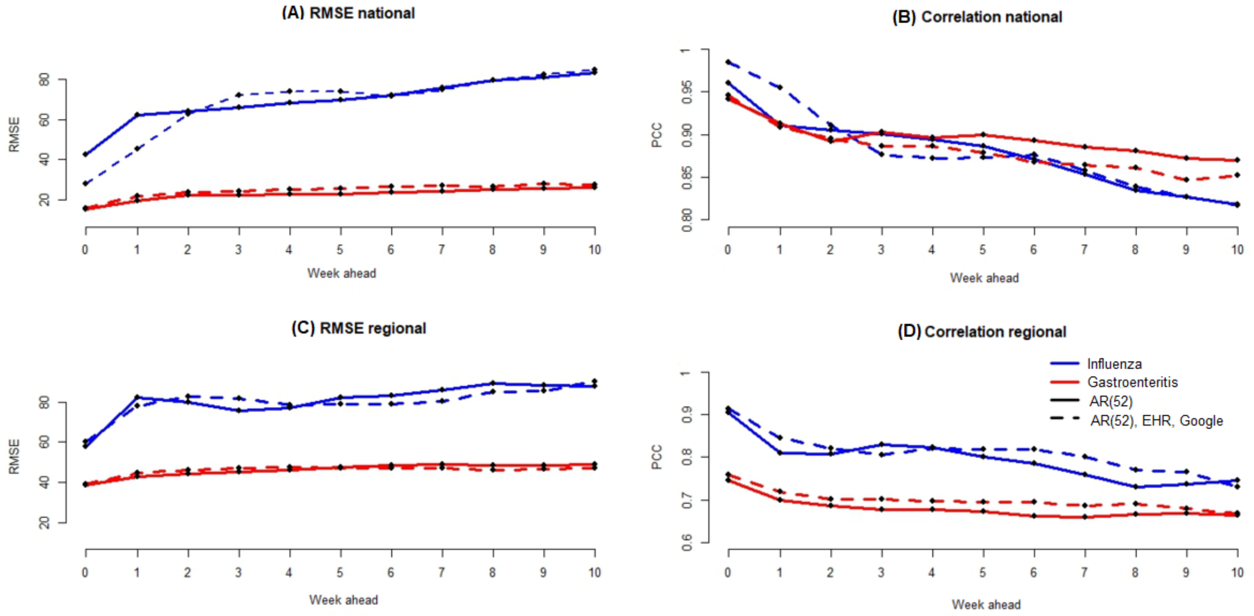


Nonlinear Approach

Figure 9 and Table S3 in Multimedia Appendix 1 show, for the nonlinear approach, errors and correlation for AG at the national and regional levels, for forecasts up to 10 weeks. At the national level, in terms of errors, the lowest values are obtained by using only historical data—AR(52). In terms of correlation, for long-term forecasts, the highest values are obtained by using only historical data. At the regional level, in terms of errors, for forecast up to 4 weeks, the lowest values are obtained by using only historical data. However, for long-term forecasts, the most accurate results are obtained by using historical data and both data sources, Google and EHR.

Figure 9 and Table S4 in Multimedia Appendix 1 show, for the nonlinear approach, errors and correlation for influenza at the national and regional levels, for forecasts up to 10 weeks. At the national level, in terms of errors and correlation, the most accurate values for forecasts up to 2 weeks are obtained by using historical data and both Google and EHR data. For forecasts from up to 3 weeks to up to 5 weeks, most accurate estimates are obtained by using only historical data. For long-term forecasts, results are similar for both models, the one using only historical data and the one using historical data and Google and EHR data. At the regional level, for forecasts up to 4 weeks, in terms of errors, the lowest values are obtained, in most cases, by using only historical data. For long-term forecasts, the most accurate estimates are obtained with the model using historical data and both Google and EHR data. In terms of correlation, in most cases, the highest values are obtained by using historical data and both Google and EHR data.

Figure 9. (A) Error values obtained at the national level for the flu and gastroenteritis for forecasts up to 10 weeks with the RF model. The solid line corresponds to the results obtained with the random forest (RF) model using only historical data. The dotted line corresponds to the results obtained with the RF model using historical data and both Google and EHR data. The red color is the results for gastroenteritis disease, whereas the blue color is the results for the flu. This style line and color code are used for the 4 panels of this figure. (B) Correlation values obtained at the national level. (C) Error values obtained at the regional level. (D) Correlation values obtained at the regional level. EHR: electronic health record.



Discussion

Principal Findings

We adjusted a methodology developed for influenza, to accurately track AG activity. Our method is able to provide forecasts up to 10 weeks for national and regional levels and for emergency and hospitalization stays (Multimedia Appendix 1). To the best of our knowledge, this is a disease and a spatial resolution (French regions and hospitals) for which no forecasting approaches have been explored previously.

In this study, we show that external data sources, EHR and Google, contribute to improving AG surveillance, in particular for long-term forecasts, with more important contribution from historical data. Specifically, when we use the linear approach (Elastic Net), in terms of errors at the national level, the lowest values are obtained by using historical data and both Google and EHR data. These results are consistent for forecasts from up to 1 week to up to 10 weeks (Table S1 in Multimedia Appendix 1). At the regional level, the model using only historical data is the model producing the lowest errors for short-term forecasts (Table S1 in Multimedia Appendix 1). However, for long-term forecasts, the inclusion of external data sources (Google and EHR) improves the estimates. We conducted a Diebold Mariano test [39] to assess if the forecasts are statistically different when using only historical data or the combination of historical data, Google data, and EHR data (Table S5 in Multimedia Appendix 1). We can see that at the national level, the estimates are statistically more accurate when using historical data and both Google and EHR data for 3-week and long-term forecasts. At the regional level, the use of external data sources produces estimates that are statistically more accurate for 7-week and long-term forecasts.

As we used a method developed for influenza outbreaks, we compared the results obtained for AG with those obtained for influenza. At the national and regional levels, with the linear approach, for both short-term and long-term forecasts, the most accurate estimates are obtained with the model using historical data and external data sources (Google and EHR data). An understanding of these results can emerge from the time series analysis (Figure 7). We show that the seasonality is more important for AG epidemics than for influenza, resulting in historical data capable of providing more information for AG than for influenza. Nonetheless, for long-term forecasts, historical data are not sufficient and external data sources can be used to supplement them. Thus, it is important to integrate external data to improve long-term estimates.

In addition to the linear approach, we conducted the same analysis with a nonlinear approach (RF). At the national level, the results differ slightly from those obtained using the linear approach. In terms of error and correlation, the model using only historical data provides more accurate estimates than the model using historical data, Google data, and EHR data. These results are consistent for real-time estimates and long-term forecasts (Table S3 in Multimedia Appendix 1). At the regional level, regarding the linear approach, in terms of error for short-term forecasts, the model using only historical data allows to produce the most accurate estimates. For long-term forecasts, the model including external data sources, Google and EHR, decreases the error. In terms of correlation, for both short-term and long-term forecasts, the model producing the highest values is the model using historical data, Google data, and EHR data. In all cases, the nonlinear approach allows us to obtain high values in terms of correlation and low values in terms of error when compared with those obtained using the linear approach. However, as seen in Figures 5 and 6, the nonlinear approach tends to smooth the estimates compared with those obtained using the linear approach. This can result in decrease in error and increase in correlation.

The fact that we could only access EHR data from Rennes University Hospital, and thus from the Brittany region, prevented us from being able to quantify the added value of nation-wide EHR information. This should be evaluated in future studies by integrating EHR data from different hospitals from all the French regions. However, it is interesting that data from a hospital in Rennes can improve AG forecasting at the national level, even if, as we described previously, EHR data seem more important for the regional level.

Data retrieved from Google Correlate are normalized by Google in a (frequently) distinct sample and over different time periods depending on the data request. This prenormalization can affect our results, but as shown in the study by Arena et al [15], the process of dynamic training minimizes the impact of this instability.

It would be interesting to test other approaches that gave good results for influenza, for example, an ensemble method that combines the power of the linear and the nonlinear approaches [14] or other machine learning methods such as Support Vector Machine or neural networks. We tested a long short-term memory model to forecast gastroenteritis up to 10 weeks. We obtained root mean squared error=2.96 for real-time forecasting. We believe that these results are really promising and could be further studied in the future by developing a neural network combining long short-term memory for historical data and another neural network for external data sources such as Google data or EHR data. In addition, other methods could be tested to obtain more information from external data sources as transformations of the input variables. Variable transformations could be tested on external data sources to check whether we could get more information. Finally, it could be meaningful to first remove the multicollinearity of our predictive variables with traditional methods such as the Variance Inflation Factor and then select the most important variables with a stepwise regression to run a linear regression on the remaining variables.

Conclusions

We show that hospital data and internet search data significantly contribute to predict AG outbreaks, in particular for long-term forecasts. The use of these external data sources in combination with historical data could supplement traditional surveillance systems. The methods we developed could help to reduce the impact of the AG peak, particularly in hospitals, by making it possible to anticipate increased activity by up to 10 weeks.

We acknowledge that there is still scope for improvement. Future studies could explore the incorporation of more information from external data sources as a way to yield more robust results.

Acknowledgments

The authors would like to thank the French Agence Nationale de Recherche for funding this study through the Integrating and Sharing Health Data for Research project (grant ANR-15-CE19-0024). The authors also thank the French Sentinel network and Google search engine for making their data publicly available. MS and CP were partially funded by the National Institute of General Medical Sciences of the National Institutes of Health, under award number R01GM130668. Abstract

Background: Sickle cell disease (SCD) was first recognized in 1910 and identified as a genetic condition in 1949. However, there is not a universal clinical registry that can be used currently to estimate its prevalence. The Sickle Cell Data Collection (SCDC) program, funded by the Centers for Disease Control and Prevention, funds state-level grantees to compile data within their states from various sources including administrative claims to identify individuals with SCD. The performance of the SCDC administrative claims case definition has been validated in a pediatric population with SCD, but it has not been tested in adults.

Objective: The objective of our study is to evaluate the discriminatory ability of the SCDC administrative claims case definition to accurately identify adults with SCD using Medicaid insurance claims data.

Methods: Our study used Medicaid claims data in combination with hospital-based medical record data from the Alabama, Georgia, and Wisconsin SCDC programs to identify individuals aged 18 years or older meeting the SCDC administrative claims case definition. In order to validate this definition, our study included only those individuals who were identified in both Medicaid's and the partnering clinical institution's records. We used clinical laboratory tests and diagnostic algorithms to determine the true SCD status of this subset of patients. Positive predictive values (PPV) are reported overall and by state under several scenarios.

Results: There were 1219 individuals (354 from Alabama and 865 from Georgia) who were identified through a 5-year time period. The 5-year time period yielded a PPV of 88.4% (91% for data from Alabama and 87% for data from Georgia), when only using data with laboratory-confirmed (gold standard) cases as true positives. With a narrower time period (3-year period) and data from 3 states (Alabama, Georgia, and Wisconsin), a total of 1432 individuals from these states were included in our study. The overall 3-year PPV was 89.4% (92%, 93%, and 81% for data from Alabama, Georgia, and Wisconsin, respectively) when only considering laboratory-confirmed cases as true cases.

Conclusions: Adults identified as having SCD from administrative claims data based on the SCDC case definition have a high probability of truly having the disease, especially if those hospitals have active SCD programs. Administrative claims are thus a valuable data source to identify adults with SCD in a state and understand their epidemiology and health care service usage.

Introduction

Sickle cell disease (SCD) is a rare genetic condition, which has consistently suffered from disparity in terms of research funding, availability of registries, and surveillance programs [1]. Recently, the National Academies of Sciences, Engineering, and Medicine (NASEM) published a strategic plan and blueprint for action addressing SCD [2]. One of the recommendations of the NASEM report includes establishing a nationwide surveillance program for SCD in addition to a longitudinal clinical registry. A clinical registry is an organized system of data collection using observational study methods to evaluate specified outcomes for a population defined by a particular disease or condition (in this case, SCD). In most cases, a registry requires patient consent to participate, which may limit the inclusion of all individuals with the specific condition. In contrast, surveillance data are defined as the ongoing, systematic collection, analysis, and interpretation of health-related data needed for the planning, implementation, and evaluation of public health practice [2]. While a registry can inform on clinically specific information including disease trajectory, a surveillance program provides a more population-based assessment and is often more inclusive of the entire population. The Centers for Disease Control and Prevention has invested in establishing the Sickle Cell Data Collection (SCDC) [3] program to establish a population-based surveillance program in multiple US states using a combination of data sources. A population-based surveillance program for SCD both helps to reveal the distribution of individuals living with SCD and inform stakeholders about the health care usage patterns to improve outcomes. Understanding the patterns of care for people with SCD can increasingly ensure sufficient staffing, and expertise is available to treat the patient population.

Administrative claims data are one of the data sources used in the SCDC population-based surveillance program. Currently, all states participating in the SCDC program include or plan to include data from different administrative sources as they establish their state-specific programs in addition to data from newborn screening programs (NBSs), SCD center–specific databases, electronic health records data warehouses, and vital health records. In contrast to data from NBS programs or clinical databases, claims data are only based on codes of the International Classification of Diseases, Ninth and Tenth Revisions (ICD-9 and -10, respectively), and not clinically verified data. Despite this limitation, claims data are a valuable source of information since they include comprehensive information on health care service usage for their beneficiaries beyond specific hospitals and clinics. This is specifically important for the SCDC surveillance efforts, which aim to include all individuals living with SCD in participating states. Prior work has validated the definition of ≥3 SCD-coded encounters within 5 years to identify a pediatric patient cohort at a large urban children’s hospital [4]. This definition, however, has not been tested in the adult population. As the SCDC program expands to multiple states, the generalizability and validity of the SCDC administrative case definition needs to be determined. Also, some of the recently participating states have limited years of available data. The objective of our study is for 3 of the SCDC states to evaluate the discriminatory ability of the SCDC administrative case definition to identify adults with SCD (≥18 years of age) who are Medicaid beneficiaries, using Medicaid insurance claims data from their state, considering confirmatory laboratory assessment of SCD as the gold standard. We hypothesize that the SCDC case definition applied to Medicaid claims data will have a high positive predictive value (PPV) for identifying SCD cases among people with SCD aged ≥18 years, but that it will be lower than that observed among pediatric cases.

Methods

Administrative Claims Data Sources to Identify Adults With SCD

Our study includes Medicaid claims data from the Alabama, Georgia, and Wisconsin SCDC programs.

Inclusion Criteria

Adult individuals (aged 18 years or older at the beginning of the study period) with 3 or more claims with an SCD ICD code (ICD-9: 282.41, 282.42, and 282.6*; ICD-10: D57.0*, D57.1, D57.2*, D57.4*, and D57.8*) in their state-specific Medicaid data were eligible for inclusion. In addition, eligible individuals also needed evidence of at least 1 visit (with any diagnosis) at the specific clinical partner institutions. Our 5-year time frame analysis included data from Alabama and Georgia. Eligible individuals identified within Alabama Medicaid claims data from 2015 to 2019 were cross-referenced with electronic health record data from the University of Alabama at Birmingham’s hospital system. Eligible individuals identified within Georgia’s Medicaid claims data from 2015 to 2019 were included if any claim contained a Grady Memorial Hospital facility code. Our 3-year time frame analysis included data from Alabama, Georgia, and Wisconsin. The inclusion criteria for Alabama and Georgia were identical, as described above, with a restricted time frame of 2015-2017. The Wisconsin data included eligible individuals identified within Medicaid claims data from 2018 to 2020 who were linked and matched with electronic health record data from Froedtert Hospital.

Ethics Approval

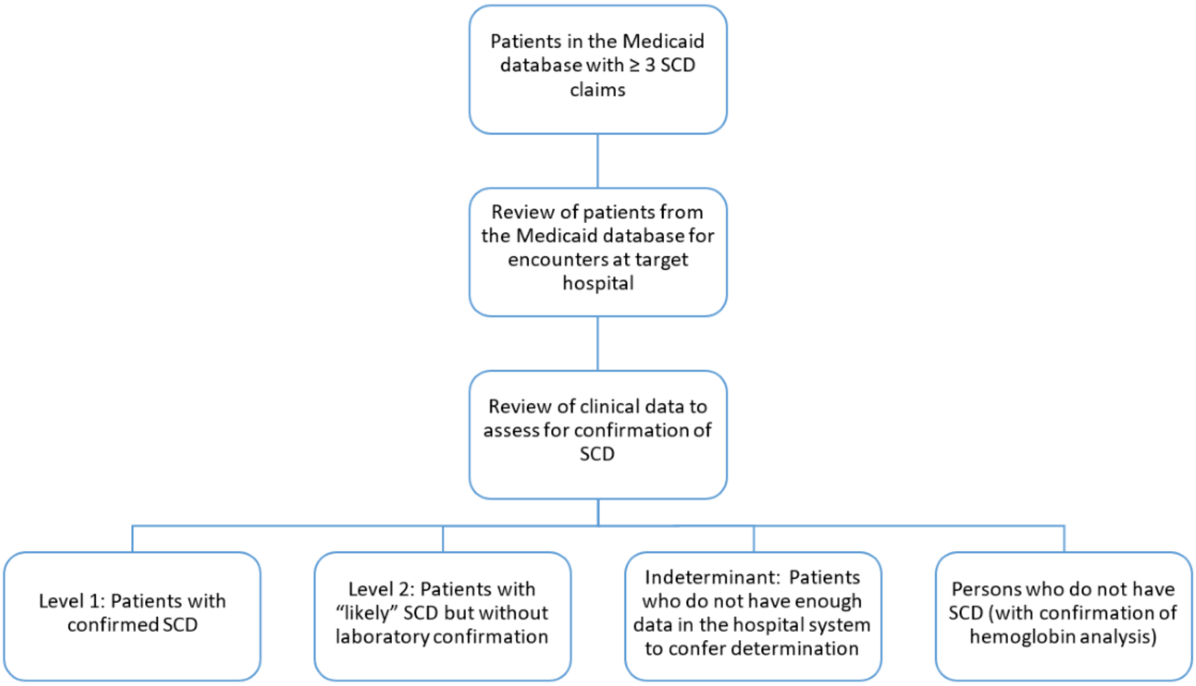
All states providing data had approvals or exemption to conduct the project. Specifically, the University of Alabama Institutional Review Board (IRB) approved the project as Non-human subjects research (IRB-300004733), the Georgia State University's IRB approved the state's SCDC program under a public health exemption (protocol #H11142), and the Medical College of Wisconsin IRB granted an exemption for the study in accordance with 45 CFR 46.104(d)(4) (PRO00043293).

Validation Data

SCD centers from the University of Alabama at Birmingham, Grady Memorial Hospital, and Froedtert Hospital contributed their patient-level databases, which included people with “confirmed” SCD. Hematologists at each site also reviewed the laboratory reports of all the individuals identified at their institutions as part of this study. An individual had confirmatory evidence of SCD if he or she had a confirmed Clinical Laboratory Improvement Amendments of 1988–certified laboratory result from a hemoglobin electrophoresis or high-performance liquid chromatography test in their medical records. All patients with confirmed SCD had these laboratory tests in their medical records (even if they were not active patients within the SCD center). For individuals without evidence of confirmatory laboratory testing, a clinical algorithm was used to evaluate nondiagnostic laboratory data available in the electronic medical record system to classify them as being “likely” to have SCD. The clinical algorithm considered individuals “likely” to have SCD if they had at least 15 laboratory values that included a total bilirubin level of >1.1 mg/dL and any one of the following: reticulocyte proportion of >2%, lactate dehydrogenase level of >250 units/L, or hemoglobin level of <11 g/dL. Individuals with a hemoglobin analysis in their medical records, confirming that they did not have SCD (including those with the sickle cell trait), were categorized as “do not have SCD.” Individuals who did not have confirmatory laboratory evidence regarding their SCD status or those who were not classified as likely cases were labeled as “indeterminant” cases, implying that there was not enough evidence in their medical record to make a diagnosis.

The stepwise method of identification of the eligible population and the classification of cases into various categories is illustrated in Figure 1.

Figure 1. Overview of study methodology. SCD: sickle cell disease.



Analysis

Summary statistics were calculated to describe the demographic characteristics of age, sex, and race and ethnicity based on information available in each state’s Medicaid data. Analysis was conducted for 2 time periods based on available data: 5 years (Alabama and Georgia) and 3 years (Alabama, Georgia, and Wisconsin). We determined the PPV, overall and by state, under various scenarios for the respective time frames. In the first scenario, true positives (TPs) included individuals “confirmed” to have SCD. In the second scenario, TPs also included individuals “confirmed” and “likely” to have SCD. The PPV was calculated using the TP as the numerator and the total number of SCD cases identified per the definition as the denominator (TPs+false positives [FPs]). As an alternate strategy, we also calculated a best-case PPV excluding individuals with an “indeterminant” SCD status for both the scenarios described above. This was done because “indeterminant” cases did not have sufficient information to be either classified as TP or FP. Exact binomial 95% CIs were reported for all proportions. For the group of patients recognized as FP cases based on confirmatory evidence of not having SCD in their clinical data, we provide a count of those with the sickle cell trait.

Results

Overview

There were a total of 3425 (Alabama, n=935; Georgia, n=2490) and 3365 (Alabama, n=803; Georgia, n=2055; Wisconsin, n=507) individuals who were aged ≥18 years and had at least ≥3 Medicaid SCD claims in the 5-year and 3-year time frame, respectively. A total of 1219 unique individuals (354 from Alabama and 865 from Georgia) in the 5-year time period and 1432 (328 from Alabama, 684 from Georgia, and 420 from Wisconsin) in the 3-year time period had at least 3 Medicaid SCD claims and an encounter with the respective partner clinical institution. Importantly, not all of those individuals with SCD claims were seen by the sickle cell center at their respective institutions (ie, they only had to be seen within the hospital system). The demographic characteristics and the total number of SCD-related Medicaid encounters are described in Table 1.

PPV Based on Data With a 5-Year Time Period

Table 2 shows the demographic characteristics of individuals in each validation category by state. The mean age of individuals with confirmed SCD from Alabama and Georgia was 27.9 (SD 8.6) years and 29.8 (SD 10.7) years, respectively, with the majority of them being in the 18-29–year age group. Overall, 69% of individuals with confirmed SCD across Alabama and Georgia had Hemoglobin SS/Sβ0 type of disease. PPV values by state are shown in Table 3. The overall PPV was 88% when considering only those with a confirmatory clinical laboratory test indicating SCD as TPs. For the scenario that included both likely and confirmed cases as TP, the PPV was slightly higher (89%).

Overall, across Alabama and Georgia, there were 58 cases (14 from Alabama and 44 from Georgia) that were FP (cases with confirmatory evidence of not having SCD). Of them, 36% (5 from Alabama and 16 from Georgia) had the sickle cell trait. There were 73 cases that were indeterminate (8 from Alabama and 65 from Georgia). When excluding the indeterminate cases from the denominator (data not shown in tables), the PPVs for the 2 scenarios of TPs were 94% and 95%, respectively. The PPVs (when excluding indeterminate cases from the denominator; data not shown in tables) remained at >83% for both the TP scenarios irrespective of age group and state.

Table 2. Demographic characteristics of individuals with confirmed sickle cell disease (SCD), likely SCD, those not having SCD, and those with an indeterminate status identified by the clinical validation process by state over a 5-year period.

PPV Based on Data With a 3-Year Time Period

Table 4 shows the demographic characteristics of individuals in each validation category by state. Similar to the 5-year time frame, the mean age of individuals confirmed with SCD was 28.0 (SD 9.5) years and 29.6 (SD 10.5) years, respectively, with the majority being in the 18-29–year age group. The individuals confirmed with SCD from the Wisconsin records had a higher mean age (36.7, SD 10.5 years), with 30% and 38% of them being in the 18-29–year and 30-39–year age group, respectively. The PPVs for all scenarios by state are shown in Table 3. The overall PPV was 89% when considering only those with a confirmatory clinical laboratory test indicating SCD as TP. For the scenario that included both likely and confirmed cases as TP, the PPV was slightly higher (91%).

Overall, across Alabama, Georgia, and Wisconsin, there were 60 cases (11 from Alabama, 21 from Georgia, and 28 from Wisconsin) that were FP (cases with confirmatory evidence of not having SCD), of whom 50% (5 from Alabama, 9 from Georgia, and 16 from Wisconsin) had the sickle cell trait. There were 79 (6 from Alabama, 25 from Georgia, and 48 from Wisconsin) indeterminate cases. When excluding the indeterminate cases from the denominator, the PPVs for the 2 scenarios of TPs were 95% and 96%, respectively. The PPVs (when excluding indeterminate cases from the denominator; data not shown in tables) remained at >83% for both the TP scenarios irrespective of age group and state.

Discussion

Principal Findings

This study supports the use of a standardized surveillance case definition within administrative claims data, specifically using Medicaid claims (≥3 ICD-9 or -10 codes), across multiple states to identify adults living with SCD. The PPVs achieved through systematic application of the case definitions among adults who receive care at hospitals with an SCD program has resulted in PPVs of ~90%, which is laudable. When excluding the indeterminate cases, the PPV of the SCDC administrative case definition for adults is similar to the PPV of >95% demonstrated in pediatric populations [4,5].

The lower PPV in adults may have resulted from inaccurate coding in Medicaid claims. A sizeable proportion of the FPs identified within Medicaid data included individuals with the sickle cell trait. This represents an opportunity to better educate providers and the general population about the distinction between the 2 conditions. The sickle cell trait is a mostly benign condition and individuals do not experience vaso-occlusive pain episodes. In contrast, individuals with SCD are at risk for significant organ damage as well as acute pain episodes. Thus, research that incorporates individuals with the sickle cell trait into the SCD cohort may lead to substantial underestimation of the disease burden. This emphasizes the need for research specific to SCD based on the combination of information from multiple data sets to minimize the inclusion of individuals with the sickle cell trait. This also supports algorithms developed for other types of data sources such as electronic health record data that exclude individuals with the sickle cell trait when defining those with SCD [6,7]. Specifically, the lower predictive value in Wisconsin, as compared to that in Alabama and Georgia, was mainly driven by the number of indeterminant cases. The indeterminant cases did not have enough information to be classified as having or not having SCD. Interestingly, Wisconsin is also the newest state to join the SCDC program, which may be affecting their number of indeterminate cases (and it may change over time). While better education of providers managing people with SCD may result in improved coding practices, these inaccuracies may also occur with ancillary providers, such as those providing radiology or laboratory testing services, who may not directly interact with the patient. These ancillary providers could contribute to both FPs if they assume that a patient has SCD because he or she was referred by a SCD specialist or had been seen at a hematology clinic, as well as to false negatives since they must often assume a patient's diagnosis based on conditions inaccurately listed on a problem list. Further, many physicians caring for people with SCD also see individuals with other hematologic conditions. Moreover, there are no codes for "hemoglobinopathy screening" to be used by providers assessing these individuals. Some individuals may be miscategorized as having “SCD” simply because they are undergoing hemoglobinopathy testing, which can be carried forward in the medical record. Fragmentation of care for adult patients with SCD [8,9] may also result in less consistent diagnosis and coding.

As efforts continue to improve access to care for adults with SCD, the SCDC program remains an important source of data to characterize SCD including evaluations of SCD management and acute care use on a population level. Administrative data are paramount to creating the surveillance database used by state SCDC programs. While many sickle cell centers have local patient databases, a single current national registry for SCD does not exist, although efforts are underway through the National Alliance of Sickle Cell Centers [10], the National Institutes of Health’s Sickle Cell Disease Implementation Consortium [11], and the American Society of Hematology’s Research Collaborative [12]. However, adults living with SCD may be excluded from these efforts if they do not receive care at one of the participating comprehensive SCD centers. Thus, it is not possible to include the entire population living with SCD in a registry, and performance metrics including sensitivity become impossible to calculate. While efforts are underway to improve access to care for those with SCD [13], it is vital that we have a surveillance program to better understand the health care usage pattern of those living with SCD to determine where additional SCD centers should be established.

Georgia and California were the first 2 states to develop robust SCD surveillance programs. Current SCD surveillance efforts are expanding as the SCDC program receives additional federal funding to extend to additional states. As new states join the SCDC program, it becomes increasingly important to ensure that epidemiologic studies resulting from these data provide an accurate portrayal of SCD in terms of its morbidity and mortality across all age groups. Notably, PPVs consistently over 80%, even among older age groups, support the use of these data to track survival and other outcomes in SCD over the individuals’ lifespans with reasonable accuracy. These findings add to the data supporting state programs in equitable resource allocation and in determining the best strategies to improve outcomes and quality of life for those living with SCD. Administrative data are especially important in identifying adults who are too old to have been screened for SCD at birth (ie, missed the NBS window) as well as those adults who have little access to SCD centers. Additionally, these findings demonstrate the importance of continued data collection and support for the SCDC program, which will allow for additional refinement of surveillance-based case definitions for SCD.

Limitations

There are several limitations to this study. First, individuals who do not have SCD are not included in the SCDC program. Thus, we are unable to comment on the number of false negative codes within the data sets. As a result, it is not feasible to assess the specificity of the data definition on a population level. In addition, these studies were conducted at hospitals that treat a large number of individuals living with SCD (and have National Alliance of Sickle Cell Centers–recognized SCD centers). Thus, it is possible that hospitals that. Although we report a conservative estimate of the definition’s PPVs, the performance of the definition might differ at nonacademic community-based hospitals or those in rural settings or both. Finally, there are several indeterminate cases where insufficient laboratory data were available to confirm an SCD diagnosis. This limitation highlights the importance of obtaining baseline data for persons with SCD newly seen at any hospital system. Confirming an SCD diagnosis is clinically important for medical management and should not be assumed based on a previously notated problem in the medical history or a previous administrative code. Instead, providers need to ensure that all individuals who present with a diagnosis of SCD (or having a chief complaint of an SCD-related symptom) have a hemoglobin analysis performed if never previously evaluated.

Conclusions

Overall, these data validate the use of the administrative case definition identified by the SCDC programs to identify adults with SCD. While there are limitations to the use of this definition, it can be highly valuable for SCD surveillance to improve the understanding of the patterns of health care usage in the SCD population over time.

Abstract

Background: Developmental surveillance, conducted routinely worldwide, is fundamental for timely identification of children at risk of developmental delays. It is typically executed by assessing age-appropriate milestone attainment and applying clinical judgment during health supervision visits. Unlike developmental screening and evaluation tools, surveillance typically lacks standardized quantitative measures, and consequently, its interpretation is often qualitative and subjective.

Objective: Herein, we suggested a novel method for aggregating developmental surveillance assessments into a single score that coherently depicts and monitors child development. We described the procedure for calculating the score and demonstrated its ability to effectively capture known population-level associations. Additionally, we showed that the score can be used to describe longitudinal patterns of development that may facilitate tracking and classifying developmental trajectories of children.

Methods: We described the Developmental Surveillance Score (DSS), a simple-to-use tool that quantifies the age-dependent severity level of a failure at attaining developmental milestones based on the recently introduced Israeli developmental surveillance program. We evaluated the DSS using a nationwide cohort of >1 million Israeli children from birth to 36 months of age, assessed between July 1, 2014, and September 1, 2021. We measured the score's ability to capture known associations between developmental delays and characteristics of the mother and child. Additionally, we computed series of the DSS in consecutive visits to describe a child's longitudinal development and applied cluster analysis to identify distinct patterns of these developmental trajectories.

Results: The analyzed cohort included 1,130,005 children. The evaluation of the DSS on subpopulations of the cohort, stratified by known risk factors of developmental delays, revealed expected relations between developmental delay and characteristics of the child and mother, including demographics and obstetrics-related variables. On average, the score was worse for preterm children compared to full-term children and for male children compared to female children, and it was correspondingly worse for lower levels of maternal education. The trajectories of scores in 6 consecutive visits were available for 294,000 children. The clustering of these trajectories revealed 3 main types of developmental patterns that are consistent with clinical experience: children who successfully attain milestones, children who initially tend to fail but improve over time, and children whose failures tend to increase over time.

Conclusions: The suggested score is straightforward to compute in its basic form and can be easily implemented as a web-based tool in its more elaborate form. It highlights known and novel relations between developmental delay and characteristics of the mother and child, demonstrating its potential usefulness for surveillance and research. Additionally, it can monitor the developmental trajectory of a child and characterize it. Future work is needed to calibrate the score vis-a-vis other screening tools, validate it worldwide, and integrate it into the clinical workflow of developmental surveillance.

Introduction

With growing awareness to the high prevalence of developmental, behavioral, or social delay among young children, and the importance of early intervention to mitigate this risk [1-5], many international organizations have recommended routine developmental surveillance for all children [2,6,7]. This process is typically conducted by evaluating the children's ability to attain a battery of age-appropriate milestones at routine clinic visits during the first few years of their life [2]. Interpreting the results of such evaluations is not straightforward. For a specific milestone, one can establish the population's age-dependent norms of attaining the milestone and use them to assess the level of concern in case a child fails to attain it, similar to the way physical growth measures are monitored [8-10]. However, unlike physical growth norms, which are continuous and whose trajectories over time are readily understood, success or failure at attaining a developmental milestone is a binary measure, and it is not obvious how to integrate the results of multiple different milestones across several developmental domains to quantitatively monitor and assess a child's development over time.

The assessment of child development can be done at varying level of details using 3 different types of tools: surveillance (or monitoring), screening, and evaluation. Developmental surveillance is based on milestone attainment checklists and is used worldwide by pediatricians and health care providers at routine encounters, as well as by educators and parents. Screening requires a more formal and elaborated assessment, typically done by caregivers or health care professionals at specific ages. Finally, developmental evaluation is an in-depth examination, typically done by a trained specialist, which aims to provide a formal diagnosis of the child. Importantly, surveillance is based on developmental norms, whereas screening tools are validated against a "gold standard" obtained from evaluation.

A commonly used screening tool is the Denver II Screening Tool [8,11], where the outcome is either "normal" or "suspicious," based on how many milestones were failed and the general rate of failure for them. A common alternative is the Ages & Stages Questionnaires (ASQ-3) [12] screening tool, where caregivers select 1 of 3 answers for an array of questions, and the total score identifies the child's development as being "on schedule," requiring "learning activities and monitor," or needing "further assessment." Both of these screening tools take about 20 minutes to administer, depending on the age of the child and the experience of the person administering them. A widely used developmental evaluation tool is the Bayley Scales of Infant and Toddler Development [13], which typically takes 30-70 minutes to complete and yields a numerical score for each developmental category, as well as an estimate for a child's developmental age—that is, at what age do neurotypical children exhibit a similar level of milestone attainment.

Previous work [14] has attempted to combine and standardize the results of 12 commonly used screening and evaluation tools into a single metric. However, doing so for surveillance tools is more challenging. There is a lack of standardization at this level of assessment, and the quantification of developmental surveillance assessments has not been previously suggested. At best, surveillance tools are calibrated using real-world data to determine the rate of milestone attainment at different ages [9] and then administered accordingly.

In this work, we suggested a relatively simple new methodology for translating a milestone-based developmental surveillance scale into a single score, denoted as the Developmental Surveillance Score (DSS), that conveys a child's developmental status during a specified time period. Based on data from a national developmental surveillance program in Israel, we demonstrated that this score consistently captures known associations between the development and characteristics of the mother and child. Moreover, the score can be used to reveal and explore new associations, which may further improve our understanding of the factors that impact developmental delay. Finally, the score can be used to track individual children longitudinally, by describing the trajectory of their development over time. We showed that by clustering these trajectories, we can identify several typical patterns of development.

The focus of this work was on defining a straightforward surveillance score (in the sense that computing it as part of the surveillance workflow adds essentially no overhead over the current practice) and establishing its coherence and potential usefulness. Further work is required to refine this score, validate it using various data sets internationally, and derive from it explicit protocols.

Methods

Developmental Surveillance in Israel

Developmental surveillance (from birth to 6 years of age) in Israel is performed routinely (and free of charge) according to national standards by trained public health nurses in approximately 1000 maternal child health clinics (MCHCs). The collected data of approximately 70% of the Israeli population of this age group are documented in a single common database managed by the Israeli Ministry of Health. The developmental assessments include 59 milestones across 4 domains: personal-social, language, fine motor, and gross motor [9].

Parents are instructed to visit the MCHC after hospital discharge and then at ages of 1, 2, 4, 6, 9, 12, 18, 24, 36, 48, and 60 months. At each visit, a predefined group of age-related milestones is evaluated, according to the expected development at that age (denoted "age step"). Children may also be evaluated on milestones of a previous age step, in cases of a missed visit or a failure to attain milestones at the preceding visit.

The child's ability to attain each milestone is reported as observed in the clinic; although in cases of difficult attainments, this may by documented according to a parent's report. If the evaluated milestone was not attained by neither observation nor parental report, it is documented as unattained.

Study Cohort

This study included all children born between July 1, 2014, and September 1, 2021, who were followed at the MCHCs and had at least one developmental evaluation recorded during the study period. In most of the analyses, we excluded children born preterm (gestational age of <37 weeks)—the one exception is the analysis of gestational age. Additionally, children with missing gestational age were excluded, as well as visits without developmental data or without the child's age. The final cohort included 1,130,005 children in total, with 1,052,905 of them born on-term.

DSS Definition

Sudry et al [9] have recently introduced the Tipat Halav Israel Surveillance (THIS) developmental scale, a data-driven developmental scale comprising curves of attainment rate by age for each of the 59 milestones evaluated in the Israeli developmental surveillance program (the scale can be downloaded from [15]). Broadly, when a child fails to attain a milestone, the THIS developmental scale categorizes the severity of this failure into 1 of 4 categories, depending on how often children of the same age fail to attain this milestone. Accordingly, in this study, we defined the Discrete Milestone Attainment Score (DMAS) for a failed milestone as the numerical order of the failure severity: a score of 1, 2, 3, or 4 is assigned for failure occurring when <75%, 75% to 90%, 90% to 95%, or >95% of the children at the same age attain this milestone, respectively. For an attained milestone, the DMAS value is 0. If an milestones is attempted multiple times, it will be scored separately each time it is attempted. The total score for a set of milestones is the average DMAS over all milestones of all developmental domains.

More formally, for each milestone, the age thresholds for attainment by 75%, 90%, and 95% of the children were calculated [9]; we denoted these age thresholds for milestone t by t_{75}, t_{90}, and t_{95}, respectively, and considered the 4 consecutive age brackets they define:

$$b_1 = [t_0, t_{75}],\ b_2 = (t_{75}, t_{90}],\ b_3 = (t_{90}, t_{95}],\ b_4 = (t_{95}, t_{100}]$$

where t_0 and t_{100} are the minimal and maximal ages at which the milestone t is assessed, respectively.

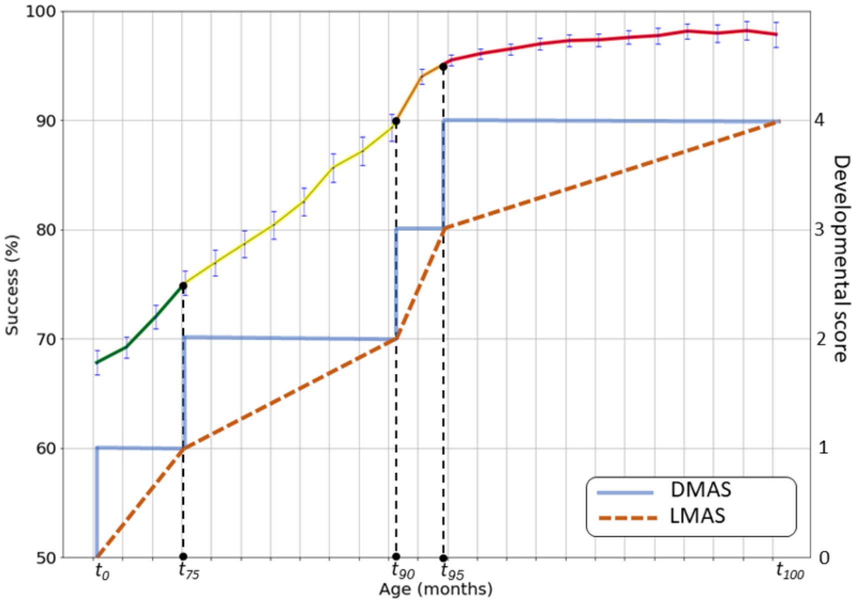
For a milestone t evaluated at age a, we defined i such that a is in the bracket b_i (i indicates the severity of failure):

To avoid noncontinuity, we extended the above definition into a Linearized Milestone Attainment Score (LMAS), using a c function as follows:

where a_{min} and a_{max} are the low and high ends of b_i, respectively.

The definitions of DMAS and LMAS are graphically illustrated in Figure 1. In the remainder of this paper, we used the LMAS version of the score, unless otherwise noted. In practice, deciding which of the 2 to use depends on the use case. DMAS is straightforward to compute from the THIS scale, whereas LMAS offers finer resolution.

Figure 1. A schematic depiction of the Discrete Milestone Attainment Score (DMAS) and the Linearized Milestone Attainment Score (LMAS) computed from the trend of milestone attainment rate versus the child's age.



For a set of milestones T, we defined the developmental surveillance score $DSS(T)$ as the average of the individual milestone attainment scores:

where a_t is the age at which milestone t was assessed. See Multimedia Appendix 1 for a concrete example of computing the score.

The set of milestones used for calculating the DSS can be defined by the evaluation period and by the types of developmental domains. For example, when computing the fine-motor score for a child during the first year of life, we computed the score for each fine-motor milestone attempted by the child during this period and then the average of the scores. In particular, if a milestone was attempted multiple times during this period, all attempts were used for the calculation of the score. Determining the evaluation period is a delicate point, which depends on the DSS application. Herein, we considered a broad period of 1 year in the subpopulation analysis and visits during each MCHC-determined age bracket (typically, a single visit) when analyzing developmental trajectories.

In this study, we aggregated personal-social milestones with language milestones, denoting them as "language-social" milestones. This was motivated by the relatively small number of milestones in the social domain and the interdependence of development in these 2 domains.

In Multimedia Appendix 1, we described an alternative score definition, the q-score, which is motivated by the notion of developmental quotient and is based on a more formal statistical approach. As described there, these 2 approaches lead to a similar ranking of children according to the quantified developmental delay, that is, when asking for which of 2 given children there is a greater concern for developmental delay, the 2 approaches tend to give the same answer.

Associations Between Mother and Child Characteristics and the Developmental Score

We examined the relations between the DSS and the characteristics of the mother and child. The children's characteristics included sex, gestational age at birth, birth weight, birth order, and records of an existing developmental tracking.

When analyzing gestational age, we partitioned preterm births to extremely preterm (less than 27 weeks), very preterm (27-31 weeks), and late preterm (32-36 weeks) [16]. This was the only analysis that included preterm children.

Characteristics of mothers included age at delivery; level of education; and the result of postpartum depression (PPD) evaluation, using the Edinburgh Postnatal Depression Scale (EPDS). For the purpose of the analysis, mothers were considered as having symptoms of PPD if their EPDS score was ≥10 or if their score in question number 10 (self-harm) was other than 0 [17].

To test whether differences between score averages were significant, we used the Mann-Whitney *U* test [18].

Developmental Trajectory Vectors

We described the developmental trajectory of a child by the series of its DSS values at each age step from birth to 36 months of age. Each age step s has an associated set of milestones $T(s)$. We further partitioned the milestones by their developmental domains, denoting by $T(s, d)$ the subset of $T(s)$ from domain d (where d can be either "language-social" or "motor"—an aggregation of fine-motor and gross-motor milestones). This allowed us to describe the trajectory per domain as the Developmental Trajectory Vectors (DTVs):

DTV(d) = DSS(T(s1,d),…, DSS(T(s7d)

where s_i goes over the steps of 1-3 months, 3-6 months, 6-9 months, 9-12 months, 12-18 months, 18-24 months, and 24-36 months.

This representation yielded DTVs of length 7 for each child that was assessed at all age steps. For this analysis, we excluded children whose data was missing for 1 or more age steps, analyzing the remaining groups of 294,624 and 294,066 children in the motor and language-social domains, respectively.

DTVs Clustering

We used the k-means clustering [19] to identify distinct patterns of DTVs. In addition, for sensitivity analysis of the clustering method (see Multimedia Appendix 1), we examined an alternative clustering method using a Gaussian Mixture Model [20]. Cluster validity was assessed using the Calinski-Harabasz score [21] (see Multimedia Appendix 1).

The clustering was done using only 6 of the 7 DTV entries. This is because for each domain, there is one step that included only a single milestone (for motor milestones, the 12-18 months step; for language-social milestones, the 6-9 months step), which may reduce the reliability of the results. Nonetheless, when computing cluster centroids, all entries were taken into account.

Analyses were done using Python (version 3.6.7; Python Software Foundation) with the *scikit-learn* package (version 0.23.2).

Ethics Approval

The study protocol was approved by the Soroka University Medical Center institutional ethical committee (MHC-0014-19) and was conducted in accordance with the principles of the Declaration of Helsinki. The need for informed consent was waived owing to the use of deidentified data.

Results

DSS of Different Population Subgroups

Table 1 shows the main characteristics of the children in the study cohort, grouped by their age at the time of the visit at the MCHC. It was evident that the number of children who visit the MCHC decreased with the child's age (880,688/1,052,905, 83.6% of the cohort visited at 0-12 months of age, whereas only 635,009/1,052,905, 60.3% visited at 24-36 months of age).

Table 1. Number of children with recorded developmental surveillance from the Israeli Ministry of Health, between July 2014 and September 2021, according to age group and stratified by child and mother characteristics. Some categories do not sum up to the total number due to missing values. Children for which the value of some characteristic is missing are not counted toward the tallies of that characteristic. Preterm children were not included in analysis, except for the analysis on gestational age.

Characteristic	Children aged 0-12 months (n=880,688), n (%)	Children aged 12-24 months (n=805,231), n (%)	Children aged 24-36 months (n=635,009), n (%)
Developmental tracking			
Tracked	8595 (1)	13,711 (1.7)	13,508 (2.1)
Not tracked	842,307 (95.6)	765,075 (95)	597,559 (94.1)
Sex			
Female	429,695 (48.8)	393,115 (48.8)	309,995 (48.8)
Male	450,993 (51.2)	412,116 (51.2)	325,014 (51.2)
Postpartum depression			
Positive	27,791 (3.2)	23,719 (2.9)	17,520 (2.8)
Negative	685,335 (77.8)	567,633 (70.5)	399,514 (62.9)
Mother's age (years)			
18-39	739,073 (83.9)	686,705 (85.3)	549,114 (86.5)
40-50	130,270 (14.8)	110,398 (13.7)	81,249 (12.8)
Birth weight (kg)			
1-2.5	30,036 (3.4)	27,761 (3.4)	22,298 (3.5)
2.5-3	193,291 (21.9)	178,017 (22.1)	142,000 (22.4)
3-3.5	393,690 (44.7)	360,481 (44.8)	284,226 (44.8)
3.5-4	226,507 (25.7)	205,010 (25.5)	159,857 (25.2)
4-4.5	44,687 (5.1)	40,366 (5)	31,412 (4.9)
4.5-6	3929 (0.4)	3580 (0.4)	2778 (0.4)
Child number			
1	316,738 (36)	310,973 (38.6)	274,206 (43.2)
2	289,212 (32.8)	274,439 (34.1)	221,029 (34.8)
3	167,647 (19)	142,394 (17.7)	97,590 (15.4)
Mothers' education			
Academic	267,199 (30.3)	246,190 (30.6)	198,099 (31.2)
Tertiary education	91,060 (10.3)	79,979 (9.9)	59,102 (9.3)
High school	233,613 (26.5)	217,952 (27.1)	176,831 (27.8)
Elementary	18,651 (2.1)	17,273 (2.1)	13,974 (2.2)
Gestational age (weeks; total includes preterm children: aged 0-12 months, n=943,354; aged 12-24 months, n=864,421; and aged 24-36 months, n=682,999)			
23-27	1410 (0.1)	1387 (0.2)	1134 (0.2)
28-31	5135 (0.5)	4912 (0.6)	4090 (0.6)
32-36	56,934 (6)	53,634 (6.2)	43,346 (6.3)
37-38	228,343 (24.2)	209,255 (24.2)	166,043 (24.3)
39-42	651,532 (69)	595,233 (68.8)	468,386 (68.5)

To assess the relations between the DSS and characteristics of the children or their mothers, we compared, for each domain, the average DSS of several subgroups during the first, second, and third years of life. Figure 2 shows that the average DSS was higher (worse) for children that were under designated developmental tracking, compared to the complementary group (Figure 2A). Higher DSS was evident in the following subgroups: male children (Figure 2B), children whose mothers reported symptoms of PPD (Figure 2C), and children of older mothers (Figure 2D).

Figure 2. Developmental surveillance score (DSS) of binary variables. (A) Children under developmental (dev.) tracking compared to those who are not; (B) female children compared to male children; (C) children whose mothers reported postpartum depression (PPD) symptoms compared to those who did not; and (D) children of younger mothers (aged 18-39 years) compared to older mothers (aged 40-50 years). Asterisks denote a statistically significant difference between a pair of bars (**P*<.05; ***P*<.01; ****P*<.001). Based on developmental surveillance data from the Israeli Ministry of Health, between July 2014 and September 2021.

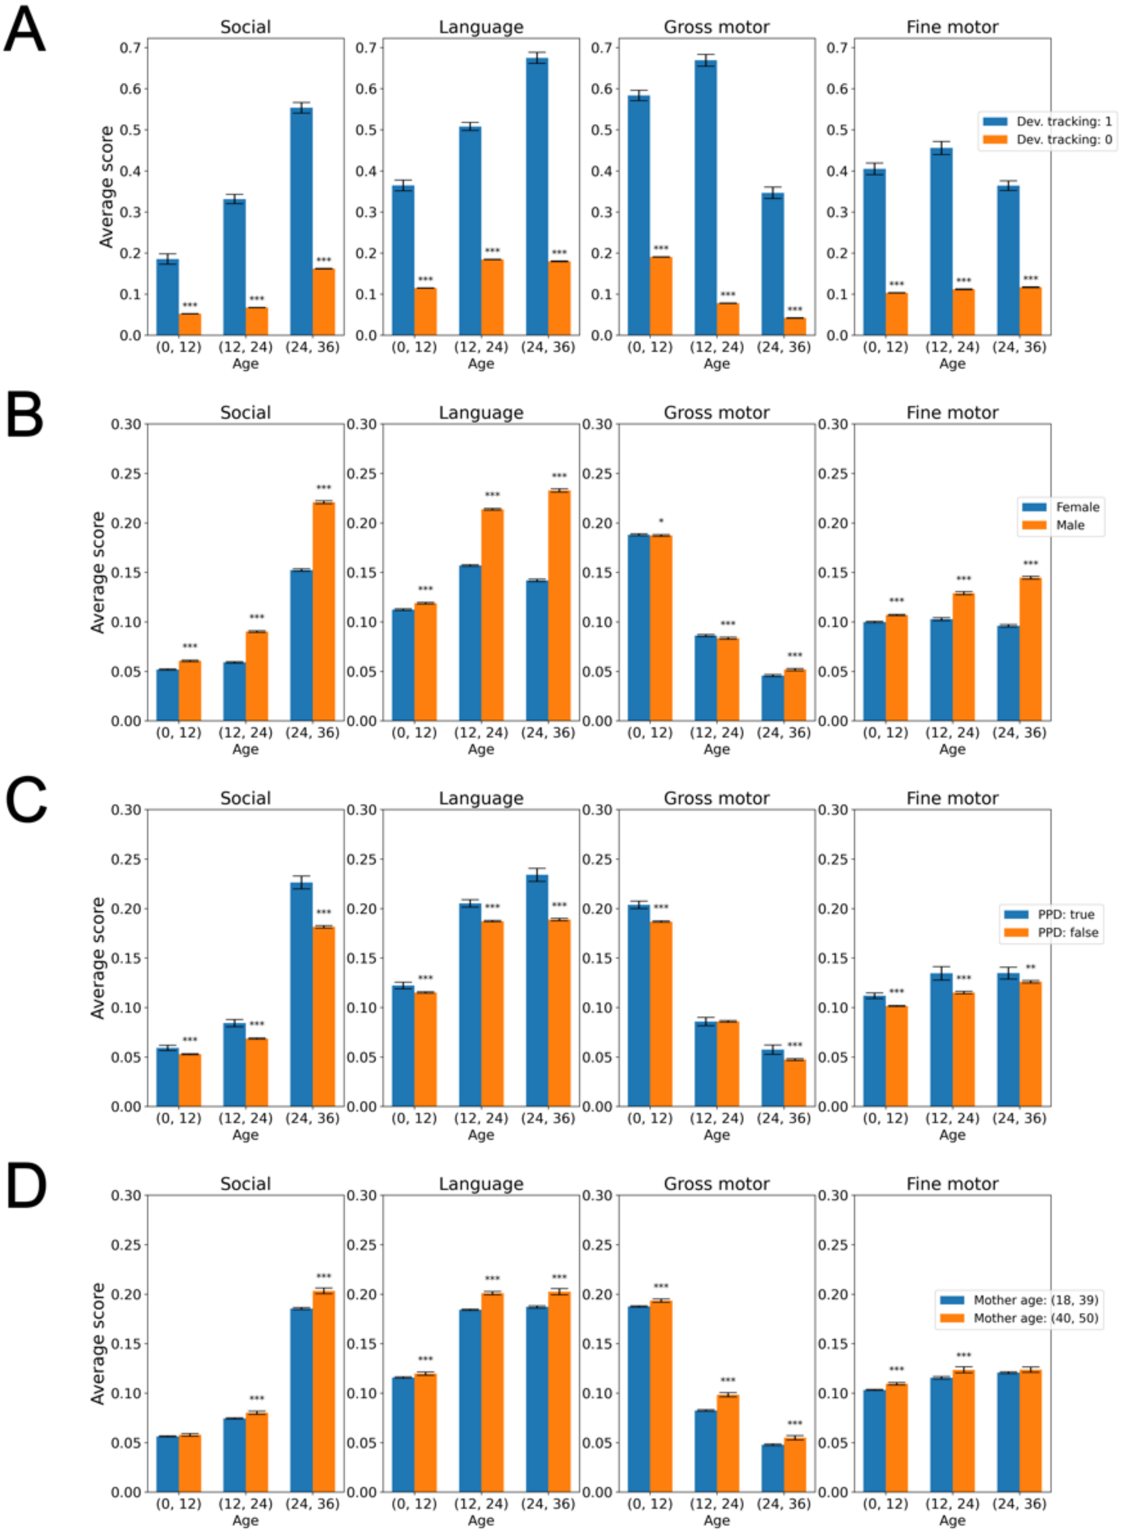


Figure 3A demonstrates the relation between the DSS and birth weight: children with birth weight of <2.5 kg or >4.5 kg had higher average DSS than children with normative birth weight (2.5-4.5 kg). Figure 3B shows that the DSS was negatively correlated to the gestational age at birth (eg, in the first year of life, Pearson *r*=–0.2 for gross motor milestones, –0.25 for fine motor milestones, and –0.18 for language-social milestones; *P*<.001). There were marked differences between preterm and on-term children, as well as between subgroups of extremely preterm, very preterm, moderate preterm, early term, and full-term children.

Figure 3. Relation between Developmental Surveillance Score (DSS) and numeric birth variables. (A) The child's birth weight and (B) gestational (gest.) age at birth. Asterisks denote a statistically significant difference between a pair of consecutive bars (*P<.05; **P<.01; ***P<.001). Based on developmental surveillance data from the Israeli Ministry of Health, between July 2014 and September 2021.

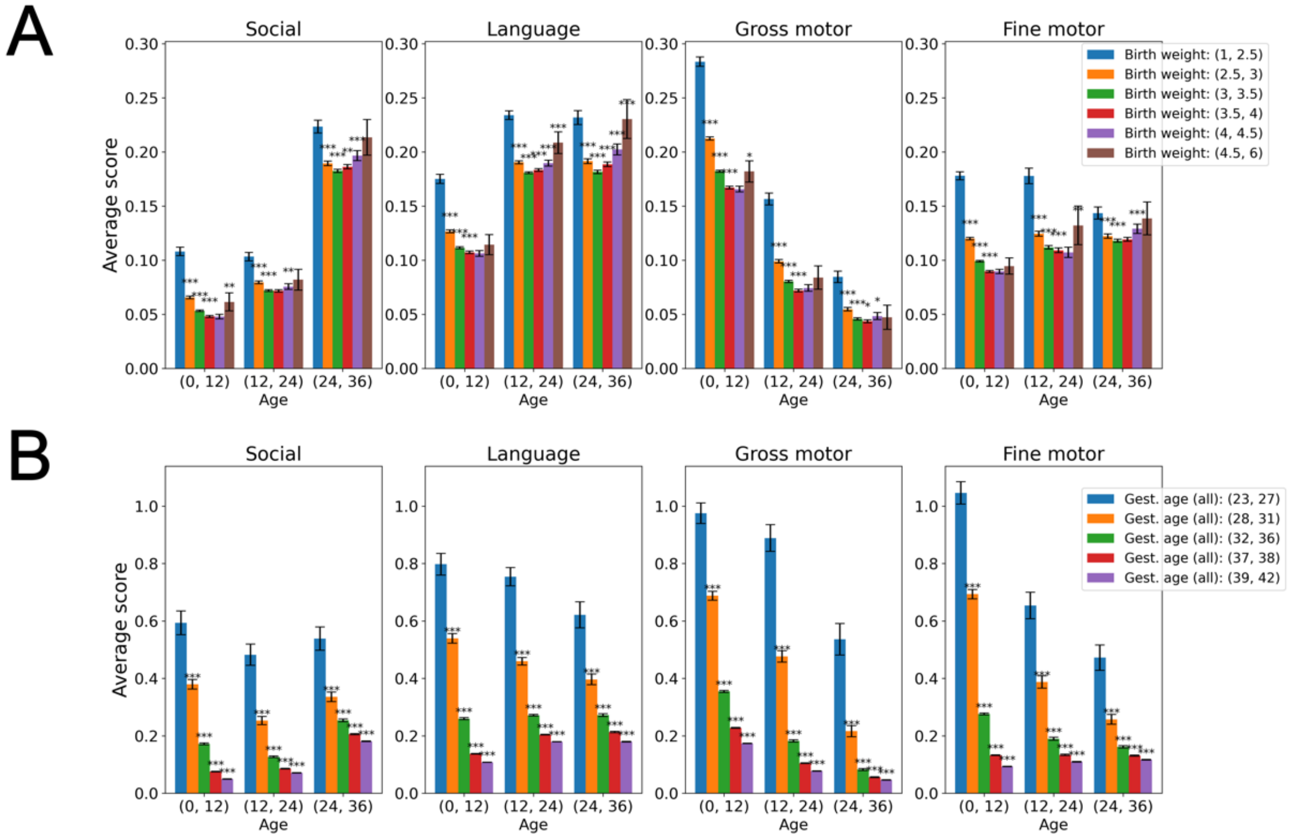

Figure 4A shows the association between the DSS and the mothers' level of education. The DSS tended to be higher among mothers with less formal education. In addition, the score appeared to be positively correlated with the child's birth order during the first year of life (Figure 4B; Pearson *r*=0.02 for gross motor milestones, 0.03 for fine motor milestones, and 0.08 for language-social milestones; *P*<.001), with firstborn children having the least average score. This trend was maintained for the gross motor and language-social scores during the second year of life (Pearson *r*=0.03 for gross motor milestones, 0.01 for fine motor milestones, and 0.07 for language-social milestones; *P*<.001). Conversely, this correlation was evident during the third year of life only for fine-motor tasks (*r*=0.02; *P*<.001). Importantly, these correlations should be considered as affirmation for the trends suggested by the graphs—their relatively low values on these large cohorts certainly do not imply that the DSS "explains" in any way the measured characteristics.

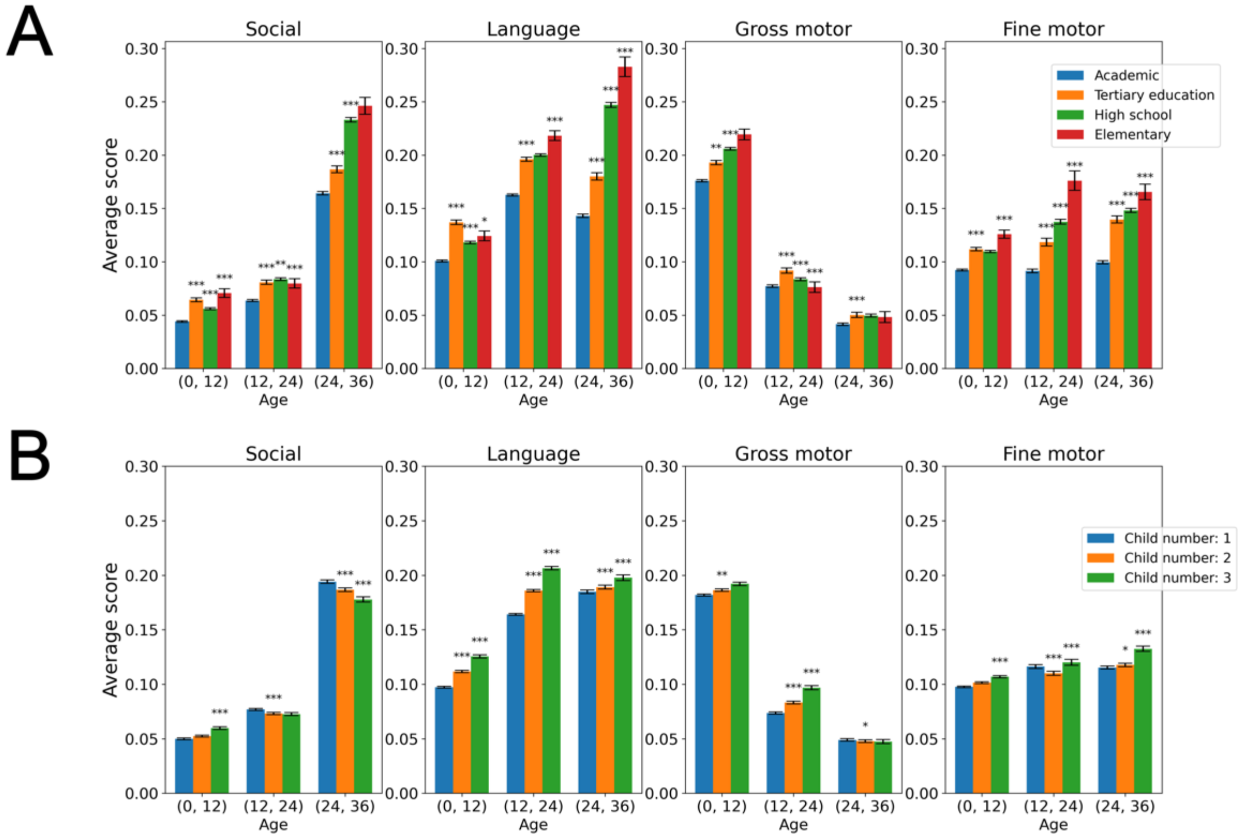
Figure 4. Relation between Developmental Surveillance Score (DSS) and categorical variables. (A) Maternal education level and (B) child's birth order. Asterisks denote a statistically significant difference between a pair of consecutive bars (*P<.05; **P<.01; ***P<.001). Based on developmental surveillance data from the Israeli Ministry of Health, between July 2014 and September 2021.

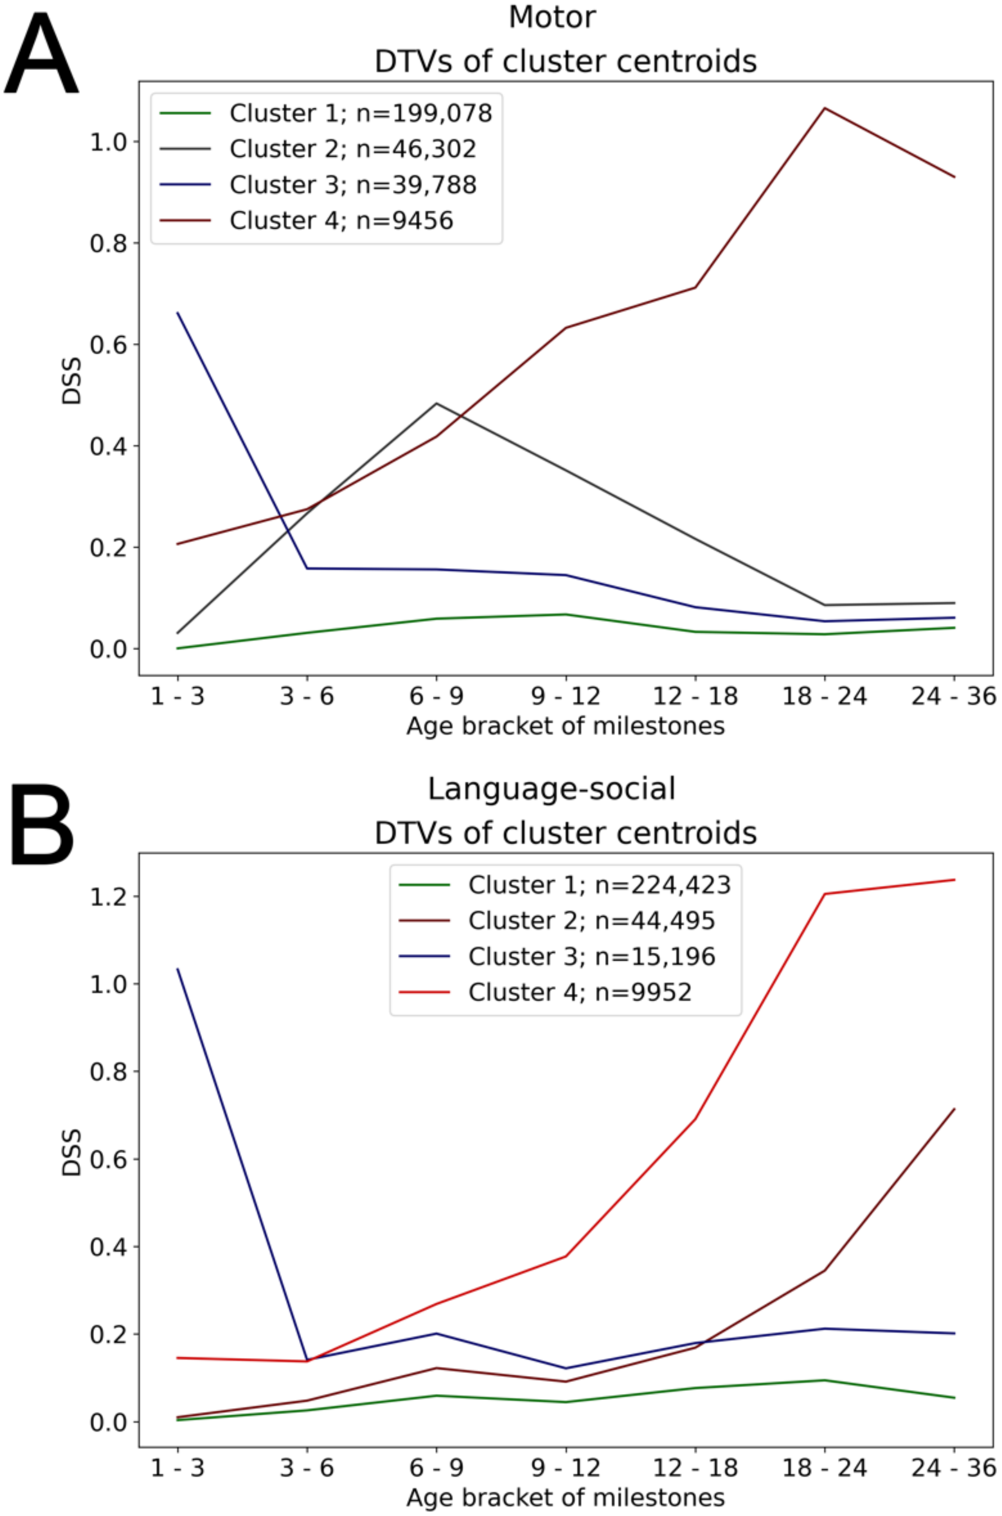


Note that all these graphs depict average values. For the most part, children attained the assessed milestones and received a score of 0. See Table S1 in Multimedia Appendix 1 for the median and IQR values of the DSS and Figures S1-S3 in Multimedia Appendix 1 for the same analysis using DMAS instead of LMAS.

Using the DSS to Describe Children's Developmental Trajectories

Figure 5 depicts the centroids derived from clustering of all children's DTVs into 4 clusters. Both motor DTVs and language-social DTVs exhibited similar patterns. There was a single cluster of children with near-zero DSS at all age steps. This cluster included the majority of children ("adequate"; motor DTVs: 199,078/294,624, 67.6%; language-social DTVs: 224,423/294,066, 76.3%). There was a single cluster of children who were "catching up"—their DSS was initially high but tended to decrease over time. There were clusters of "worsening" children whose scores tended to increase over time (2 clusters for language-social milestones and 1 for motor milestones). For motor milestones, there was also a cluster of children whose DSS increased at an early age but then decreased back to normal values and, so, did not conform to any of these 3 patterns.

Figure 5. Centroids of motor Developmental Trajectory Vectors (DTV) clusters. (A) Scores derived from fine motor and gross motor milestones and (B) scores derived from language and social milestones. Centroids of clusters are (A): 1. [0.01, 0.03, 0.06, 0.07, 0.03, 0.03, 0.04]; 2. [0.03, 0.27, 0.48, 0.35, 0.22, 0.08, 0.09]; 3. [0.66, 0.16, 0.16, 0.14, 0.05, 0.05, 0.06]; 4. [0.21, 0.27, 0.42, 0.63, 0.71, 1.07, 0.93]; and (B): 1. [0, 0.03, 0.04, 0.04, 0.08, 0.09, 0.05]; 2. [0.01, 0.05, 0.11, 0.09, 0.17, 0.35, 0.71]; 3. [1.03, 0.14, 0.15, 0.12, 0.18, 0.21, 0.20]; 4. [0.15, 0.14, 0.26, 0.38, 0.69, 1.20, 1.24]. Based on developmental surveillance data from the Israeli Ministry of Health, between July 2014 and September 2021. DSS: Developmental Surveillance Score.



Tables 2 and 3 show the distributions of child and mother's characteristics among the 4 different clusters in each domain. In the clusters depicting an increasing trajectory, there was an overrepresentation of male children relative to the "adequate" cluster. Specifically, in the motor domain, 50.7% (100,901/199,078) of the children in the "adequate" cluster were male, compared to 57.8% (5466/9456) in the "worsening" cluster. In the language-social domain, male children were 48.1% (107,970/224,423) of those in the "adequate" cluster, compared to 71.3% (7093/9952) and 62% (27,566/44,495) in the rapidly “worsening” and moderately “worsening” clusters, respectively. In addition, the “worsening” clusters had larger proportions of children that were born by cesarean section, had low birth weight, or were under developmental tracking.

Table 2. Distribution of child and mother characteristics in motor milestones clusters. Based on developmental surveillance data (N=294,624) from the Israeli Ministry of Health, between July 2014 and September 2021.

Characteristic	Cluster 1 (“adequate”; n=199,078, 67.6%), n (%)	Cluster 2 (n=46,302, 15.7%)	Cluster 3 (“catching up”; n=39,788, 13.5%), n (%)	Cluster 4 (“worsening”; n=9456, 3.2%), n (%)
Developmental tracking				
Tracked	4310 (2.2)	3200 (6.9)	1853 (4.7)	2471 (26.1)
Not tracked	194,768 (97.8)	43,102 (93.1)	37,935 (95.3)	6985 (73.9)
Sex				
Female	98,177 (49.3)	22,783 (49.2)	19,108 (48)	3990 (42.2)

In Multimedia Appendix 1, we demonstrate that qualitatively, these results were consistent over different range of clusters number, as well as when using an alternative clustering method.

Discussion

The goal of this study was to construct a DSS that can be used for comparative tracking of children's development, quantifying milestones attainment in a concise and straightforward way. We presented a simple methodology for calculating the DSS, a quantitative developmental surveillance score that aggregates age-dependent milestones results over a chosen time frame and domain into a single score. To demonstrate its coherence, we explored 2 main use cases for this score: comparing its value among subpopulations and using it to depict the developmental trajectory of individuals. We demonstrated that the DSS reflects known associations between developmental status and characteristics of the child and mother and its potential for suggesting possible new associations and insights, which may be a stepping stone for further research.

Children who have been referred to developmental tracking, indicating that they are likely to exhibit a developmental delay, had on average a much higher score than their counterparts, at all 3 examined age groups and for all 3 developmental domains. In addition, the score was shown to reflect previously reported associations between developmental status and the child's sex [22-28], birth weight [27,29-32], gestational age [30-34], birth order [32,35-37], maternal age [31,38,39], maternal education [28,31,32,38], and maternal symptoms of PPD [28,40-43].

For some of these variables, the DSS suggests a possible association with developmental delays, depicting different score distributions among subgroups stratified by the variable, even within the normal range. For example, it is well established that low birth weight is associated with developmental delays [27,29-32], yet the results herein suggest that this may also be true for birth weight within the lower normal range (2.5-3 kg) and for birth weight above the normal range (more than 4.5 kg). Similarly, although the scores of preterm children are higher than full-term children, there is a gradual decrease in the average score by the level of prematurity (extreme preterm, very preterm, and late preterm children), as well as a difference between early term and full-term children.

At the same time, some characteristics show a more complex behavior; for example, the DSS tends to be positively correlated with the child's order, yet for language-social tasks evaluated at 24-36 months of age, the correlation becomes negative. Indeed, although previous work generally associate primipara with lower risk for development delay [32,35,36], Oshima-Takane et al [37], who focused on language development at 21 and 24 months of age, observed higher language skills among second-born children.

Cluster analysis consistently identified 3 types of developmental trajectories: 1 cluster of children who succeed in attaining nearly all milestones, containing most of the children; 1 cluster of children who tend to fail early-age milestones but show improvement over time and succeed in attaining later milestones; and 1 or more clusters of children whose performance grow worse over time, with different clusters depicting different severities of failures. These clusters correspond to common types of developmental patterns observed in clinical practice; although, importantly, not all clusters can be categorized as 1 of these 3 types. Future work may use these clusters as class labels, in an attempt to predict the developmental trajectory type of a child at an early age and, accordingly, consider timely intervention when needed.

This work has several limitations. Importantly, the main goal was to present the DSS and show that it is consistent with current knowledge on risk factors for developmental delay such as low birth weight, preterm birth, older maternal age, symptoms of PPD, or lower level of maternal education, as well as to suggest interesting new observations. It is not proposed as a screening tool, and although we demonstrated its rationale and coherence, we lacked a "ground truth" of developmental delay for validating the score against. Future work should aim to assess the score's potential contribution to the clinical workflow of developmental assessment, for example, by comparing it to developmental screening tools such as the Bayley [13] and Denver [8,11] scales, as well as to developmental outcomes beyond those in the current data set, such as a diagnosis of autism.

Such a comparison is also needed for the calibration of the method with respect to milestones and age windows used to derive the score. For example, deriving the score by averaging milestone attainment during a full year implicitly assumes that a single number can represent the developmental delay over this entire period. Conversely, calculating a new score per visit does not take into account valuable information from past evaluations.

Another limitation stems from the use of slightly different cohorts for each age group. As depicted in Table 1, the cohorts differ in size and some of the characteristics, which may introduce some bias to the comparisons of age groups. However, as most of the presented results compare stratified population groups, the existence of similar differences in each age group strengthens the derived observations.

The results described herein pertain to the milestones used in Israeli MCHCs and the age thresholds computed in the THIS developmental scale [9]. Generalizing these results to other settings can be done by adopting the same methodology but would require having, or constructing, a developmental scale that is suitable for that setting. With such a scale at hand, one can compute a DSS from milestone attainment data by comparing them to the age thresholds and defining the score accordingly.

Taken together, our results suggest the potential usefulness of incorporating the DSS into the developmental surveillance workflow. We envision it as being computed automatically once a child's electronic health record is updated with new milestone attainment results and compared to the child's trajectory of past achievements, as well as to the population's norm. In cases where the score deviates significantly on either count, the system would notify the nurse, possibly leading to a more thorough evaluation. When calibrated correctly, such a system could identify developmental delays in a timely manner and foster interventions for improving the prospective outcomes.

Acknowledgments

The data were extracted with the help of TIMNA—a national research platform established by the Israeli government to enable big-data studies combining deidentified health data from multiple organizations.

This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

Data Availability

The deidentified patient-level data used for this study contain sensitive information and therefore are not available outside the secured research environment of the Israeli Ministry of Health. Summary aggregate-level data and analysis code for this study can be made available upon reasonable request to the corresponding author.

Conflicts of Interest

YS is a shareholder in LinkCaring LTD. LinkCaring develops intelligent decision-support systems that gather medical information using smartphones, tablets, computers, wearables, and sensors; analyze this information; and generate smart decision support reports for children. All other authors declare no other conflicts of interest.

Abstract

Background: Many nations swiftly designed and executed government policies to contain the rapid rise in COVID-19 cases. Government actions can be broadly segmented as movement and mass gathering restrictions (such as travel restrictions and lockdown), public awareness (such as face covering and hand washing), emergency health care investment, and social welfare provisions (such as poor welfare schemes to distribute food and shelter). The Blavatnik School of Government, University of Oxford, tracked various policy initiatives by governments across the globe and released them as composite indices. We assessed the overall government response using the Oxford Comprehensive Health Index (CHI) and Stringency Index (SI) to combat the COVID-19 pandemic.

Objective: This study aims to demonstrate the utility of CHI and SI to gauge and evaluate the government responses for containing the spread of COVID-19. We expect a significant inverse relationship between policy indices (CHI and SI) and COVID-19 severity indices (morbidity and mortality).

Methods: In this ecological study, we analyzed data from 2 publicly available data sources released between March 2020 and October 2021: the Oxford Covid-19 Government Response Tracker and the World Health Organization. We used autoregressive integrated moving average (ARIMA) and seasonal ARIMA to model the data. The performance of different models was assessed using a combination of evaluation criteria: adjusted R^2, root mean square error, and Bayesian information criteria.

Results: implementation of policies by the government to contain the COVID-19 crises resulted in higher CHI and SI in the beginning. Although the value of CHI and SI gradually fell, they were consistently higher at values of >80% points. During the initial investigation, we found that cases per million (CPM) and deaths per million (DPM) followed the same trend. However, the final CPM and DPM models were seasonal ARIMA (3,2,1)(1,0,1) and ARIMA (1,1,1), respectively. This study does not support the hypothesis that COVID-19 severity (CPM and DPM) is associated with stringent policy measures (CHI and SI).

Conclusions: Our study concludes that the policy measures (CHI and SI) do not explain the change in epidemiological indicators (CPM and DPM). The study reiterates our understanding that strict policies do not necessarily lead to better compliance but may overwhelm the overstretched physical health systems. Twenty-first–century problems thus demand 21st-century solutions. The digital ecosystem was instrumental in the timely collection, curation, cloud storage, and data communication. Thus, digital epidemiology can and should be successfully integrated into existing surveillance systems for better disease monitoring, management, and evaluation.

Introduction

SARS-CoV-2 is contagious, capricious, and hysteric—it adversely affected the social, mental, and physical well-being of individuals and societies—from the time the first case of COVID-19 was reported from Wuhan, China, in December 2019 [1]. The World Health Organization (WHO) declared COVID-19 a pandemic in March 2020 [2]. The viral disease occurred almost a century later than the deadliest viral disease in history—the influenza of 1918-1919 [3]. Globally, COVID-19 is associated with morbidity and mortality of 458 and 6.1 million people, respectively, till March 15, 2022 [4]. However, the official numbers underestimate actual morbidity and mortality estimates—a significant reason for concern among health experts [5]. The literature points to various reasons for deflating figures: differences in disease monitoring and reporting, testing strategy, asymptomatic cases, medically unattended cases, and deaths across nations [6-8].

Many nations swiftly designed and executed government policies to contain the rapid rise of COVID-19 cases [9]. Government actions can be broadly categorized as movement and mass gathering restrictions (such as travel restrictions and lockdown), public awareness (such as face masking and hand washing), emergency health care investment, and social welfare provisions (such as poor welfare scheme and providing food and shelter to migrant workers) [10]. However, the intermix of culture, communication, society, religion, politics, socioeconomic disparities, and education plays a dominant role in successfully implementing government policies [11,12]. Despite aggressive interventions by the Government of India (GOI), mass migration and verbal and physical abuse against health care providers were perplexing during the COVID-19 crisis [12-14]. These problems indicate that implementing policies to contain the public health crisis is one part of the puzzle, and understanding, adherence, and participation by citizens to make it a success is the other. Thus, a mismatch and mistrust between the public and policy makers will determine how the crises unfolds [15,16]. Despite these constraints, the principal priority was to contain the pandemic and mitigate future waves.

Traditional surveillance systems are robust and well-developed in many countries, but these were insufficient during the COVID-19 pandemic. Prominent challenges are that physical networks are extremely slow to upgrade (such as surveillance and physical structure), resource-intensive (in terms of finances and personnel), and involve bureaucratic hurdles (such as permissions and administrative authority). An emergency or crisis demands agile and innovative solutions. Internet technology can supplement the already existing traditional structure. The technological innovation of the internet and digital devices has fundamentally reshaped how people seek information and adhere to guidelines [17,18]. Therefore, blending existing surveillance systems with a digital ecosystem is ideal for harnessing and optimizing their untapped potential. Technology, medical development, health infrastructure, and lifestyle are pivotal in combating public health crises.

Many studies have highlighted the importance of nonpharmaceutical Interventions (NPIs) in containing the COVID-19 crisis [19-22]. Internet and digital devices played a critical role in screening, surveillance, monitoring spread, sharing, and managing data [23]. However, most of the studies focused on mobility during the current crisis. Mobility is vital, but many other essential indicators of disease spread exist. The Oxford tracker keeps track of various policy initiatives to mitigate COVID-19 and releases them as Comprehensive Health Index (CHI) and Stringency Index (SI) data [24]. CHI and SI are composite indicators covering the various aspects of NPIs; these indicators provide a systematic approach to understanding how the government has responded to mitigate disease spread over a period. We aimed to assess the utility of CHI and SI—innovative measures of the University of Oxford—to gauge and evaluate government responses for containing the spread of COVID-19. We hypothesize that there is a significant inverse relationship between policy indices (CHI and SI) and COVID-19 severity indices (morbidity and mortality). The analyses hope to inform and better prepare the experts to face and refine epidemiological indicators for future contagious disease crises.

Methods

Study Design

An ecological time-series study design was adopted, using secondary data.

Study Period

The first case of COVID-19 in India was reported from Kerala on January 27, 2020 [25]. The GOI responded to the COVID-19 threat by issuing travel advisories and screening at airports in January and later restricting international travel from March 2020 onward [26,27]. As the cases in India started escalating, the GOI called for a *Janata* curfew on March 23, 2020, and implemented a national lockdown from March 24 to June 7, 2020, for 75 days [28]. The GOI started phased unlocking from June 8, 2020, onward [28]. COVID-19 and SI data for India are available from January 21, 2020, to March 2022. This study used data from March 4, 2020 (when India crossed 10 cumulative cases), to October 24, 2021.

Data Sources

We used 2 publicly available data sources from the Oxford Covid-19 Government Response Tracker (OxCGRT) [29] and the WHO [4] licensed under the Creative Commons Attribution (CC BY) standard.

COVID-19 Data

The WHO collects the numbers of confirmed COVID-19 cases and deaths through official communications under the

International Health Regulations of 2005. WHO experts monitor the official ministries of health's websites and social media accounts for data validation. The data set, after curation, is made available as a .csv file and can be downloaded from the website [24].

CHI and SI Data

The OxCGRT for containment and closure and health data set evaluates the government response to containing the COVID-19 crisis. The OxCGRT collected 23 indicators to capture government policies related to closure and containment, health, and economics for more than 180 countries since January 1, 2020. The policy indicators are captured on an ordinal or numerical scale to describe each category's degree or the strength of the government response. Each ordinal indicator is transformed to a value between 0 and 100 per the formula given in the codebook [25]. Finally, to gauge government performance, individual indicators are aggregated and published in 5 composite indices: Government Response Index, Containment and Health Index, SI, Economic Support Index, and Legacy Stringency Index. The CHI uses 14 indicators and SI uses 9 indicators out of 23. The value for composite indices on any given day represents the aggregated average of each indicator for the day. The composite indices report a number between 0 and 100 that reflects the overall stringency of the government's response. A higher index indicates a higher overall response level. Table 1 shows details regarding individual indicators used to calculate the CHI and SI, both of which are updated regularly. The indicators are reported for each day that a policy was implemented (not on the day it was announced). A continuously updated OxCGRT index provides comparable information regarding various countries' policy measures. Many indicators have another flag variable to imply whether they are targeted (applying only to a subregion of a jurisdiction or to a specific sector) or general. The OxCGRT uses simple, additive, and unweighted indices that are easier to interpret. The missing value contributes a zero to the index. Multimedia Appendix 1 demonstrates the steps to download the OxCGRT data sets. Details of all the indicators and calculations for the composite index are provided in the working paper entitled, "Variation in government responses to COVID-19" [30].

Table 1. Details regarding individual and composite Oxford Covid-19 Government Response Tracker indicators.

ID	Policy measures	Scale	Score, maximum (range)	Stringency Index	Comprehensive Health Index	Flag[a]
Containment and closure						
C1	School closing	Ordinal	3 (0-3)	✓	✓	Yes=1
C2	Workplace closing	Ordinal	3 (0-3)	✓	✓	Yes=1
C3	Cancel public event	Ordinal	2 (0-2)	✓	✓	Yes=1
C4	Restriction on gathering size	Ordinal	4 (0-4)	✓	✓	Yes=1
C5	Close public transport	Ordinal	2 (0-2)	✓	✓	Yes=1
C6	Stay-at-home requirements	Ordinal	3 (0-3)	✓	✓	Yes=1
C7	Restriction on internal movement	Ordinal	2 (0-2)	✓	✓	Yes=1
C8	Restriction on international travel	Ordinal	4 (0-4)	✓	✓	No=0
Health systems						
H1	Public information campaign	Ordinal	2 (0-2)	✓	✓	Yes=1
H2	Testing policy	Ordinal	3 (0-3)		✓	No=0
H3	Contact tracing	Ordinal	2 (0-2)		✓	No=0
H6	Facial covering	Ordinal	4 (0-4)		✓	Yes=1
H7	Vaccination policy	Ordinal	5 (0-5)		✓	Yes=1
H8	Protection of older individuals	Ordinal	3 (0-3)		✓	Yes=1

[a] A value of 0 indicates that the policy is targeted to a subregion.

Study Variables

Dependent Variables

The data about morbidity and mortality were downloaded in the .csv file and reported using standardized metrics such as cases per million (CPM) and deaths per million (DPM). CPM and DPM are valuable indicators for intergeographical comparisons—the same metrics were calculated and reported using standard formulae provided by the WHO. Multimedia Appendix 2 provides details about the 7-day moving average, CPM, and DPM.

Independent Variables

Government policies and timing are vital indicators of morbidity and mortality related to disease during and after the crisis. Therefore, we used time, CHI, and SI, which are cumulative nonweighted indices of government policies as predictor variables. Table 1 provides detail of both CHI and SI.

Data Analysis

Data Processing and Summarization

We retained originally downloaded data sets of COVID-19 and OxCGRT for record and referral. Subsequently, a copy of each original data set was generated to clean, code, and analyze. Data cleaning in both files involved renaming, relabeling, and removing of undesired variables. Subsequently, we used the *date* variable to merge and prepare a final data set for analysis. The raw day–wise data were smoothed using a 7-day moving average that was subsequently used to calculate and report CPM and DPM. The morbidity indicator in the country was summarized using frequency and percentage increase. Initially, time-series plots were used to gauge the disease burden. Subsequently, a dual-axis chart was used to visualize the pattern between disease burden and policy indicators. The descriptive tables and graphs were prepared using Excel (Microsoft Corp).

Time-Series Modeling

The daily SARS-CoV-2 data follow the characteristics of the time series. As an initial step, we carefully inspected the daily incidence (morbidity and mortality), descriptive statistics (mean and variance), and seasonality (weekly and periodicity). We subsequently used second-order differencing for CPM and first-order differencing for DPM to make them stationary, which is an essential requirement to apply time-series analysis [31]. The twin advantage of simple structure and immediate applicability of autoregressive integrated moving average (ARIMA) and seasonal ARIMA (SARIMA) made them lucrative for analyzing the current study data set [32]. ARIMA considers only the past values for prediction, whereas SARIMA also considers the seasonality patterns, making it a more robust algorithm for prediction. We plotted autocorrelation function (ACF) and partial ACF (PACF) values to assess autoregressive and moving average components of the ARIMA and SARIMA.

Model Construction and Comparison

We could not finalize the order of autoregressive and moving average components from ACF and PACF plots. Therefore, considering the Expert Modeler and Box-Jenkins 5-step methodology (describe data, identify model, estimate parameters, diagnosis check, and forecasting), we relied on an expert modeler for an initial model from multiple candidate models. Subsequently, we used the Box-Jenkins technique that gives the flexibility to customize and attain the final model [33]. We used the date (time) as an explanatory variable in the initial model. Subsequently, CHI or SI and time were added to an expanded model to build and evaluate the models. The performance of different models was assessed using a combination of evaluation criteria: adjusted R^2, root mean square error, and Bayesian information criteria (BIC). After attaining the final model, we performed the diagnosis check to validate model assumptions. Multimedia Appendix 3 elucidates the step-by-step approach to attain the final model. We used a 2-tailed P value of <.05 to declare statistical significance. The time-series analysis of data was performed using SPSS (version 23; IBM Corp).

Ethical Considerations

Ethical clearance for the study was obtained from the institutional review board of the Postgraduate Institute of Medical Education and Research, Chandigarh, India (vide letter INT/IEC/2020/SPL–1594).

Results

Disease Burden

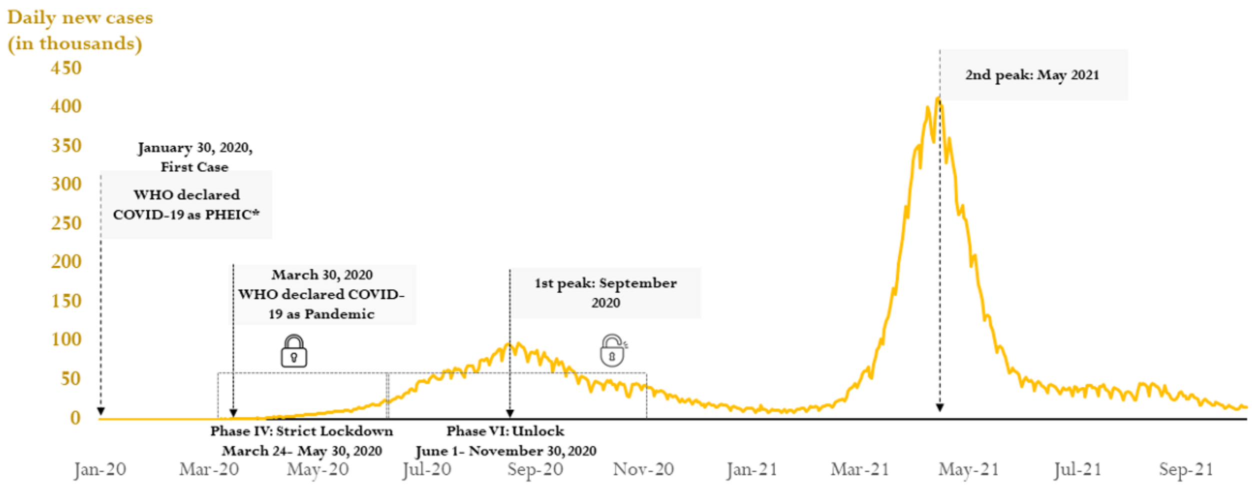
The first case of COVID-19 was detected in India on January 27, 2020. It took 46 days for the infection to spread among 100 people. India had 60 COVID-19–infected individuals on March 11, 2020, when the WHO declared COVID-19 a pandemic. True to its nature, COVID-19 started spreading rapidly, and it took only 15 days to reach 1000 cases from 100. Public health experts and policy makers were on high guard after GOI notification—a fact also reflected by the SI and CHI. Table 2 provides details about different milestones regarding the rise in disease burden. The increase in cases followed a linear trajectory during the lockdown stage. After unlocking, India achieved its first peak in September 2020, which was almost 100,000 cases per day. Subsequently, the second peak in May 2021 was characterized by a maximum caseload of ~400,000 cases per day. Figure 1 shows the change in India's disease burden from January 2020 to October 2021.

Table 2. Different milestones in the rise of the COVID-19 burden in India.

Date	Lockdown phases	Cumulative COVID-19 cases in India, n	Time from the report of the first COVID-19 case in India	Stringency index, median (range)	Comprehensive Health Index, median (range)
January 27, 2020	No	1	Frist case	—[a]	—
March 4, 2020	No	10	n=35 (1 month)	10.2 (10.2-10.2)	17.3 (13.7-17.3)
March 15, 2020	No	100	n=46 (1.5 months)	29.4 (26.9-38.9)	29.6 (27.9-35.7)
March 30, 2020	Phase 1: March 25-April 14, 2020	1000	n=61 (2 months)	81.7 (48.2-100)	66.8 (41.7-80.9)
April 14, 2020	Phase 2: April 15-May 3, 2020	10,000	n=76 (2.5 months)	100 (100-100)	86.2 (80.9-91.9)
May 19, 2020	Phase 4: May 18-May 31, 2020	100,000	n=111 (4 months)	90.3 (81.9-100)	84.1 (76.8-91.9)
July 17, 2020	Unlock 2.0: July 1-July 31, 2020	1,000,000	n=170 (5.5 months)	86.4 (81.9-87.5)	74.9 (74.4-76.8)
December 19, 2020	Partial	10,000,000	n=325 (10.5 months)	75.9 (61.6-87.5)	68.8 (61.3-74.4)
May 4, 2021	Partial	20,000,000	n=461 (15 months)	65.6 (57.9-74.5)	71.3 (66.1-81.1)
June 23, 2021	Partial	30,000,000	n=547 (18 months)	81.1 (73.6-81.9)	79.4 (74.5-79.8)

[a] Not determined.

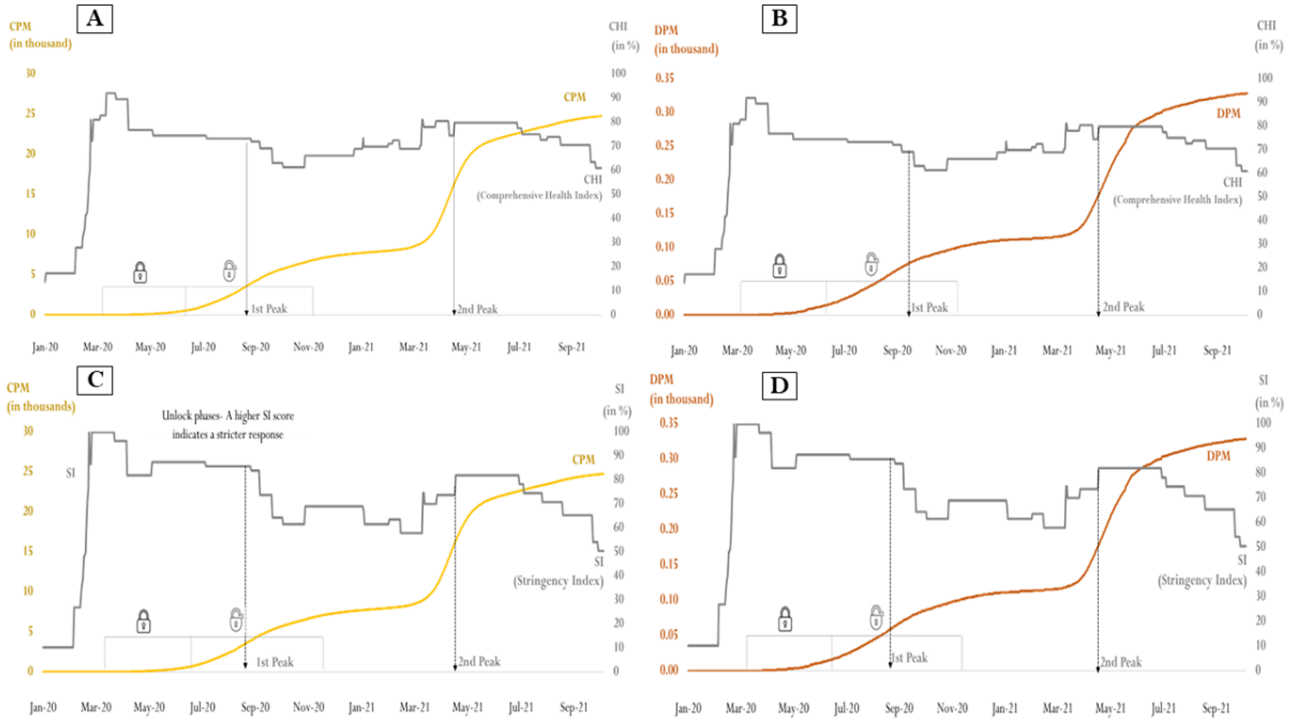
Figure 1. A line graph (epidemic curve) showing daily new COVID-19 cases in India. Adapted from the World Health Organization's (WHO's) Coronavirus Dashboard [4]. PHEIC: public health emergency of international concern.



Epidemiological and Policy Indicators

The strict implementation of policies by the government to contain the COVID-19 crisis led to a very high value of CHI and SI in the beginning. Figure 2A shows that the CPM was near the x-axis from the beginning till the end of the fourth lockdown. Subsequently, CHI reduced gradually; in contrast, the CPM swiftly increased after the GOI initiated unlocking from July 2020. Figure 2B shows that the DPM also increased steadily with time—the highest during the unlock phase. Although the CHI and SI reduced marginally, there were spikes during the first and second peaks. The CPM and DPM also displayed similar increasing trends with the SI. Figures 2C and 2D depict CPM and DPM changes with SI over time.

Figure 2. Line graphs depicting changes in the Comprehensive Health Index or Stringency Index (SI) versus cases per million (CPM) or deaths per million (DPM) for SARS-CoV-2 in India. (A) Change in the Comprehensive Health Index and CPM, (B) change in the Comprehensive Health Index and DPM, (C) change in the Stringency Index (SI) and CPM, and (D) change in the SI and DPM. Data obtained from the World Health Organization's Coronavirus Dashboard [4] and from GitHub [28].



Time-Series Modeling

Figures 1 and 2A-2D show that both positive (symptomatic) and deaths (mortality) were nonstationary time series. On the surface, the CPM and DPM followed the same trend. However, the final CPM and DPM model were SARIMA (3,2,1)(1,0,1) and ARIMA (1,1,1), respectively. Multimedia Appendix 3 provides details regarding the steps involved in obtaining the final models. There was no improvement in model performance for CPM: the BIC values for both time (BIC 2.42) and the expanded model (BIC 2.46) were almost the same. Similarly, the BIC values for both time (BIC –1.35) and the expanded model (BIC –1.34) models for DPM were the same. Despite the appearance of an inverse relationship between COVID-19 and policy indicators, neither CHI nor SI were significant predictors of CPM and DPM. Table 3 displays the final model's output and performance indicators: BIC, stationary R^2, and root mean square error.

Table 3. The output of the final model for COVID-19 cases per million and deaths per million in India from March 2020 to October 2021.

Model and parameter	Estimate	*P* value	Bayesian information criteria	Stationary R^2	Root mean square error
Seasonal autoregressive integrated moving average (3,2,1)(1,0,1)			2.42	0.62	3.22
AR1	0.67	<.001			
AR2	0.12	.02			
AR3	0.10	.04			
MA1	0.73	<.001			
SAR1	0.86	<.001			
SMA1	0.25	<.001			
Autoregressive integrated moving average (1,1,1)			–1.35	0.64	0.50
AR1	0.99	<.001			
MA1	0.82	<.001			

Discussion

Principal Findings

We used the CHI and SI data from the Blavatnik School of Government, University of Oxford, response tracker to evaluate and model COVID-19 morbidity and mortality. There are specific critical findings in our study. COVID-19 displayed the typical characteristic of a highly contagious disease that spread rapidly after a slow start. At the beginning of the pandemic in India, cases were geographically scattered and scarce; thus, the CHI and SI were low as neither the GOI issued any guidelines nor did the people adhere to preventive behaviors. There was a sharp increase in cases after unlocking, and India witnessed 2-clear and visible peaks in September 2020 and May 2021; this was in line with a temporary increase in CHI and SI during peaks. The value of CHI and SI gradually decreased; similarly, however, these were consistently higher at values of >80% points.

For intercountry comparisons, the CPM and DPM were calculated and reported, since these are better measures than the raw number of cases. The CPM and DPM linearly increased when stringency was high during the lockdowns and rapidly increased after the government lifted the restrictions. Despite initial indication, both CHI and SI were (rather surprisingly) not significant predictors of COVID-19 morbidity and mortality.

People's participation is vital to the success of public health interventions. Thus, the GOI tested people's moods and sentiments with the *Janata Curfew* (self-restricted curfew) before implementing strict public health measures. After the success of the Janata curfew, the GOI enforced a nationwide lockdown to close schools, parks, transport, offices, and borders to contain the COVID-19 crisis. The daily incidence was relatively flat during the entire lockdown period; the strict response to epidemic control measures reduced daily incidence [26]. However, social control measures mitigate contagious diseases; they do not eradicate them [27,28]. The rate of disease spread increased rapidly after the unlocking process began. Despite the nationwide lockdown, significant intra- and interstate variation was a cause of concern—the majority (~76%) of cases were reported from 10 out of 36 states and union territories in India [29]; the disparity can be partially attributed to constitutional provisions besides factors such as mobility, urbanization, and population density. Moreover, while the central government has the power to make public health laws, the state government develops infrastructure and executes public health policy because health care and hospitals are subject matters in the state list [4].

NPIs such as tests, contact tracing, masking, social distancing, mobility, hygiene, and vaccination form the backbone for controlling contagious diseases. However, in the absence of vaccination, strategic implementation of NPIs helps mitigate the rapid spread of COVID-19 [13-16]. The CHI and SI are more comprehensive than specific mobility indicators—these cover various aspects of NPIs. The CHI and SI attain very high values, and the results are in parallel with those of Ma et al [34], which indicate that countries that implemented nationwide lockdowns in March took strict measures [26]. The high value of CHI and SI during the lockdown reflects public health experts' and policy makers' comprehensive and dynamic responses to contain the COVID-19 crisis. Government-enforced lockdowns are significant contributors to restrictions on activities. People also respond to contagious threats by restricting socializing and travelling [35]. Overall, CHI and SI reflected high stringency; this further increased during the peak. Initial investigation reveals a distinct inverse relationship between restriction indicators (CHI and SI indices) and disease burden (morbidity and mortality); this relationship was explicit as the unlocking phase began.

We fitted a time-series model to investigate the relationship between policy and disease indicators. The time-series model with dates explained more than 60% of variability for both CPM and DPM models. The initial investigation indicated the relationship between predictors (CHI and SI) and disease burden (CPM and DPM). However, the expanded inferential models do not increase the models' performances—neither CHI nor SI contributed significantly explaining the change in CPM and DPM. In other words, stringency measures such as CHI and SI do not explain the change in both COVID-19 morbidity and mortality. The results of our study are in contrast to those of other studies [26,30,31]. However, it may be crucial to note that strict implementation of policies does not necessarily lead to strict compliance [32,33]. A thorough inspection of CHI and SI indicates the government's proactiveness on different indicators compared to participation. India saw the mass movement of migrant workers [34,36] and multiple attacks on health care workers during the lockdowns [34,37]. Further, COVID-19 was a relatively urban phenomenon; most of India is rural.

Strengths and Limitations

A significant strength of our study is that this is the first study to investigate the relationship between policy indicators CHI and SI and epidemiological indicators CPM and DPM. It is the first pan-India study that has used WHO and OxCGRT data to quantify and model COVID-19 transmission. Our study is different from other studies focused on NPIs including mobility or SI but not CHI.

However, a significant limitation of this study, and perhaps most digital epidemiological studies, is the validity and reliability of the data. As already highlighted, CHI and SI are proxy measures that do not reflect strict compliance with the implementation of policies. There may be an inherent bias or reporting error in composite CHI and SI indices at the country level due to within and between heterogeneity at the state and union territory levels. The unweighted indices (CHI and SI) are easy to interpret but make strong assumptions, and a user may obtain different results when using weighted indices. Lastly, correct reporting of the daily incidence of COVID-19 cases depends on a country's accuracy and testing capacity.

Future Work

Countries with vast geographical and administrative regions may differ significantly in implementing policies. Therefore, further research is required to develop and validate the metrics to identify whether country- or county-level (state and union territory) metrics are needed. The capacity to test, trace, and treat varies from country to country. Do disease morbidity and mortality reporting reflect the actual scenario? What logical steps and weightage must be given to each region is also a perplexing problem vouching for researchers' attention. The media plays a vital role in containing public health crises. However, did it aid in signaling by motivating people to adhere to guidelines, or has it added to noise by creating panic among the public? Lastly, are OxCGRT indicators enough to capture people's participation and policy makers' execution or do they require appropriate weightage? The aforementioned issues invite attention from health experts and policy makers.

Conclusions and Recommendations

Our study concludes that the policy measures (CHI and SI) do not explain the change in epidemiological indicators (CPM and DPM). The study reiterates our understanding that strict policies do not necessarily lead to better compliance but may overwhelm the overstretched physical health systems. Twenty-first–century problems thus demand 21st-century solutions. The digital ecosystem was instrumental in the timely collection, curation, cloud storage, and data communication. Thus, digital epidemiology can and should be successfully integrated into existing surveillance systems for better disease monitoring, management, and evaluation. An OxCGRT policy metric is a novel innovation to assess government actions during the epidemic, which have the potential for future use and refinement. Therefore, policy makers, public health experts, and programmers must start collaborating to design a hybrid health system that can borrow from the strengths of the existing physical surveillance system and the ever-expanding digital ecosystem.

Abstract

Background: Community-based telemedicine screening for diabetic retinopathy (DR) has been highly recommended worldwide. However, evidence from low- and middle-income countries (LMICs) on the choice between artificial intelligence (AI)–based and manual grading–based telemedicine screening is inadequate for policy making.

Objective: The aim of this study was to test whether the AI model is more worthwhile than manual grading in community-based telemedicine screening for DR in the context of labor costs in urban China.

Methods: We conducted cost-effectiveness and cost-utility analyses by using decision-analytic Markov models with 30 one-year cycles from a societal perspective to compare the cost, effectiveness, and utility of 2 scenarios in telemedicine screening for DR: manual grading and an AI model. Sensitivity analyses were performed. Real-world data were obtained mainly from the Shanghai Digital Eye Disease Screening Program. The main outcomes were the incremental cost-effectiveness ratio (ICER) and the incremental cost-utility ratio (ICUR). The ICUR thresholds were set as 1 and 3 times the local gross domestic product per capita.

Results: The total expected costs for a 65-year-old resident were US $3182.50 and US $3265.40, while the total expected years without blindness were 9.80 years and 9.83 years, and the utilities were 6.748 quality-adjusted life years (QALYs) and 6.753 QALYs in the AI model and manual grading, respectively. The ICER for the AI-assisted model was US $2553.39 per year without blindness, and the ICUR was US $15,216.96 per QALY, which indicated that AI-assisted model was not cost-effective. The sensitivity analysis suggested that if there is an increase in compliance with referrals after the adoption of AI by 7.5%, an increase in on-site screening costs in manual grading by 50%, or a decrease in on-site screening costs in the AI model by 50%, then the AI model could be the dominant strategy.

Conclusions: Our study may provide a reference for policy making in planning community-based telemedicine screening for DR in LMICs. Our findings indicate that unless the referral compliance of patients with suspected DR increases, the adoption of the AI model may not improve the value of telemedicine screening compared to that of manual grading in LMICs. The main reason is that in the context of the low labor costs in LMICs, the direct health care costs saved by replacing manual grading with AI are less, and the screening effectiveness (QALYs and years without blindness) decreases. Our study suggests that the magnitude of the value generated by this technology replacement depends primarily on 2 aspects. The first is the extent of direct health care costs reduced by AI, and the second is the change in health care service utilization caused by AI. Therefore, our research can also provide analytical ideas for other health care sectors in their decision to use AI.

KEYWORDS

artificial intelligence; cost; diabetic retinopathy; utility; low- and middle-income countries; screening

Introduction

Diabetic retinopathy (DR) is a leading cause of blindness worldwide. It often develops 10-15 years after the onset of diabetes and can take several forms—all potentially causing vision loss or blindness, including diabetic macular edema (DME) due to increased retinal vascular permeability and central retinal thickening, retinal ischemia resulting in the damage or death of light-sensing retinal photoreceptors, and proliferative DR, where the growth of fragile new blood vessels causes vitreous hemorrhage and retinal detachment [1].

In 2020, the global burden of DR and sight-threatening DR (STDR) was estimated to be 103 million and 29 million people, respectively, which will increase to 161 million and 45 million by 2045 due to the increasing prevalence of diabetes mellitus (DM) [1,2]. From 1990 to 2010, visual impairment due to DR increased by 64% and blindness by 27% [1], both of which were due to the rising DM prevalence in low- and middle-income countries (LMICs). Several studies have confirmed the benefits of telemedicine screening for DR [3-6]. Compared to no screening and traditional face-to-face screening, telemedicine screening is highly cost-effective in the long term. As a result, telemedicine screening will become the main form of community-based eye disease screening [5]. Some recent studies have suggested that using artificial intelligence (AI) can further reduce the costs of telemedicine screening [3,7-10]. Studies in high-income countries such as the United Kingdom and Singapore have shown that when AI is used in DR screening programs, screening costs can be reduced by up to approximately 20% compared with the costs incurred in manual grading [7-9]. This can be easily understood: from the perspective of a health economic evaluation, the main difference between the AI model and manual grading is that technology costs replace labor costs. Therefore, in settings where labor costs are high, such as in high-income countries, using AI instead of manual grading would save a lot of screening costs, making the screening more cost-effective [10]. However, because labor costs are low in low-income countries, conclusions from high-income countries may not be equally suitable, and evidence from LMICs is inadequate. Therefore, the objective of our community-based telemedicine screening for DR was to examine whether the AI model can be more cost-effective than manual grading in LMICs. We conducted a health economic evaluation by using real-world data from a large community-based telemedicine screening program for DR in Shanghai, China. We expect that this study will provide a reference for policy making with regard to DR screening in the context of low labor costs.

Methods

Study Setting

This study was conducted in Shanghai, China, wherein the prevalence of type 2 diabetes among adults was 6.25% between 2016 and 2019 [11]. Since 2010, Shanghai has conducted a teleophthalmology-based DR screening program under which residents can undergo fundus photography at community health service centers. After retinal experts at designated DR diagnosis centers have made a diagnosis based on these images, screening results are fed into the community health service center, where patients are counselled by general practitioners, and medical advice is offered. By 2017, all 250 community health service centers in Shanghai were equipped to participate in this program, and plans had begun to build an AI-assisted DR screening system [12,13]. A convolutional neural network, a type of deep learning model [14], was applied to the problem of diagnosing DR from fundus images, with the aim of replacing retinal experts in DR diagnosis centers with the AI algorithm on a cloud-based server. Since 2020, 56 community health service centers have shifted to an AI-assisted DR screening system. In 2021, these centers screened approximately 40,000 community residents for DR by using AI. To maximize the efficiency of the Shanghai program, community health service centers coordinated voluntary screening for residents of a given community at a particular place and time. Those who were diagnosed with DR at hospitals could still participate in the free annual community screening to monitor disease progression.

Model Overview

TreeAge Pro (TreeAge Software) was used to build a decision-analytic Markov model to compare the actual cost, effectiveness, and utility of manual grading telemedicine screening and AI-based assessment for DR (Multimedia Appendices 1-4). The incremental cost-effectiveness ratio (ICER) and incremental cost-utility ratio (ICUR) were calculated as the primary results. The effectiveness was defined as years without blindness per 100,000 people with DM, and the utility was evaluated by quality-adjusted life years (QALYs). Although all residents with DM could participate in our community-based screening, the majority were older people [15,16]; therefore, a hypothetical cohort of community residents with DM was followed in the model from the age of 65 years through a total of 30 one-year Markov cycles [5]. The characteristics of the simulated cohort were extracted using the Shanghai Digital Eye Disease Screening Program (Table 1).

Table 1. Characteristics of the simulated cohort and comparisons between community health centers using artificial intelligence and those using manual grading.

	All CHCs[a]	CHCs using artificial intelligence	CHCs using manual grading	*P* value
Community health center characteristics[b], mean (SD)				
Number of full-time or part-time ophthalmologists	1.1 (0.7)	1.1 (0.5)	1.2 (0.7)	.62
Annual numbers of ophthalmology outpatients	6248.6 (6019.0)	6774.8 (6238.2)	6016.2 (5946.4)	.54
Screened residents' characteristics[c]				
Age (years), mean (SD)	69.3 (7.2)	69.8 (6.9)	68.8 (7.4)	<.001
Sex (male), n (%)	15,032 (46.0)	7225 (46.1)	7807 (45.8)	.60
Duration of diabetes (years), mean (SD)	10.3 (7.7)	9.8 (8.0)	10.7 (7.3)	<.001
Visual acuity of right eye (logMAR), mean (SD)	0.4 (0.4)	0.4 (0.4)	0.3 (0.4)	<.001
Visual acuity of left eye (logMAR), mean (SD)	0.4 (0.4)	0.4 (0.4)	0.3 (0.4)	<.001

[a] CHC: community health center.

[b] In 2019, we conducted an investigation of the ophthalmic resources in Shanghai. Out of 250 community health centers, 111 were randomly selected. After matching with the Shanghai Digital Eye Disease Screening program data, 34 community health centers using artificial intelligence and 77 community health centers using manual grading–based telemedicine screening were investigated. We compared both these groups to see whether the community health centers' characteristics were different between those choosing new technology and those who did not.

[c] A total of 32,695 residents with diabetes were screened in the Shanghai Digital Eye Disease Screening program. Among them, 15,663 residents were in the community health centers with artificial intelligence, and the rest 17,032 were in the community health centers with manual grading. We compared the residents' characteristics in both groups of community health centers. Although some residents' characteristics were significantly different owing to the large sample size in the 2 groups, the differences were not clinically meaningful. Therefore, it can be assumed that there is no practical difference between the 2 groups.

Individuals were enrolled as healthy (free from DR) or unhealthy (experiencing DR) and could die due to any reason. According to the English National Screening Program for Diabetic Retinopathy, a Markov model was constructed that included non-STDR, STDR, and DME [5,15-17]. The category was assigned based on the DR grade in the worse eye. During each 1-year cycle, an individual had a risk of progressing to the more severe stage or staying in the same stage. However, the model does not allow returning to an earlier stage even with treatment because of the nature of the disease. Moreover, the treatment can only decrease the probability of progression to the next stage. The prevalence of DR, the incidence of DR (including STDR and DME), transition probabilities, characteristics of DR screening tests, referral and treatment compliance, utility, mortality, and other relevant parameters were collected from published studies specific to Shanghai, other cities in China, and other Asian regions, as well as unpublished data sources (eg, Shanghai Digital Eye Disease Screening Program). The costs of screening, ocular examinations, and treatment were all derived from a real-world eye disease screening program in Shanghai and the unified health care service pricing of the Shanghai Municipal Health Commission. The parameters used in the basic analysis and the ranges used in the sensitivity analyses are listed in detail in Multimedia Appendices 1-4.

Overview of the Screening Strategies

Manual Grading–Based Telemedicine Screening

We invited the entire population with DM living in communities to participate in the DR screening program at local community health centers. All the participants underwent a series of screening tests conducted by trained general practitioners, ophthalmic technicians, optometrists, and ophthalmologists. The screening included a vision acuity test, refraction measurement by an autorefractor, and fundus photography using a non–mydriatic fundus camera. The data were transferred to the corresponding designated diagnosis center through a telemedicine platform after the completion of all the tests. After all the participants in 1 community health center completed the annual screening, the community health center contacted the designated diagnosis center, and 2 retinal experts (ophthalmologists) began to make the diagnosis based on retinal photography. In 2 weeks, screening results were provided as feedback to the community health center, where residents could receive medical advice from the general practitioners. Finally, patients with suspected STDR were referred to specialized ophthalmic hospitals or tertiary hospitals for a detailed re-examination to confirm the diagnosis (Multimedia Appendix 5 shows the screening and referral pathway). Those who were confirmed to have STDR were assumed to receive appropriate treatment and routine clinical care according to the severity of DR.

AI-Assisted DR Telemedicine Screening

We invited the entire population with DM living in the community to participate in the DR screening program at the local community health center. The screening process was the same as that described for the manual grading–based telemedicine screening. However, after all the screening tests were completed, the data were transmitted to the AI algorithm on a cloud-based server center through the telemedicine platform. The screening results were provided as feedback immediately. Further management of patients with suspected STDR was the same as that described for manual grading–based telemedicine screening.

Prevalence and Transition Probabilities

Data on the prevalence and incidence of DR, DME, and STDR were collected from published studies in Shanghai [15,18]. Because Jin et al's [18] study only reported the 5-year incidence of STDR and DME, the 1-year incidence was calculated based on the formula: $r = -\log(1 - p)/t$, where r represents the 1-year incidence and p represents the cumulative incidence over time interval t [19]. Other transition probabilities were obtained from published studies specific to China, and if few data were available for Chinese patients, data from other Asian regions were used. We searched PubMed and China National Knowledge Infrastructure by using the following combinations of terms: "diabetic retinopathy" AND "progression" OR "transition" AND "Chinese" OR "China."

Screening and Intervention Costs

Our study included both direct and indirect costs and analyzed them from a societal perspective. Direct medical costs comprised the charges of screening, examination, and treatment. Direct nonmedical costs consisted of transportation costs related to hospital visits, and indirect costs consisted of family members' time associated with the visits and their wage loss. All costs were collected in Chinese yuan and then converted into US dollars at an exchange rate of CNY 6.90 per dollar [20]. All cost data are listed in Multimedia Appendices 4 and 6-8.

The screening costs were determined based on the Shanghai Digital Eye Disease Screening Program. The screening costs consisted of the purchase and maintenance costs of equipment, labor costs of medical personnel, transportation fees, and income loss for residents. We calculate the annualized cost for fixed assets by assuming a life span of 5 years and no salvage value. The construction and maintenance costs of the telemedicine platform were based on the Shanghai Digital Eye Disease Screening Program. Based on our field observations, it took 6.2, 3, 3.3, and 4.8 minutes on average for 1 participant to complete registration, visual acuity test autorefraction, and retinal photography, respectively. Theoretically, a team with 4 optometrists could screen approximately 100 participants per day, but under real-world working conditions, this is nearly 30 per day. As the participants in our model were older than 65 years, we assumed that they did not incur wage loss. Moreover, we did not include wage loss for the accompanying family members in the screening costs. Therefore, the total costs per person for manual grading–based and AI-based telemedicine screening were US $10.10 and US $9.60, respectively. Multimedia Appendix 6 shows the detailed composition of the screening costs.

To calculate the costs of the detailed re-examinations after referral, direct medical costs consisted of the costs of ocular examinations and equipment and wages for medical personnel; direct nonmedical costs comprised transportation fees related to the visits; and indirect costs included 1 accompanying family member's wage loss for time spent and per capita daily income in Shanghai in 2020. The examination costs were the unified pricing of the Shanghai Municipal Health Commission. Because public hospitals are nonprofit institutions, the money from these fees is mainly used to subsidize the cost of health care services. Hence, prices in public hospitals can be used to estimate the direct medical costs. Detailed information on the hospital-based examination costs is provided in Multimedia Appendix 7. It was assumed that the wage loss of the accompanying family member for referral was 0 because the majority of them were older than 65 years.

For treatment costs, direct medical costs included the costs of treatment, equipment, and wages for medical personnel; direct nonmedical costs consisted of costs of transportation related to the visits; and indirect costs included 1 accompanying family member's wage loss based on time spent and per capita daily income in Shanghai in 2020. In the first year, patients with DME were assumed to have received 3 antivascular endothelial growth factor injections. Photocoagulation or vitrectomy was administered to patients with severe nonproliferative DR or proliferative DR. In the follow-up years, an average of 1 antivascular endothelial growth factor injection was administered, and an annual outpatient review was required for patients with STDR. Direct medical costs were estimated using the prices of health care services in public hospitals. The total economic burden for blind patients in the first year was estimated to be US $8920, which included 53.2% direct medical costs, 6.4% direct nonmedical costs, and 40.4% indirect costs (loss of labor resources for family members and low-vision services costs), and there were only indirect costs in the follow-up years [5,21]. Detailed information on the treatment costs is provided in Multimedia Appendix 8.

Utility and QALYs

We estimated the utility values for each DR stage (seen in Multimedia Appendix 9) to calculate QALYs. Utility values were based on published studies from China and other Asian countries [21,22]. Because the residents who participated in the screening should have diabetes, utility was assumed to be 0.87 but not 1.0 for people without DR, 0.79 for those with non-STDR, and 0.7 for those with STDR (including severe nonproliferative DR, proliferative DR, and DME). The utility value for people with blindness was assumed to be 0.55 [22]. All the values for the base case and sensitivity analyses are listed in Multimedia Appendix 3.

Compliance

Compliance with referral to specialized ophthalmic hospitals or tertiary hospitals for a full examination among patients screened for signs of STDR was assumed to be 50.4% for manual grading–based telemedicine screening, according to our investigation in Shanghai [23]. However, compliance with AI-based telemedicine screening was unclear. Because only 1 published study suggested that adopting an AI-assisted diagnosis model in DR screening may impact the participants' adherence to ophthalmic care [24], the evidence is insufficient. Therefore, we assumed that compliance with referral in AI-based telemedicine screening was the same as that in manual grading–based telemedicine screening, while we set a wide range (±25%) for sensitivity analysis (Multimedia Appendix 3).

Screening Accuracy

The accuracy of AI-based telemedicine screening was extracted from published studies specific to the AI-assisted screening model conducted in Shanghai based on the current dominant architecture of convolutional neural networks (Multimedia Appendix 10) [25]. Briefly, the sensitivity was 80.47% (95% CI 75.07%-85.14%) and the specificity was 97.96% (95% CI 96.75%-98.81%) for STDR [25]. In our screening program, 2 experienced ophthalmologists were employed to make the diagnoses based on the retinal images. Furthermore, the accuracy of the manual grading–based telemedicine screening was assumed to be 100%, which was in accordance with the DR diagnosis criteria [8,9,26,27]. However, as described in some other studies, since trained graders instead of ophthalmologists performed the grading and diagnosis [5,7] in the sensitivity analysis, we adopted the accuracy range of the manual grading based on the Singaporean study (Multimedia Appendix 3) [7].

Other Parameters

The natural age-specific mortality rates of the general Chinese population reported by Zhang and Wei [28] were used in this study. Increased odds of mortality were assumed for people without DR but with DM, non-STDR, STDR, and blindness (Multimedia Appendix 3) [29,30]. Both costs and health state utilities were discounted at a 3.5% annual rate in the base analysis, following the National Institute for Health and Care Excellence recommendations [31]. For the cost-effectiveness threshold, 2 thresholds representing cost-effectiveness and high cost-effectiveness were used according to the World Health Organization recommendations [5,21]. Among the interventions improving the patients' utilities, those that cost less than the gross domestic product (GDP) per capita are defined as highly cost-effective, those that cost 1-3 times the GDP per capita are defined as cost-effective, and those that cost more than 3 times the GDP per capita are determined as not cost-effective [32]. On the contrary, among the interventions reducing the participants' utilities, among those saving costs higher than 3 times, the GDP per capita was defined as highly cost-effective; among those saving between 1 and 3 times, the GDP per capita was defined as cost-effective; and those costing less than the GDP per capita were determined as not cost-effective [32]. As the GDP per capita in Shanghai in 2020 was reported to be US $22,600, the thresholds in this study were defined as US $22,600 and US $67,800 [33].

Outcomes

The ICER and ICUR were calculated as the difference in the total costs between the AI-assisted and manual grading telemedicine screening divided by the difference in the total years without blindness and the QALYs between the 2 conditions, respectively. Values for the AI-assisted screening cohort minus those for the manual grading screening cohort, which were set as the baseline, were calculated as the differences.

Sensitivity Analysis

Extensive 1-way deterministic and probabilistic sensitivity analyses were performed to calculate the uncertainties of the base-case results. A variation of 10% was adopted because probability-related statistics (ie, utility, prevalence, sensitivity, specificity, transition probability, and compliance) were mainly derived from previously published studies. For the influence of AI use on compliance with referral, a range of 25% was used. A large floating range of 50% was adopted for these costs. In addition, we adopted the accuracy range for manual grading according to the Singaporean study (Multimedia Appendix 3) to account for the influence of trained graders performing the grading and diagnosis instead of retinal experts [7]. A probabilistic sensitivity analysis was conducted using Monte Carlo simulation for 10,000 simulations to assess the robustness of the base case analysis. Beta distributions were adopted for probability-related data and utility values, gamma distributions were used for costs, and log-normal distributions were used for odds ratios. The methods and results conformed to the Consolidated Health Economic Evaluation Reporting Standards (2022) (Multimedia Appendix 11).

Ethics Approval

This study was mainly based on the secondary analyses of published data. Written informed consent was obtained from all the participants. All the study data were anonymous. There were no compensation fees for the participants. This study was approved by the Institutional Review Board of the Shanghai General Hospital (2022SQ272) and Shanghai Eye Diseases Prevention and Treatment Center (2022SQ007).

Results

The cost-effectiveness and cost-utility analyses showed that AI-based telemedicine screening was dominated by manual grading–based telemedicine screening in Shanghai (Table 2). In the manual grading–based telemedicine screening, a community resident with DM would incur a total cost of US $3265.40, including screening, hospital referral for confirmation, and treatment as needed, with 9.83 years without blindness and 6.753 QALYs. In the AI-based telemedicine screening, a community resident with DM would incur a total cost of US $3182.50, with 9.80 years without blindness and 6.748 QALYs. Therefore, compared with the cost of manual grading–based telemedicine screening, that of the AI-based telemedicine screening model was 2.5% lower, while the years without blindness was 0.3% less, and the QALYs were 0.1% less.

Table 2. Base-case cost-effectiveness and cost-utility results[a].

	Costs per person (USD)	Incremental costs per 100,000 people screened (USD)	Years without blindness per person	Incremental years without blindness per 100,000 people screened	QALY[b] per person	Incremental quality-adjusted life years per 100,000 people screened	ICER[c] (USD)	ICUR[d] (USD)
AI[e]-assisted model	3182.47	–8,289,840.65	9.80	–3121.32	6.748	–544.78	2553.39	15,216.96
Manual grading	3265.37	N/A[f]	9.83	N/A	6.753	N/A	N/A	N/A

[a] Costs, years without blindness, and quality-adjusted life years are lifetime values per person, whereas incremental costs, incremental years without blindness, incremental cost-effectiveness ratio, incremental quality-adjusted life years, and incremental cost-utility ratio are calculated against the manual grading–based telemedicine screening scenario per 100,000 people screened.

[b] QALY: quality-adjusted life year.

[c] ICER: incremental cost-effectiveness ratio.

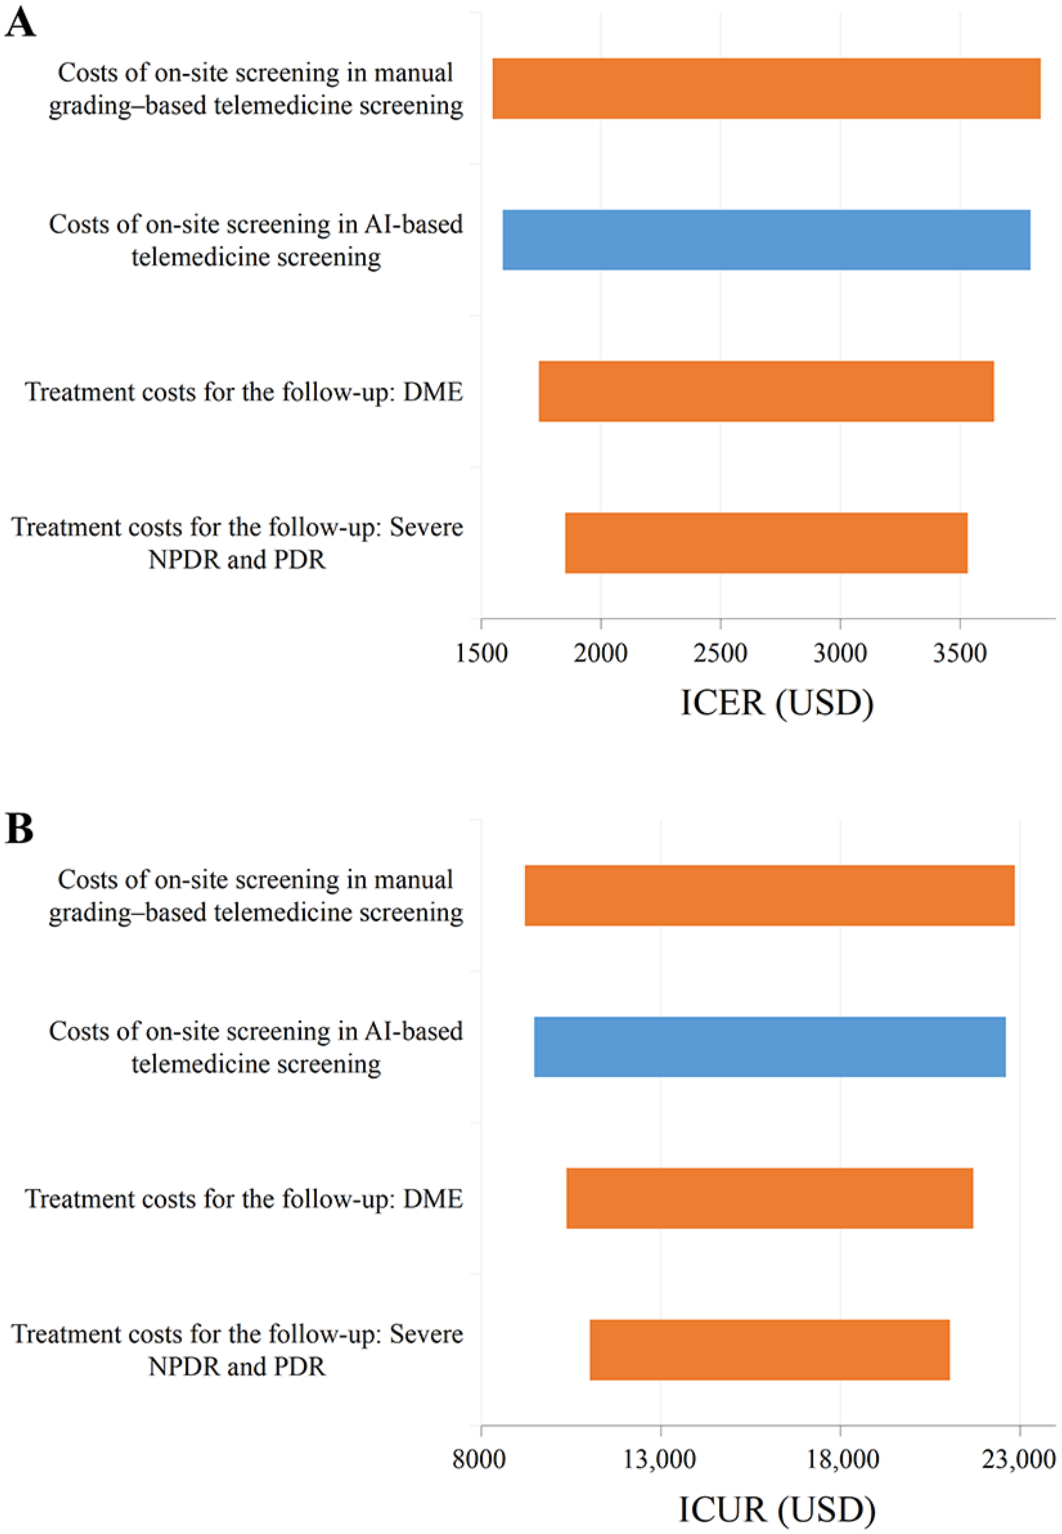
[d] ICUR: incremental cost-utility ratio.

[e] AI: artificial intelligence.

[f] N/A: not applicable.

Our results showed that by replacing manual grading–based telemedicine screening with AI-based telemedicine screening, 1 participant could save US $15,216.96 but needed to lose 1 more QALY (ICUR=US $15,216.96), indicating that AI-based telemedicine screening was not cost-effective as in Shanghai in 2020; at least US $22,600 (GDP per capita) should be saved if 1 more QALY is lost due to the shift in interventions. A 1-way deterministic sensitivity analysis of cost-effectiveness and cost-utility analyses indicated that the impact of the adoption of AI on compliance with referral, costs of on-site screening in manual grading–based telemedicine screening, costs of on-site screening in AI-based telemedicine screening, treatment costs for the follow-up of patients with DME, and treatment costs for the follow-up of patients with severe nonproliferative DR and proliferative DR were the 5 most influential variables. In particular, according to the cost-utility analysis, if the adoption of AI could improve compliance with referrals by 7.5%, the AI-assisted model might be cost-effective; if compliance was improved by 17.5%, the AI-assisted model might be highly cost-effective; and if compliance was improved by 25%, the AI-assisted model might be the absolutely dominant strategy, as it could save costs and increase the years without blindness and QALYs (Multimedia Appendix 12). Moreover, the increase in the costs of on-site screening in manual grading–based telemedicine screening and the decrease in the costs of on-site screening in AI-based telemedicine screening might help the AI-based telemedicine screening to be cost-effective (Figure 1). The detailed sensitivity analysis results of the other parameters are shown in Multimedia Appendices 13 and 14.

Figure 1. One-way deterministic sensitivity analysis (Tornado diagram). A. One-way sensitivity analysis of cost-effectiveness. B. One-way sensitivity analysis of cost-utility. Since negative values of incremental cost-effectiveness ratio or incremental cost-utility ratio might occur due to the change of compliance with referral after the adoption of artificial intelligence (multiplier), detailed results have been shown in Multimedia Appendix 12 separately. Therefore, in this Tornado diagram, the impact of the change of compliance with referral after the adoption of artificial intelligence (multiplier) is not shown. AI: artificial intelligence; DME: diabetic macular edema; ICER: incremental cost-effectiveness ratio; ICUR: incremental cost-utility ratio; NPDR: nonproliferative diabetic retinopathy; PDR: proliferative diabetic retinopathy.



Probabilistic sensitivity analysis showed that the base-case ICER and ICUR were robust to randomly distributed parameters (Figure 2). We obtained cost-effectiveness acceptability curves by taking 10,000 random draws (Figure 3). This means that when both AI-based and manual grading–based telemedicine screening were available, manual grading–based telemedicine screening was the dominant strategy in 60.6% of the simulations under the threshold of GDP per capita (US $22,600) and in 84.5% of the simulations under the threshold of 3 times the GDP per capita (US $67,800).

Figure 2. Probabilistic sensitivity analysis. A. Probabilistic sensitivity analysis of cost-effectiveness. B. Probabilistic sensitivity analysis of cost-utility. GDP: gross domestic product.

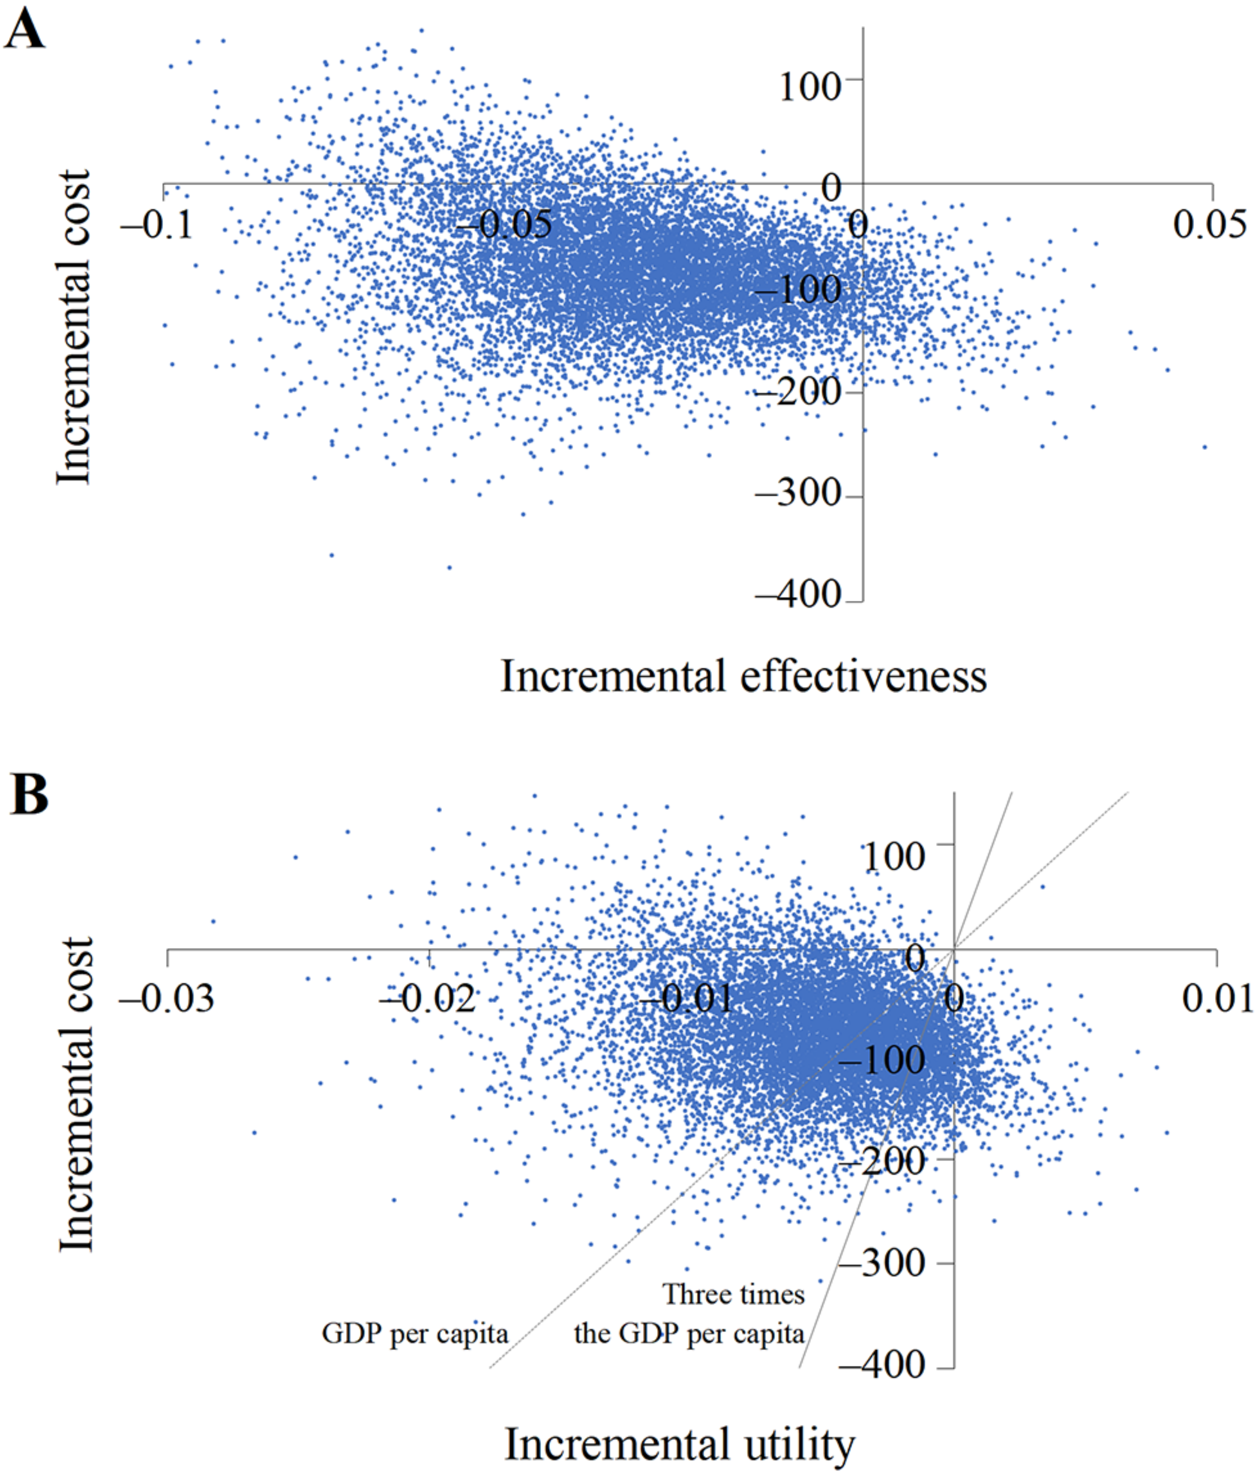


Figure 3. Cost-effectiveness acceptability curves. AI: artificial intelligence; GDP: gross domestic product.

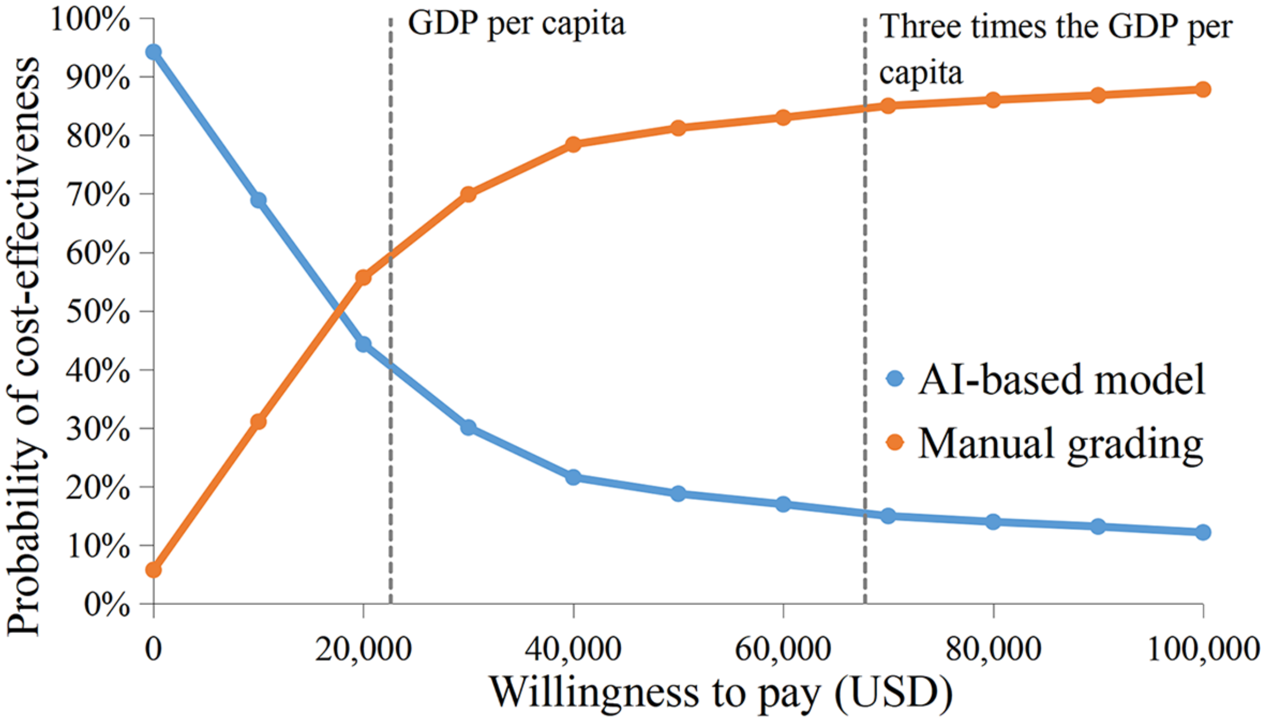

Discussion

Principal Findings

This study presents one of the first health economic evaluations in the context of low labor costs in an LMIC setting of competing telemedicine models for community-based DR screening using manual grading and AI models. In line with previous studies [7,8], our analysis was based on an established telemedicine screening program. We showed that, in this context, the value of AI-based telemedicine DR screening depended heavily on the referral compliance of patients with suspected STDR. If this compliance did not increase, AI-based telemedicine DR screening would not be more cost-effective than manual grading–based telemedicine DR screening because it would decrease the long-term screening effectiveness and individuals' health utility and not save enough costs.

Prior studies in Singapore and the United Kingdom [7,8] showed that replacing manual grading with an AI model for DR screening led to a 12%-20% cost reduction. A study in Scotland reported an even greater cost reduction of 46.7% [9]. These studies were conducted in high-income countries in the context of high labor costs. However, China's national conditions differ from those in high-income countries. One of the most important differences is that the labor costs of the medical staff are much lower in China. For example, in Singapore, the labor cost for DR grading is US $26 per participant [7], which is over 20 times that of the labor cost for manual grading in Shanghai. Consequently, in the context of low labor costs, a reduction in screening costs resulting from the use of AI solutions is limited in China.

In the Shanghai program, the on-site screening cost for 1 participant, including screening examinations and diagnosis, was US $10.10 in the manual grading model and US $9.60 in the AI-assisted model—a reduction of only 5%. Moreover, the labor costs of the medical staff in our screening program were among the highest in China. For example, according to the Wenzhou ophthalmologic screening program, the labor cost for on-site screening examinations and diagnosis of glaucoma was US $1.70 per participant, which was about a quarter of the labor costs in our Shanghai program (US $7.20 per participant for manual grading–based telemedicine screening, Multimedia Appendix 6) [21], and according to the Finance Department and Procurement Center of Beijing Tongren Hospital, Beijing Tongren Eye Centre Ocular Reading Centre, and China Intelligent Ophthalmology Big Data Research Center, the labor costs for on-site screening examinations and diagnosis were US $1.75 per participant for traditional face-to-face screening and US $0.80 per participant for manual grading–based telemedicine screening [5], which is only one-ninth of the labor costs in our Shanghai program (US $7.20 per participant for manual grading–based telemedicine screening, Multimedia Appendix 6). Because the main difference between the cost components of the AI-assisted model and those of the manual grading model is that equipment and telemedicine platform costs replace labor costs, in settings where labor costs are extremely low, cost reduction via the adoption of AI is expected to be even lesser. Therefore, AI-assisted DR screening is less cost-effective in other urban areas of China.

Our sensitivity analysis confirmed these results. The on-site screening costs of both manual grading and AI-assisted models are among the most influential variables. An increase in the on-site screening costs of manual grading by 50% or a decrease in the on-site screening costs of the AI-assisted model by 50% may help AI-based telemedicine screening be cost-effective. In other words, the gap between the on-site screening costs of the manual grading model and the AI-assisted model is the key point. Moreover, the cost of AI software was only 7% of the on-site costs in AI-based telemedicine screening (Multimedia Appendix 6). Therefore, even if the AI software were completely free, a 50% reduction in the on-site screening costs of the AI-assisted model would not be achieved. As a result, unless the labor costs of medical staff increase dramatically in the future, the AI-assisted model will be hardly cost-effective in Shanghai, holding all the other conditions constant.

However, there was one exception to this. Our sensitivity analysis shows that if the referral compliance of patients with suspected STDR increased after the adoption of AI even to a small extent, then the AI-assisted model would be cost-effective. A study in Missouri [24] suggested that after the adoption of the automated retinal image assessment system, which is based on AI, the rates of completed referral eye examinations at 3, 6, and 12 months after screening increased from 9.4% to 32.6%, from 13.4% to 46.7%, and from 18.7% to 55.4%, respectively [24]. However, relevant evidence is still inadequate; therefore, it is difficult to determine whether this improvement is an isolated case. Previously, we implemented a discrete choice experiment in Shanghai to measure individuals' preferences for AI-based screening [34]. The results suggested that the impact of the adoption of AI on individuals' preferences may be bidirectional. On the one hand, algorithm aversion should be noted, which means that compared to manual grading, the residents were in disfavor of the AI-assisted screening technology [34,35]. On the other hand, the immediate feedback of retinal screening results by the adoption of AI could increase the individuals' preferences and have profound effects on participants' follow-up behavior [24,34]. Nevertheless, there is still a lack of empirical studies on the association between the results of feedback efficiency and residents' referral compliance.

This study has several strengths. This study may provide a reference for policy making in planning community-based DR screening in LMICs by modelling 2 practical telemedicine screening models for DR by using real-world data from an ongoing program in urban China. In addition, we conducted a sensitivity analysis of our models within wide ranges and identified the most influential variables affecting the decision to use AI and manual grading in telemedicine screening. Therefore, our conclusions provide practical value in the policy-making process regarding when to deploy AI-assisted diagnostic technology.

Limitations

Our study had several limitations despite its numerous strengths. Most notably, we only compared the models for centralized screening. Other models must also be considered going forward. For example, in Shanghai, some community health service centers are beginning to provide DR screening as part of their outpatient services for patients with diabetes. This change in the model may impact both the costs and patients' compliance, thus altering the results of health economic evaluations such as ours. Second, our comparison is based on the premise that both human- and AI-based models are available and affordable. However, in some remote regions, due to the lack of human resources, manual screening for eye disease may be impractical, and AI-based screening, if available, may be the only option. Third, our study is mainly based on empirical data from Shanghai; therefore, it cannot be representative of the whole of China because of the huge regional and medical care differences between urban and rural areas. Therefore, there is an urgent need for more extensive and in-depth studies. However, as we have discussed above, the labor costs of medical staff in Shanghai are among the highest in China, and AI-based telemedicine screening will become even more less cost-effective if the labor cost of medical staff is further reduced. Therefore, our findings can be extrapolated within the Chinese context.

Conclusion

Our study may provide a reference for policy making in planning community-based telemedicine screening for DR in LMICs. Our findings indicate that unless the referral compliance of patients with suspected STDR increases, the adoption of the AI model may not further improve the value of telemedicine screening compared to that of manual grading in LMICs. The main reason is that in the context of low labor costs, the direct health care costs saved by replacing manual grading with AI are limited, and screening effectiveness will decrease. In conclusion, our study suggests that the magnitude of the value generated by this technology replacement depends mainly on 2 aspects. The first is the extent of direct health care costs reduced by using AI, and the second is the change in health care service utilization caused by using AI. Therefore, our research also provides analytical ideas for other health care sectors in addition to eye care when deciding whether to use AI.
