This study has limitations. Firstly, all data were self-reported; many studies have commented on the underreporting of alcohol consumption during pregnancy by mothers [44,45]. Our calculations of AAC need to be interpreted with caution, as the retrospective manner in which study participants were interviewed made it difficult to collect exact, day-to-day measurements of the quantity, frequency, and type of alcoholic beverage consumed.

As mentioned above, our sample size was also limited and not nationally representative of the United States, which may have resulted in sampling bias owing to the clinical locations where patients were recruited for the CIFASD project. This is likely the reason why the prevalence of pregnant drinkers among certain races and ethnicities in our sample differed from that of previous studies that used nationally representative data sets, such as the NBDPS or PRAMS [42]. Due to the manner in which the CIFASD collected data at certain sites (eg, word of mouth, advertisements in tribal and community health centers, and existing patients at referral clinics), the data on the prevalence of FAS and pregnant drinkers and nondrinkers by race or ethnicity presented in Table 1 should not be interpreted as representative of the general United States or AI/AN population. Among AI/AN people, FASDs are widely recognized as a “major public health priority” [46], since higher patterns of alcohol consumption result in a higher prevalence of FASDs compared to the general population [47].

The small number of FAS-diagnosed individuals (n=2) in the AI/AN sample (n=23) is reflected by the highly imprecise PR estimate for AI/AN individuals (PR 9.44, 95% CI 1.78-50.09). In the United States, AI/AN individuals are only around 2% of the population (for a total of approximately 5.2 million people) [48], and only 14 states (including New Mexico, where the CIFASD collected data for this study) have more than 100,000 AI/AN residents [49]. FAS remains a major concern for the AI/AN community, and previous studies have noted that AI individuals have 3 times the rate of fetal alcohol births [50], possibly because of polymorphisms related to aldehyde dehydrogenase and acetaldehyde dehydrogenase genes found in AI populations [51].

However, until more data are collected for this community, we believe that caution is warranted in ascribing racial disparities in FAS diagnosis to genetic or biological susceptibility [51]. For example, the high prevalence of alcohol use disorders in AI/AN groups has been shown to be driven by primarily nonbiological factors [52].

Furthermore, previous studies have highlighted the importance of considering immigration history and its interaction with race and ethnicity [53]. Trends in child health in the United States, especially with regard to Hispanic- or Asian-origin populations, may be influenced by immigration status and extent of acculturation [53]; for example, relative to United States–born women, it is believed that non–United States–born women are less likely to initiate early prenatal care (PNC) or receive adequate PNC due to lower rates of insurance coverage and patient-provider communication gaps [54]. The CIFASD data set does not include information on maternal immigration or health insurance status, and we encourage future studies to explore the interaction between such factors and FAS onset, as mothers of children who have FAS are more likely to be without PNC, be on Medicaid at childbirth, and potentially have different health-related behaviors, depending on naturalization status [55].

Because of the small sample size of individuals with FAS at different clinical locations, as seen in certain parts of our analyses (ie, the log-binomial analysis of FAS individuals from Minnesota University [n=0] and the subgroup analysis of other races [n=2] for FAS onset associated with a 1-gram increase in AAC), some PRs could not be calculated. In future studies with larger sample sizes, we hope that there will be more information on FAS incidence, so that quantitative analyses with various stratifications of variables are possible.

Conclusions

The current IOM guidelines for FASD diagnosis recommend that racial/ethnic variations in the expression of key features of FASDs be carefully examined, if possible, for the detection of minor physical variations [56]. However, more research that takes into consideration drinking behaviors and cultural drinking norms among each racial/ethnic group in the United States is warranted to determine whether the onset of FAS and related disabilities is biological or behavioral.

Acknowledgments

We thank the National Institute on Alcohol Abuse and Alcoholism Collaborative Initiative on Fetal Alcohol Spectrum Disorder for providing us with the dysmorphology (U24AA014815), neurobehavior (U01AA014834), and management (U01AA014809) data sets used in this project. We thank Leah Wetherill for providing us with her insight and guidance. SHL received a scholarship from Brain Korea 21 FOUR Project funded by National Research Foundation (NRF) of Korea, Yonsei University College of Nursing.

Data Availability

Our agreement with the Collaborative Initiative on Fetal Alcohol Spectrum Disorder for accessing the CIFASD database does not include authorization of access to a third party. Request for database access should be addressed to CIFASD’s data committee [57].

Conflicts of Interest

None declared.

Abstract

Background: Compared with adults with normal glucose metabolism, those with prediabetes tend to be frail. However, it remains poorly understood whether frailty could identify adults who are most at risk of adverse outcomes related to prediabetes.

Objective: We aimed to systematically evaluate the associations between frailty, a simple health indicator, and risks of multiple adverse outcomes including incident type 2 diabetes mellitus (T2DM), diabetes-related microvascular disease, cardiovascular disease (CVD), chronic kidney disease (CKD), eye disease, dementia, depression, and all-cause mortality in late life among middle-aged adults with prediabetes.

Methods: We evaluated 38,950 adults aged 40 years to 64 years with prediabetes using the baseline survey from the UK Biobank. Frailty was assessed using the frailty phenotype (FP; range 0-5), and participants were grouped into nonfrail (FP=0), prefrail ($1 \leq FP \leq 2$), and frail ($FP \geq 3$). Multiple adverse outcomes (ie, T2DM, diabetes-related microvascular disease, CVD, CKD, eye disease, dementia, depression, and all-cause mortality) were ascertained during a median follow-up of 12 years. Cox proportional hazards regression models were used to estimate the associations. Several sensitivity analyses were performed to test the robustness of the results.

Results: At baseline, 49.1% (19,122/38,950) and 5.9% (2289/38,950) of adults with prediabetes were identified as prefrail and frail, respectively. Both prefrailty and frailty were associated with higher risks of multiple adverse outcomes in adults with prediabetes (*P* for trend <.001). For instance, compared with their nonfrail counterparts, frail participants with prediabetes had a significantly higher risk (*P*<.001) of T2DM (hazard ratio [HR]=1.73, 95% CI 1.55-1.92), diabetes-related microvascular disease (HR=1.89, 95% CI 1.64-2.18), CVD (HR=1.66, 95% CI 1.44-1.91), CKD (HR=1.76, 95% CI 1.45-2.13), eye disease (HR=1.31, 95% CI 1.14-1.51), dementia (HR=2.03, 95% CI 1.33-3.09), depression (HR=3.01, 95% CI 2.47-3.67), and all-cause mortality (HR=1.81, 95% CI 1.51-2.16) in the multivariable-adjusted models. Furthermore, with each 1-point increase in FP score, the risk of these adverse outcomes increased by 10% to 42%. Robust results were generally observed in sensitivity analyses.

Conclusions: In UK Biobank participants with prediabetes, both prefrailty and frailty are significantly associated with higher risks of multiple adverse outcomes, including T2DM, diabetes-related diseases, and all-cause mortality. Our findings suggest that frailty assessment should be incorporated into routine care for middle-aged adults with prediabetes, to improve the allocation of health care resources and reduce diabetes-related burden.

KEYWORDS

frailty; adverse outcomes; diabetes; prediabetes; prospective study

Introduction

In 2021, the International Diabetes Federation estimated that there were more than 500 million adults with prediabetes among those aged 20 years to 79 years worldwide [1]. As an intermediate hyperglycemia state, prediabetes increases the risk of diabetes [2] and diabetes-related complications (eg, cardiovascular disease [CVD], chronic kidney disease [CKD], and dementia) [3]; the latter contributes to a large proportion of diabetes-related burden [4,5]. The latest guidelines from the American Diabetes Association (ADA) recommend annual diabetes screening for adults with prediabetes [6]. However, this is challenged by emerging evidence showing the very low rates of diabetes progression among older adults with prediabetes [7]. Conversely, middle-aged adults (ie, <65 years) with prediabetes should be monitored for adverse outcomes, which is of high value and appropriate [8].

Prediabetes is highly heterogeneous, impeding the application of a one-size-fits-all health management strategy. Recently, a simple health aging indicator—frailty—has been demonstrated to be able to predict the risk of adverse outcomes (eg, CVD and mortality) [9-12] even in the younger population [13]. Frailty is defined as a state of decreased reserve and resistance to stressors, characterized by functional decline in multiple systems [9]. Frailty and disorders of glucose metabolism share common physiological mechanisms, such as insulin resistance [14,15] and chronic inflammation [15,16]. Frailty has been found to be an important risk factor for disability [17], fracture [18], CVD [19,20], hospitalization [20], intensive care unit admission [20], and mortality [20,21] among adults with diabetes. A few studies have shown that frailty incidence is slightly higher in older adults with prediabetes compared with those with normal glucose metabolism [22]. Only 1 prospective study recently reported that frailty was positively associated with the progression of prediabetes to type 2 diabetes mellitus (T2DM), as well as higher risks of CVD and all-cause mortality, in middle-aged and older adults with prediabetes [23]. However, whether these positive associations remain in those aged less than 65 years is not yet clear. In addition, impaired glucose metabolism is also associated with higher risks of CKD [3], eye disease (eg, cataract) [24], dementia [3], and depression [25]. However, relatively little is known about whether frailty could identify middle-aged adults with prediabetes who are most at risk of these adverse outcomes.

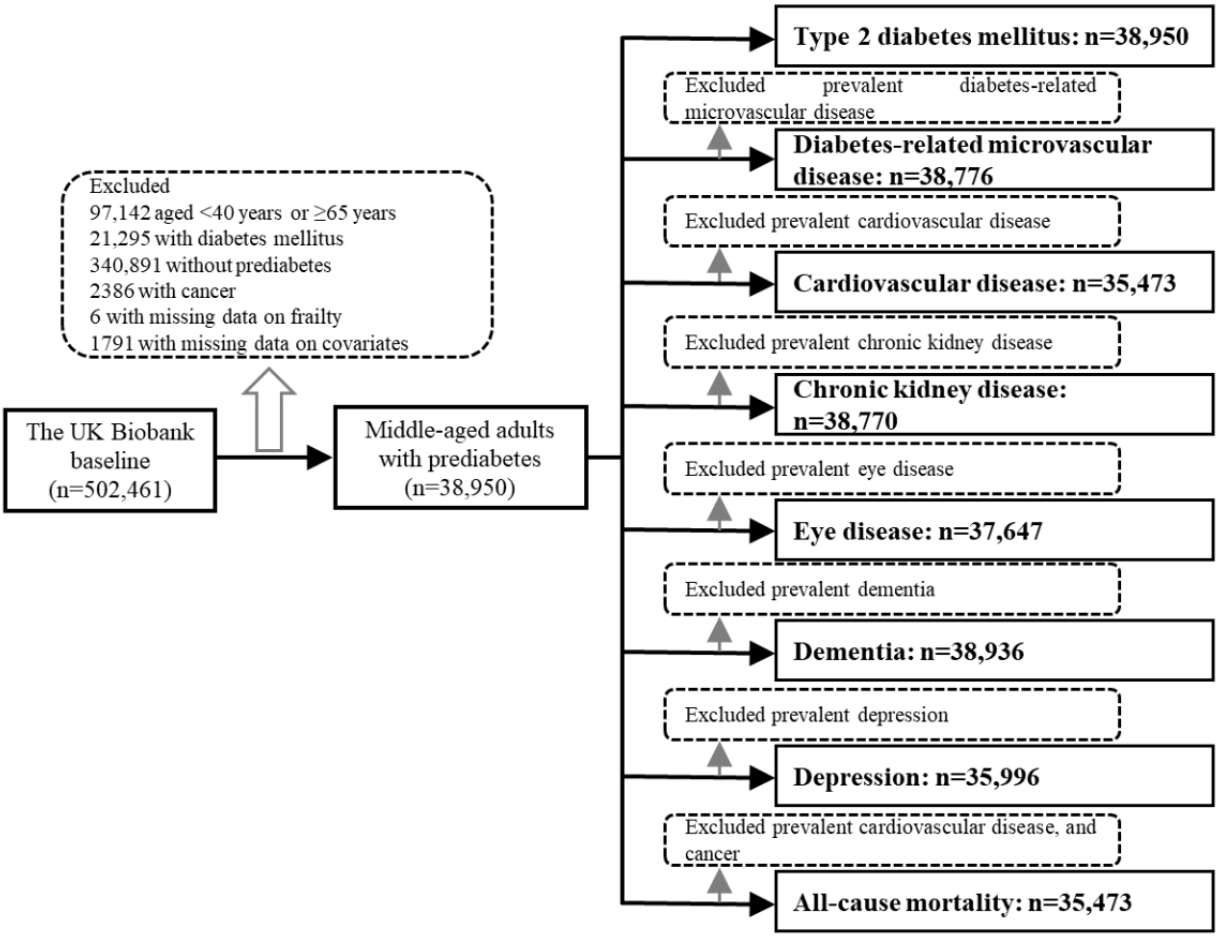
Therefore, we performed a prospective cohort study among 38,950 middle-aged adults with prediabetes from the UK Biobank (UKB). Using a widely validated frailty measurement—frailty phenotype (FP) [9]—the objective of this study was to systematically evaluate the associations of frailty with the risk of multiple adverse outcomes, including incident T2DM, diabetes-related microvascular disease, CVD, CKD, eye disease, dementia, depression, and all-cause mortality.

Methods

Study Participants

The UKB is a large-scale health research study with a long-term follow-up that began in 2006 to 2010 with the recruitment of approximately 500,000 adults in the United Kingdom [26]. Adults in the UKB were recruited through 22 assessment centers across England, Scotland, and Wales. Data were collected through a touch screen questionnaire and verbal interviews (eg, demographic, health, lifestyle variables), physical measures (eg, handgrip strength), and biological sample collection (eg, blood). Since recruitment, all adults have given consent for the UKB to follow up to determine the incidence of health outcomes through links to health-related records (eg, hospital inpatient episodes and death registrations), and only about 0.3% of the adults have been lost to follow-up because they left the United Kingdom or withdrew consent for future linkage. The protocol of the UKB is available online [27]. At baseline, there were 405,319 middle-aged adults (age: 40-64 years), of whom 43,133 had prediabetes. Prediabetes was defined by a nonfasting glycated hemoglobin (HbA_{1c}) level of 5.7% to 6.4% (39-47 mmol/mol) following the ADA criteria [6]. After the exclusion of adults with prevalent cancer (n=2386) or with missing data on frailty (n=6) and covariates (eg, ethnicity, educational level; n=1791), 38,950 middle-aged adults with prediabetes were included in the final analytic samples. Additionally, because the number of prevalent cases for each outcome varied, we assembled different analytic samples for each outcome (see details in Figure 1).

Figure 1. Flow chart of the sample for analyses.



Ethical Considerations

The UKB was approved by the North West Multi-Centre Research Ethics Committee (11/NW/0382). Written informed consent from all participants was obtained. The data used in this study were anonymized and de-identified for privacy and confidentiality protection.

Outcomes

In this study, the outcomes included T2DM, diabetes-related microvascular disease (including retinopathy, neuropathy, and nephropathy), diabetes-related macrovascular disease (ie, CVD including ischemic heart disease and stroke), CKD, eye disease (including cataract and glaucoma), dementia, depression, and all-cause mortality.

We defined prevalent and incident T2DM using a UKB algorithm that combined self-reported medical history and medication information (for the ascertainment of prevalent cases only), as well as linked hospital admissions records (Table S1 in Multimedia Appendix 1). In addition, according to the ADA criteria [6], undiagnosed prevalent T2DM cases were identified using random glucose (≥11.1 mmol/L) or HbA$_{1c}$ (≥6.5% [48 mmol/mol]) levels. We ascertained prevalent and incident cases of diabetes-related microvascular disease through linked hospital admissions records using the International Statistical Classification of Diseases and Related Health Problems, 9th version (ICD-9) and 10th version (ICD-10; Table S1 in Multimedia Appendix 1). We ascertained prevalent and incident cases of CVD, CKD, eye disease, dementia, and depression using self-reported medical history (for the ascertainment of prevalent cases only) and linked hospital admissions records using ICD-9 and ICD-10 (Table S1 in Multimedia Appendix 1). We ascertained death through linkage to national death registries. For analyses of each outcome, the time to event was calculated from the baseline (ie, the years 2006-2010) to the occurrence of the specific disease outcome, death, loss to follow-up, or end of follow-up (the year 2021), whichever came first. For instance, for analysis of incident T2DM, time to event was calculated from the baseline to the occurrence of T2DM, death, loss to follow-up, or end of follow-up, whichever came first.

Frailty Measurement

We used FP, a widely used physical frailty measurement proposed by Fried et al [9]. FP was evaluated using 5 criteria (unintentional weight loss, exhaustion, weakness, slow gait speed, and low physical activity) and was used previously in the UKB [28]. Of the 5 criteria, weakness was assessed using objectively measured handgrip strength; the other 4 criteria were assessed using a self-reported questionnaire (see details in Table 1). The FP score ranged from 0 to 5, with a higher score indicating greater frailty. Participants were categorized into nonfrail (FP score=0), prefrail (FP score≥1 and ≤2), and frail (FP score≥3), as done in previous studies [9,28].

Table 1. The 5 criteria for the frailty phenotype in the UK Biobank.

Number	Criteria description	Categories
1	Unintentional weight loss: Participants were asked “Compared with one year ago, has your weight changed?”	1: “Yes, loss weight”; 0: Others
2	Exhaustion: Participants were asked “Over the past 2 weeks, how often have you felt tired or had little energy?”	1: “More than half the days or nearly every day”; 0: Others
3	Weakness: Weakness was measured using grip strength with a Jamar J00105 hydraulic hand dynamometer (Lafayette Instrument). Participants were asked to complete a grip assessment for both hands once. The maximal value of the right and left hands was used.	1: (1) Men: ≤29 kg for BMI ≤24 kg/m^2; ≤30 kg for BMI 24.1-26 kg/m^2; ≤30 kg for BMI 26.1-28 kg/m^2; or ≤32 kg for BMI >28 kg/m^2; (2) Women: ≤17 kg for BMI ≤23 kg/m^2; ≤17.3 kg for BMI 23.1-26 kg/m^2; ≤18 kg for BMI 26.1-29 kg/m^2; or ≤21 kg for BMI >29 kg/m^2; 0: Others
4	Slow gait speed: Participants were asked “How would you describe your usual walking pace?”	1: “Slow pace”; 0: Others
5	Low physical activity: Participants were asked “In the last 4 weeks, did you spend any time doing light DIY[a] activity, heavy DIY activity, or strenuous sports?”	1: “None or light activity with a frequency of once per week or less”; 0: Others

[a] DIY: do it yourself.

Covariates

Baseline data on age, sex (female or male), ethnicity (White, mixed race, South Asian, Black, Chinese, or other background), educational level (high, intermediate, or low), occupational status (working, retired, or other), alcohol consumption (never or special occasions only, 1 to 3 times per month, 1 to 4 times per week, or daily or almost daily), smoking status (never, previous smoker, or current smoker), healthy diet (yes or no), and family history of disease (including diabetes, CVD, dementia, and depression) were collected through a questionnaire interview. The Townsend deprivation index (TDI) was calculated based on areas before participants were recruited in the UKB. BMI was calculated as measured weight/height^2 (kg/m^2).

Statistical Analyses

Baseline characteristics of the complete analyzed sample and by frailty status are presented as median (IQRs) and number (percentage) for continuous variables and categorical variables, respectively. Kruskal-Wallis tests and chi-square tests were used to compare the differences in characteristics by frailty status.

To evaluate the associations between frailty status (nonfrail, prefrail, and frail) and adverse outcomes, Cox proportional hazards regression models were performed. The Schoenfeld residuals test was used to verify the proportional hazard assumption, and no significant violation was found. We calculated hazard ratios (HRs) and corresponding 95% CIs using 2 models. Model 1 was adjusted for age and sex. Model 2 was further adjusted for ethnicity, educational level, occupational status, TDI, alcohol consumption, smoking status, healthy diet, BMI, and family history of disease based on Model 1. Additionally, we calculated HRs (95% CIs) for adverse outcomes per 1-point increase in FP score.

Several sensitivity analyses were conducted to confirm the robustness of the results. First, we compared the characteristics of included and excluded study participants. Second, to minimize the influence of reverse causality, we repeated the main analyses after excluding those without 2 years of follow-up. Third, to reduce the influence of poor health on frailty status, we repeated the main analyses after excluding participants with poor self-rated health status at baseline. Fourth, to account for the influence of missing data on results, we performed multiple imputations by chained equations [29] for missing values and repeated the primary analyses. Finally, we validated the associations between frailty and adverse outcomes among adults with T2DM. For adults with T2DM, HbA$_{1c}$ level (≥7.0% [≥53 mmol/mol] or <7.0% [<53 mmol/mol]), diabetes medication use (oral antidiabetes drug only, insulin, or neither), diabetes duration (in years), and prevalent diabetes-related microvascular disease (except for incident diabetes-related microvascular disease) were also included in Model 2.

We used SAS version 9.4 (SAS Institute) and R version 3.6.3 (2020-02-29) to conduct all statistical analyses. To account for multiple testing, we used Bonferroni correction in all analyses (P<.006).

Results

Baseline Characteristics

Among the 38,950 participants with prediabetes, the median age was 58.6 (IQR 53.1-62.0) years, and the majority were women (21,155/38,950, 54.3%) and White (34,705/38,950, 89.1%; Table 2). The prevalences of prefrailty and frailty were 49.1% (19,122/38,950) and 5.9% (2289/38,950), respectively. Prefrail and frail adults were more likely to be women, have a lower educational level, and have a higher level of TDI and BMI, compared with the nonfrail adults. Table 2 shows the detailed baseline characteristics by frailty status.

Table 2. Baseline characteristics of study participants with prediabetes by frailty status.

Variables	Total (n=38,950)	Nonfrail (n=17,539)	Prefrail (n=19,122)	Frail (n=2289)	*P* value[a]

Frailty and Risks of Adverse Outcomes in Middle-aged Adults With Prediabetes

During a median follow-up of 12 years, there were 5289 incident T2DM cases, 2657 incident diabetes-related microvascular disease cases, 3234 incident CVD cases, 1439 incident CKD cases, 3525 incident eye disease cases, 325 incident dementia cases, 1265 incident depression cases, and 2016 deaths. We found that frail participants developed more adverse outcomes than did their prefrail and nonfrail counterparts over the 12-year follow-up (Figure 2).

Table 3 shows the associations between frailty and the risks of multiple adverse outcomes in middle-aged adults with prediabetes. In the age- and sex-adjusted model, both prefrailty and frailty were associated with higher risks of all adverse outcomes (all *P* for trend <.001). After further adjusting for additional covariates, these associations remained statistically significant. When comparing prefrail participants with their nonfrail counterparts, the multivariable-adjusted HRs were 1.35 (95% CI 1.27-1.43) for T2DM, 1.29 (95% CI 1.18-1.40) for diabetes-related microvascular disease, 1.17 (95% CI 1.08-1.26) for CVD, 1.22 (95% CI 1.09-1.37) for CKD, 1.12 (95% CI 1.04-1.20) for eye disease, 1.57 (95% CI 1.23-2.01) for dementia, 1.48 (95% CI 1.30-1.68) for depression, and 1.25 (95% CI 1.14-1.38) for all-cause mortality. For frail participants, the multivariable-adjusted HRs were 1.73 (95% CI 1.55-1.92) for T2DM, 1.89 (95% CI 1.64-2.18) for diabetes-related microvascular disease, 1.66 (95% CI 1.44-1.91) for CVD, 1.76 (95% CI 1.45-2.13) for CKD, 1.31 (95% CI 1.14-1.51) for eye disease, 2.03 (95% CI 1.33-3.09) for dementia, 3.01 (95% CI 2.47-3.67) for depression, and 1.81 (95% CI 1.51-2.16) for all-cause mortality, compared with their nonfrail counterparts. Additionally, with each 1-point increase in FP score, the incidence risks of these adverse outcomes significantly increased by 10% to 42% (Model 2).

[a] Calculated to test linear trend using frailty status (3 categories) as a continuous variable.

[b] Not applicable.

[c] Model 1 was adjusted for age and sex.

[d] Model 2 was further adjusted for ethnicity, educational level, occupational status, Townsend deprivation index, alcohol consumption, smoking status, healthy diet, BMI, and family history of disease based on Model 1.

Sensitivity Analyses

The differences in characteristics between included and excluded participants were observed. Those who were excluded were more likely to be older, women, non-White, and frail (Table S2 in Multimedia Appendix 1). Robust results were generally observed when excluding the participants with less than 2 years of follow-up (Table S3 in Multimedia Appendix 1), excluding the participants with poor self-rated health status at baseline (Table S4 in Multimedia Appendix 1), or imputing missing data on frailty and covariates (Table S5 in Multimedia Appendix 1). In addition, we confirmed that frailty was positively associated with the risks of diabetes-related microvascular disease, CVD, CKD, eye diseases, dementia, depression, and all-cause mortality in middle-aged adults with T2DM, and these associations were independent of factors related to diabetes severity at baseline (Table S6 in Multimedia Appendix 1).

Discussion

Principal Findings

In a large sample of UKB participants with prediabetes, we, for the first time, demonstrated that both prefrailty and frailty were associated with higher risks of multiple adverse outcomes, including T2DM, diabetes-related microvascular disease, CVD, CKD, eye disease, dementia, depression, and all-cause mortality. Our findings support the heterogeneity of prediabetes in middle-aged adulthood and suggest that assessing frailty status among middle-aged adults with prediabetes may help to identify those who were most at risk of subsequent adverse outcomes.

We observed a nearly twice higher prevalence of frailty among middle-aged adults with prediabetes (ie, 5.9%) in this study than that in general adults (ie, 3.3%) from the UKB as well [28]. Similarly, the prevalence of frailty among older adults with diabetes [30] is almost twice as high as that in those without diabetes (20.1% vs 12%) [31]. It seems that adults with glucose metabolism disorders are experiencing an accelerated aging process [32]. Multiple age-related metabolic disturbances are present in adults with prediabetes, including chronic inflammation, hyperglycemia, insulin resistance, and β-cell dysfunction [2,16], creating a pathophysiological environment that contributes to frailty. Given the sharp increase in frailty after the age of 65 years [33], our findings suggest that there is a need for early identification of frailty, an aging indicator, in this middle-aged population with prediabetes.

To the best of our knowledge, this study provided new evidence on the associations between frailty and higher risks of a series of adverse outcomes in middle-aged adults with prediabetes. A few studies on the relationship between frailty and adverse outcomes included middle-aged adults with diabetes as part of the study sample [19,20,34]. One prospective study of 998 African Americans aged 49 years to 65 years has shown that frail adults with diabetes had an increased risk of mortality [21]. Except for this study, only 1 study conducted in middle-aged and older adults with prediabetes found that frailty was associated with the progression of prediabetes to diabetes, as well as higher risks of CVD and all-cause mortality [23]. This large prospective study (n=38,950) showed that frailty was positively associated with higher risks of more outcomes including CKD, eye disease, and dementia in middle-aged adults with prediabetes.

This study draws attention to the accelerated aging process in adults with prediabetes, which may lead to rapid diabetes progression and contribute to the development of diabetes-related complications [32]. Nutritional and pharmacological anti-aging interventions have been revealed to help mitigate or reverse the accelerated aging process [35]. A recent review suggested that the most effective and easiest intervention strategy targeting frailty is to combine strength exercise and protein supplements in primary care [36]. Thus, our findings implicate that frailty assessment might help primary care providers identify the subpopulation at higher risk of adverse outcomes even in middle-aged adults with prediabetes in communities. It is worth noting that the application of technological solutions in assessing frailty is constantly expanding [37,38]. The major types of technologies include information and telecommunications technology–based platforms, smartphones, remote monitoring, and wearable sensors and devices [39]. For example, a frailty prediction model based on a points system and integrated into a mobile app for Android phones has been developed in the clinical setting, enabling professionals to identify frailty using clinical information and further improve decision-making [40]. With the aid of these technological tools, frailty screening becomes more convenient and flexible. Next, early preventive and interventive programs targeting frailty in adults with prediabetes are urgently needed. On the one hand, they may directly help reduce the occurrence of T2DM; on the other hand, they may indirectly help reduce diabetes-related burden. Meanwhile, pharmacologic interventions or other aggressive approaches to diabetes prevention are also encouraged [41,42]. Before formal implementation, considerably more research on the effectiveness and cost-effectiveness of interventional programs in this population is required.

Strengths and Limitations

The major strengths of this study were the large sample of middle-aged adults with prediabetes, the long follow-up time, rich phenotype data, and linked hospital admissions records, enabling us to systematically evaluate the prospective associations between frailty and multiple adverse outcomes. There were several potential limitations. First, the UKB was not representative of the sampling population, and the majority of included adults were White. Also, there were differences in baseline characteristics between included and excluded participants. Thus, selection bias existed in this study, and the results may not be generalizable to populations from other countries. Second, transitions in frailty status may occur over time [43], and evidence has suggested that transitions in frailty status were associated with adverse outcomes [44]. However, repeated measurements of frailty were lacking; thus, we were unable to estimate the influence of frailty transitions on the subsequent adverse outcomes in this study. Future longitudinal studies incorporating data on frailty transition are needed. Third, multiple outcomes were considered in this study, and thus, type Ⅰ errors inevitably increased. To reduce the possibility of chance findings, we used Bonferroni correction. Finally, because of the observational study design, we could not draw a causal inference.

Conclusion

In this prospective cohort study of middle-aged UKB participants with prediabetes, both prefrailty and frailty were significantly associated with increased risks of multiple adverse outcomes, including T2DM, diabetes-related microvascular disease, CVD, CKD, eye disease, dementia, depression, and all-cause mortality. The findings underscore the importance of frailty assessment in routine care for middle-aged adults with prediabetes. Detecting frailty at an early stage (ie, accelerated aging) and implementing timely targeted interventions may help to improve the allocation of health care resources and to reduce diabetes-related burden.

Acknowledgments

This research was conducted using the UK Biobank resource under application number 61856. We wish to acknowledge the UK Biobank participants who formed the sample that made the data available. This study was supported by a grant from the National Natural Science Foundation of China (82171584); the Fundamental Research Funds for the Central Universities, Key Laboratory of Intelligent Preventive Medicine of Zhejiang Province (2020E10004); and Zhejiang University Global Partnership Fund (188170-11103). TMG is supported by the Claude D. Pepper Older Americans Independence Center at Yale School of Medicine from the National Institute on Aging (P30AG021342) and the National Center for Advancing Translational Sciences (UL1TR001863). Abstract

Background: A life-course immunization approach would enhance the quality of life across all age groups and improve societal well-being. The herpes zoster (HZ) vaccine is highly recommended for older adults to prevent HZ infection and related complications. The proportions of willingness to receive the HZ vaccine varies across countries, and various kinds of factors, including sociodemographics and individual perceptions, influence the willingness to vaccinate.

Objective: We aim to estimate the HZ vaccination willingness rate and identify factors associated with vaccine uptake willingness across all World Health Organization (WHO) regions.

Methods: A global systematic search was performed on PubMed, Web of Science, and the Cochrane Library for all papers related to the HZ vaccine published until June 20, 2022. Study characteristics were extracted for each included study. Using double arcsine transformation, vaccination willingness rates with 95% CIs were pooled and reported. The willingness rate and associated factors were analyzed by geographical context. Associated factors were also summarized based on Health Belief Model (HBM) constructs.

Results: Of the 26,942 identified records, 13 (0.05%) papers were included, covering 14,066 individuals from 8 countries in 4 WHO regions (Eastern Mediterranean Region, European Region, Region of the Americas, and Western Pacific Region). The pooled vaccination willingness rate was 55.74% (95% CI 40.85%-70.13%). Of adults aged ≥50 years, 56.06% were willing to receive the HZ vaccine. After receiving health care workers' (HCWs) recommendations, 75.19% of individuals were willing to get the HZ vaccine; without HCWs' recommendations, the willingness rate was only 49.39%. The willingness rate was more than 70% in the Eastern Mediterranean Region and approximately 55% in the Western Pacific Region. The willingness rate was the highest in the United Arab Emirates and the lowest in China and the United Kingdom. The perception of HZ severity and susceptibility was positively associated with vaccination willingness. The perceived barriers to vaccination willingness (main reasons for unwillingness) included low trust in the effectiveness of the HZ vaccine, concerns about safety, financial concerns, and being unaware of the HZ vaccine's availability. Older individuals, those having lower education, or those having lower income levels were less likely to willing to be vaccinated.

Conclusions: Only 1 in 2 individuals showed a willingness to be vaccinated against HZ. The willingness rate was the highest in the Eastern Mediterranean Region. Our findings show the critical role HCWs play in promoting HZ vaccination. Monitoring

HZ vaccination willingness is necessary to inform public health decision-making. These findings provide critical insights for designing future life-course immunization programs.

KEYWORDS

herpes zoster vaccine; willingness; associated factors; systematic review

Introduction

A life-course immunization approach would enhance the quality of life across all age groups and improve societal well-being through a healthier population [1,2]. Older adults are at high risk of being ill, being hospitalized, and dying from many vaccine-preventable diseases [3]. The World Health Organization (WHO) and health authorities in various countries have recommended several vaccines for older adults, including the seasonal influenza vaccine; pneumococcal vaccine; hepatitis B vaccine; the tetanus, diphtheria, and pertussis (Tdap) vaccine booster; and, most recently, COVID-19 vaccines [2]. The herpes zoster (HZ) vaccine is highly recommended for older adults for reducing the incidence of HZ [4].

Caused by varicella zoster virus (VZV), HZ is a distinctive syndrome occurring when immunity to VZV declines due to age or immunosuppression [5]. It presents a disproportionate risk to adults aged 50 years and over, with estimated incidence rates reaching 5.2-10.9 cases per 1000 person-years [6]. Due to the potential for serious complications, postherpetic neuralgia (PHN), neurological sequelae, HZ ophthalmicus with eye involvement, and disseminated disease, this disease has a significant impact on the quality of life [6,7]. It was reported that 5%-30% of patients with HZ are likely to develop PHN with persistent pain for more than 1 month [7].

Existing evidence supports the substantial efficacy of the HZ vaccine; a meta-analysis showed that the efficacy of the adjuvant recombinant subunit HZ vaccine is 94% when compared with the placebo [8]. Additionally, HZ vaccination was found to be cost-effective versus no vaccination for older adults in high-income countries based on health economics evaluations [9,10].

Currently, 2 types of HZ vaccines (Zostavax and Shingrix) are commonly used in over 60 countries, being recommended to adults aged ≥50 years or adults aged ≥18 years with an immunocompromised state [11]. Noticeably, HZ vaccination uptake is relatively low worldwide. In the United States, 24.1% of adults aged ≥50 years received an HZ vaccine in 2018 [12]. The coverage rates among older adults in Australia and Canada were reported to be lower than 10% [13,14]; only 1.8% of adults over 65 years old received the HZ vaccine in Turkey [15].

Vaccine uptake is positively associated with the willingness to vaccinate. The willingness to receive the HZ vaccine has been surveyed in previous studies [16-18]. However, the proportions of the willingness to receive the HZ vaccine varies across countries, ranging from 17% (China) to 90% (Australia) [16,17]. Importantly, vaccination willingness is influenced by multiple factors, which include sociodemographic, cognitive, psychologic, and politics-and-culture contexts [19]. According to recent evidence, various kinds of factors, including sociodemographics (age and income level) and individual perceptions (perception of disease susceptibility), influence HZ vaccination willingness [16-18]. Additionally, these associated factors may differ across different regions.

Summarizing and understanding the willingness to receive the HZ vaccine and its associated factors is thus essential for obtaining insights into intervention strategies to improve its uptake among older adults. It is also necessary to explore methods mitigating vaccine hesitancy among older adults, which is also an indispensable part of life-course immunization practices. However, there has only been scant attention paid to HZ vaccination willingness in the research literature. To fill this gap, this systematic review seeks to summarize the up-to-date evidence on the HZ vaccination willingness rate and identify its associated factors.

Methods

Study Design

The Preferred Reporting Items for Systematic Reviews and Meta Analyses (PRISMA) statement was used for this systematic review [20].

Search Strategy and Selection Criteria

A systematic search was conducted in 3 electronic databases (PubMed, Web of Science, and the Cochrane Library) using the following search terms: ["Herpes Zoster" OR "Herpesvirus 3" OR shingles OR zoster OR "varicellovir*" OR hhv3 OR hhv-3 OR varicella-zoster OR postherpetic] AND ["vaccin*" OR "immuniz*" OR "inocul*"]. All studies published from the inception of the databases until June 20, 2022, were included. After combining all search records, duplicate records were identified and removed. Titles and abstracts were then screened for relevance, and full texts of the included records were retrieved and reviewed.

The screening process was independently performed by 2 reviewers (authors QW and LQY) with the following inclusion criteria: (1) cross-sectional surveys or cohort studies and (2) relevance to HZ vaccine attitudes, intentions, willingness, and acceptance. There were no restrictions on language or paper type. Papers were excluded if they met any of the following criteria: (1) willingness data were not reported, (2) insufficient data were provided for pooling (at least 2 of the 3 following topics were absent: total number of surveyed individuals, number of individuals willing to receive the HZ vaccine, and willingness rate), (3) they were duplicate data or surveys, or (4) they were experimental and observational studies that reported the willingness rate after interventions. Any disagreement was resolved by discussions with a third reviewer (author LL). The review protocol is available in the International Prospective Register of Systematic Reviews (PROSPERO id: CRD42022348426).

Data Abstraction and Quality Assessment

For each included study, we extracted the following data: title, first author, journal name, published date, paper type, sampling method, study setting, study period, study population, study location, and inquiry questions (were there any assumptions, for example, free vaccination was provided). The number of surveyed individuals, the number of individuals who accepted HZ vaccination, and the willingness rate were also extracted for pooling. Additionally, influencing factors examined in each study were abstracted.

The Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) statement was used to assess the quality of the included papers [21]. Data abstraction and quality assessment were conducted by QW and LQY independently. A third researcher, LL, resolved disputes when the data extracted or quality assessment scores for papers were not consistent between the 2 initial reviewers.

Statistical Analysis

Using double arcsine transformation on 2 variables, number of surveyed individuals and number of individuals accepting HZ vaccination, we calculated and reported the pooled willingness rate and the 95% CI [22,23]. If these data were not included in the study, the number of individuals accepting HZ vaccination could be calculated by multiplying the total number by the willingness rate. Due to high heterogeneity, DerSimonian-Laird random effects were used in the calculation.

Stratified subgroup analysis was subsequently performed to explore the causes of heterogeneity according to the study characteristics (eg, sampling method, study setting, study period, and study population). Studies that shared the same characteristics were grouped together (eg, surveyed using the random sampling method or the convenience sampling method); when the characteristic was unclear, the study was labeled as “not mentioned” in the subgroup analysis. For each subgroup, the willingness rate was pooled. To examine the potential impact of the COVID-19 pandemic on the willingness to receive the HZ vaccine, we divided the study period into 2 subperiods, before the pandemic and during the pandemic. The study locations were categorized by their WHO regions and economic levels [24,25]. Due to the limited availability of data, it was difficult to further estimate the willingness rate by age group. We only reported the willingness rate among individuals aged ≥50 years in further analysis of age.

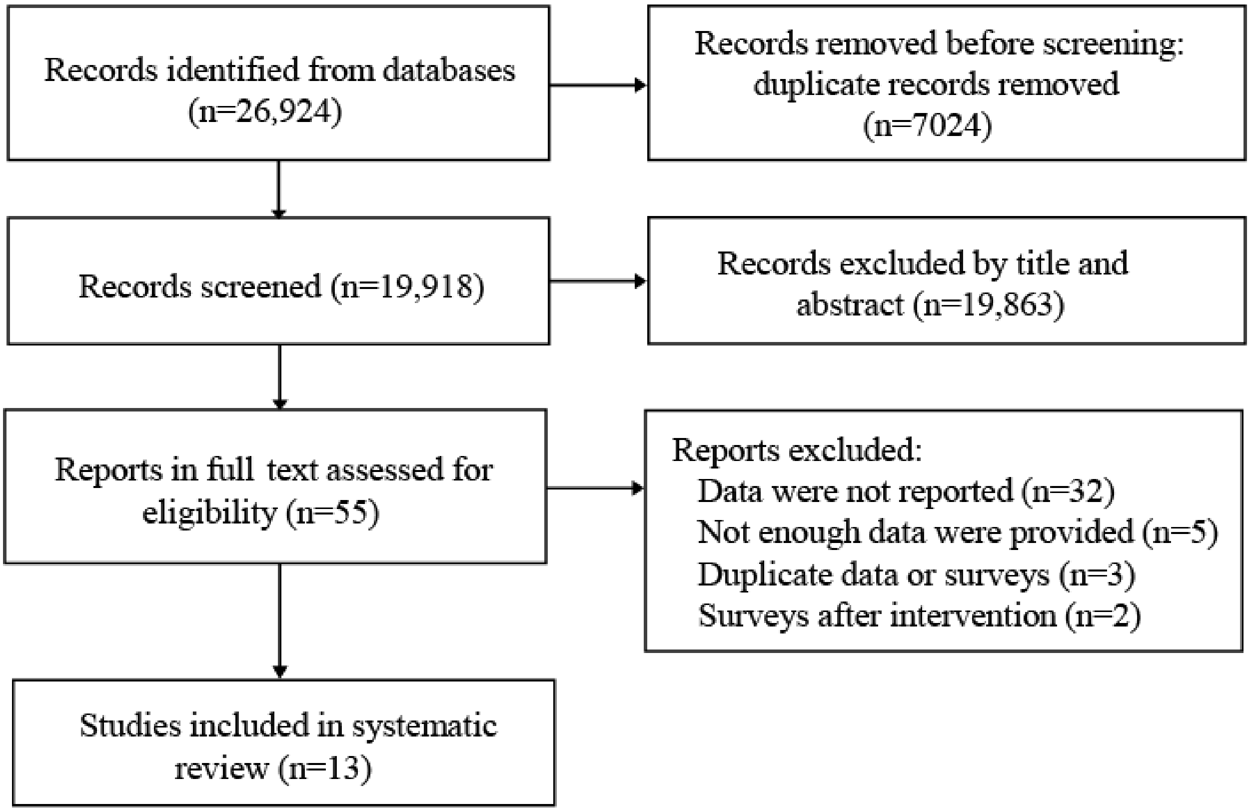
The willingness rate and its associated factors were examined by geographical context in order to explore potential differences. We also classified factors based on Health Belief Model (HBM) constructs. This method was previously used to identify factors associated with seasonal influenza vaccination, human papillomavirus vaccination, and COVID-19 vaccination [26-28]. Following the HBM construct, the influencing factors were summarized and classified according to the perceived susceptibility and severity of HZ, the perceived benefits of and barriers to vaccination willingness (reasons for vaccination willingness or unwillingness), modified factors, and cues to action. We evaluated the publication bias using the funnel plot [29]. The publication bias was not adjusted because of the presence of substantial heterogeneity [30]. All analyses were conducted in STATA version 14.0 (StataCorp) and Microsoft Excel 2016.

Results

Search Results and Quality Assessment

The initial search identified 26,942 papers. After deduplication and screening by title and abstract, 55 (0.20%) papers were screened by full text. A total of 13 (23.6%) papers were included in this review. The detailed selection process is illustrated in Figure 1. Of the 13 studies, 10 (76.9%) were empirical studies [16,18,31-38], 2 (15.4%) were meeting abstracts [17,39], and 1 (7.7%) was a letter [40]. All 13 studies belong to cross-section surveys. The final analysis included 14,066 individuals from 8 countries (Australia, Canada, China, France, South Korea, the United Arab Emirates, the United Kingdom, and the United States). The 13 studies were conducted in 4 WHO regions: the Eastern Mediterranean Region, the European Region, the Region of the Americas, and the Western Pacific Region. Study populations were adults aged ≥50 years in 10 (76.9%) studies, adults aged ≥18 years in 2 (15.4%) studies, and not specified in the remaining 1 (7.7%) study. The quality assessment scores of the included studies ranged from 10 to 20, with an average of 16.30 (SD 3.86). Detailed study characteristics and quality assessment results of the included studies are provided in Multimedia Appendix 1, Tables S1 and S2.

Figure 1. Flowchart of paper selection.



Vaccination Willingness Rate

The pooled HZ vaccination willingness rate was estimated to be 55.74% (95% CI 40.85%-70.13%). The asymmetry plots in the funnel plot indicated that there might be publication bias (Multimedia Appendix 1, Figure S1). It was estimated that 56.06% (95% CI 37.26%-74.02%) of adults aged ≥50 years were willing to receive an HZ vaccine. There were no significant differences between pooled willingness rates from surveys in the hospital context (58.29%, 95% CI 34.35%-80.33%) and surveys in the community context (53.45%, 95% CI 33.07%-73.26%), as seen in Multimedia Appendix 1, Figure S2. The willingness rate was 71.90% (95% CI 67.42%-75.99%) in the Eastern Mediterranean Region and 55.68% (95% CI 22.03%-86.67%) in the Western Pacific Region. The willingness rate was estimated to be 60.18% (95% CI 47.53%-72.18%) in high-income economies and 23.97% (95% CI 22.22%-25.77%) in upper-middle-income economies. Under health care workers' (HCWs) recommendations, 75.19% (95% CI 54.61%-91.07%) of individuals were willing to receive the HZ vaccine, which was higher than the willingness rate among individuals (49.39%, 95% CI 30.42%-68.45%) without HCWs' recommendations.

Rate and Associated Factors by Geographical Context

Eastern Mediterranean Region

Only 1 (7.7%) study was conducted in the United Arab Emirates [35], which reported a willingness rate of 71.9%, as shown in Multimedia Appendix 1, Figure S3. This study found that persons who were unsure about their chickenpox infection history were less likely to receive the HZ vaccine. In this study, the top 3 reasons respondents provided explaining their unwillingness were "prefers to take medication when sick," "side effects of vaccine," and "not at risk since I am healthy."

European Region

Of the 13 studies, 2 (15.4%) reported findings from surveys conducted in France (68.91%) [31] and the United Kingdom (34.62%) [36]. In France, women and persons in a relationship/married were more likely to vaccinate themselves against HZ. This study also identified that persons who agreed with the statements "HZ causes pain," "HZ is always severe," or "vaccination is a good prevention tool against HZ" preferred to receive the HZ vaccine. In the United Kingdom, Nicholls et al [36] reported the association between vaccine hesitancy using the Vaccination Attitudes Examination (VAX) scale and the 5C scale. Lower scores on "collective responsibility" on the 5C scale and higher scores on "concerns" on the VAX scale were associated with a lower likelihood of receiving the HZ vaccine.

Region of the Americas

A total of 4 (30.8%) studies were conducted in the Region of the Americas, including the United States (n=3, 75%) [33,34,40] and Canada (n=1, 25%) [32]. The willingness rates in the United States and Canada were 53.28% and 55.01%, respectively. People in the United States with a higher income were more likely to receive an HZ vaccine [34]. Two surveys in the United States reported reasons for the refusal of the HZ vaccine; the top 3 reasons in Lu et al's [34] study were "the vaccination was not needed," "not a risk, healthy, or high immune," and "not trusting doctors or medicine"; according to Funovits et al [40], the top 3 reasons were "believes vaccine is not important," "not covered by insurance," and "would like to obtain primary care physician recommendations."

Western Pacific Region

There were 6 (34.6%) surveys carried out in Australia (n=1, 16.7%), South Korea (n=1, 16.7%), and China (n=4, 66.6%). More than 85% of individuals were willing to accept the HZ vaccine in Australia and South Korea, considerably higher than that observed in China (35.13%). As shown in surveys in South Korea [37], younger people were more likely to accept the HZ vaccine. Individuals with a college education were more likely to accept the HZ vaccine than those with incomplete high school education. In this study, the top 3 reasons for unwillingness were "low perceived risk of developing HZ," "concerns about the adverse effects following immunization," and "concerns about the vaccination cost" [37].

Of the 4 studies in China, 2 (50%) were conducted in Hong Kong and 2 (50%) in Shanghai City. In the studies in Hong Kong, the most frequent reason listed for refusal was "they were unaware of its availability" [18]. According to Lu et al [16], in Shanghai City, younger people, people with higher monthly incomes, people who know the elderly are susceptible to HZ, and people with lower vaccine hesitancy levels were more willing to receive the vaccine. Qiu et al [38] reported that people who know about the HZ vaccine, are concerned with getting an HZ infection themselves, and who believe the vaccine can prevent HZ have a greater likelihood of receiving the HZ vaccine [38].

Associated Factors Using HBM Constructs

Information about how factors associated with vaccination willingness relate to HBM constructs is provided in Table 1 and Multimedia Appendix 1, Table S3.

Table 1. Description of influencing factors using HBM[a] constructs.

HBM framework	Factors	References
Individual perceptions		
Perceived susceptibility and severity of HZ[b]	• Perception of HZ infection susceptibility and severity	• [16,31,38]
Perceived barriers to vaccination willingness	• Low trust to the effectiveness of HZ vaccines, unawareness of HZ vaccine availability, concerns about side effects and safety, and cost	• [18,34,35,37,39]
Modifying factors		
Sociodemographics	• Age	• [16,31,33,34,37,38,40]
	• Education level	• [16,31,34,37,38,40]
	• Gender	• [31,34,37,38,40]
	• Income level	• [16,34,37,38]
	• Marital status	• [31,34,36]
	• Insurance	• [16,34,35]
	• Race	• [34]
	• Nationality	• [35]
	• Occupation	• [35]
Knowledge, attitude, beliefs, and prior experience	• Confidence in the effectiveness of the HZ vaccine	• [31,38]
	• Knowing the HZ vaccine	• [31,38]
	• Receiving influenza vaccination	• [34,37]
	• HZ infection history	• [31,35,37,38]
	• With chronic diseases	• [35,38]
Cues to action		
Interpersonal relationships	• Knowing someone with a history of HZ	• [31,37,38]
Community	• Doctors' recommendations	• [17]

[a] HBM: Health Belief Model.

[b] HZ: herpes zoster.

Perceived Susceptibility and Severity of Herpes Zoster

Of the 13 studies, 2 (15.4%) reported that the perception of disease severity is positively associated with vaccination willingness [31,38], while 1 (7.7%) study found a positive relationship between perceived infection susceptibility and vaccination willingness [16].

Perceived Benefits of and Barriers to Vaccination Willingness

Of the 13 studies, 5 (38.5%) explored reasons for vaccination unwillingness (perceived barriers to willingness). Low trust in the effectiveness of the HZ vaccine, concerns about safety, low perception of disease risk, financial concerns, and unawareness of the HZ vaccine's availability contributed to the unwillingness to receive the HZ vaccine [18,34,35,37,40].

Modified Factors

Modified factors included (1) sociodemographics and (2) knowledge, attitude, beliefs, and prior experience in the analysis.

Sociodemographics

Age (7/13, 53.8%), education level (6/13, 46.2%), gender (5/13, 38.5%), and income level (4/13, 30.8%) were the most frequent factors reported in the included studies. Of the 13 studies, 3 (23.1%) found a nonsignificant association between age and vaccination willingness [31,34,40], whereas 4 (30.8%) reported a significant relationship [16,33,37,38]. Nonsignificant relationships between education level and willingness were reported in 3 (23.1%) studies [31,34,40], while the other 3 (23.1%) studies found that a higher education level is associated with higher willingness rates [16,37,38]. In addition, 4 (30.8%) studies showed a nonsignificant association between gender and vaccination willingness [34,37,38,40]; however, 1 (7.7%) study reported that males are more likely to receive the HZ vaccine [31]. It was reported that individuals with higher income levels are more likely to receive the HZ vaccine [16,34], but 2 (15.4%) studies found no significant association between income level and willingness rate [37,38]. Additionally, 1 (7.7%) study reported a significant association between marital status and vaccination willingness [31], whereas 2 (15.4%) studies found no significant association between these factors [34,36].

Knowledge, Attitude, Beliefs, and Prior Experience

We found that confidence in the effectiveness of the HZ vaccine is positively associated with the willingness to receive the HZ vaccine [31,38]. Individuals who knew about the HZ vaccine were more likely to receive it [38], a finding that was not observed in another study [31]. Having a history of HZ infection was positively correlated with vaccination willingness [38]; however, 2 (15.4%) studies reported only nonsignificant associations between infection history and vaccination willingness [31,37]. Influenza vaccination history was not found to be an influencing factor for HZ vaccination acceptance [34,37]. In addition, 1 (7.7%) study reported that individuals without chronic diseases are more likely to receive the HZ vaccine [38], whereas another study did not find a significant association between these factors [35].

Cues to Action

Doctors' recommendations to receive the HZ vaccine were positively associated with vaccination willingness [17]. The experience of knowing someone with a history of HZ was positively associated with vaccination willingness [38], albeit this relationship was found to be insignificant in 2 (15.4%) studies [31,37].

Discussion

Principal Findings

This systematic review demonstrated that the pooled HZ vaccination willingness rate is 55.74% worldwide. The main reasons for the unwillingness to receive the HZ vaccine include low trust in the effectiveness of the HZ vaccine, concerns about safety, low perceptions of disease risk, financial concerns, and unawareness of the availability of the HZ vaccine. Our findings showed that HCWs' recommendations are correlated with a greater likelihood of receiving an HZ vaccine.

A large variability in HZ vaccination rates was found; however, certain patterns could still be deduced. Higher vaccination acceptance rates were observed in countries with an earlier license date of the HZ vaccine. From 2006 onward, countries with developed economies gradually licensed the HZ vaccine, such as the United States, France, Australia, South Korea, and the United Kingdom [11]. People living in these countries may have a greater awareness of HZ vaccine availability and may have received more frequent recommendations from HCWs to receive the vaccine. The willingness rate in China was considerably lower than that in these countries. HZ vaccines were first licensed in China in 2019 [11]. Less than one-third of the participants knew about the availability of the HZ vaccine in Shanghai, China [38]. The lack of awareness of HZ vaccine availability among the public may contribute to the low vaccination willingness rate in China. However, although the United Kingdom approved the HZ vaccine in 2006, the observed vaccination willingness rate remains low. The willingness rate might also be associated with the incidence of HZ across the countries. According to van Oorschot et al [6], the cumulative incidence of HZ in South Korea and Australia (more than 10 cases per 1000 population) is considerably higher than that in Canada, China, and France (between 2.9 and 8.67 cases per 1000 population) [6]. Thus, the higher incidence rate might result in individuals having an increased perception of susceptibility to HZ infection.

Recommendations from HCWs were associated with a higher HZ vaccination willingness rate; the impact of HCWs' recommendations on vaccine uptake has been observed in previous studies [41,42]. In turn, this channel can be an effective communication strategy to tackle vaccine hesitancy [43]. Glenton et al [44] summarized HCWs' views and experiences of communicating about vaccination with individuals over 50 years old and found that misinformation, fears, and concerns about vaccines are commonly voiced among older adults during their communications with HCWs. Hence, HCWs' attitudes and practices regarding the HZ vaccine are crucial. Reassuringly, HZ vaccination was reportedly recommended by 65.6% of HCWs in Italy [45]. A study in the United States reported that more than 90% of HCWs reported were willing to recommended HZ vaccination to their patients [46]. However, there remains a gap in relevant data in countries with upper-middle-income economies; therefore, more studies in upper-middle-income economies should be carried out to determine provider willingness to recommend an HZ vaccine.

Sociodemographic factors, while inconclusive, are essential to understanding and predicting HZ vaccination willingness rates. Individuals with lower education and income levels might be less likely to receive the HZ vaccine. Similar results have been observed in previous reviews of factors associated with influenza vaccination uptake and COVID-19 vaccination willingness among older adults [47,48]. Low socioeconomic status can be an important barrier to vaccination for older adults. Worryingly, the price of the HZ vaccine is considerably higher (about 10 times) than that of other vaccines, such as the influenza vaccine and the Tdap vaccine [49,50]. Along with a low perception of disease risk, low trust in the HZ vaccine, and awareness of HZ vaccine availability, the price of the vaccine might also represent a significant barrier to vaccination willingness.

Implications for Policy and Practice

Our findings have important implications for developing intervention strategies for increasing HZ vaccine acceptance across multiple levels. Countries with earlier licensing dates should pay attention to methods to improve individuals' confidence in the HZ vaccine and decrease their complacency. It is essential for countries with later licensing dates, such as China, to increase the awareness of the availability of the HZ vaccine first. Embracing the idea of communication strategies could be a potentially effective way to improve the acceptance of the HZ vaccine. One such strategy is engaging HCWs, as HCWs play a crucial role in older peoples' vaccination decisions [44]. Active recommendations from HCWs could be an effective way to increase vaccine awareness and willingness, as well as vaccine confidence. Using social media, such as posting content on Facebook or YouTube, is another feasible way to educate people about HZ vaccination [51]. At the individual level, our findings could facilitate greater awareness of people with identified factors for unwillingness (eg, age and income) and may help create tailored interventions for these populations using behavioral change strategies and techniques [52]. Our findings also indicate that some challenges exist toward the practice of life-course immunization, such as individuals being might face some challenges. Due to a lack of information, individuals might need to be aware of age-specific immunizations, which further emphasizes that the role of HCWs in promoting life-course immunization is vital and critical.

Limitations

Several limitations of this review were identified. First, the representativeness of the samples in the included studies was unclear. Only 3 of the 13 studies used a random sampling method. However, stratified subgroup analysis was adopted to mitigate this potential bias. Although no significant differences were observed among sampling methods, the results need to be interpreted with caution. Second, a lack of studies in this area limited the diversity and representativeness of our review findings. Since most studies were performed in countries with high-income economies, more studies need to be carried out in less economically developed countries. Additionally, some associated factors might not be reported, because the included studies did not explore them. For example, vaccination policy and smoking habits were determined to be associated with influenza vaccination willingness [53,54]; trust in the government and information exposure were associated with the COVID-19 vaccine [28,55]. These could be explored in future research.

Conclusion

Only 1 in 2 individuals showed a willingness to be vaccinated against HZ. The willingness rate was the highest in the Eastern Mediterranean Region. A higher acceptance rate could be generally observed in countries licensing HZ vaccines earlier or having higher HZ incidence, such as Australia and South Korea. The reasons for unwillingness included low trust in the effectiveness of the HZ vaccine, concerns about safety, low perceptions of disease risk, financial concerns, and unawareness of the availability of the HZ vaccine. Our findings showed the critical role HCWs play in promoting HZ vaccination. Countries with earlier vaccine licensing dates and high HZ incidence should improve individuals' confidence in the vaccine and decrease their complacency. It is necessary for countries with later licensing dates to prioritize the improvement of the awareness of HZ vaccine availability. Monitoring HZ vaccination willingness is necessary to inform public health decision-making. These findings will also be of interest to the practice of life-course immunization.

Abstract

Background: Salt substitutes are edible salts that contain less sodium chloride owing to its partial substitution with other minerals, which serve as an important and effective intervention and public health strategy targeting hypertension and its secondary diseases, despite a small degree of controversy.

Objective: This study aimed to identify the current salt substitute initiatives in various nations and intergovernmental organizations (IGOs) worldwide and summarize their types and characteristics.

Methods: A scoping review was performed based on Arksey and O'Malley's framework and the latest guidance from the Joanna Briggs Institute. Searches were conducted on Google; government websites on food, health, and other related topics; PubMed; Web of Science; and Google Scholar from January 2022 to May 2022. Initiatives related to salt substitutes that were included in the study focused on the involvement of governments or IGOs through the publication of standards, actions, collaborations, funding, and so on. Data were extracted into Microsoft Excel (version 2019; Microsoft Corp) based on predefined items and analyzed using narrative synthesis and frequency count methods.

Results: A total of 35 initiatives from 11 countries (of which 9 are high-income countries) and 3 IGOs were identified. We classified all salt substitute initiatives into 5 types, namely benefit-risk assessments and cautions; plans and actions; regulations and standards; labels; and food reformulation, cooperation with the food industry, and media. More than half (18/35, 51%) of the salt substitute initiatives were launched within the past 5 years. Except for regulations and standards, salt substitute initiatives are, in general, part of the salt reduction framework. No nation or IGO has yet reported on the monitoring and implications of the use of salt substitutes.

Conclusions: Despite the limited number of salt substitute initiatives worldwide at present, a review on the different types and characteristics of such initiatives could be helpful in providing a reference for policy makers and stakeholders. Given the great potential of salt substitutes in improving hypertension and stroke, we call on more nations to pay attention to these substitutes and propose salt substitute initiatives in line with their national conditions.

Introduction

Background

Hypertension is a common chronic disease, accounting for approximately 11 million deaths, or approximately one-fifth of all deaths, in 2019 [1]. Hypertension and cardiovascular disease continue to be the leading cause of disability and death among patients with COVID-19 during the pandemic, who are affected by the lack of health care resources caused by the spread of the pandemic [2,3].

Salt reduction is one of the most important public health strategies for the prevention and control of hypertension. In China, a high-sodium diet was identified as the third most significant risk factor for both the number of deaths and the percentage of disability-adjusted life-years in 2017, accounting for over 1.5 million fatalities [4]. The World Health Organization (WHO) advocated for a 30% decrease in population salt intake as one of the primary interventions to reduce premature death from noncommunicable diseases [5]. Although the WHO recommends that adults consume <5 g of salt or 2000 mg of sodium per day, most people consume up to twice the recommended amount: an average of 9 to 12 g of salt per day [6]. A systematic review of global salt reduction initiatives shows that as of 2019, a total of 96 countries or regions have adopted different structural or regulatory approaches to salt reduction [7]. At the same time, the WHO also recommended that adults consume at least 3510 mg (90 mmol) of potassium per day [8]. Potassium has a blood pressure control effect [9], and potassium intake has been shown in many randomized controlled trials and modeling studies to be a good initiative for blood pressure and cardiovascular disease control [10,11]. In addition, sodium-potassium interaction is an important mechanism of hypertension [12]. However, the amount of potassium intake is generally not enough, such as the 1997 mg/day reported by the United States [13]. It was also reported that potassium intake and 24-hour urinary potassium excretion were less than half of the current recommendations in China [14,15].

As an emerging approach to salt reduction, salt substitutes are gaining attention in more and more countries. Salt substitutes or low-sodium salts usually refer to table or cooking salts that either do not contain sodium chloride or contain lower levels of sodium chloride owing to its partial replacement with potassium chloride, magnesium sulfate, or other minerals [16]. Salt substitutes have a similar taste to that of regular table salt. With an extra amount of potassium added, it serves as an ideal solution to reduce sodium and increase potassium and other mineral intake at the same time. Studies have shown the benefits of salt substitutes in controlling blood pressure and reducing the risk of cardiovascular disease and mortality [17]. A global environmental scan of salt substitution products showed that as of September 2020, a total of 87 salt substitutes were available in 47 countries worldwide [16]. However, many people still have concerns about the risk of adverse reactions associated with the intake of salt substitutes, such as hyperkalemia [18].

This Review

Salt reduction is one of the most important methods of preventing and controlling noncommunicable diseases in most countries [7]. Among others, salt substitute, as a new means of salt reduction, is gradually gaining attention and being popularized. However, there is no research summarizing and analyzing national salt substitute initiatives. In this context, the objectives of this scoping review were to (1) search for and document existing national salt substitute initiatives (before May 2022), (2) analyze the types and characteristics of national salt substitute initiatives, and (3) provide recommendations on the promotion and regulation of salt substitute applications in different regions and countries.

Methods

Approach

The scoping review was developed based on Arksey and O'Malley's [19] framework and the latest guidance from the Joanna Briggs Institute [20]. We reported according to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) recommendations [21]. The PRISMA-ScR checklist is presented in Multimedia Appendix 1 [21].

Definition of Salt Substitutes and National Initiatives on Salt Substitutes

The expression of salt substitutes and the content of sodium varied across countries and regions for different products. Salt substitutes and low-sodium salts were considered synonymous in this study and defined as table salts or cooking salts whose sodium chloride was replaced with other minerals such as potassium chloride or magnesium sulfate, including sodium-reduced and sodium-free salts.

National initiatives on salt substitutes referred to initiatives related to salt substitutes that national governments and subsidiary organizations were engaged in through cooperation, development, publication, and implementation, as described in the *Eligibility Criteria* section. Nations in this study refer to the 193 United Nations (UN) member states [22]. Notably, intergovernmental organizations (IGOs) were organizations with international legal personalities established through treaty or other agreement between member states [23,24]. The main IGOs searched included UN agencies and regional organizations related to health, food, and agriculture [25] (all nations and IGOs searched in this study are listed in Multimedia Appendix 2).

Eligibility Criteria

The inclusion criteria were as follows: (1) participation of the national government (through funding, commissioning, the publication of standards, etc); (2) a national document or statement stressing on salt reduction and including the use of salt substitutes as a strategy; (3) a salt substitute program developed by the government in partnership with the food or salt industries; (4) a scheme about the labels, slogans, ingredient lists, etc printed on the package of salt substitute or the dietetic product with salt substitutes; and (5) mainstream media initiatives, consumer education, and other means used to increase knowledge on, improve attitudes toward, and behaviors related to salt substitutes.

The exclusion criteria were as follows: (1) salt substitute initiatives without the participation of nations or IGOs, for instance, initiatives led by nongovernmental organizations or local governments, and (2) the definition of salt substitutes differs from that used in this study, for example, flavor enhancers such as pepper and lemon.

Search Strategy

Three methods were used to conduct the research: government website search, Google search, and literature search. The search concepts included salt substitutes, countries, IGOs, portal function, government portals, states, and initiatives. Multimedia Appendix 2 lists the specific search process, all the keywords used to address the different aspects of the search concepts, and all the countries and IGOs involved. The government websites were obtained by searching the name of the 193 UN member states and the keywords related to government portals on Google Chrome with Boolean operators. First, keywords related to concepts such as government portals and portal function and country names were used to sort out government portal websites on health, food, medicine, and other related topics on Google Chrome, followed by a more in-depth exploration of keywords related to salt substitutes on these websites. With regard to IGOs, the official websites of a total of 66 IGOs related to global or regional political, economic, health, and agricultural cooperation were searched on Google Chrome. In addition, Google Chrome was directly used for keywords related to the concepts of salt substitutes, initiatives, nations, and IGOs with suitable Boolean operators. The first 5 pages of each Google search result were evaluated for eligibility, which usually contain almost all the information needed. All UN member countries were searched, with no language limitations set. If a country's official language was not English, the built-in translation service in Google Chrome was used to translate this language into English [26]. Finally, literature searches on PubMed, Web of Science, and Google Scholar were carried out using the corresponding search keywords and search formulas shown in Multimedia Appendix 2. The language of the literature search was restricted to English. All information was collected between January 2022 and May 2022.

Data Selection and Extraction

After receiving training, BK, SY, and JL individually conducted data identification and retrieval based on the established search strategy and eligibility criteria under the supervision of CG. The collected data was subsequently summarized. The checks during the summarization phase primarily focused on identifying and removing duplicates. Discrepancies were reviewed independently by CG, YT, YL, and PY and resolved through discussion. Data accuracy was independently checked by CG, PY, ZG, SR, YW, GD, and YY. The data eventually included in this study were extracted by BK and YL into a standardized table in a Microsoft Excel (version 2019; Microsoft Corp) sheet, which was independently reviewed by CG and PY and discussed in case of discrepancies. For government documents, the key information extracted included the (1) name of the document, (2) initiative enactment time, (3) the nation which published the document, (4) ministry that mandated the document, and (5) key content. From academic literature, we collected the following information: (1) the type of literature (article, review, letter, etc), (2) the year of publication, (3) the methods used, (4) the study population, and (5) relevant results.

Data Analysis

Data analysis was mainly performed through narrative synthesis and frequency count [27]. The research team collated and categorized the information obtained, summarizing and analyzing them through words and text. Data were also categorized based on the date of the publication of the initiatives, the WHO regional categorization, and the countries' income levels in the 2022 World Bank classification. Software used included Microsoft Excel 2019, ArcMap (version 10.8; Environment Systems Research Institute), and GraphPad Prism (version 8.0.1; Graph Pad Software, Inc).

Ethical Considerations

This study did not involve human participants, human participant research ethics, or related secondary analyses; therefore, ethics approval and consent to participate were not required.

Results

Search Results

A total of 16,889 records were identified after removing duplicates. On the basis of titles and abstracts, 16,260 (92.28%) records were excluded. After full-text reading, of the remaining 629 records, 594 (94.4%) were excluded for the reasons listed in Figure 1, the PRISMA-ScR flow diagram. As a result, 35 initiatives from 11 countries and 3 IGOs were eligible. Multimedia Appendix 3 [28-63] contains all the national and IGO initiatives for salt substitutes that were included.

The 11 countries were the United Kingdom, Germany, Norway, Ireland, and Finland in Europe; the United States and Canada in North America; Singapore, China, and Australia in East Asia and the Pacific; and India in South Asia (Figure 2). Except for China, which is an upper-middle-income country, and India, which is a lower-middle-income country according to the recently updated (2022) World Bank income ranking, all countries are high-income countries [64]. The 3 IGOs are the European Union (EU), the Eurasian Economic Union (EAEU), and The Codex Alimentarius Commission (CAC). Salt substitute initiatives were divided into five types, namely (1) benefit-risk assessments and cautions; (2) plans and actions; (3) regulations and standards; (4) labels; and (5) food reformulation, cooperation with the food industry, and media, all of which are detailed in Multimedia Appendix 4.

The total number of countries classified as belonging to the given regions according to the WHO regional categorization is shown within parentheses. Some initiatives fall under several categories.

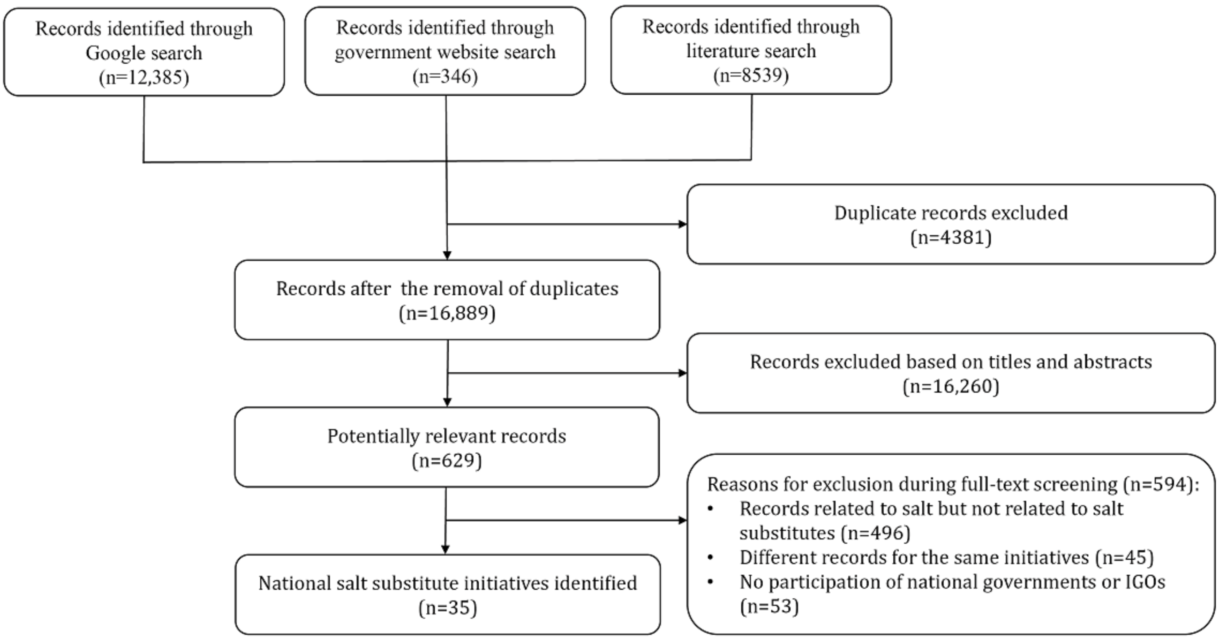

Figure 2. National salt substitute initiatives.

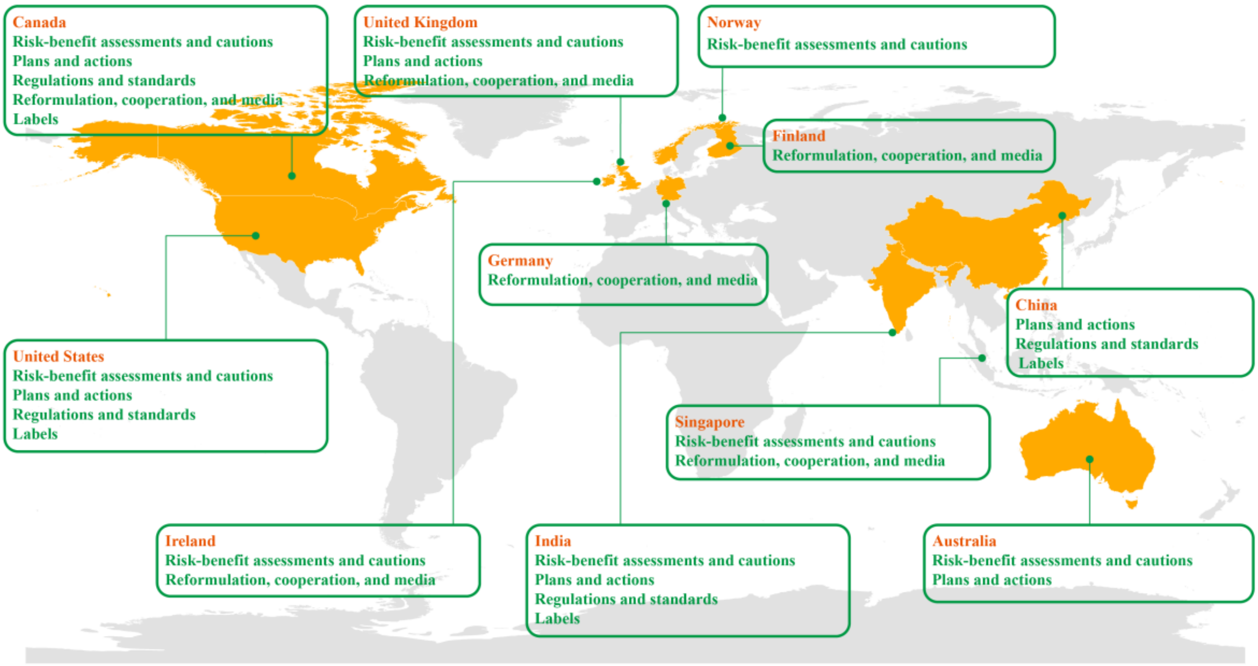

Types and Characteristics of National Salt Substitute Initiatives

Benefit-Risk Assessments and Cautions

The benefit-risk assessments of salt substitutes are usually carried out by a nutrition-related scientific committee appointed by the relevant government food safety department, providing recommendations on the use of salt substitutes. The benefit-risk assessments are an important part of determining national attitudes toward salt substitutes, which are a prerequisite for some countries to develop salt reduction–related initiatives. Assessments have been conducted in the United Kingdom [28], Ireland [29,30], Norway [31,32], and Australia [33].

In the United Kingdom, the Scientific Advisory Committee on Nutrition and the Committee on Toxicity of Chemicals in Food, Consumer Products and the Environment published *Potassium-Based Sodium Replacers: Assessment of the Health*

Benefits and Risks of Using Potassium-Based Sodium Replacers in Foods in the UK, which was an important evaluation of evidence for the application and promotion of salt substitutes [28]. The Scientific Advisory Committee on Nutrition and Committee on Toxicity of Chemicals in Food, Consumer Products and the Environment applied the benefit-risk analysis for foods methodology to hypothesize the benefits and risks of reduced sodium intake and increased potassium intake in the general UK population by replacing 15% to 25% of sodium with potassium (potassium chloride, potassium carbonate, or potassium bicarbonate). This report recognized that the potential benefits of salt substitutes outweighed the potential risks and that although the impact at the individual level would be small, salt substitutes would have a beneficial effect on a large proportion of the UK population. The report recommended that the government encourage food businesses to use salt substitutes, but the level of potassium in foods and the types of foods in which salt substitutes are used needed to be monitored.

In addition to the United Kingdom, Norway conducted 2 assessments, one in 2014 and another in 2021. In 2014, the Norwegian Scientific Committee for Food and Environment, commissioned by the Norwegian Food Safety Authority and The Norwegian Directorate of Health, conducted a benefit-risk assessment by assuming the benefits and risks of 3 scenarios in which 30%, 50%, or 70% of sodium chloride was replaced by potassium, concluding that it was reasonable to anticipate that the percentage of persons likely to face an increased risk was far greater than the percentage of persons likely to benefit [31]. In 2021, the scientific committee was commissioned again to hypothesize the potential health effects of replacing 0% to 30% of sodium chloride with potassium chloride, and the report has not yet been published [32].

Ireland conducted *Salt and Health: Review of the Scientific Evidence and Recommendations for Public Policy in Ireland* in 2005 and 2016 (revision 1). In 2005, the scientific committee indicated that salt substitutes may increase susceptibility of the health of some populations (including those with type 1 diabetes, chronic renal insufficiency, end-stage renal disease, severe heart failure, or adrenal insufficiency) and did not contribute to lowering the population salt taste thresholds [29]. However, in 2016, the scientific committee concluded that the potassium intake at that time in the Irish diet was not enough and that the use of potassium-based salt replacement ingredients by the food industry could help supplement potassium intake among Irish people. However, the reduction of salt taste thresholds in the population was a major requirement for the food industry. Because the use of salt substitutes was not the preferred way to reduce the thresholds of salt taste, it should only be considered if reducing the sodium content independently could be detrimental to food safety or the physical or organoleptic properties of the food. Meanwhile, the scientific committee recommended that the Irish Food Safety Authority develop guidelines for the food industry regarding the use of potassium and other mineral salt replacements and make these guidelines available to all susceptible groups, that the sodium and potassium content of foods continue to be monitored, and that sodium and potassium intake be reassessed regularly [30].

The Australian Government Department of Health published *Food Reformulation: Risk Assessment* in 2020, which stated that salt substitutes did not necessarily bring about a change in population consumption patterns. In addition, potassium-based replacements could affect the health of susceptible people ("with major impairment of renal function because of chronic kidney disease or other morbidity, and those taking medications such as angiotensin-converting enzyme inhibitors and potassium-sparing diuretics that reduce renal excretion of potassium"). The report recommended that product monitoring and the monitoring of temporal trends in the incidence of hyperkalemia be performed when using salt substitutes and that clear labeling of relevant foods and sound physician recommendations be made for patients at risk [33].

To reduce the potential harm caused by salt substitutes for the higher-risk individuals mentioned earlier, some countries have proposed cautions for salt substitutes, including the recommendation that susceptible groups should use salt substitutes with caution or under professional supervision. For example, in Singapore, salt substitutes are included in the precautions for the use of potassium chloride [34] and the management of chronic heart failure [35]. In China, a warning label (shown in the *Labels* section) is required on the package of salt substitutes [36].

Despite the risk of hyperkalemia that potassium chloride may pose, since 1983, the US Code of Federal Regulations has announced that potassium chloride is generally recognized as safe as a direct human food ingredient when used in accordance with the current good manufacturing practice conditions of use (as a flavor enhancer, flavoring agent, nutrient supplement, pH control agent and stabilizer, or thickener) [37].

Plans and Actions

Plans and actions mainly refer to a series of guidelines and solution plans formulated and released by the government for specific problems, such as salt reduction, nutrition, and pollution. The use of salt substitutes in salt reduction plans or actions has been noted in 5 nations (the United Kingdom, Canada, Australia, China, and India).

Guidelines usually address 2 main aspects of salt substitute use. First, the processed food industry should consider reducing the salt content in their products to produce low-salt foods and then consider the use of salt substitutes when necessary (as proposed by the United Kingdom [38] and Canada [39]). Second, when using salt substitutes, attention should be paid to their safety and efficacy. Besides benefit-risk assessments, the disclosure of potassium content on nutrition labels, monitoring of potassium intake, and technological innovations are all possible approaches (as proposed by Canada [39] and Australia [40]). The focus of the salt reduction initiatives in China is different from that of the salt reduction initiatives in other countries, as the Chinese diet is predominantly homemade, especially in rural areas. Because of the high sodium intake, very low potassium intake, and high cardiovascular disease burden in these areas, the initiatives recommended adjusting the salt supply in the whole population while promoting and popularizing low-sodium and potassium-enriched salt. Baseline data collection and follow-up studies were conducted in a nationally representative population using dietary surveys and 24-hour urinary potassium excretion test [41]. In its book *Do You Eat Right*, the Food Safety and Standards Authority of India acknowledged the potential of salt substitutes for salt reduction but also noted that salt substitute brands were currently limited on the market and that salt substitutes should be used only under medical supervision [42].

In addition, although the US *Dietary Guidelines for Americans (2020-2025)* did not address potassium-rich salt substitutes, they stated that Americans' potassium intake was low and sodium intake should be limited and that the requirements for the nutrition fact label mandated the inclusion of the amount of potassium in packaged foods in the nutrition label [43].

Regulations and Standards

Regulations and standards provide reference for the production, packaging, trading, and use of salt substitutes and are issued by government departments to ensure safety and effectiveness. Regulations are mandatory and have legally binding effects. A total of 4 countries (the United States, Canada, China, and India; Table 1) have established regulations or standards for salt substitutes or have addressed salt substitutes in other regulations or standards.

First, the United States [44], India [45], and China [36] had clear but varied regulations on the composition of salt substitutes. For example, the commercial item description of salt substitutes developed by the US Department of Agriculture in 1997 divided salt substitutes into 2 categories, potassium chloride (type I) and potassium chloride with L-lysine (type II) [44]. China has established an industry standard (QB/*t* 2019-2020) on *low-sodium salt*, which stated that sodium chloride and potassium chloride should reach 65.0-80.0 g/100 g and 20.0-35.0 g/100 g on a dry basis, respectively [36]. In addition to active ingredients, these countries also imposed requirements on other ingredients, such as ingredients used for food grade bulking, anticaking agents, flavor enhancers, nutrition enhancers, and pollutants. For example, India not only requires salt substitutes to contain no more than 120 mg/100 g of sodium but also restricts the component of cations in some acidity regulators [45]. Canada has not developed standards for salt substitutes, but the *Labelling Requirements for Salt* issued by the Canadian Food Inspection Agency in 2019 stated that salt substitutes were generally sodium-reduced or sodium-free alternatives that usually contain potassium chloride. When a salt substitute was used as an ingredient in another food, it was an additive [46]. In addition, Goods and Services Identification Number of Salt Substitute released by the Canadian Food Inspection Agency classified salt substitutes as special dietary foods and food specialty preparations [47]. The regulations on salt substitute composition could be clearly seen in Table 1, whereas the regulations and standards on labeling are introduced in the next section.

Table 1. Regulations and standards for salt substitutes in countries.

Category and country	Title	Year	Department	Regulation and standard for salt substitutes
Regulations and standards of formula				
United States	Commercial Item Description—Salt Substitutes [44]	1997	The US Department of Agriculture	• Classification: the salt substitutes shall conform to the following list which shall be specified in the solicitation, contract, or purchase order: • Type I: potassium chloride • Type II: potassium chloride with L-lysine • All ingredients, including food grade bulking and anticaking agents, used in the preparation of the salt substitutes shall be of Food Chemicals Codex purity or US Pharmacopeia-National Formulary quality. The active ingredient in the salt substitutes shall be potassium chloride. Type II salt substitutes shall include L-lysine. The salt substitutes may contain flavor enhancers and anticaking agents such as, but not limited to monopotassium glutamate, glutamic acid hydrochloride, tricalcium phosphate, and calcium stearate.
China	Light Industry Standard of the People's Republic of China QB/*t* 2019-2020 Low Sodium Salt [36]	2020	Ministry of Industry and Information Technology of the People's Republic of China	• This standard specifies the sensory, physical, and chemical properties of; food additives used in; nutritional fortification of; and contaminants of salt substitutes. The dry basis of sodium chloride and potassium chloride should reach 65.0-80.0 g/100 g and 20.0-35.0 g/100 g, respectively.
India	Ministry of Health and Family Welfare (Food Safety and Standards Authority of India) Notification F. No. Stds/03/Notification (LS)/ FSSAI-2017 [45]	2017	Ministry of Health and Family Welfare (Food Safety and Standards Authority of India)	• Salt substitutes may contain:(a) Colloidal silica or calcium silicate: not more than 1% m/m of the salt substitute mixture, individually or in combination.(b) Diluents: safe and suitable nutritive foods as normally consumed namely, sugars, cereal flour. • The addition of iodine-containing compounds to salt substitutes shall be as per the Foods Safety and Standards Regulations, 2011. • The sodium content of salt substitutes shall be not more than 120 mg/100 g of the salt substitute mixture. • The composition of salt substitutes shall be as follows: • Potassium sulphate, potassium, calcium or ammonium salts of adipic; glutamic; carbonic; succinic; lactic; tartaric; citric; acetic; or hydro-, chloric, or orthophosphoric acids, and/or good manufacturing practice, except that phosphorus not to exceed 4% m/m and NH4+ 3% m/m of the salt substitute mixture • Magnesium salts of adipic; glutamic; carbonic; citric; succinic; acetic; tartaric; lactic; or hydro-, chloric, or orthophosphoric acids, mixed with other Mg-free salt substitutes as listed in 6.(1) (a), 6.(1) (c) and 6.(1) (d), and/or Mg++ to be not more than 20% m/m of the total of the cations K+, Ca++and NH4+ present in the salt substitute mixture and phosphorus not to exceed 4% m/m of the salt substitute mixture • Choline salts of acetic, carbonic, lactic, tartaric, citric, or hydrochloric acids, mixed with other choline-free salt substitutes as listed in 6.(1) (a), 6.(1) (b) and 6.(1) (d), and/or the choline content not to exceed 3% m/m of the salt substitute mixture • Free adipic, glutamic, citric, lactic, or malic acids—good manufacturing practice
Regulations and standards of labeling				
Canada	Labelling Requirements for Salt [46]	2019	Canadian Food Inspection Agency	• Salt substitutes do not have a prescribed standard and are generally a sodium reduced or sodium free alternative. Salt substitutes usually contain potassium chloride. Table salt substitutes, while not required to, are permitted to contain added iodine.
Regulations and standards of product classification				
Canada	Goods and Services Identification Number (GSIN)—Salt Substitute [47]	2018	Public Services and Procurement Canada	• GSIN[a] Category: Goods • GSIN Group Description: Subsistence • GSIN Class Description: Special Dietary Foods and Food Specialty Preparations

[a] GSIN: Goods and Services Identification Number.

Labels

Labels refer to the list of nutritional composition and health claims printed on packages, front-of-package labels, etc. Regulations on the labels of salt substitute products and the labels of packaged foods with added salt substitutes are part of the national strategy for salt substitutes to guide consumers in choosing or not choosing relevant products and are one of the important policy tools. Canada [46], the United States [48], Singapore [65], China [49], and India [45] have all regulated salt substitute labels (Table 2).

For salt substitutes, Canada required all the ingredients in the salt substitute to be labeled [46]. In China, salt substitute product labels must mention the potassium content and clearly indicate that salt substitutes should be used with caution by people for whom high potassium intake is not suitable, such as those who work at high temperatures, those who engage in high-intensity physical labor, those with kidney dysfunction, and those with hypertension who are taking antihypertensive medication [36,49].

For packaged foods containing salt substitutes, India required the labels to carry information on the presence of salt substitutes and the amount of potassium in them [45]. Because potassium chloride was not well known to consumers, research suggested that consumers may erroneously associate it with other chemicals and avoid consumption [66]. To change the negative public perception of potassium chloride and improve the health of the US population, NuTek Food Science, supported by food companies as well as public health organizations such as the Center for Science in the Public Interest and World Action on Salt & Health, submitted a citizen's petition proposing that the US Food and Drug Administration rename "potassium chloride" as "potassium salt" in food labels in 2016, and the proposal was passed after a public consultation in 2020 [48,67]. Thereafter, potassium chloride in packaged foods could be renamed to "potassium salt," but this is only a recommendation, not a mandatory responsibility, and is at the discretion of the food company. Canadian health promotion organizations such as Heart and Stroke and Hypertension Canada followed the lead of the United States and proposed to Health Canada and the Food Inspection Agency in 2019 to allow the use of the alternate name of "potassium chloride" [68]. The current Canadian law necessitates that the ingredient be identified by its common name along with "salt substitute" in parentheses. An example of this would be "potassium chloride (salt substitute)" [46]. Meanwhile, Canada has developed health claims for sodium and potassium, which can be made when processed foods meet the Food and Drugs Regulations' requirements, such as "a healthy diet containing foods high in potassium and low in sodium may reduce the risk of hypertension. [Name of the food] is a good source of potassium and is low in sodium." [50]. Health Canada's reforms to nutrition labeling has been considering the inclusion of potassium in the nutrition fact label [39].

In addition, Singapore's Healthier Choice Symbol (HCS) on packaged foods indicated to consumers which foods are healthier and more suitable choices for them [51]. The HCS label was found on approximately 4000 different foods and included 3 types of salt substitutes: Pagoda Less Sodium Mineral Salt, PanSalt, and GoodSalt [65].

Table 2. The regulations for the labels of salt substitute products and packaged foods with added salt substitutes.

Country	The regulation for labels
Salt substitute products	
Canada [46]	• All ingredients and their components must appear in the list of ingredients of table salt substitutes. This includes the declaration of iodide if present.
India [45]	• A declaration on the label as "low sodium salt substitute" or "low sodium dietetic salt" • A declaration on the label regarding the amount of cations, that is, sodium, potassium, calcium, magnesium, ammonium, and choline/100 g (m/m), in the salt substitute mixture
Packaged foods added salt substitutes	
United States [48]	• Exercise enforcement discretion for the declaration of "potassium salt" in the place of "potassium chloride" in the ingredient statement of food labels when potassium chloride is used as an ingredient in the food. • Potassium and sodium are listed on the nutrition fact label on packaged foods and beverages.
Canada [46]	• Salt substitute must be declared by its common name in the list of ingredients. The term "salt substitute" on its own would not be acceptable. However, it would be acceptable to declare the additive's function in brackets after the common name, for example, "potassium chloride (salt substitute)." • A salt substitute that meets the compositional and labeling criteria for a free of sodium or salt claim or for a low in sodium or salt claim may be represented as a food for special dietary use, such as "for salt free diets" or "for salt reduced diets."
China [49]	• "低钠盐的产品标签中应标示钾的含量，并应清晰标示：'高温作业者、重体力劳动强度者、肾功能障碍者及服用降压药物的高血压患者等不适宜高钾摄入的人群应慎用。'" • Translation: the product label of low-sodium salt should indicate the potassium content and should clearly indicate that "it should be used with caution by people who are not suitable for high potassium intake, such as those who work in high temperature, those who work with heavy physical strength, those who have kidney dysfunction and those who take antihypertensive drugs for hypertension."

Food Reformulation, Cooperation With the Food Industry, and Media

Many companies in the food industry are trying to reduce the amount of sodium in processed foods through food reformulation, that is, by replacing some or the entire amount of salt with salt substitutes and finding formulations that maintain good organoleptic, microbiological, physical, and chemical properties and the safety and quality of food. Some reformulations were carried out by professional technicians or companies commissioned or supported by the government. The German Federal Ministry of Food and Agriculture produced healthy and safe sodium-reduced fish [52,53], semihard cheese [54,55], raw and salted meat products [56], etc.

In other countries such as Canada and Singapore, the government encourages food companies to use salt substitutes as a means of reducing salt in processed foods. In Singapore, in addition to the HCS labeling, the government is also running the Healthier Ingredient Promotion Scheme based on the HCS, which supports a variety of food companies, including salt producers, to innovate and market healthier and more locally flavored products with government funding that covers (1) marketing and publicity, (2) trade promotion, and (3) ingredient thematic promotion [57]. The salt selected for the program was IMI Lifestyle Products' "GoodSalt." The sodium content in GoodSalt was replaced by essential minerals such as potassium, magnesium, lysine, and iodine [69]. Finland is an example of countries that successfully promoted salt substitutes through the media, with a salt substitute called "Pansalt" being reported and promoted by mainstream media such as Helsingin Sanomat. With salt substitutes becoming well known in Finland, the media has significantly contributed to the realization of salt reduction in Finland [58].

Salt Substitute Initiatives From 3 IGOs

Although IGOs are not countries, the initiatives proposed by them are often an important basis for regional or global food trade to ensure safety and health and are consciously abided by member states. These initiatives can be used as a basis for national legislation [24,70]. Therefore, this study also collected these initiatives on salt substitutes as a supplement to national initiatives (Multimedia Appendix 5 [59-62]).

Regarding the classification of salt substitutes, unlike Canada, the EU's food additive standard stated that when table salt substitutes and minerals were used for flavor, mouthfeel, or nutritional purposes, they were considered substances and not food additives [59]. In addition, in terms of food reformation, the *Institut National de la Recherche Agronomique* commissioned by the EU produced sausages, in which 20% to 30% of sodium was replaced with potassium [60].

The CAC and the EAEU regulated the composition and labeling of salt substitutes and have similar requirements [61,62]. In terms of ingredients, they limited the maximum quantity of different substitutable ingredients; for example, they required "the choline content not to exceed 3% m/m of the salt substitute mixture." For the labels of salt substitutes, the CAC required the mention of the name "low sodium salt substitute" or "low sodium dietetic salt," whereas the EAEU required the mention of "the substitute of salt with low content of sodium" or "dietetic salt with low content of sodium." Both regulations required companies to declare on the product label the full list of ingredients and the amount of cations in a 100 g mixture. For dietetic products containing salt substitutes, the presence of salt substitutes should be declared. The total potassium content and cation content in 100 g of the product should also be stated.

Discussion

Principal Findings

In this review, a total of 35 initiatives on salt substitutes from 11 countries and 3 IGOs were assessed in detail. Several major types of salt substitute initiatives, namely benefit-risk assessments and cautions; plans and actions; regulations and standards; labels; and food reformulation, cooperation with the food industry, and media, were summarized.

These initiatives had some significant features. First, the focus on salt substitutes reflects an interest in salt reduction. For most of the national initiatives that proposed salt substitutes as a means of salt reduction in the food industry, reducing the salt content of food has been regarded as a prerequisite. It has been shown that human preferences for salt taste could be shaped, with taste buds gradually adapting to saltier or less salty taste as dietary salt intake increases or decreases, respectively [71]. By contrast, replacing common salt with salt substitutes does not achieve the effects of lowering the taste threshold and changing the consumption pattern of the population. Salt substitutes as a means of salt reduction would only be considered in food categories if salt reduction is difficult because of microbial food safety, functional, and taste reasons.

Second, the mention of "potassium salt" or "potassium chloride (salt substitute)" as an alternative to "potassium chloride" on packaged food labels may be a new possible strategy. The International Food Information Council Foundation conducted a web-based survey of 1000 consumers and found that compared with potassium salt, consumers had a more negative association with potassium chloride, and their familiarity with "potassium" was very low [66]. However, there are still some issues to consider before implementation. For example, whether a name change would lead to a massive and rapid introduction of potassium salt products by the food industry, resulting in the lack of consideration of food safety and increased risk to susceptible groups, and the need to ensure appropriate mandatory nutrition labels, warning labels, and front-of-pack labels for potassium should be considered. Therefore, the implementation may need to be coupled with consumer education and monitoring.

Third, high-income countries are more concerned about the application and promotion of salt substitutes in the food industry, which is the industry where salt is mainly used. Several countries have funded research on innovative foods prepared with salt substitutes and cooperated with enterprises to encourage them to produce and sell packaged foods prepared with reduced salt and salt substitutes. However, some food companies have expressed the presence of barriers. For example, the effects of salt substitutes on product quality and taste have led to the frequent failure of companies' research on reformulation with salt substitutes as well as increased costs. Companies have also expressed concerns about the consumer acceptability of salt substitutes [63]. It is important to consider the complex industry chain that includes salt substitute manufacturers, processed food manufacturers, retailers, consumers, media, and many others [72]. All stakeholders should work together to implement locally adapted initiatives to promote salt substitutes, such as establishing public-private partnerships and promoting salt substitutes through subsidies, tax incentives, awareness campaigns, promotions, and consumer education.

In middle-income countries, such as China, the source of sodium chloride intake is more likely to be household salt, especially in rural areas. A large randomized controlled trial in a Chinese population of >20,000 older people from 600 villages with a history of stroke or hypertension demonstrated that salt substitutes significantly reduced the risk of stroke, major cardiovascular events, and death (rate ratios=0.86, 0.87, and 0.88, respectively) [73]. Moreover, if all Chinese households were to switch to salt substitutes, 450,000 lives could be saved each year [10]. However, there are still some issues with the use of salt substitutes in households. For example, the possibility of adding more salt substitutes for taste demand; the bitter taste of potassium chloride, which may discourage some people with sensitive tastes from choosing it; the need to consider the balance between salt substitute intake and iodine intake in areas where iodine intake is inadequate; and a lack of recommendations or standards for the use of salt substitutes in the household preparation of some foods, such as cured meats, salted fish, and spicy cabbages, which may pose microbiological risks.

Fourth, there is a controversy among the benefit-risk assessments carried out in different countries with regard to the percentage of sodium expected to be replaced by potassium. In the United Kingdom, the assumption of replacing 15% to 25% of sodium with potassium gave an overall positive conclusion [28]. However, in Norway, assumptions of 30%, 50%, and 70% substitutions translated into potentially higher-risk conclusions in 2014 [31]. A new assessment in Norway in 2021 changed the assumption to 0% to 30% substitution of sodium with potassium [32]. Considering the different demographic profiles, sodium and potassium intakes of the population, average blood pressure, and epidemiology of cardiovascular disease in various countries, this study recommends the establishment of appropriate assumptions and benefit-risk assessments based on national realities.

In fact, benefit-risk assessments have always been focused on the possible harm of the use of potassium in salt substitutes. People with limitation of renal potassium excretion, such as patients with renal failure; those with diabetes mellitus; and those using potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, or angiotensin receptor blockers, may experience cardiac arrhythmia and have an increased level of death risk after consuming excessive potassium [74]. Several cases of hyperkalemia caused by the use of salt substitutes have been reported in high-risk participants [75,76]. Nevertheless, 2 clinical trials from China conducted salt substitute interventions among older people in 600 villages and 48 residential older adult care facilities. No significant increase in adverse clinical outcomes was found in both studies, although the second study found that the use of salt substitutes may result in more frequent hyperkalemia biochemically [73,77]. These studies provided high level of evidence on the safety of salt substitute when it comes to promotion. Furthermore, monitoring of the use of salt substitutes after national or regional promotion campaigns is very important, namely population consumption of salt substitutes, levels of sodium and potassium consumed and excreted, changes in blood pressure, cardiovascular disease and mortality, and cases of adverse effects.

Fifth, media campaigns are an important part of consumer education for salt reduction efforts. For example, in Finland, where salt reduction efforts began early and achieved good results, there was a long-standing media campaign on salt reduction with a strong promotion of salt substitute brands [58,78]. By contrast, a company in India with a wide range of salt products, including salt substitutes, became the subject of fake news stating that their products contained toxic ingredients. Widely circulated on social media, the fake news caused panic among consumers, only to be clarified with a statement from the government [79].

Sixth, there are currently no proposed measures on the price control and taxation of salt substitutes in various countries. As of September 2020, the price of salt substitutes ranged from US $0.46 to US $87.00 per kg worldwide, which is higher than the price of regular salt [16]. In non–high-income countries, lowering the price of salt substitutes is undoubtedly an important factor in promoting salt substitutes. In high-income countries, the cost of input is an equally important consideration in whether companies choose to reformulate high-sodium foods with salt substitutes. If countries wish to actively promote the use of salt substitutes, they may consider controlling the price by reducing the tax. As of 2019, a total of 5 countries around the world tax high-sodium foods [7], yet there are currently no policies to increase or reduce taxes on salt substitutes in any individual country. At the same time, governments could invest resources to support technology development aimed at reducing the cost of producing salt substitutes.

So far, there have been few reports issued by governments on the effects of the implementation of salt substitute policies, such as changes in sodium and potassium intakes, cardiovascular health, and potential risks. Most of the salt substitute initiatives were proposed in recent years. It is possible that such assessments of effects may have not been published or remain internal government documents. By contrast, governments usually reported the overall effect of salt reduction, including changes in salt intake and the salt content of foods [7]. Nevertheless, the process and results of policy development in one country have implications for other countries, thanks to the extensive communication among stakeholders. According to press reports, after food and health organizations in the United States submitted a petition to the Food and Drug Administration to use an alternate name of potassium chloride, stakeholders in Canada also took action. Eventually, they both contributed to the renaming of potassium chloride [68]. The benefit-risk assessment published in the United Kingdom also had a wide impact, being mentioned in published documents in both Norway [32] and Ireland [30].

On the basis of the classification of country regions by the World Bank and WHO, salt substitutes are of interest in high-income countries and European countries or organizations [64,80] (Multimedia Appendix 4). Despite the neutral, positive, or conservative attitudes toward salt substitutes shown in the published initiatives in different countries, the publication itself represents a concern for salt substitutes. With higher importance attached to salt reduction and health, salt substitutes will be circulated and popularized around the world. Therefore, we call on more countries to implement salt substitute initiatives. It is necessary for all countries to conduct benefit-risk assessments and develop regulations or standards for salt substitutes and their labeling according to the circumstances. In addition to this, depending on the source of dietary salt (homemade food or packaged foods), the inclusion of salt substitutes in national salt reduction initiatives, appropriate interventions, and consumer education are also important approaches.

This review has some strengths and limitations. We did not coordinate with country program leaders, global experts in salt substitutes, or regional WHO representatives. However, a literature search that covered the peer-reviewed and gray literature, Google search, and government website search were used to obtain as much information as possible from the web. Owing to the limitations and time lags in the information published on the web, it is possible that not all country-level salt substitute initiatives are properly included. In addition, instead of multilingual translators, Google Translate was used to identify and filter non-English information, which might have resulted in the omission and misinterpretation of relevant initiatives in non–English-speaking countries. Furthermore, this review focused on official national initiatives on salt substitutes and did not include stakeholders, academic institutions, or subnational recommendations and initiatives, such as the salt substitute promotion initiative of the China National Salt Group in Beijing [81]. These subnational initiatives also have high relevance to the application and promotion of salt substitutes in the world and in the corresponding region and are references for many salt substitute initiatives at the national level.

Conclusions

This scoping review has shown that although there are only a limited number of national initiatives focusing on salt substitutes at present, relevant initiatives are increasing year by year and involve multiple aspects, including regulations, guidelines, and cooperation with the industry. Given the great potential of salt substitutes in improving hypertension and stroke, we call on more countries to pay attention to and propose salt substitute initiatives. This requires the government to conduct a comprehensive evaluation and extensively cooperate with stakeholders, such as companies, media, and consumers.

Abstract

Background: The COVID-19 booster vaccination rate has declined despite the wide availability of vaccines. As COVID-19 is becoming endemic and charges for regular booster vaccination are being introduced, measuring public acceptance and the willingness to pay for regular COVID-19 boosters is ever more crucial.

Objective: This study aims to (1) investigate public acceptance for regular COVID-19 boosters, (2) assess the willingness to pay for a COVID-19 booster shot, and (3) identify factors associated with vaccine hesitancy. Our results will provide crucial insights into and implications for policy response as well as the development of a feasible and effective vaccination campaign during Vietnam's waning vaccine immunity period.

Methods: A cross-sectional study was conducted among 871 Vietnamese online participants from April to August 2022. An online questionnaire based on the discrete choice experiment (DCE) design was developed, distributed using the snowball sampling method, and subsequently conjointly analyzed on the Qualtrics platform. A history of COVID-19 infection and vaccination, health status, willingness to vaccinate, willingness to pay, and other factors were examined.

Results: Among the participants, 761 (87.4%) had received or were waiting for a COVID-19 booster shot. However, the willingness to pay was low at US $8.02, and most participants indicated an unwillingness to pay (n=225, 25.8%) or a willingness to pay for only half of the vaccine costs (n=222, 25.4%). Although information insufficiency and a wariness toward vaccines were factors most associated with the unwillingness to pay, long-term side effects, immunity duration, and mortality rate were the attributes the participants were most concerned with during the vaccine decision-making period. Participants who had children less than 18 years old in their homes infected with COVID-19 had a lower willingness to pay (odds ratio [OR] 0.54, 95% CI 0.39-0.74). Respondents who had children under 12 years old in their family who received at least 1 vaccine dose had a higher willingness to pay (OR 2.03, 95% CI 1.12-3.66). The burden of medical expenses (OR 0.33, 95% CI 0.25-0.45) and fear of the vaccine (OR 0.93, 95% CI 0.86-1.00) were negative factors associated with the level of willingness to pay.

Conclusions: A significant inconsistency between high acceptance and a low willingness to pay underscores the role of vaccine information and public trust. In addition to raising awareness about the most concerning characteristics of the COVID-19 booster, social media and social listening should be used in collaboration with health professionals to establish a 2-way information exchange. Work incentives and suitable mandates should continue to encourage workforce participation. Most importantly, all interventions should be conducted with informational transparency to strengthen trust between the public and authorities.

(JMIR Public Health Surveill 2023;9:e43055) doi:10.2196/43055

KEYWORDS

COVID-19; epidemic; vaccine; booster; willingness to take; willingness to pay; Vietnam; policy; feasibility; acceptability; infection; vaccination; social media; intervention

Introduction

The COVID-19 pandemic has profoundly affected numerous facets of life worldwide in the past 3 years, ranging from health, well-being, and socioeconomic status to the behavioral pattern and structural characteristics of societies [1-3]. Given its effectiveness in reducing virus severity and transmission, the COVID-19 vaccine has been used as the key pandemic control measure [4,5]. According to the World Health Organization (WHO), the COVID-19 vaccination decreased the number of deaths and severe disease from COVID-19, as well as decreasing COVID-19 transmission [6]. The Centers for Disease Control and Prevention (CDC) revealed that the protection by COVID-19 vaccination is up to 90% [7]. In Vietnam, the COVID-19 vaccine was highly accepted by the general population, including high-risk groups, such as pregnant women and the elderly [8,9]. As of July 2022, 82.2% of the Vietnamese population had received at least 2 doses of the COVID-19 vaccine [10]. However, vaccine effectiveness is dependent on the individual acceptance of the vaccine as well as the type of vaccine received, lasting on average up to a year with infection-induced antibodies and up to 6 months with vaccine-induced antibodies [11-14]. The resurgence of COVID-19 can be caused by several factors, including the decline in immunity to the COVID-19 vaccine, which emphasizes the importance of booster shots. Devenport et al [15] revealed that every 108 days or so, persons inoculated against COVID-19 would lose almost half of their protective antibodies [15]. Hence, immunizations that provided 90% protection against mild episodes of illness may only be 70% effective after 6 or 7 months [15]. Immunological studies have also shown a steady decline in antibody levels in people who have been vaccinated against COVID-19, and suggest an increased risk of an infection outbreak [16,17].

Given the effectiveness of COVID-19 booster shots, the current health focus of COVID-19 worldwide has shifted from disease control to booster regularity and long-term maintenance [18-21]. As COVID-19 progresses to its endemic phase, a pattern observed in previous major pandemics, the disease will likely not be eradicated but instead will be controlled by regular vaccinations [22,23]. Therefore, the promotion of booster vaccination is a key intervention in the new response scheme. However, unlike mandatory doses, the current COVID-19 booster shots record relatively low acceptance, even in the biggest COVID-19 vaccine–supplying countries, such as India (55.9%) [24] or the United States (61.8%) [23]. China's contribution to the COVID-19 vaccine cannot be ignored. Although China is among the top countries with the highest acceptance of the COVID-19 vaccine in the world [25], the acceptance to take COVID-19 booster shots rate has dropped to only 76.8% [26]. In Vietnam, this rate is below 60% compared to nearly 95% coverage for mandatory shots [10]. Many countries have also experienced a recent halt in booster administration rates due to concerns about their long-term effects and importance. In the coming endemic phase, the current vaccine policy in Vietnam will undergo major revisions, the most concerning of which is the transition from free-of-charge vaccines to with-charge and regular vaccination. Therefore, assessing the willingness of the population to pay for COVID-19 boosters is crucial to inform policy makers and public health practitioners on how to proceed with and promote vaccination costs.

Several frameworks have strived to describe the correlations between different factors for the acceptance of vaccines, most commonly the integrated framework of the Health Belief Model (HBM) and the theory of reasoned action (TRA) [27,28]. Indicators in this model have been consulted, such as the perception of severity and benefits, as well as the limitations of vaccination, attitude, and subjective norms, during previous pandemics [29]. During the COVID-19 outbreak in Malaysia, Ng et al [30] added contextual factors, such as susceptibility, trust, and vaccine preference, to improve the applicability of this framework to COVID-19 vaccine acceptance [30]. Integrated models were perfected through pandemics and effectively used to inform COVID-19 vaccine campaigns. However, the acceptance of initial shots and booster shots differs immensely in that multiple doses of COVID-19 boosters are required over time and depend on individual progress instead of single or 2-dose mass public vaccinations. Thus, conventional vaccine acceptance models cannot be easily applied to understand booster shot hesitancy [31].

Moreover, the effectiveness and side effects of booster shots have been well documented. Therefore, one's decision to receive a booster is influenced by a personal preference for known vaccine characteristics rather than a hypothetical evaluation of the vaccine's severity, benefits, or public attitude, as suggested by previous frameworks. This change in the nature of predictors calls for a new approach to understanding vaccine acceptance:

to investigate personal priorities for vaccine characteristics and assess the extent to which one is willing to take or pay in acknowledgment of risks.

Although the initial acceptance of the COVID-19 vaccine has been well studied for 3 years, little is known about the public's willingness to pay due to the free-of-charge policy for the COVID-19 vaccine in most countries worldwide and in Vietnam [26,32,33]. However, given current economic damages, it is unlikely that COVID-19 boosters can be provided under the same policy. Thus, the measurement of the willingness to pay for a COVID-19 booster has become a priority to inform an important transition of the vaccine implementation approach. We conducted this study during Vietnam's waning vaccine immunity period to (1) investigate public acceptance for regular COVID-19 boosters, (2) assess the willingness to pay for a COVID-19 booster shot, and (3) identify factors associated with vaccine hesitancy. Our results will provide crucial insights into and implications for policy response as well as the development of a feasible, effective, and sustainable vaccination campaign.

Methods

Study Design

The PREVENT (Preference For Vaccine Evaluation & Trail) study was Vietnam's nationwide assessment using a patient-centered design to inform health technology development and acceleration. Designed using the Qualtrics system, the PREVENT study included an online interactive questionnaire to target subjects across different regions of Vietnam from April to August 2022. Respondents were Vietnamese who live in Vietnam, who were aged 16 years and above (in Vietnam, people from the age of 16 years must take responsibility for their actions; moreover, they must bear penal liability like adults), and who were being referred to and agreed to complete the survey. The PREVENT study included 2 groups: (1) the general population and (2) health professionals and medical students. Snowball sampling was used for disseminating the survey, involving 20 "seeders" in all 3 regions: northern, middle, and southern. Participants took 30 minutes to complete the questionnaire and were encouraged to introduce more acquaintances and colleagues to the survey. Respondents were able to review and change their answers through a Back button in the Qualtrics system.

The PREVENT study included 5 topics of interest: (1) COVID-19 vaccine booster for adults, (2) monkeypox, (3) COVID-19 vaccine for children, (4) HIV vaccine, and (5) a hypothetical pandemic in the future. After answering general social demographic questions, each respondent was randomly assigned to 1 of these 5 topics, generating 5 separate data sets. In total, 5700 respondents were included in the PREVENT study. The substudy of the COVID-19 vaccine booster for adults included 871 complete records.

Ethical Considerations

Participants were informed of the benefits and risks of participating in this study, and they provided informed consent. Records were monitored and tracked using IP addresses using the Qualtrics system to ensure the validity of the data set; they were then extracted, analyzed, and stored safely and confidently and used merely for research purposes. The protocol was approved by ethical review committees designated by the Vietnam Ministry of Health (decision no. 164/GCN-HDDDNCYSH-DHYHN and 13/HDDD-DHDT).

Measurement and Instrument

We applied a standard procedure for generating the research instrument. Initially, a systematic review was conducted to identify important facets that emerged from previous studies. Next, we constructed the questionnaire, covering the breadth of measurements of interest. A group of experts in public health, infectious diseases, health services, econometrics, linguistics, representatives of target groups, and research assistants joined in the deliberation of translating, rephrasing, piloting, and shortening the questionnaire. Finally, the tool included 5 major sessions: (1) sociodemographics, (2) a history of COVID-19 infection and vaccination, (3) the willingness to take a COVID-19 vaccine booster for adults, and (4) the willingness to pay for it.

Outcome Variables

Willingness to Vaccinate

A short questionnaire was designed to determine the participants' willingness to take the COVID-19 vaccine booster for adults using the following 3 items:

- Will not vaccinate
- Intend to inject COVID-19 booster shots
- Have completed the COVID-19 booster shots

Willingness to Pay for the Vaccine

A questionnaire was designed to determine the participants' willingness to pay for vaccines using the following 5 options:

To what extent are you willing to pay for the vaccine?

- Unwilling to pay
- 20% of the cost
- 50% of the cost
- 80% of the cost
- Full cost

The actual cost of the vaccines was not known to participants. This question was used to examine the participants' willingness to pay when financial support/a discount was provided.

Socioeconomic Status

Participants responded to questions about their sociodemographics, including age, gender (male/female), marital status (single, others), job, monthly household income per capita, and area.

History of COVID-19 Infection and Vaccination

Participants responded to questions about their personal and family history of COVID-19, time since the last COVID-19 infection, health status, and personal and family history of COVID-19 vaccination.

Factors Affecting Vaccination to Prevent Disease

We used 10 items corresponding to 2 factors to measure the factors affecting vaccination to prevent disease. A 3-point Likert scale was used to evaluate the answers.

Factor 1: concerns about the vaccine and responsibility to the community

- Item 1. Concerned that the vaccine is newly developed.
- Item 2. Concerned about immediate side effects of the vaccine.
- Item 3. Concerned about long-term side effects of the vaccine.
- Item 4. Concerned about new components of the vaccine.
- Item 5. Concerned about the immunity duration of the vaccine.
- Item 9. Vaccinate so the community can maintain normal living and working conditions.
- Item 10. Vaccinate to fulfill personal responsibility of disease prevention.

Factor 1 included 7 questions. The total score was calculated by adding the scores of the 7 items and then converted to a 10-point scale.

Factor 2: fear of the vaccine

- Item 6. Fear of vaccines and injections in general.
- Item 7. Fear of insufficient information to make decisions.
- Item 8. Wait for others to vaccinate first.

Factor 2 included 3 questions. The total score was calculated by adding the scores of the 3 items and then converted to a 10-point scale.

Hence, the score of factors 1 and 2 ranged from 1 to 10. Participants with a higher score indicated a heightened concern about the vaccine and responsibility to the community and a heightened fear of the vaccine. The Cronbach α of factors 1 and 2 was good at .89 and .84, respectively.

Interpersonal Factors

We included 8 items to assess the interpersonal factors related to vaccination. A 3-point Likert scale was used to evaluate the answers. There were 2 domains included:

Factor 1: risks of infection and fear of the impact of the disease on health and economy

- Item 1. How is the risk of reinfection for you and your family members?
- Item 2. How is the risk of reinfection for children in your family?
- Item 3. How afraid are you of the spread of this disease?
- Item 4. Ho afraid are you of the impact on the health of this disease?
- Item 5. How afraid are you of the impact on the economy of this disease?

Factor 2: service satisfaction

- Item 6. How satisfied are you with vaccination services?
- Item 7. How satisfied are you with COVID-19 consultation services?
- Item 8. How satisfied are you with health care services for pandemics?

After summing the total score of each item, the total score of factors 1 and 2 was converted to a 10-point scale. Respondents with a higher score indicated a higher risk of infection and fear of the impact of the disease on health and economy or service satisfaction. The Cronbach α of factors 1 and 2 was good at .87 and .91, respectively.

Discrete Choice Experiment

We conducted a literature review of factors affecting the willingness to take and to pay for vaccination services and the designs of previous discrete choice experiments (DCEs) on adult vaccination. The results informed our selection of 6 major attributes of such services that influence an individual's preference, including effectiveness (<60%, 60%-90%, and >90%), immunity duration (3-6 months to a lifetime), side effects (minor [can maintain daily functioning] to major [severe fatigue and immobility]), mortality rate (0.001%-0.01%), limitations if not vaccinated (yes or no), cost of the vaccine (VND 100,000 [US $4.27] to VND 2,000,000 [US $85.33]) [34-39]. These attributes were then assigned 2-5 levels for choosing, contributing to a total of 31 × 41 × 23 × 51 = 480 possible alternatives (Table 1). Each participant was asked to respond to 7 different scenarios based on generated combinations by selecting which scenarios they preferred.

The sample size for the DCE was determined using Sawtooth software to determine the number of responses: sample size = (multiplier*c)/(t*a) = 357, where multiplier=1000, “c” is the largest number of levels across all features (n=5), “t” is the number of tasks or questions (n=7), and “a” is the number of alternatives or choices per question (n=2). This sample size was reached for both target groups of the survey, with 461 (52.9%) in the general population and 410 (47.1%) in health professionals and medical students.

Table 1. Vaccine attributes in the DCE[a].

Attributes	Response options
Effectiveness (%)	<60 60-90 >90
Immunity duration	3-6 months 6-12 months 1-3 years Lifetime
Side effects	Minor: can maintain daily functioning Major: severe fatigue and immobility
Mortality rate	0.001% 0.01%
Limitations if not vaccinated	No Yes: traveling banned and social gatherings restricted
Cost (VND/US $)[b]	100,000/4.27 200,000/8.53 500,000/21.33 1,000,000/42.67 2,000,000/85.33

[a] DCE: discrete choice experiment.

[b] VND 23,437.98=US $1.00.

Statistical Analysis

Statistical analysis was performed using Qualtrics and STATA software (version 15). Descriptive data were generated for all variables. With missing data, we used the listwise deletion method to clean data before analyzing them; 1071 records were collected, of which 871 (81.3%) records were complete, so 200 (18.7%) records were excluded from the analysis. Continuous variables were presented as the mean (SD), while categorical variables were presented as frequencies with percentages.

Factorial Structure

Exploratory factor analysis (EFA) using principal component analysis (PCA) was performed to evaluate the optimal structural model of the instrument according to the observed data. The number of factors was determined based on the Scree plot, and parallel analysis, along with eigenvalues and the proportion of variance explained (Multimedia Appendices 1 and 2). Items with a loading value of ≥0.5 were included in the relevant component.

Potential covariates for full models of the decision to take and the willingness to pay for COVID-19 boosters for adults included socioeconomic data, COVID-19 characteristics, related information regarding the COVID-19 vaccine, factors affecting the intention to vaccinate for disease prevention, and interpersonal factors (Multimedia Appendices 1 and 2). We used multivariate ordered logistic regression to identify factors related to the willingness to pay for COVID-19 booster and multinomial logistic regression to identify factors associated with the willingness to take a COVID-19 booster for adults. *P*<.05 was considered statistically significant.

In DCE data analysis, individual-based utility models were yielded using hierarchical Bayes estimation that uses Bayesian methods to probabilistically derive the relative value of each tested variable. The models estimated the optimal package of the preferred attributes of COVID-19 vaccination and the contribution of each attribute.

Results

Participant Characteristics

Table 2 demonstrates the demographic characteristics of the respondents. More than two-thirds of the participants (n=607, 69.7%) were females, and 661 (75.9%) were aged from 16 to 24 years. Most respondents finished college, university, postgraduate education (n=702, 80.6%) and were not married (n=707, 81.2%). Health care professionals and medical students (n=410, 47.1%) constituted the largest occupational group. The mean average monthly income per household was VND 3-10 million (US $128.00-$426.66; n=337, 38.7%).

Table 2. Demographic characteristics of respondents (N=871).

Characteristics	Participants, n (%)
Gender	
Male	264 (30.3)
Female	607 (69.7)
Age group (years)	
16-19	305 (35.0)
20-24	356 (40.9)
>25	210 (24.1)
Education level	
Not graduated from high school	95 (10.9)
Graduated from high school	74 (8.5)
College/university/postgraduate	702 (80.6)
Marital status	
Single/divorced/widowed	707 (81.2)
Married	164 (18.8)
Job	
Health care worker/medical student	410 (47.1)
Other students	190 (21.8)
Stable jobs	64 (7.3)
Other jobs	207 (23.8)
Monthly household income per capita (VND/US $)	
<1 million/<42.67	249 (28.6)
1-2.9 million/42.67-123.73	175 (20.1)
3-10 million/128.00-426.66	337 (38.7)
>10 million/>426.66	110 (12.6)
Children	
No children	710 (81.5)
Pregnant/have children	161 (18.5)
Area	
Hanoi	391 (45.0)
Other northern provinces/cities	102 (11.7)
Southern provinces/cities	101 (11.6)
Central provinces and Central Highlands	192 (22.1)
Other provinces	85 (9.6)

Table 3 presents the history of previous infections, vaccinations, and health characteristics of the respondents. Of 871 participants, 492 (56.3%) were infected with COVID-19 and 249 (28.5%) had children in the family infected with COVID-19. The most prevalent infection period was the recent 3-6 months. The largest proportion of participants (n=400, 46.1%) reported a moderate health status, followed by 359 (41.4%) who self-reported that they were completely healthy. Regarding the COVID-19 vaccination for self and family, two-thirds of the participants had taken the third, or booster, dose (n=582, 66.7%), while only 46 (5.3%) participants had children below 12 years old in their family who had been vaccinated. The most popular information sources were health care officials (n=592, 67.8%) and the media (n=457, 62.7%).

Table 3. Personal and family history of COVID-19 infection and vaccination of study subjects (N=871).

Characteristics	Participants, n (%)
Personal and family history of COVID-19	
Nobody in my family has been infected COVID-19.	128 (14.7)
I was infected with COVID-19.	492 (56.3)
Adults in my family were infected with COVID-19.	481 (55.1)
Children <18 years old in my family were infected with COVID-19.	249 (28.5)
Time since the last COVID-19 infection	
Not yet infected	381 (43.7)
1-3 months	154 (17.7)
3-6 months	283 (32.4)
>6 months	54 (6.2)
Health status	
Completely healthy (100%)	359 (41.4)
Relatively healthy (80%-100%)	400 (46.1)
Slightly compromised health (<80%)	109 (12.5)
History of COVID-19 vaccination of self and family	
I have received 2 doses.	213 (24.4)
I have received 3 doses or a booster or both.	582 (66.7)
Children under 12 years old in my family have received at least 1 vaccine dose.	46 (5.3)
Children 12-17 years old in my family have received at least 1 vaccine dose.	105 (12.0)
All adults in my family have received at least 2 doses.	436 (49.9)
Vaccine information sources	
Health care officials	592 (67.8)
Relatives, friends, neighbors	371 (42.5)
Media (health consultation switchboard, radio, newspaper, television)	547 (62.7)
Others	77 (8.8)

Willingness to Take and Willingness to Pay for a COVID-19 Booster

Table 4 and Multimedia Appendix 3 demonstrates the respondents' willingness to receive and their reasons for vaccine refusal. Nearly two-thirds of the participants received a booster shot (n=524, 60%), and only 61 (7%) participants did not want a booster vaccine. The most common reasons for vaccine hesitancy included insufficient time since the last shot (n=38, 34.6%) and the wait-and-see approach (n=31, 28.2%). In addition, 225 (25.8%) respondents were unwilling to pay for a COVID-19 booster, and 222 (25.4%) were willing to pay half of the vaccine cost (ie, the other half of the cost had to be covered by someone else). A considerable proportion (n=571, 65.6%) viewed the booster shot as an economic burden.

Table 4. Willingness to take and willingness to pay for a COVID-19 booster.

Characteristics	Participants, n (%)
Willingness to take a COVID-19 booster	
Will not vaccinate	61/871 (7.0)
Intend to inject COVID-19 booster shots	288/871 (33.0)
Have completed COVID-19 booster	524/871 (60.0)
Reasons for refusal to vaccinate	
Not enough time between COVID-19 shoots	38/109 (34.6)
Feeling unwell	9/109 (8.2)
Have underlying medical problems or other medical treatment	6/109 (5.5)
Allergic history	3/109 (3.6)
Am waiting for my turn to be vaccinated	14/109 (12.7)
Wait and see	31/109 (28.2)
No means of transport and money to travel to the place of injection	0
Suffered from severe side effects of the previous injection	17/109 (15.5)
Feel that booster is unnecessary as COVID-19 has become irrelevant	29/109 (26.4)
Have just been infected	28/109 (25.5)
Willingness to pay for a COVID-19 booster	
Unwilling to pay	225/871 (25.8)
20% of the cost	133/871 (15.2)
50% of the cost	222/871 (25.4)
80% of the cost	93/871 (10.7)
Full cost	200/871 (22.9)
Financial burden of COVID-19 booster	
No	300/871 (34.4)
Yes	571/871 (65.6)

Multivariable Analyses to Identify Factors Associated With the Decision to Take and the Willingness to Pay for a COVID-19 Vaccine

Table 5 reveals the factors associated with the decision to take the COVID-19 vaccine. People who had higher education (odds ratio [OR] 17.22, 95% CI 2.86-103.63), who had graduated from high school (OR 12.35, 95% CI 3.46-44.00), who had received 3 doses or a booster or both (OR 13.31, 95% CI 4.31-41.09), and in whose family all adults had received at least 2 doses (OR 2.88, 95% CI 1.31-6.31) were likely to have completed the COVID-19 booster. Relatively healthy participants were likely to intend to get the COVID-19 vaccine (OR 2.98, 95% CI 1.37-6.47).

Multivariate ordered logistic regression results to identify factors associated with the willingness to pay for the COVID-19 vaccine are presented in Table 6. Participants aged 20-24 years, who had a monthly household income per capita of >VND 10 million, in whose family adults were infected with COVID-19, in whose family children under 12 years old had received at least 1 vaccine dose, who used media to access information about the vaccine, and who had higher concerns about vaccine characteristics and responsibility to the community were likely to have a higher level of willingness to pay for the COVID-19 vaccine. Children <18 years old in the family infected with COVID-19 and the burden of medical expenses were harmful factors that reduced the level of willingness to pay for the COVID-19 vaccine.

Figure 1 presents the feature importance of each vaccine attribute generated by the conjoint analysis. The mortality rate had the most influence on the decision-making process, at 27 points, followed by immunity at 22.8 points and vaccine effectiveness at 22.4 points. The cost was the least weighted attribute, at 7.6 points.

Table 7 shows the willingness to pay based on current COVID-19 vaccine attributes: more than 90% effectiveness, 6-12 months’ immunity, minor side effects, insignificant mortality rate, and major limitations if not vaccinated. For this package, the generated willingness to pay was VND 188,000 (US $ 8.02).

Table 5. Factors associated with the decision to take the COVID-19 vaccine.

Factors	Willingness to get the vaccine	
	“Will not vaccinate” vs “have completed the COVID-19 booster,” OR (95% CI)	“Intend to inject” vs “have completed the COVID-19 booster,” OR (95% CI)
Education level (reference: not graduated from high school)		
Graduated from high school	0.06[a] (0.01-0.35)	0.20[b] (0.06-0.68)

Figure 1. Feature importance of vaccine attributes during the decision-making process.

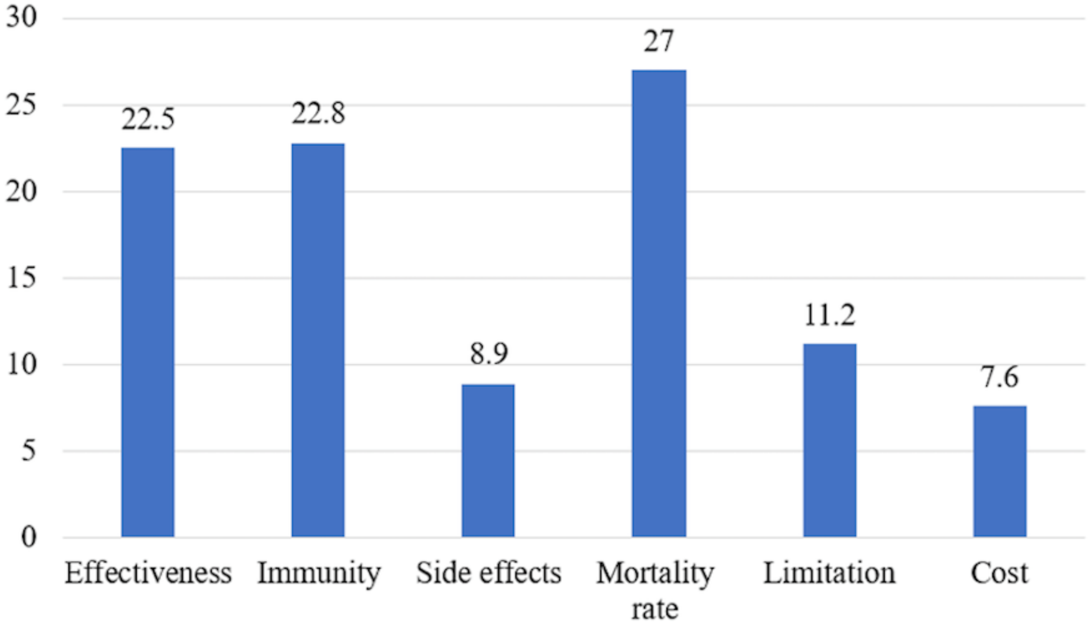

Table 7. Willingness to pay for a hypothetical COVID-19 vaccine booster for adults generated by the DCE[a].

Vaccine attribute	Value
Vaccine effectiveness	More than 90%
Immunity	6-12 months
Side effects	Minor, does not affect daily functioning
Mortality rate (/100,000 people)	1 death
Limitation if not vaccinated	Yes: traveling banned and social activity restricted
Cost (VND/US $)	188,000/8.02

[a] DCE: discrete choice experiment.

Discussion

Principal Findings

This study results indicated the participants' high willingness to take COVID-19 vaccine booster shots. Their willingness to pay, however, was scattered between price levels, the most common of which were willingness to pay the full price, willingness to pay half the price, and total unwillingness to pay at all. The reasons for an unwillingness to pay and booster hesitancy were concerns of long-term effects, immunity duration, information insufficiency, lack of confidence in the vaccine, unawareness of the risk of reinfection, and dissatisfaction with COVID-19 care services. Based on the identified issues of lack of information and weakening public trust in the vaccine, we proposed personal, interpersonal, and managerial solutions to ensure affordable vaccinations and consistent uptake. The burden of medical expenses and the fear of vaccines were negative factors associated with the willingness to pay; in contrast, participants who had children under 12 years old in their family who had received at least 1 vaccine dose used the media to access information about vaccines, while concerns about vaccine characteristics and responsibility to the community had the opposite impact.

In our study, 87% of the participants had taken a booster dose or were waiting to get vaccinated, which is generally higher than that in low-, middle-, and high-income countries (73.4% in low-income countries, 67.9% in middle-income countries, and 83.0% in high-income countries) [40].

When examined at the national level, the willingness to pay generated in our study accounted for a small fraction of the per capita monthly income of our sample (VND 3,000,000-10,000,000, or US $ 128.00-426.66). Since the effects of the COVID-19 vaccine typically start to diminish after 6 months, the actual monthly cost of a booster is even lower when spread out over months, making it a low financial burden. Indeed, a critically low willingness to pay despite a high acceptance rate might be a proxy for people’s underestimation of vaccine importance, suggesting gaps in communication between the general public and authorities. This is consistent with the fact that the most common reason for vaccine hesitancy was a lack of knowledge about the vaccine.

Public information about COVID-19 boosters does not cover the main factors highlighted by this study that influence the vaccine decision and willingness to pay, such as potential side effects, mortality rate, induced immunity, and effectiveness. Furthermore, as health care professionals and the media were deemed to provide the most trusted information, public education approaches should be more comprehensive and interactive, allowing for televised question-and-answer (Q&A) sessions with experts, hotline services staffed by trained practitioners, and open informational portals made available on social media. Social listening is another recommended approach to be used by governments and health organizations to understand people's perceptions and concerns, to refute false information and handle controversies, and to identify other social leaders or influencers who may have a positive impact on the general public.

Our findings emphasize the importance of building public trust when disseminating information about vaccinations. Contrary to traditional vaccines with a long history of development and trials, the COVID-19 vaccine was made available on an emergency warranty after preclinical studies and only 12-18 months of multiphase trials [41]. Despite ongoing efforts to map the long-term effects of the COVID-19 vaccine, the lack of longitudinal evidence leaves them unconfirmed to both clinicians and the general public. Although rarely, the COVID -19 vaccine can also have adverse side effects, such as myocarditis, Guillain-Barre syndrome, or thrombotic syndrome [42]. This information, if not communicated clearly and transparently, may cause public distrust, which in turn undermines the national sustainable vaccine uptake [43]. Making COVID-19 vaccinations a regular/seasonal requirement may also prove challenging in the absence of public transparency. During the COVID-19 outbreak, it was evident that public trust differed between the types of response, specifically between countries whose governments showcased true surveillance results and those whose governments intentionally provided incomplete information in an attempt to comfort the public [44,45]. The widespread availability and ease of use of social media platforms hastened the spread of false information online. This issue is further exacerbated if there exists low vaccine literacy in the country [46]. Public distrust, if it already exists, can be tackled through social listening, educating, and engaging with advocates, as in the case of the influenza outbreak [47].

Other significant factors promoting vaccine acceptance were fear of disrupting normal working and living conditions, reinfection, and re-emergence of the outbreak. In the work sphere, various interventions can be implemented to improve vaccine uptake, including paid time off for vaccinations or recovery time. A study among US workers observed that such incentives could improve vaccination rates, and they have been frequently implemented since the beginning of vaccination programs [48]. Financial plans that allow the cost of the COVID-19 vaccine to be deducted directly from one's salary and the payments to be spread over months should be encouraged to relieve the financial burden. The inclusion of the booster vaccine in the standard workplace health requirements or routine health check-ups must be endorsed by relevant institutions. Since COVID-19 has been identified as a massive public burden affecting the entire economy, the costs associated with its prevention could be shared by both public and private sectors.

Interventions drawing on the fear of a COVID-19 pandemic re-emergence are numerous. Nudge interventions, such as mobile phone personal reminders or fixated appointments, have been found to be effective in increasing vaccine uptake in Denmark [49]. In Vietnam, a new "Vaccine Reminder" extension can be added to the national COVID-19 portal, which was made available and effectively used for case surveillance during the pandemic peak. Restrictions regarding social gatherings and traveling should continue to be imposed to make boosters informally mandatory [50].

Strengths and Limitations

The strengths of our study included a large sample size and diverse demographics, which enabled high generalizability. Our DCE design and conjoint analysis allowed us to imitate real-life conditions of the willingness to pay and generate a more reliable result.

Numerous limitations also exist, including the inability to infer causal relationships due to a cross-sectional design, the influence of the current vaccine policy on respondents' perception, and personal bias due to self-reporting. Nonetheless, this study is 1 of the first and most significant in our country to provide early insights into the public acceptance and willingness to pay for COVID-19 boosters, thus making substantial contributions to Vietnam's efforts to integrate COVID-19 boosters into its regular health care requirements.

Conclusion

Our study showed a high willingness to take yet a low willingness to pay for a COVID-19 vaccine booster among Vietnamese participants. More importantly, the low willingness to pay was traced to insufficient information and underestimating vaccine importance. To resolve the lack of knowledge, we proposed a vaccine promotion approach with emphasis on side effects, mortality rate, immunity duration, and effectiveness, as well as social listening to counter misinformation. As the media and health experts are the most trusted information providers, their role in monitoring, directing, and resolving issues of public perception can be optimized through interactive interventions, such as Q&A sessions between influential health figures on television or an online platform, a COVID-19 vaccine–specialized hotline by health officials, and use of social listening insights. Work incentives, such as assistance for COVID-19 vaccine sick leave and technical convenience for vaccine reminders, can also be provided to encourage vaccine uptake. Above all, all vaccine promotion campaigns should be based on an open display of benefits as well as unwanted limitations of vaccines to achieve a nationally accepted regular COVID-19 vaccination in the long term.

Abstract

Background: The success of pediatric COVID-19 vaccination strongly depends on parents' willingness to vaccinate their children. To date, the role of socioeconomic position (SEP) in pediatric COVID-19 vaccination has not been thoroughly examined.

Objective: We evaluated the association between COVID-19 vaccination and SEP in a large pediatric cohort.

Methods: A case-control study design nested into a pediatric cohort of children born between 2007 and 2017, living in the Veneto Region and followed up to at least January 1, 2022, was adopted. Data on children were collected from the Pedianet database and linked with the regional COVID-19 registry. Each child vaccinated with at least one dose of any COVID-19 vaccine between July 1, 2021, and March 31, 2022, was matched by sex, year of birth, and family pediatrician to up to 5 unvaccinated children. Unvaccinated children with a positive outcome on the swab test within 180 days before the index date were excluded from the analyses. Children were geo-referenced to determine their area deprivation index (ADI)—a social and material deprivation measure calculated at the census block level and consisting of 5 socioeconomic items. The index was then categorized in quintiles based on the regional ADI level. The association between ADI quintiles and vaccination status was measured using conditioned logistic regression models to estimate odds ratios and the corresponding 95% CIs. Quantile-g-computation regression models were applied to develop a weighted combination of the individual items to estimate how much each component influenced the likelihood of vaccination. All analyses were stratified by age at vaccination (5-11 and 12-14 years).

Results: The study population consisted of 6475 vaccinated children, who were matched with 32,124 unvaccinated children. Increasing area deprivation was associated with a lower probability of being vaccinated, with approximately a linear dose-response relationship. Children in the highest deprivation quintile were 36% less likely to receive a COVID-19 vaccine than those with the lowest area deprivation (95% CI 0.59-0.70). The results were similar in the 2 age groups, with a slightly stronger association in 5-11–year-old children. When assessing the effects of the weighted combination of the individual items, a quintile increase was associated with a 17% decrease in the probability of being vaccinated (95% CI 0.80-0.86). The conditions that influenced the probability of vaccination the most were living on rent, being unemployed, and being born in single-parent families.

Conclusions: This study has shown a significant reduction in the likelihood of receiving a COVID-19 vaccine among children living in areas characterized by a lower SEP. Findings were robust among multiple analyses and definitions of the deprivation index. These findings suggest that SEP plays an important role in vaccination coverage, emphasizing the need to promote targeted public health efforts to ensure global vaccine equity.

Introduction

Given the high contagiousness of SARS-CoV-2 and the constant development and selection of new variants with increased pandemic potential, the success of population-based vaccination campaigns strongly depends on vaccination coverage [1]. It is largely accepted that COVID-19 vaccines are highly effective in reducing severe disease outcomes in adults, and numerous studies suggest they are also safe and effective in children [2-4]. In Italy, the first COVID-19 vaccines were approved for individuals aged between 12 and 15 years in May 2021 [5]. Since December 2021, the national drug regulation agency (Agenzia italiana del farmaco) has authorized the administration of a reduced dose of the vaccine also for children aged 5 to 11 years [5]. In December 2022, first dose coverage was 28.9% among children aged 5-11 years and 78.8% in those aged 12-19 years (information on children aged 12-14 years was not available) [6]. Before the end of the study period (March 2022), most of those first doses had been administered (with more than 95% coverage in both age groups) [6].

COVID-19 strongly impacts children from numerous perspectives, including interference with social interactions and mental health [7]. Children with COVID-19 are also at increased risk of developing multisystem inflammatory syndrome, and COVID-19 vaccines seem to reduce this risk [8,9]. Therefore, the importance of vaccination among children should not be ignored, in addition to the role played by the pediatric population in the COVID-19 transmission chain.

Depending on the characteristics of new SARS-CoV-2 variants and the mutating epidemiological scenario, future studies on vaccine effectiveness and safety in children will determine if vaccinating the pediatric population will remain a priority [1]. In 2019, the World Health Organization identified vaccine hesitancy as one of the 10 greatest threats to global health [10]. Some studies have suggested that a lower socioeconomic position (SEP) may be associated with a reduced chance of receiving a COVID-19 vaccine in adults [11-13]. However, evidence in children is scarce [14-22] also due to the shorter time since the approval of most COVID-19 vaccines. Furthermore, there are limitations to the generalizability of these works related to low numbers in the study populations and analyses exclusively based on referred data (ie, parental propensity to vaccinate their children or reported vaccine status), as opposed to actual recorded vaccination.

The surge of new variants could severely endanger public health by effectively eluding the immune system of previously immunized people, including children, increasing the population at risk of being infected and facing the consequences of COVID-19. If this were to occur, a prompt public health response would be required, and a vaccination campaign with booster doses or updated vaccines against new variants might have to rapidly reach very high portions of the population and potentially also the pediatric population. Therefore, identifying the socioeconomic determinants that most heavily affect the chances of children being vaccinated is crucial. Reducing these determinants' effects by increasing and diversifying vaccination campaign approaches and facilitating access to vaccination centers in specific at-risk groups should become a public health priority [7,23-26].

The area deprivation index (ADI) is a composite index that has been extensively used to examine socioeconomic status [27,28]. Having low education, being unemployed, living on rent, living in crowded households, and being born in single-parent families in the area are the items that compose the index and are among the most relevant socioeconomic determinants.

The aim of this study was to examine the association between ADI and its specific components with COVID-19 vaccine status in a large cohort of children aged 5-14 years in northern Italy. Given that socioeconomic variables are strongly correlated with one another, a weighted combination of the indicators (weighted deprivation index [WDI]) was also generated to assess which components most influence the likelihood of vaccination.

Methods

Setting and Study Design

A case-control study design nested into a large pediatric cohort of children living in the Veneto region, Italy, was adopted. Children were defined as being vaccinated if they had received at least one vaccine dose by the end of follow-up. Vaccination status in children aged 5-14 years was examined between July 1, 2021, and March 31, 2022. Each vaccinated child was matched by sex, year of birth (from 2007 to 2017), and family pediatrician (FP; among the 33 doctors included in the analyses) to up to 5 unvaccinated children. Based on the residential status of each child, an ADI was computed at the census block level.

Data on all children included in the study derive from the Veneto Pedianet database [29]. Pedianet is an Italian network of more than 400 FPs who use an established pediatric primary care database based on the Junior Bit software in their clinical practice. Data generated by Pedianet FPs are anonymized, in compliance with Italian regulations, stored in a protected "cloud" under a unique numerical identifier, and regularly checked for validation and quality control. The database includes patient demographic and clinical characteristics, containing diagnoses (free text or coded diagnoses using the International Classification of Diseases, Ninth Revision, Clinical Modification system), drug prescriptions (recorded in accordance with the Anatomical Therapeutic Chemical codes), health care copayment exemptions, specialist visits, diagnostic procedures, hospital admissions, growth parameters (repeated measures of height and weight in accordance with national indications), and free text to report symptoms or other medical observations related to the visit. Moreover, through the electronic health record of each child included in the cohort, we were able to link the Veneto Pedianet database with the regional COVID-19 registry—where results from COVID-19 swab tests are recorded—and the regional immunization database, for vaccination history.

Inclusion in the Pedianet database is voluntary; parents or legal guardians provided consent for their children's anonymized data to be used for research purposes in accordance with national and international regulations.

Pedianet is a large database rich in numerous clinical variables, but information on parental SEP is often missing or incomplete. SEP was first measured by means of an ADI, computed at the census block level retrieved from the 2011 Italian Census [27] (with a median number of residents of 66, IQR 28-181, per census block).

The ADI is based on 5 items that recurrently describe social and material deprivation: (1) low education, (2) unemployment, (3) living on rent, (4) crowded households, and (5) single-parent families [27,28]. The index is calculated as the sum of standardized indicators. The index was then categorized in quintiles based on the regional ADI level to ensure within-region appropriately represented categories.

The addresses of the children included in the study population were geo-referenced and linked to the census block of each Italian municipality. Through record linkage with the census block number, the ADI and all the variables defined at the census block level were retrieved for each address.

Ethical Considerations

This is an observational, retrospective, noninterventional study. According to a bylaw on the classification and implementation of observational drug-related research, as issued by the Italian National Drug Agency (an entity belonging to the Italian Ministry of Health), this study does not require approval by an ethics committee in Italy (Italian Drug Agency note on August 3, 2007). This study was conducted in accordance with the tenets of the Declaration of Helsinki and was compliant with the European Network of Centres for Pharmacoepidemiology and Pharmacovigilance's *Guide on Methodological Standards in Pharmacoepidemiology*.

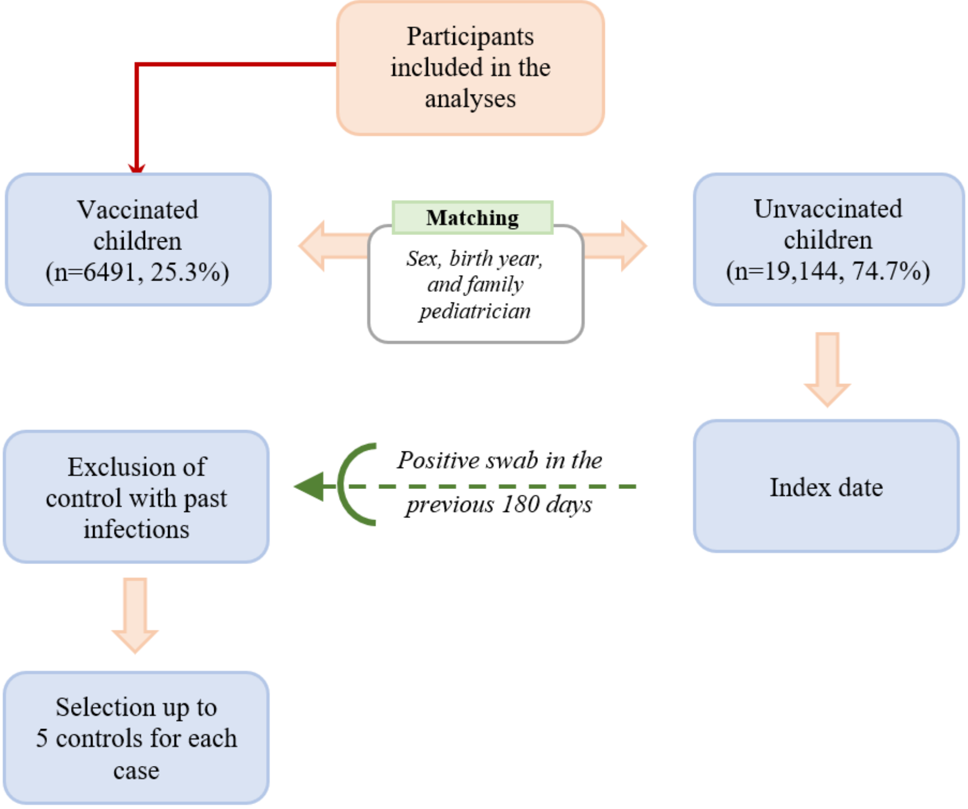
Ethical approval of the study and access to the database was approved by the Internal Scientific Committee of So.Se.Te. Srl, the legal owner of Pedianet.

Study Population

We identified 160,720 children from the Veneto Pedianet database. Exclusion criteria were (1) children born before 2007 or after 2017, (2) those who had the end of follow-up or the last contact with the FP before January 1, 2022, (3) those who were not properly geo-referenced or for whom it was not possible to determine an ADI, and (4) those for whom individual linkage with the COVID-19 registry was not possible (Figure S1 in Multimedia Appendix 1, details provided in Multimedia Appendix 2). Of the 25,635 children aged 5 to 14 years included in the study, 6491 (25.3%) received a COVID-19 vaccine between July 2021 and March 2022, and 19,144 (74.7%) did not. For the purpose of our analyses, we defined children as vaccinated if they received at least one dose of any COVID-19 vaccine.

Each vaccinated child was first matched by sex, year of birth, and FP to all possible available unvaccinated children. The same control was eligible for more than one case. Each control was then assigned an index date that corresponded to the date of COVID-19 vaccination of the matched case. Since matching by year of birth has led some controls to have a different age (±1 year) compared to cases, only controls who belonged to the same age group as cases at the index date (5-11 years and 12-14 years) were included. Given the indication of government agencies to vaccinate children with a previous SARS-CoV-2 infection only after 6 months, unvaccinated children with a positive swab within 180 days before the index date were excluded from the analyses. Finally, for each vaccinated child (case), up to 5 controls were randomly selected from the matched unvaccinated children (Figure 1). Matching was implemented to control for confounding and improve statistical efficiency.

Figure 1. Flowchart of the study design.



Statistical Analysis

Spearman rank correlation (ρ) was used to describe pair-wise relations between the ADI items.

Conditional logistic regression models were fitted to estimate odds ratios (ORs) and the corresponding 95% CIs for receiving a COVID-19 vaccine associated with ADI and the single items included in the index. All variables were treated as categorical with the first quintile (least deprived) as a reference. Age, sex, and FP confounding were controlled for by the study design.

To account for the strong correlation between the socioeconomic determinants that composed the ADI, we then applied a quantile-g-computation regression model to develop a weighted combination of socioeconomic variables (weighted deprivation index [WDI]) to examine its association with the outcome. Quantile-g-computation is a parametric, generalized linear model–based implementation of g-computation, which quantifies the expected change in the outcome, given a single quantile change in all exposures (the items included in the ADI) simultaneously while controlling for covariates. This method first transforms all exposures into quintiles and then fits a linear model with the dependent variables. Finally, weights are defined for each exposure, corresponding to the partial effect attributed to a specific exposure. Following these steps, the ADI items were combined to calculate a weighted index that was then categorized in quintiles. Both positive and negative relations between each indicator of the index and the outcome were allowed without any directional homogeneity assumption [30]. We defined as an item of concern any socioeconomic determinant contributing to the overall effect with a negative weight that exceeded the threshold of *1/p* (where *p* varied depending on the number of items with estimated negative weight in each stratum).

As a sensitivity analysis, the prevalence of foreigners in the area was also included among the area-based socioeconomic variables under study. All analyses were stratified by age at the index date (5-11 years and 12-14 years). Analyses were performed using SAS [31] and R [32] statistical software. We used *survival* [33] and *qgcomp* [30] packages to conduct conditional logistic regression and quantile-g-computation with R, respectively. Results with estimated *P* values of <.05 were considered significant.

Results

General Characteristics

The general characteristics of the study population are reported in Table S1 in Multimedia Appendix 1. Among the 25,635 children included in the study, the proportion of those who were vaccinated against COVID-19 was markedly higher for older children. The prevalence of vaccinated children varied largely based on the pediatrician and birth year (Table S1 in Multimedia Appendix 1). The distribution of the ADI quintiles of the children included in the study did not differ from the regional ADI distribution (Table S2 in Multimedia Appendix 1).

Among the specific items that composed the deprivation index, we observed strong correlations, especially between living on rent and being unemployed (ρ=0.31), followed by living on rent with crowded households (ρ=0.26). When including the presence of non-Italian ethnicity in the area, in the correlation matrix, an even stronger correlation was observed with living on rent (ρ=0.68), being unemployed (ρ=0.36), and living in crowded households (ρ=0.26).

The analyzed population consisted of 6475 vaccinated children, 3694 aged 5-11 years and 2781 aged 12-14 years, matched with 18,429 and 13,695 unvaccinated children, respectively.

Association With Vaccination Status

Results from the conditioned logistic regression models are shown in Table 1.

This analysis revealed negative associations between the probability of being vaccinated and increasing ADI quintiles, with approximately a linear dose-response relationship. Children in the highest deprivation quintile were 36% less likely to be vaccinated against COVID-19 than those living in the least deprived areas (OR 0.64, 95% CI 0.59-0.70). The results were similar in the 2 age groups, with more pronounced differences among 5-11–year-old children. For each quintile increase of ADI, the chances of being vaccinated against COVID-19 decreased by 10% (OR 0.90, 95% CI 0.88-0.91; Table 2).

Table 1. Association between the quintiles of area-deprivation index (ADI) and COVID-19 vaccination status, stratified by age groups (N=38,599).

Quintile of ADI	Vaccinated (n=6475), n (%)	Unvaccinated (n=32,124), n (%)	Odds ratio (95% CI)[a]
Total			
ADI 1	1501 (23.2)	6160 (19.2)	1 (reference)

[b] *P*<.001.

Table 2. Association between a quintile increase of deprivation index and COVID-19 vaccination status, stratified by age-group.

Interquintile increase in the deprivation index	Total (n=38,599), odds ratio (95% CI)	Age group of 5-11 years (n=22,123), odds ratio (95% CI)	Age group of 12-14 years (n=16,476), odds ratio (95% CI)
IQ ADI[a]	0.90 (0.88-0.92)[b]	0.88 (0.86-0.91)[b]	0.92 (0.89-0.95)[b]
IQ WDI[c]	0.83 (0.80-0.86)[b]	0.81 (0.77-0.85)[b]	0.84 (0.80-0.89)[b]
IQ WDI[d]	0.82 (0.79-0.85)[b]	0.81 (0.77-0.85)[b]	0.83 (0.79-0.88)[b]

[a] From the conditional logistic regression model; ADI: area deprivation index.

[b] *P*<.001.

[c] From the quantile g-computation model; WDI: weighted deprivation index.

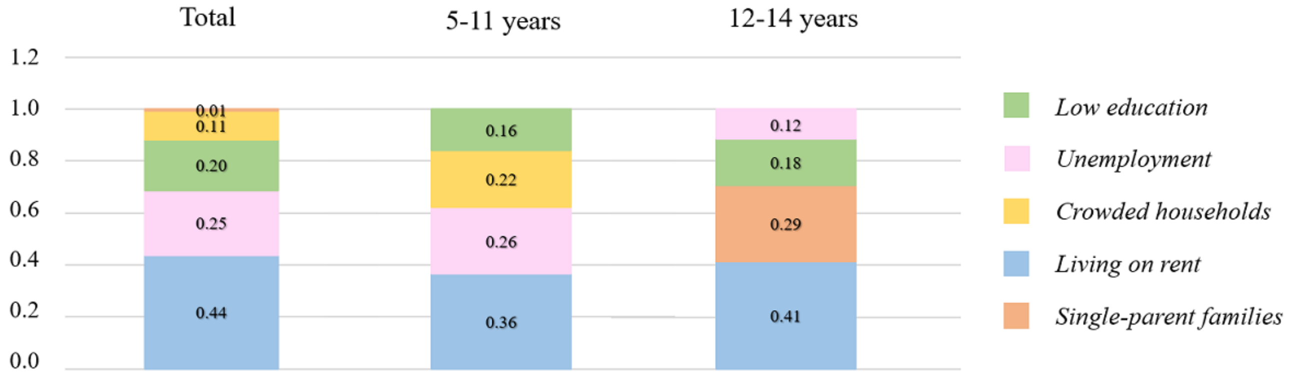
[d] From the quantile g-computation model including the presence of foreigners in the area.

This effect seems to be slightly stronger among children aged 5-11 years, where the chances of being vaccinated decreased by 12% (OR 0.88, 95% CI 0.86-0.91) for each quintile increase of the ADI, while the decrease corresponded to 8% among children aged 12-14 years (OR 0.92, 95% CI 0.89-0.95; Table 2).

When assessing the effects of the WDI, a quintile increase was associated with a decrease in the probability of being vaccinated of 17% (overall OR 0.83, 95% CI 0.80-0.86; Table 2). The most influential condition on the probability of being vaccinated was living on rent (weight –0.44), which showed the highest weight in both 5-11–year-old children (weight –0.36) and 12-14–year-old children (weight –0.41; Figure 2). Being unemployed was also influential both overall and among the 5-11–year-old children (weights –0.25 and –0.26, respectively), while among 12-14–year-old children, single-parent families weighed the most (weight –0.29; Figure 2).

When including the prevalence of foreigners in the area among the area-based socioeconomic variables, no significant differences were observed in the WDI estimates (overall OR 0.82, 95% CI 0.79-0.85; Table 2). Nevertheless, on observing the weights of single indicators, a stronger association was found among younger children; the multiracial area was always identified as an influential condition, with the greatest weight, compared to the other variables both in the overall population and among children aged 12-14 years (weights –0.45 and –0.64, respectively; Table S3 in Multimedia Appendix 1). WDI analysis confirmed that living on rent remained the greatest determinant in the association of socioeconomic deprivation with COVID-19 vaccination in 5-11–year-old children (weight –0.24).

Figure 2. Quantile-g-computation model regression index negative weights for the probability of being vaccinated.



Discussion

Principal Findings and Comparison With Prior Work

The findings of this study have shown a significant reduction in the likelihood of receiving a COVID-19 vaccine among children living in areas characterized by greater socioeconomic deprivation. The dose-response gradient was strongest among children aged 5-11 years, for whom social and material deprivation reduced the chances of being vaccinated the most. The robustness of these findings is confirmed by results that were consistent across multiple analyses and definitions of the deprivation index.

Previous studies, mainly conducted in the United States, have shown how social inequalities affect COVID-19 vaccination rates in children [14-21]. To the best of our knowledge, this is one of the first studies to examine the association between a robust and largely used ADI and the registered vaccination status against COVID-19. Most other studies examining this association were surveys and mainly focused on parental willingness to vaccinate their children [14-16,18,20,21]. Only a few studies examined the COVID-19 vaccination status of children [17-19,22], but in most cases, data were reported by the parents [17-19].

When examining single indicators of lower socioeconomic status, items that were most negatively associated with the chances that a child received a COVID-19 vaccine were lower education [16,18-20], low income levels [14,18,20], high unemployment rates [16], living on rent [15], as well as living in a multiethnic area [14,18].

Comparable results to ours were reported by a study conducted in the United Kingdom based on over 27,000 students aged 9-18 years, which showed that the hesitancy toward vaccinating their children among both undecided parents (n=1688) and those against vaccination (n=4874) was higher among children in the most deprived quintile [15]. Regarding studies on reported vaccination status, in a large US survey of 59,424 children aged 12-17 years, Nguyen et al [19] found greater vaccination coverage among children whose parents had more than college education (adjusted prevalence ratio 1.15, 95% CI 1.05-1.25) [19]. Furthermore, a recent study elucidated variables associated with COVID-19 vaccination among Israeli adolescents (n=43,919) using data from an electronic database, showing that adolescents of low SEP had a very low vaccination rate (42.3%) compared to those having a high SEP (80.4%), which was highly significant upon univariate analysis but did not reach statistical significance using a multivariate approach [22].

Vaccination of children and adolescents largely depends on the vaccine hesitancy or antivaccination positions of the parents. Lower parental SEP has been associated with a lower parental propensity to vaccinate their children. In Europe, over the past decades, the link between SEP and vaccine coverage has been weakening, and a much more relevant role seems to be played by the lack of vaccine confidence or alternative health beliefs [34]. In the present mutating context, the pandemic may have determined hardly predictable effects. The increase in the vaccine coverage rate may have been primarily driven by the fear of infection and long-term consequences of COVID-19, while vaccine hesitancy may have increased as a result of the fear of adverse effects for newly registered vaccines, which may have been greater due to the novelty of mRNA vaccines [35-37].

Public perception of the pandemic and of COVID-19 vaccines was extremely heterogeneous. Mass vaccination campaigns and government incentives such as vaccine passports, which had not been implemented for decades in high-income countries, may have also affected vaccine hesitancy in different ways [38,39]. Nonetheless, it remains unclear how these opposing tendencies may have affected the association between SEP and COVID-19 vaccination.

When assessing the association between interquintile changes in the deprivation index and the likelihood of receiving a COVID-19 vaccine, the effects estimated from the WDI were always stronger. The ADI treats each dimension as if they were of equal importance by summing up their relative contribution with equal weight [27], rather than weighing indicators in accordance with their association with the outcome. This approach also allowed us to assess the role of the ethnic composition in each area, which was not included in the ADI. This variable was strongly associated with the likelihood of being vaccinated when considered individually as a socioeconomic determinant, but its inclusion in the WDI did not change the magnitude of the association of each quintile with the chances of being vaccinated, although this component weighted more than the others. This helps confirming the robustness of the national deprivation index (ie, ADI) to the inclusion of such a component.

We observed large differences in vaccination coverage by age, with much higher percentages among older children. A reasonable explanation could be found in the Italian COVID-19 regulations, issued differently in accordance with age: all adolescents aged ≥12 years had to exhibit a vaccine passport (a certificate provided to all people immunized against COVID-19) in order to participate, to most public, leisure, and sport activities, while there were no restrictions for younger children. This may also have contributed to a reduction in the role of SEP on the likelihood of vaccination specifically in adolescents, flattening the differences in this group. We can expect that this effect could be more evident in older adolescents (aged 15-19 years), who exceeded the maximum age required to be followed up by a FP. As age increases, the parental willingness to vaccinate their children may play a weaker role, as well as the SEP itself, given a greater autonomy of the adolescent.

Our study also showed how FPs were among the most relevant elements in determining the chances of receiving a COVID-19 vaccine. This suggests that promoting vaccination campaigns and raising awareness of the importance of pediatric vaccinations may significantly affect vaccination coverage among the children they assist.

Strengths and Limitations

Our study has several strengths. First, the large cohort study was based on more than 25,000 children with real data on the vaccination status, regardless of the willingness or hesitancy to get a COVID-19 vaccine. Vaccinations were entirely managed by the National Health Service, and all vaccinations were promptly recorded in a centralized register, so data on vaccination coverage were complete and constantly updated. Data on previous SARS-CoV-2 infections that determined changes in the vaccination schedule based on government indications allowed us to perform more accurate analyses, thereby including only children who did not receive a COVID-19 vaccine for reasons likely not related to vaccine indications. Furthermore, we controlled by design the interpediatrician variability, which emerged as one of the main determinants of receiving a COVID-19 vaccination in our study population.

Another strength of this study was addressing the presence of intercorrelation between social determinants by using an ADI, both nonweighted and weighted, through a data-driven method for modeling the exposure to multiple socioeconomic determinants. This method provided a measure of the simultaneous effect of the included socioeconomic indicators after a quantile transformation, which makes the exposure more robust to extreme values and more comparable to other settings, as opposed to using value-based cutoffs [40]. This supervised approach empirically examines single contributions of each indicator to the association, allowing us to understand which condition most influences the likelihood of receiving a vaccine.

The main limitation of this work is the absence of comprehensive individual information on socioeconomic status, which is why a census block–level deprivation index was used. Still, we know that ADI represents a simplification that may not exactly correspond to the reality, but it acts as a good proxy of individual socioeconomic status or as a comparative measure of socioeconomic background [27].

A possible bias could derive from the exclusion of some FPs that did not adhere to the COVID-19 data registry linkage or that were missing up-to-date information about the children they assisted. However, we believe that this bias should be negligible, since the distribution of the ADI quintiles among the children included in the study did not differ from the regional ADI quintile distribution, suggesting that the study population is likely to be representative of the regional population.

Moreover, some residual confounders related to specific indications to not vaccinate children (ie, due to specific health conditions) cannot be entirely ruled out. However, the magnitude of the association between the likelihood of being vaccinated and the deprivation indexes we used makes an overturning of the results unlikely.

The relatively short study period also is unlikely to have affected our results, given the low vaccination rates in children from April 2022 onward.

Conclusions

In a rapidly evolving pandemic scenario, achieving good vaccination coverage in adults is crucial, and high vaccination coverage could become a priority among children as well. It is of utmost importance for public health experts to identify population strata at risk of not achieving adequate vaccine coverage in order to remove barriers to accessing vaccines and to promoting targeted campaigns for these groups at increased risk. The relevance of vaccine coverage applies to COVID-19 vaccines, but also to other vaccines such as those against seasonal influenza.

Abstract

Background: Evidence suggests that individuals may change adherence to public health policies aimed at reducing the contact, transmission, and spread of the SARS-CoV-2 virus after they receive their first SARS-CoV-2 vaccination when they are not fully vaccinated.

Objective: We aimed to estimate changes in median daily travel distance of our cohort from their registered addresses before and after receiving a SARS-CoV-2 vaccine.

Methods: Participants were recruited into Virus Watch starting in June 2020. Weekly surveys were sent out to participants, and vaccination status was collected from January 2021 onward. Between September 2020 and February 2021, we invited 13,120 adult Virus Watch participants to contribute toward our tracker subcohort, which uses the GPS via a smartphone app to collect data on movement. We used segmented linear regression to estimate the median daily travel distance before and after the first self-reported SARS-CoV-2 vaccine dose.

Results: We analyzed the daily travel distance of 249 vaccinated adults. From 157 days prior to vaccination until the day before vaccination, the median daily travel distance was 9.05 (IQR 8.06-10.09) km. From the day of vaccination to 105 days after vaccination, the median daily travel distance was 10.08 (IQR 8.60-12.42) km. From 157 days prior to vaccination until the vaccination date, there was a daily median decrease in mobility of 40.09 m (95% CI –50.08 to –31.10; *P*<.001). After vaccination, there was a median daily increase in movement of 60.60 m (95% CI 20.90-100; *P*<.001). Restricting the analysis to the third national lockdown (January 4, 2021, to April 5, 2021), we found a median daily movement increase of 18.30 m (95% CI –19.20

to 55.80; *P*=.57) in the 30 days prior to vaccination and a median daily movement increase of 9.36 m (95% CI 38.6-149.00; *P*=.69) in the 30 days after vaccination.

Conclusions: Our study demonstrates the feasibility of collecting high-volume geolocation data as part of research projects and the utility of these data for understanding public health issues. Our various analyses produced results that ranged from no change in movement after vaccination (during the third national lock down) to an increase in movement after vaccination (considering all periods, up to 105 days after vaccination), suggesting that, among Virus Watch participants, any changes in movement distances after vaccination are small. Our findings may be attributable to public health measures in place at the time such as movement restrictions and home working that applied to the Virus Watch cohort participants during the study period.

Introduction

The UK response to the COVID-19 pandemic has included multiple rounds of restrictions on nonessential movement to reduce contacts and control transmission [1]. Examples of permissible travel included necessary shopping, exercise, medical need, or travel to and from essential work [2]. However, the restriction of movement can have a detrimental impact on a wide variety of outcomes such as reduced physical activity [3], mental health, domestic accidents, the economy, and education [4]. Adherence to travel-based public health interventions and those especially aimed at limiting nonhousehold contact has varied through time [5]. A brief timeline of the United Kingdom’s approach to restrictions can be found in Figure 1 [6].

The introduction of vaccinations against COVID-19 reduces SARS-CoV-2 transmission and disease [7] and, as a result, is a critical part of the strategies to allow more normal societal mixing due to increased immunization. However, in the UK context, there are concerns that misunderstandings about the effectiveness of the COVID-19 vaccine after the first dose, which may be leading to a reduction in adherence to other public health policies and increased exposure of partially protected individuals [8]. Preliminary research on vaccination in February 2021 found that 41% of individuals age >80 years who had their first dose of the vaccine had met at least one other person outside their household within 3 weeks. These contacts did not include care workers or members of their support bubble that were permitted by the restrictions in place at the time [8]. This finding is concerning as antibody levels would not have risen in the 1-2 weeks following the first dose of vaccine [9,10]. Further evidence also suggests that those aged >80 years are more likely to have a positive polymerase chain reaction test in the first 9 days after vaccination compared to a control group, which might be explained by increased mobility and contacts between people in the period following vaccination [11]. During the emergence of the Delta (B.1.617.2) SARS-CoV-2 variant, the effectiveness of both the Oxford-AstraZeneca and Pfizer-BioNTech vaccines were estimated to be 33% against symptomatic disease after a first dose [12], although protection against hospitalization appears to be much higher [13]. Therefore, if those who are not fully vaccinated increase their level of social contact and mobility after vaccination, their risk of becoming infected and infecting others may also be increased.

Understanding movement after the first vaccination is important, as it could help policy makers understand how perceived protection from the vaccination program may negatively offset the effectiveness of other policies designed to reduce transmission. Such arguments can also be extended beyond the first vaccination with the introduction of booster shots and variant-specific vaccines in relation to future SARS-CoV-2 variants. Although previous studies have attempted to investigate travel distances after vaccination [14], these studies were conducted using mobile call data based on cellular tower location, which is considered less accurate compared to GPS location. Alternative methods for movement tracking exist, such as tracking debit/credit card usage [15] and QR code check-in for venues [16]. Although such technology can be used to track specific activities, it can be limited as they require active interaction from users, and assessing travel distance can be limited if travel occurs beyond the use of such technology. GPS technology, on the other hand, uses satellites to allow users to passively submit longitude and latitude data globally, both indoors and outdoors [17].

In this analysis, we aimed to quantify the effect that the first SARS-CoV-2 vaccination had on travelling behavior, using mobile phone GPS data collected from study participants who consented and voluntarily downloaded the ArcGIS Tracker app onto their mobile phones.

Methods

Study Design and Setting

The study design used prospective observational data from the Virus Watch cohort; a full description of the Virus Watch study has been published previously [18]. Briefly, households were recruited starting in mid-June 2020, which was aimed at creating a representative cohort of England and Wales. To rapidly recruit participants at the start of the pandemic, we used a range of methods aimed at creating a representative cohort of England and Wales. We used the Royal Mail Post Office Address File to generate a random list of residential addresses that were sent recruitment postcards (n=3914), placed social media advertisements on Facebook and Twitter (n=18,594), and sent SMS text messages (n=11,151) and letters to participants and households from their general practitioners (n=3803). We invited a random sample of eligible participants to our tracker subcohort who were adults (aged ≥18 years) on entry that agreed to participate in installing the ArcGIS Tracker on their compatible smartphone and who provided full details on gender, ethnicity, and a registered address.

The ArcGIS Tracker app is available for the Apple iOS (iOS 12 or later) and Google Android (version 5.0 or later) platforms and can be downloaded from their respective app stores [19]. The ArcGIS Tracker app requires users to log in (using provided credentials) and share their location using an on-off toggle button that allows users to control when and where they would like to share their location. The location app is designed to run in the background to collect data; however, on certain models of phones, this function had to be enabled in the smartphones' settings menu. Using the ArcGIS Tracker app, the subcohort provided the following data: date; time; longitude; latitude; travel mode; and GPS accuracy, which was defined by the phone manufacturer's GPS algorithm. See Figure 2 for screenshots of the ArcGIS Tracker app.

Intervention

The date of receiving the first dose of vaccine was self-reported through the weekly Virus Watch questionnaire. We began collecting weekly vaccination status on January 11, 2021, and asked about any prior vaccination during the first 2 weekly surveys. Subsequently, participants were asked to provide a weekly update only. The options available were "Pfizer/BioNTech," "Oxford/AstraZeneca," "Moderna," and "Other/Can't remember."

Study Population

The study population included adults (aged ≥18 years on entry) in the subcohort of the Virus Watch study who were vaccinated and submitted at least 10 days of readings. Participants had to submit at least 5 days of readings before and after their self-reported vaccination date. We excluded readings that were outside of England and excluded analysis from days where there were fewer than 5 contributors. We only used location readings with an accuracy rating of less than 30 m.

Study Period

We started sending out invitations for the Tracker cohort between September 2020 and February 2021, with the data extraction for this analysis being undertaken in May 2021.

Outcomes

The unit of the analysis was the aggregated median daily travel distance, with the outcome being the change in median daily travel distance. To calculate the group's median daily travel distance, we aggregated the daily movement from each participant's registered address for each day. The median daily distance was chosen to account for the distribution of the cohort's daily travel patterns.

Analysis

For each individual and each day, we calculated the cumulative outdoor travel distance recorded using the ArcGIS Tracker app from their registered household address. This was calculated by summing up the distance (*d*) computed by the Euclidean distance method (equation 1) between the 2 sequential outdoor GPS records. Considering the accuracy of the GPS records, we set up a 25 m radius buffer zone (the average horizontal accuracy is 25 m) around a participant's home location. Points that fall within the buffer are considered as at-home travel activities and therefore considered as zero distance in analyses.

The equation to calculate the distance travelled by each participant is as follows:

where $d(p_i, p_j)$ is the Euclidean distance between 2 sequential GPS points (ie, p_i and p_j); the Cartesian coordinates are (p_{ix}, p_{iy}) for p_i and (p_{jx}, p_{jy}) for p_j. We used the British National Grid as the reference system.

Our statistical analysis was conducted using an interrupted time series, where we used segmented linear regression to estimate the trends in travel patterns, with the first segment estimating the median travel distance for the cohort before vaccination and the second segment estimating the median travel distance for the cohort after vaccination. Therefore, we defined the interruption time point in our analysis as the date of the first vaccination for each individual, with negative days denoting days prior to vaccination and positive days denoting days after vaccination; for each day, we then calculated the median travel distance.

To calculate the travel trajectory before vaccination, we conducted linear regression analysis using data before vaccination to estimate the sample's median daily travel distance from their home with time (days before vaccination) as the explanatory variable. To calculate the travel trajectory after vaccination, we conducted linear regression analysis using data after vaccination to estimate the sample's median daily travel distance from their home with time (days after vaccination) as the explanatory variable. For both models, each day represented 1 data point, with the points for each day being the median travel distance of those who submitted readings on that day. The segmented regression equations can be found in equation 2; linear regression was chosen a priori as we expected the limitations on movement to create a stable pattern in movement. Our alternative hypothesis was that after vaccination, we would see an increase in movement that would be expressed if $a_2 > a_1$ (a slope change) or $b_2 > b_1$ when $a_2 \geq a_1$ (a level change) [27] in equation 2.

Equation 2 uses segmented linear regression models with model (and subscript) 1 representing the trends before vaccination and model (and subscript) 2 representing the trends after vaccination; y_n represents the estimated median daily travel distance with coefficient a_n, x represents the days since vaccination (negative for model 1 and positive for model 2), and b_n is a constant:

$$y_1 = a_1x + b_1 \text{ for } x < 0 \quad \textbf{(2)}$$

$$y_2 = a_2x + b_2 \text{ for } x > 0$$

The UK vaccination program prioritized people by (older) age and clinical risk groups, which, in addition to differences in the socioeconomic backgrounds between those invited and accepting a vaccination, meant that selecting an appropriate control group for this analysis was not feasible.

Covariates

Due to the study design, which compared the same individuals' movement before and after vaccination, we did not use covariates for regression adjustment. For each eligible individual, we used the following data: days since vaccination and the total travel distance for the corresponding day.

Sensitivity Analyses

We performed various sensitivity analyses. First, after reviewing the data, we repeated the analyses with outliers removed. Three cutoff points were used: days with a median travel distance lower than 50 km, days with a median travel distance lower than 25 km, and days with a median travel distance lower than the median travel distance on the day of vaccination. This third cutoff point was used as the day of vaccination is the 1 day in which we were sure people had travelled (to be vaccinated).

Our second sensitivity analysis accounts for the effect of the removal of national restrictions on movement as alternative explanations for differences in movement after vaccination. We conducted a sensitivity analysis that limited travel and vaccination events to the third national lockdown. This period was from January 4, 2021, to April 5, 2021, and represents a time period when restrictions did not change in relation to rules regarding travel and social distancing.

Ethics Approval

The Virus Watch study was approved by the Hampstead National Health Service Health Research Authority Ethics Committee (20/HRA/2320). All members of participating households provided informed consent for themselves and, where relevant, for children that they were responsible for. To contribute to the tracker subcohort of Virus Watch, adults had to provide explicit consent during our registration process.

Information Governance

This research was registered with the University College London (UCL) data protection office and reviewed by the UCL information security and governance teams. The Virus Watch Data Privacy Impact Assessment can be found on the web [28]. During the consent and registration process, adult participants were invited to contribute geolocation data using the ArcGIS mobile phone tracker app. For those who chose to participate, we sent personal identifiable data from the UCL data safe haven to a secure memory stick on a UCL computer, from which we transferred the data via HTTPS into the ArcGIS Online (Esri UK) subscription. The purpose of this data transfer was to set up participants' tracker app accounts. The transferred data, along with the account passwords, were stored in North America. The UCL Virus Watch study team undertook the data transfer process and had access to the Participant Profile within the ArcGIS Online subscription. Only a small number of named ArcGIS employees had access to the participant profile area and only for the purposes of assisting the UCL study team when necessary. Once the tracker app accounts were created, the UCL study team emailed tracker app participants instructions on how to download the app and sign into the tracker app.

The geolocation data collected by the app were stored securely on a section of the ArcGIS Online subscription hosted in Europe, which is securely cleared every 30 days. Participants' geolocation data were transferred on a regular basis via HTTPS to a secure memory stick on a UCL machine and were then imported via a secure gateway technology onto the UCL secure memory stick and into the UCL data safe haven.

Geolocation data were linked with other participant study data in the data safe haven. Once analyzed, aggregate data (generated from geolocation and other study data) were exported from the data safe haven and published on the public study website and in research publications.

The aggregated data set used in this analysis will be securely destroyed after 20 years, in line with UCL's record retention policy. In line with policies developed for electronic health care research, we did not report any data with a cell containing <5 events, and where necessary, we protected these counts with secondary suppression.

Results

Cohort Demographics

By February 2021, Virus Watch recruited a total of 45,963 individuals, of whom 39,558 were at least 18 years old when registering. Of these 39,558 individuals, 79% (n=31,317) provided consent to install the ArcGIS Tracker app. Of the 31,317 participants, a sample of 13,120 adults (aged ≥18 years on entry) were chosen to be randomly invited based on having complete information on gender, ethnicity, and address details. Of these participants, 2193 contributed at least one GPS reading. After removing invalid data points, including those outside of England and those that did not submit accurate readings (eg, points that exhibit extremely high horizontal and vertical accuracy), 1376 participants were included. Of the 1376 individuals, 1244 individuals were vaccinated by May 2021. After removing individuals with fewer than 5 data points on either side of their vaccination date, 249 individuals were included in our final analysis. See Figure 3 for the Consolidated Standards of Reporting (CONSORT) diagram of how the cohort was analyzed.

Of the 249 participants, there were more women (n=141, 56.6%) than men, with a median age of 62 (IQR 55-67) years, which is older than the whole Virus Watch cohort. Individual residents in local super output areas in the 3 least deprived quintiles represented 79.1% (n=197) of the population. In all, 88.8% (n=221) of our cohort self-identified as “White—English/Welsh/Scottish/Northern Irish/British,” which is more than the whole Virus Watch cohort. See Table 1 for a sociodemographic breakdown of the cohort.

From the 249 participants, there were 157 days of eligible readings prior to the first vaccination, that is, 157 days before vaccination was the earliest day where there were at least 5 people who submitted readings; there were 105 days of readings under the same eligibility criteria after vaccination. The median number of people who contributed per day was 89 (IQR 34.75-135.50) people, with a median of 91 (IQR 35.00-132.00) people contributing before vaccination and a median of 88 (IQR 30.50-149.25) people contributing after vaccination. The median number of days contributed by the 249 participants was 87 (IQR 58.00-128.00) days, with a median contribution of 51 (IQR 26-77) days before vaccination and a median contribution of 36 (IQR 19.00-56.00) days after vaccination. Zero participants produced data for every day and 5 participants produced an equal amount of data before and after vaccination. Before vaccination (–157 days to –1 day), the median daily travel distance was 9.05 (IQR 8.06-10.09) km, and after vaccination (+1 day to 105 days), the median daily travel distance was 10.08 (IQR 8.60-12.42) km. The median travel distance on the day of vaccination was 19.1 (IQR 8.75-37.90) km.

During the first segment of the linear regression model, from 157 days before the first vaccination to the vaccination date, there was a median daily decline of 40.09 m (95% CI –50.08 to –31.10; *P*<.001) of movement with a constant of 6.90 m (95% CI 6.02-7.79; Figure 4A). During the second segment of the linear regression model, from the first vaccination date to 105 days after vaccination, there was a median daily increase of 60.6 m (95% CI 20.9-100; *P*<.001) of movement with a constant of 8.00 m (95% CI 5.59-10.40).

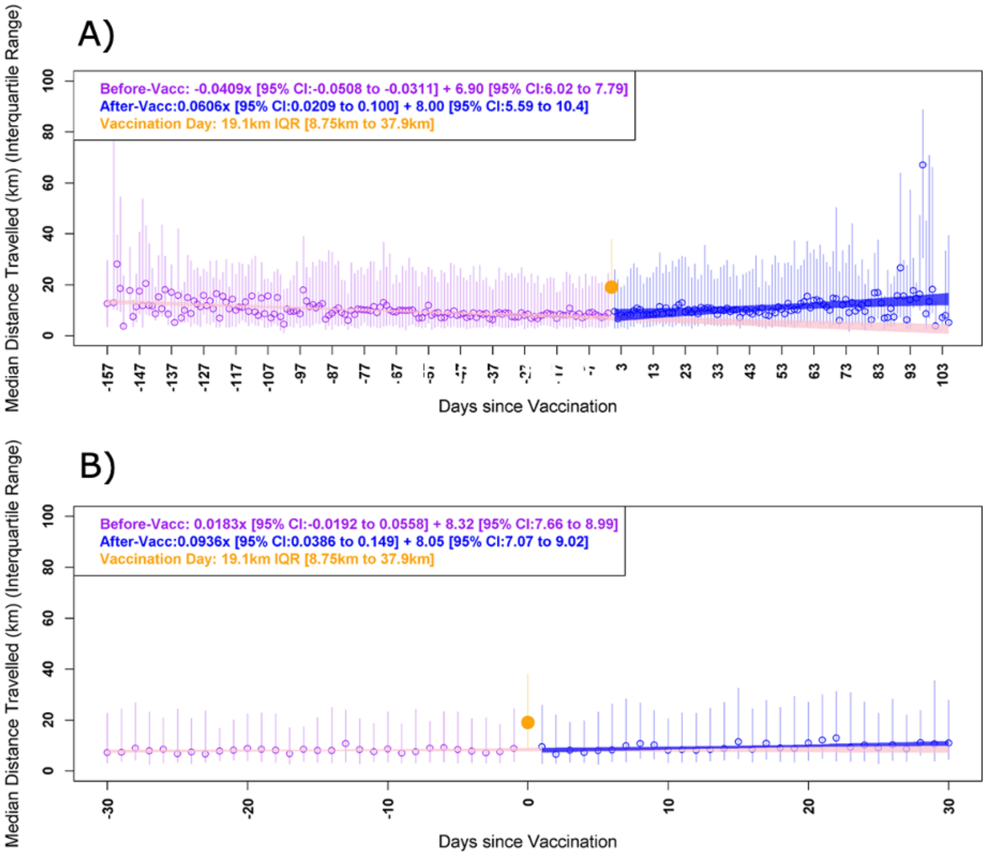
Figure 4. Graphical representation of the interrupted time series. Median daily travel distance from home in reference to vaccination date: (A) unrestricted (primary analysis); (B) only accounting for movement and vaccinations that occurred during the third national lockdown (January 4, 2021 to April 5, 2021) with a 30-day period either side of the vaccination date.



Sensitivity Analysis 1

After reviewing the data, we believe that certain median travel distances were outliers; therefore, we conducted sensitivity analyses to remove days that had readings higher than 50 km, 25 km, and the median distance travelled on the day of vaccination (19.1 km). Under these analyses, all median travel distances before and after vaccination, as well the coefficients and constants, stayed similar (ie, they did not cross the 95% CIs) when compared to the primary analysis. See Table 2 for the coefficients and median travel distances before and after vaccination. See Multimedia Appendices 1-3 for graphical representations of the interrupted time series for these sensitivity analyses.

Table 2. Results of various sensitivity analysis involving the removal of outlier points.

Maximum median distance	Median travel distance before vaccination (km; IQR)	Coefficient before vaccination (95% CI)	Constant before vaccination (95% CI)	Median travel distance after vaccination (km; IQR)	Coefficient after vaccination (95% CI)	Constant after vaccination (95% CI)
Unrestricted (primary analysis)	9.05 (8.06 to 11.34)	–0.041 (–0.051 to –0.031)	6.90 (6.02 to 7.79)	10.08 (8.60 to 12.42)	0.061 (0.021 to 0.100)	8.00 (5.59 to 10.40)
50 km	9.07 (8.06 to 11.34)	–0.041 (–0.051 to –0.031)	6.90 (6.02 to 7.79)	10.07 (8.59 to 12.21)	0.034 (0.014 to 0.055)	8.83 (7.63 to 10.00)
25 km	9.05 (8.05 to 11.32)	–0.037 (–0.046 to –0.028)	7.10 (6.29 to 7.90)	10.07 (8.58 to 12.07)	0.028 (0.011 to 0.046)	9.01 (7.95 to 10.10)
19.1 km (vaccination day)	9.05 (8.05 to 11.29)	–0.035 (–0.044 to –0.026)	7.18 (6.40 to 7.97)	10.07 (8.58 to 12.06)	0.029 (0.011 to 0.046)	9.01 (7.95 to 10.10)

Sensitivity Analysis 2

To account for the effect of national restrictions on movement, we conducted a sensitivity analysis that limited travel and vaccination events to the third national lockdown from January 4, 2021, to April 5, 2021. Due to the asymmetry of the number of data points before and after vaccination in this analysis, we analyzed movement 30 days before vaccination and 30 days after vaccination.

From 30 days prior to vaccination to the vaccination date, there was a median daily movement of 8.06 (IQR 7.49-8.51) km with a median daily movement increase of 18 m (95% CI –19 to 56; *P*=.57). From the vaccination date to the following 30 days (during the third national lockdown), there was a median daily movement of 9.16 (IQR 8.35-10.71) km with a median daily movement increase of 9.35 m (95% CI 39-149; *P*=.69). See Figure 4B for a graphical representation of the interrupted time series for this sensitivity analysis.

Discussion

Principal Findings

Our study demonstrates the feasibility of collecting high-volume geolocation data as part of research projects and the utility of these data for understanding public health issues. Our results require cautious interpretation. Our initial analysis found evidence of a modest increase in the rate of change in median daily distance travelled after participants received their first dose of SARS-CoV-2 vaccine, but when restricting our analysis to a period of lockdown, we did not find evidence of a difference in mobility following 1 vaccination dose. On balance, our results do not provide evidence that people increase the rate of their movements following the first vaccination, as the results are consistent with both an increase and no movement after vaccination and suggest that any change in mobility after vaccination is likely to be modest.

We used GPS data to measure the travel distance of vaccinated individuals. Not only does this improve accuracy over other methods of distance estimation by using the GPS system (as compared to cellular location), but it also reduces recall bias when compared with using self-reported data. Our interrupted time series study design aids in reducing the impact of non–time-varying confounders as the same individual's data are considered before and after vaccination.

Comparisons With Prior Work

Compared to prior work [14], our methodology builds on that work by using techniques that produce more accurate measures of distance by using the GPS system as compared to cell phone towers. That study took a different-in-difference approach with 1 week of data on either side of vaccination and found that there was an increase in movement after vaccination by 8.6% 1 week after vaccination when compared to the week prior to vaccination. Although our sensitivity analysis, where we restricted to 30 days before and after vaccination, found a 13.6% increase in median movement after vaccination, the CIs of our regression models did not support an overall change in movement and are reflective of the overlapping IQR ranges before (median 8.06, IQR 7.49-8.51 km) and after (median 9.16, IQR 8.35-10.71 km) vaccination.

Given that previous studies have suggested people increase their nonhousehold contacts after their first vaccination, further research on behavior change following vaccination is warranted. In the meantime, it is important that public health communications are clear about the differential protection against SARS-CoV-2 infection offered by the first and second doses of the vaccine, such that people can exercise sound personal judgement on how they alter their behavior following vaccination.

Limitations

Our studies' sample size means that we may be underpowered to detect small changes in mobility, particularly when restricting to a period of national lockdown. Our GPS collection was automated but could be switched on and off by participants and is more likely to have been switched off on days when participants stayed at home. The use of the app in this way would result in our analysis overestimating the median distance travelled per day, through the nonreporting of GPS data (eg, switching the app off) on days when participants stayed at home. Due to technological requirements of tracking apps, the results were skewed toward those who had access to a smartphone and were able to contribute their data plan toward research activities, leading to a low initial uptake rate. Furthermore, for those who did provide data, there was an inconsistent provision of data over time, which could be caused by participants switching off the app. With a draining effect on battery life from the GPS app used, the dropout rate from the tracker cohort of Virus Watch was relatively high. People taking part in Virus Watch are self-selecting and motivated to contribute to COVID-19 research, and therefore, their movement patterns may not be generalizable to all vaccinated groups.

An important limitation in our primary analysis is that it does not control for time-varying confounders such as changes in national physical distance rules that were likely to have led to an increase in the rate of change in median daily travel distance. Other time-varying SARS-CoV-2–related events that we could not control for included changes in infection rates, which may have influenced people's decision to travel. As we centered our analysis around the vaccination date, our analysis did not account for different time-varying public health interventions on different vaccination dates. It is also possible that other non–SARS-CoV-2 events such as weather changes may have affected the findings, with participants increasing mobility during this same time period after vaccination as a result of improvements in weather conditions.

Conclusions

Although previous research found that nearly half of those who were vaccinated (after 1 dose) met with others outside their households or support bubbles [8], our findings provide a mixed picture about movement after the first dose of vaccination, and we found no evidence of an increase in movement when we conducted our analyses during a period of national movement restrictions.

Acknowledgments

The research costs for the Virus Watch study have been supported by the Medical Research Council (MRC) grant (MC_PC 19070) awarded to University College London (UCL) on March 30, 2020, and MRC grant (MR/V028375/1) awarded on August 17, 2020. The study also received US $15,000 of Facebook advertising credit to support a pilot social media recruitment campaign on August 18, 2020. Access to the ArcGIS Tracker and supporting software was provided by Esri UK free of charge. The contributors associated with Virus Watch Collaborative are as follows: Alison Rodger, Institute for Global Health, University College London, London, UK; Susan Michie, Centre for Behaviour Change, University College London, London, UK; Linda Wijlaars, Department of Population, Policy and Practice, UCL Great Ormond Street Institute of Child Health, London, UK; Eleni Nastouli, Department of Population, Policy and Practice, UCL Great Ormond Street Institute of Child Health, London, UK and Francis Crick Institute, London, UK; Moira Spyer, Department of Population, Policy and Practice, UCL Great Ormond Street Institute of Child Health, London, UK and Francis Crick Institute, London, UK; Ben Killingley, Department of Population, Policy and Practice, UCL Great Ormond Street Institute of Child Health, London, UK, Health Protection and Influenza Research Group, Division of Epidemiology and Public Health, University of Nottingham School of Medicine, Nottingham, UK, and University College London Hospital, London, UK; Ingemar Cox, Department of Computer Science, University College London, London, UK; Vasileios Lampos, Department of Computer Science, University College London, London, UK; Rachel A McKendry, London Centre for Nanotechnology and Division of Medicine, London, University College London; Anne M Johnson, Institute for Global Health, University College London, London, UK; Jo Gibbs, Institute for Global Health, University College London, London, UK; and Richard Gilson, Institute for Global Health, University College London, London, UK.

Conflicts of Interest

AH serves on the UK New and Emerging Respiratory Virus Threats Advisory Group. RM, BF, and AP were employed by Esri UK at the time of the study, who provided the ArcGIS Tracker and supporting software free of charge. All other authors declare no other conflicts of interest.

Abstract

Background: The third most severe COVID-19 wave in the middle of 2021 coincided with the dual challenges of limited vaccine supply and lagging acceptance in Bangkok, Thailand. Understanding of persistent vaccine hesitancy during the "608" campaign to vaccinate those aged over 60 years and 8 medical risk groups was needed. On-the-ground surveys place further demands on resources and are scale limited. We leveraged the University of Maryland COVID-19 Trends and Impact Survey (UMD-CTIS), a digital health survey conducted among daily Facebook user samples, to fill this need and inform regional vaccine rollout policy.

Objective: The aims of this study were to characterize COVID-19 vaccine hesitancy, frequent reasons for hesitancy, mitigating risk behaviors, and the most trusted sources of COVID-19 information through which to combat vaccine hesitancy in Bangkok, Thailand during the 608 vaccine campaign.

Methods: We analyzed 34,423 Bangkok UMD-CTIS responses between June and October 2021, coinciding with the third COVID-19 wave. Sampling consistency and representativeness of the UMD-CTIS respondents were evaluated by comparing distributions of demographics, 608 priority groups, and vaccine uptake over time with source population data. Estimates of vaccine hesitancy in Bangkok and 608 priority groups were tracked over time. Frequently cited hesitancy reasons and trusted information sources were identified according to the 608 group and degree of hesitancy. Kendall tau was used to test statistical associations between vaccine acceptance and vaccine hesitancy.

Results: The Bangkok UMD-CTIS respondents had similar demographics over weekly samples and compared to the Bangkok source population. Respondents self-reported fewer pre-existing health conditions compared to census data overall but had a similar prevalence of the important COVID-19 risk factor diabetes. UMD-CTIS vaccine uptake rose in parallel with national vaccination statistics, while vaccine hesitancy and degree of hesitancy declined (−7% hesitant per week). Concerns about vaccination side effects (2334/3883, 60.1%) and wanting to wait and see (2410/3883, 62.1%) were selected most frequently, while "not liking vaccines" (281/3883, 7.2%) and "religious objections" (52/3883, 1.3%) were selected least frequently. Greater vaccine acceptance was associated positively with wanting to "wait and see" and negatively with "don't believe I need (the vaccine)" (Kendall tau 0.21 and −0.22, respectively; adjusted $P<.001$). Scientists and health experts were most frequently cited as trusted COVID-19 information sources (13,600/14,033, 96.9%), even among vaccine hesitant respondents.

Conclusions: Our findings provide policy and health experts with evidence that vaccine hesitancy was declining over the study timeframe. Hesitancy and trust analyses among the unvaccinated support Bangkok policy measures to address vaccine safety and efficacy concerns through health experts rather than government or religious officials. Large-scale surveys enabled by existing widespread digital networks offer an insightful minimal-infrastructure resource for informing region-specific health policy needs.

Introduction

The third COVID-19 wave in Thailand, spanning June to October 2021, presented a serious challenge to health infrastructure [1-3]. A rapid increase in COVID-19 severity and spread coincided with slow vaccine rollout to nonhealth care workers. Vaccine distribution was further impeded by limited supply and lagging demand. Thailand initially targeted vaccination of the “608” group that included high-risk people defined as those aged 60 years or older and those with 1 of 8 pre-existing health conditions (PHCs) such as diabetes, respiratory disease, or pregnancy [4,5]. The government offered expanded vaccine supply and options [6,7], and focused institutional support in conjunction with incentives and, in some instances, punitive measures [8-10]. Nevertheless, vaccine hesitancy remained a persistent public health problem in Thailand [11], and yet, studies of vaccine hesitancy trends in the region were sparse. There was an urgent need to understand these trends, understand the reasons for vaccine hesitancy, and understand how best to persuade the unvaccinated in Thailand.

Vaccine hesitancy literature on the psychological and sociological drivers of this public health issue identified common correlates such as lack of social pressure, complacency toward the disease, lack of trust in medicine, false beliefs about vaccination, lack of trust in the government, and conspiratorial thinking [12]. Specific reasons for vaccine hesitancy in Thailand were often connected to fears of side effects and of lack of benefits, most notably regarding the Sinovac vaccine offered by the government early in vaccine rollout [13,14]. However, these surveys were either narrowly focused on particular subgroups, such as health care workers or seniors, or were otherwise offered for short windows of time [13,15-20]. Policy and public health officials working to change sentiment and behaviors in the region might use data from more detailed longitudinal studies inclusive of broader population demographics.

The University of Maryland Global COVID Trends and Impact Survey (UMD-CTIS) is an innovative data stream covering the health attitudes and practices of a large population sample (the global Facebook active user base [FAUB]) from early in the COVID-19 pandemic (April 2020). A large proportion of the population of Thailand, especially Bangkok, is represented in the FAUB. As such, the UMD-CTIS was well suited to address the limitations of prior surveys and fill the need for context-specific information to combat vaccine hesitancy in the region. Leveraging UMD-CTIS responses from the residents of Bangkok, the most populous and most densely populated urban area with the highest COVID-19 burden [21], we sought to understand vaccine uptake, attitudes, and opportunities to better address vaccine messaging in the 608 vaccine rollout era.

Methods

Study Design

UMD-CTIS

This research is based on survey responses from the UMD-CTIS, which has been approved by the University of Maryland (UMD) Institutional Review Board (1587016-10) and has been described previously [22]. Briefly, the UMD-CTIS, in partnership with Facebook, is a cross-sectional survey of daily samples of the FAUB population. Sampled FAUB users were invited to participate in the UMD-CTIS through a special banner. Respondents aged ≥18 years who consented to participate in the UMD-CTIS study completed an online Qualtrics survey administered by the UMD [23]. Though statistical resampling of users from the FAUB over time is possible, these resampled FAUB users cannot be identified, and their UMD-CTIS responses cannot be linked longitudinally by design.

Survey Instrument

The UMD-CTIS instrument was designed to evaluate a range of public health topics through a single cross-sectional survey requiring limited time burden. Survey questions were updated by the UMD periodically in response to evolving epidemiologic needs. A consistent survey instrument (version 11) was used during the study period described below. This instrument covered vaccination status and vaccine hesitancy, in addition to questions on demographics, knowledge, attitudes, health practices, and health status. One of two additional survey modules was offered randomly to each respondent, either module A (media trust) or module B (PHCs). Survey logic and language (English and Thai) for version 11 are summarized in Multimedia Appendix 1, and are available online [24].

Because survey questions administered to each respondent target different subject matter by design and responses from the resampled FAUB cannot be linked, possible dependence of observations and measures of internal consistency are not available. Assuming that the large FAUB population, statistical sampling scheme, and response/participation rates are stable relative to the study timescale, respondents are a consistent sample of the FAUB population. Respondent characteristics (eg, age and gender) may be used as a measure of sampling response consistency for those characteristics. Trends in survey-estimated metrics (eg, vaccination proportion among

UMD-CTIS respondents) are assumed to be estimates of trends in the source population for the FAUB population. The UMD-CTIS compared to external benchmark data may be used as a measure of the representativeness of FAUB respondents relative to the source population of interest for those survey questions.

UMD-CTIS Study Population in Bangkok, Thailand

This study analyzed UMD-CTIS responses from self-identified residents of Bangkok, Thailand from June 14, 2021, to October 4, 2021. This period coincided with the third COVID-19 wave and the 608 campaign rollout. To evaluate for possible differences among those targeted in the 608 campaign, we separately analyzed 2 subgroups of survey responses representative of those groups, that is, respondents self-reporting older age and self-reporting at least one of the targeted PHCs.

The UMD-CTIS in conjunction with Facebook provided survey weights, which combine design weights (for disproportional population stratification sampling), nonresponse weights (inverse of response propensity), and poststratification weights (standardizing to regional age-gender distributions), to simultaneously adjust for regional demographics, nonresponse bias, and sampling bias, as described previously in greater detail [23]. The individual component weights are not provided by design. Thus, when evaluating subregional data (eg, PHC subgroups), it is not possible to apply only the design and nonresponse weights, without also applying poststratification weights for the region. Estimates with and without survey weights were nevertheless similar both regionally and in subgroups, and are presented for comparison in Multimedia Appendices 2-4.

Covariates and Outcome Measures

Demographics and 608 Campaign Groups

Respondents self-reported demographic characteristics, including 4 gender and 7 age categories. UMD-CTIS age categories were in 10-year brackets, which did not align with the 60-year-old threshold in the 608 campaign. To avoid including subjects aged 55 to 59 years, the elderly risk group was identified as those aged ≥65 years (ie, selected 65-74 or ≥75 years UMD-CTIS age categories). When evaluating age-gender distributions, gender was limited to binary responses ("male" and "female"). Those with self-reported targeted PHCs in the 608 campaign were identified from the subpopulation of respondents randomly offered survey module B. Those who received module B did not receive module A. We included surveys from those who received module B and reported at least one of the targeted PHCs on module B. Pregnancy was only queried among those not reporting male gender. The 608 campaign PHCs were mapped to reasonable UMD-CTIS proxies of those PHCs. These included pregnancy, diabetes, obesity, cancer, chronic kidney disease, chronic respiratory diseases (asthma and chronic obstructive pulmonary disease combined), and cardiovascular diseases (heart attack, heart disease, or other heart conditions). The 608 campaign PHCs of neurovascular diseases did not have reasonable proxies in the UMD-CTIS and were not evaluated.

Vaccine Uptake

We evaluated vaccine uptake in the UMD-CTIS in Bangkok and the 608 subpopulations relative to the publicly reported vaccine uptake measures. Self-reported vaccination status was ascertained using the questions "Have you had a COVID-19 vaccination?" and "How many COVID-19 vaccinations have you received?" Complete vaccination was assessed with the response "Vaccinated, two doses," which is consistent with the primary formulations available widely during the study period. Additionally, we evaluated uptake trends by assessing the responses "Vaccinated, one dose" and "Scheduled" (for vaccination) to the question "Do you have an appointment to receive a COVID-19 vaccine?" Vaccine uptake in the region was trended over the course of the study period.

Vaccine Acceptance and Hesitancy

The degree of vaccine acceptance was characterized as a nominal scale with decreasing willingness to be vaccinated. The 3 groups with the highest vaccine acceptance were those fully vaccinated ("Vaccinated, two doses"), partially vaccinated ("Vaccinated, one dose"), and about to be vaccinated ("Scheduled"). The remaining unvaccinated and unscheduled respondents were categorized into 4 groups of increasing hesitancy to become vaccinated according to their responses to the question "If a vaccine to prevent COVID-19 was offered to you today, would you choose to get vaccinated?" The 4 groups were as follows: "Definitely," "Probably," "Probably not," and "Definitely not." Multimedia Appendix 1 details the survey questions, response options, and survey logic for the following questions: "Have you had a COVID-19 vaccination?" "How many COVID-19 vaccinations have you received?" "Do you have an appointment to receive a COVID-19 vaccine?" and "If a vaccine to prevent COVID-19 was offered to you today, would you choose to get vaccinated?" Surveys with missing responses to enable categorization into these 7 groups were excluded.

Reasons for Vaccine Hesitancy

Reasons for vaccine hesitancy were examined among the 4 most vaccine hesitant subgroups ("Definitely," "Probably," "Probably not," and "Definitely not"). The question stem text varied slightly to align with the respondents' self-identified degree of willingness to be vaccinated (ie, "Which of the following, if any, are reasons that you definitely wouldn't/probably wouldn't/only probably would choose to get a COVID-19 vaccine?"). Hesitancy reasons were presented as multichoice responses and included a range of options from concerns about vaccine side effects to beliefs about vaccine efficacy (Multimedia Appendix 1).

Reasons for Not Believing Vaccination is Necessary

Hesitant respondents who endorsed "I don't believe I need a vaccine" were further questioned for their reasons for holding that belief. Proportions were calculated for each individual reason and for the incidence of co-selected pairs in this multichoice response.

Trusted Media for COVID-19 Information

Potential avenues for communicating with vaccine hesitant individuals in the region were evaluated among the 4 most vaccine hesitant subgroups and those who accepted vaccination in some form (scheduled or received any number of doses). Survey module A surveyed preferred sources of information relating to COVID-19. This module was presented to a random subset of respondents; those who received module A did not receive module B. Subjects were asked "How much do you trust the following sources to provide accurate news and information about COVID-19?" The 3 response options "Trust," "Somewhat trust," and "Do not trust" were dichotomized by combining the first two into a single "Trust" option. For each respondent, "trusted sources" are therefore sources of COVID-19 information that respondents indicated they "Somewhat trust" or "Trust."

External Data and Benchmarking

To compare the Bangkok UMD-CTIS estimates and trends to external benchmark measures of population-level statistics, we compiled population demographics, PHCs, and vaccine data from publicly available sources. Further methodology, data sources, and results are provided in Multimedia Appendix 5. To compare the Bangkok UMD-CTIS vaccine uptake relative to government-reported trends over the 608 campaign study period, we estimated the proportion of fully vaccinated (2-dose) respondents in the UMD-CTIS over time. The daily sample size of the Bangkok UMD-CTIS is small in comparison to the rate of change in the source population vaccinated proportion. Thus, to show temporal trends in vaccine uptake in the Bangkok UMD-CTIS study over time, 28-day rolling averages of the proportion vaccinated are shown in relation to the national daily reports. Bangkok vaccination data over time were obtained from the Thailand Department of Disease Control daily reports [25]. Complete vaccination per population was calculated using data on 2 doses administered as described above, consistent with the daily vaccination reports.

Statistical Analyses

Estimates and CIs for proportions were calculated with the Wilson Score method, using the count of affirmative responses per total survey in the subgroup of interest, unless noted otherwise. For multichoice questions (eg, PHCs and hesitancy reasons), we used the count for that choice item. Survey-weighted and raw proportions are shown in Multimedia Appendix 5, though subgroup demographics differed from Bangkok, Thailand demographics from which UMD-CTIS weights were, in part, derived. A test of the trend for demographic differences between the UMD-CTIS and census over time was conducted using linear regression and applying Bonferroni correction for multiple comparisons to generate an adjusted *P* value. Among hesitant respondents, we evaluated associations between the degree of vaccine acceptance and reasons for hesitancy by using Kendall tau and applying Bonferroni correction for multiple comparisons. We repeated this analysis for 608 campaign group subsets.

Ethics Approval

The Institutional Review Board of Boston Children's Hospital (P00023700) approved this study that used the UMD-CTIS.

Results

Bangkok UMD-CTIS

Demographics of the Bangkok UMD-CTIS

Table 1 shows that the Bangkok UMD-CTIS respondents (N=36,334) were more frequently male and under 65 years of age. There were 1265 (3.5%) respondents in the ≥65 years elderly risk group targeted by the 608 campaign. Of the 19,734 respondents who received the PHC survey module, 3407 (17.3%) reported having at least one of the 7 PHCs covered by the survey. Diabetes (1090/19,734, 5.5%) and obesity (1555/19,734, 7.9%) were the most frequently reported PHCs targeted in the 608 campaign. Comparisons of the Bangkok UMD-CTIS and 608 subgroups to benchmark census data, along with survey weight-adjusted estimates, are presented in Multimedia Appendix 5. Multimedia Appendix 6 shows that demographics were consistent over time, while in Multimedia Appendix 7, linear regression results for demographic differences between the UMD-CTIS and census showed that adjusted *P* values never met the threshold for significance and coefficients were always close to zero. While Bangkok UMD-CTIS respondents were similar to the Bangkok general population in terms of age, gender, and diabetes status, Bangkok UMD-CTIS respondents, who were selected from the Bangkok FAUB population, indicated that they were healthier than the general population with respect to other COVID-19 risk factors.

Table 1. Demographic and pre-existing health condition characteristics of survey respondents in the cross-sectional survey (June 14, 2021, to October 4, 2021).

Characteristic	Value, n (%)
Age group (years) (N=36,334)	
18-24	2759 (7.6)
25-34	7641 (21.0)
35-44	8907 (24.5)
45-54	6439 (17.7)
55-64	3569 (9.8)
65-74	1102 (3.0)
≥75	163 (0.4)
Not reported	5754 (15.8)
Sex (N=36,334)	
Male	16,308 (44.9)
Female	13,468 (37.1)
Other	331 (0.9)
Prefer not to answer	477 (1.3)
Not reported	5750 (15.8)
PHC[a,b] (N=19,734)	
At least one condition	3407 (17.3)
Obesity	1555 (7.9)
Diabetes	1090 (5.5)
Chronic respiratory diseases[c]	641 (3.2)
Asthma	575 (2.9)
Cardiovascular diseases	488 (2.5)
Chronic kidney disease	207 (1.0)
Cancer	171 (0.9)
Chronic lung diseases	155 (0.8)
Pregnancy[d]	92 (0.3)
Vaccine uptake and hesitancy (N=36,334)	
Vaccinated, 2 doses	8596 (23.7)
Vaccinated, 1 dose; unspecified dose	13,712 (37.7)
Scheduled	5505 (15.2)
Definitely willing	2909 (8.0)
Probably willing	2619 (7.2)
Probably not willing	652 (1.8)
Definitely not willing	522 (1.4)

[a] PHC: pre-existing health condition.

[b] Of the 36,334 respondents, 19,734 (54.3%) received the module about PHCs and 16,600 (45.7%) did not receive the module.

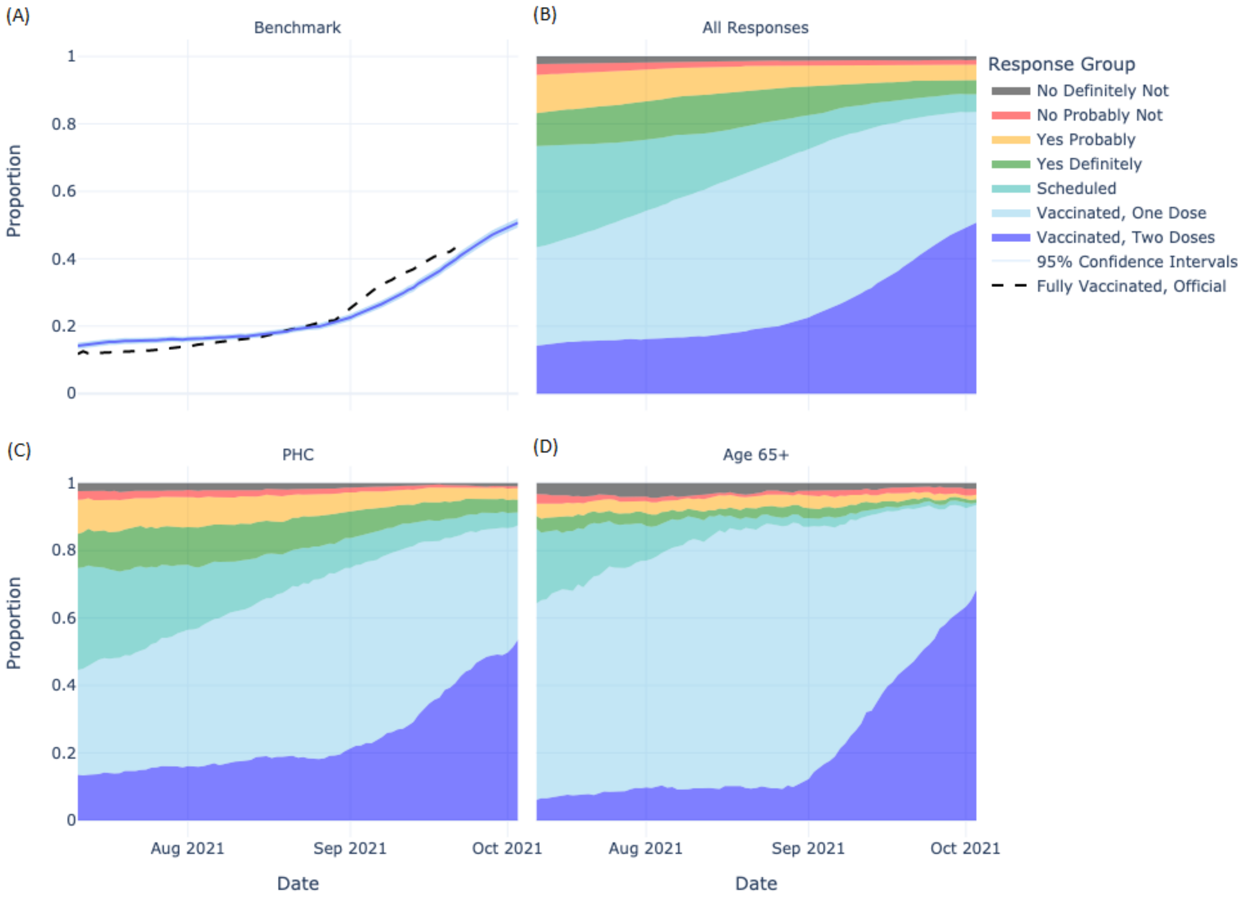
[c] Includes respondents who self-identified being diagnosed with asthma or chronic lung diseases such as chronic obstructive pulmonary disease, chronic bronchitis, or emphysema.

[d] A total of 7405 (25.0%) responded “No.”

Vaccine Uptake

In Figure 1, we show vaccine uptake tracked over the 608 campaign study period using the proportion of Bangkok UMD-CTIS respondents who indicated they were scheduled to or had received one or two doses of the COVID-19 vaccine. Vaccination trends in 2-dose vaccinated respondents closely mirrored Bangkok government statistics (Figure 1A). The proportion scheduled to be vaccinated declined (−14.0%/week) as the proportion vaccinated with at least one dose rose. While elderly people received their first dose more quickly than others (158/246, 64.2% vs 3305/7617, 43.4% with at least one dose at the start of the study period), uptake of the second dose increased more gradually during the summer. Uptake patterns among those with PHCs were not noticeably different from responses overall. The 95% CIs were very small owing to the large sample size (Multimedia Appendix 8). The UMD-CTIS–weighted trends were similar.

Figure 1. Vaccine uptake and acceptance in Bangkok over time and within 608 vaccination campaign priority groups from June 14, 2021, to October 4, 2021. (A) The 4-week moving average government vaccination uptake trend (dashed line) compared against the fully vaccinated trend in the COVID-19 Trends and Impact Survey overall (dark blue line) with 95% CIs (light blue line). (B-D) Stacked proportion of respondents indicating vaccine acceptance (2-dose vaccinated, dark blue; 1-dose vaccinated, blue; scheduled, turquoise; definitely, green; probably, yellow; probably not, red; definitely not, black) across all responses (B), and further faceted across pre-existing health condition (PHC) (C) and elderly (D) subgroups.



Vaccine Acceptance and Hesitancy

To evaluate vaccine hesitancy over time, we classified unvaccinated and unscheduled respondents according to their degree of vaccine acceptance. The proportions of those who said that they would probably, probably not, and definitely not get vaccinated steadily declined, though more gradually (−7.3%/week) compared to the rise in vaccine uptake (Figure 1). Vaccination hesitancy did not increase over the study period overall or within the 608 targeted groups (Figure 1). However, the rise in vaccine uptake appeared to mirror changes in those who were scheduled to receive vaccination and accepting of vaccination, rather than a decline in those hesitant to do so.

Reasons for Vaccine Hesitancy

We evaluated the reasons cited by the 3 groups of hesitant respondents who indicated they would probably, probably not, or definitely not get vaccinated (N=3883). Figure 2 shows that reasons relating to the risk-benefit of vaccination were more frequently selected among hesitant respondents. Respondents reported concerns over side effects (2434/3883, 62.7%), wanting to wait and see for longer to determine whether the vaccines are safe (2410/3883, 62.1%), and not feeling sure that the vaccines will be effective in protecting against COVID-19 (1407/3883, 36.2%). Concerns about side effects and lack of vaccine benefit were the most frequently selected together with wanting to wait and see (45.8% and 27.9%, respectively).

Figure 3 shows that when stratifying according to respondents' vaccine acceptance, risk-benefit concerns were similar in frequency. In Table 2, we see that the strength of the association of endorsing a specific concern with acceptance of vaccination was small, with Kendall tau mostly below ±0.2, even though adjusted *P* values were mostly <.001 from the large survey size. The most hesitant were more averse to vaccination ("Don't believe I need," tau=−0.22; "Don't like vaccines," tau=−0.13) and were less likely to consider vaccination later ("Wait and see," tau=+0.2). The most hesitant were nevertheless unsure of the benefits of vaccination, similar to the less hesitant groups ("Don't know if it will work," tau=−0.01). Those remaining unvaccinated and hesitant at the end of the study period (August 27 to October 3, 2021) selected "Don't believe I need" more frequently than at the start of the study period, while "Don't know if it will work" did not shift over time.

In Multimedia Appendix 9, we see that among the 608 campaign groups, the reasons for hesitancy patterns were broadly similar to the patterns for all respondents. The unvaccinated and hesitant respondents aged ≥65 years selected "Don't believe I need" more frequently but were similarly most often concerned about "side effects."

Figure 2. Frequency matrix of hesitancy reasons in the cross-sectional survey (June 14, 2021, to October 4, 2021). Intersection of 2 reasons is the frequency that both reasons were chosen by a respondent. Intersection of a reason with itself is the frequency for that single reason across all respondents.

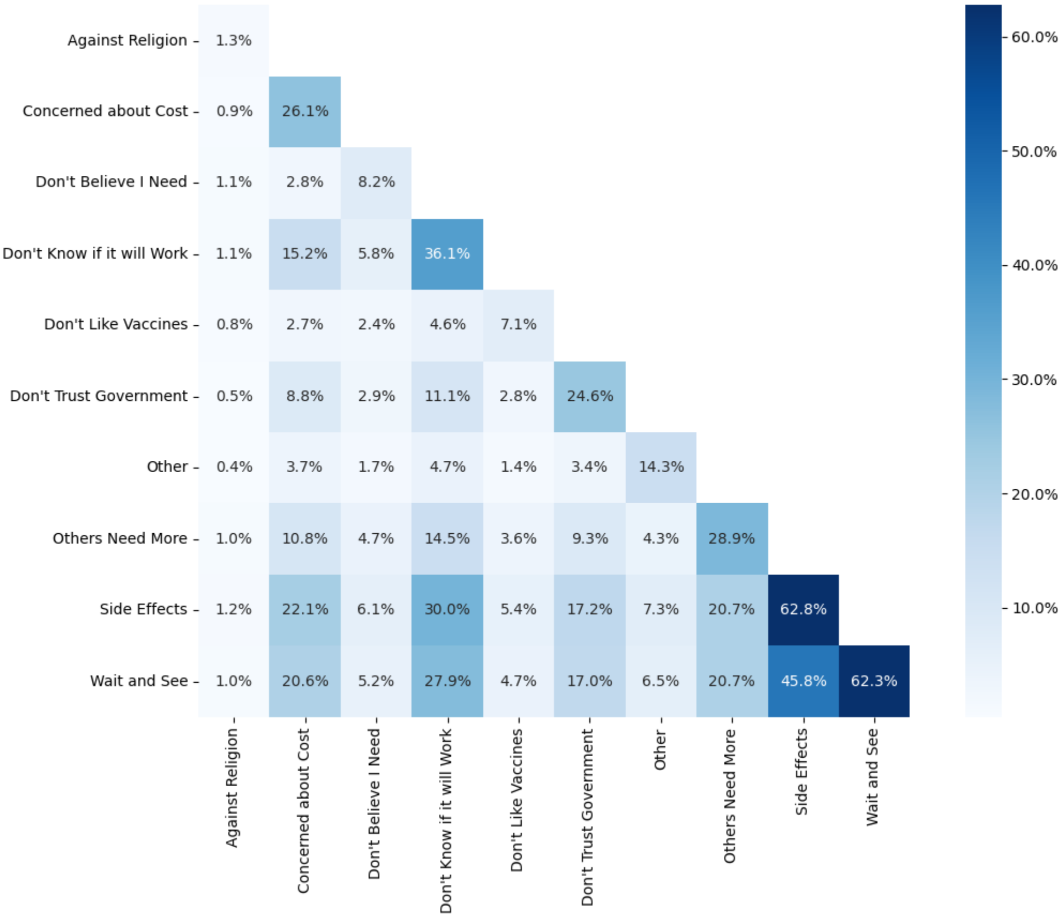


Figure 3. Reasons for hesitancy by degree of vaccine acceptance in the cross-sectional survey (June 14, 2021, to October 4, 2021).

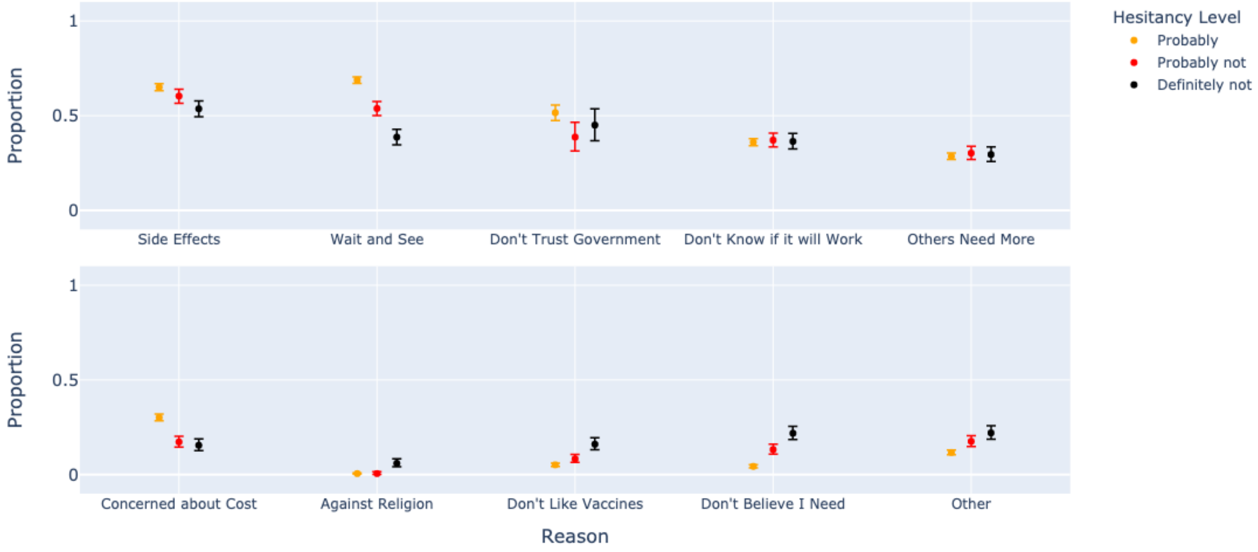

Table 2. Association between vaccine acceptance and individual reasons for hesitancy measured by Kendall tau in the cross-sectional survey (June 14, 2021, to October 4, 2021).

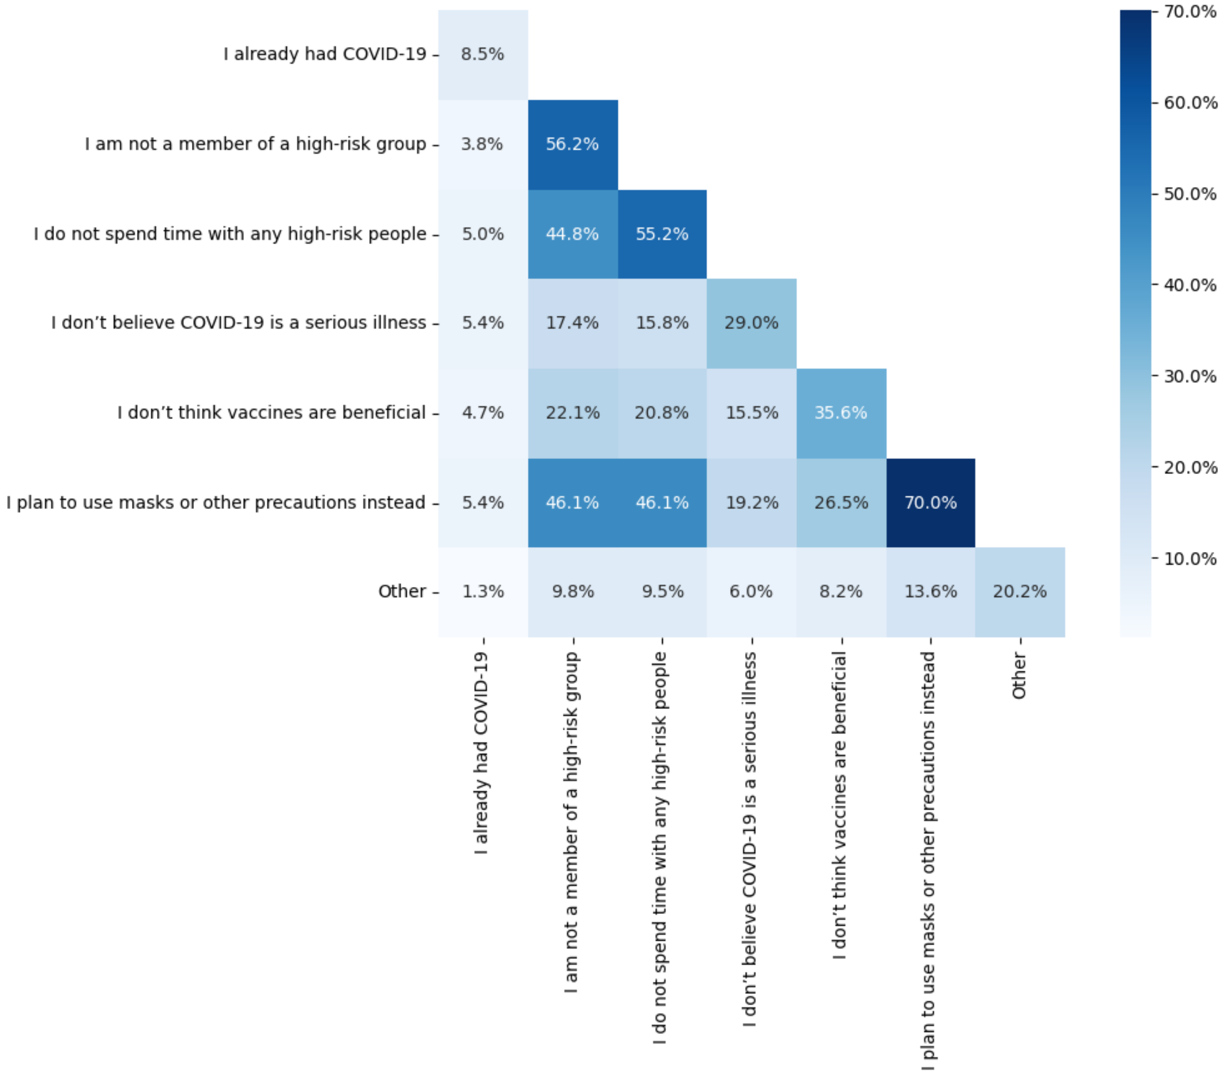
Hesitancy reason	Kendall tau	Adjusted *P* value
Wait and see	0.21	<.001
Concerned about cost	0.14	<.001
Side effects	0.08	<.001
Don’t know if it will work	−0.01	>.99
Others need it more	−0.01	>.99
Other	−0.1	<.001
Against religion	−0.11	<.001
Don’t like vaccines	−0.13	<.001
Don’t believe I need	−0.22	<.001

Reasons for Not Believing Vaccination is Necessary

Given the consistent endorsement of “I don’t believe I need a COVID-19 vaccine” among the unvaccinated and most hesitant respondents across risk groups and over time, we further evaluated the behaviors and attitudes of respondents who selected this reason for hesitancy. In Figure 4, we see that those who did not believe they needed a COVID-19 vaccine (N=317) generally endorsed other protective behaviors and beliefs overall and within the 608 campaign groups. They most frequently reported their intention to mask or pursue other mitigation strategies instead of vaccination (222/317, 70.0%), and least frequently indicated low confidence in vaccines (113/317, 35.6%) or in COVID-19 as a serious illness (92/317, 29.0%).

Over half (35/60, 58%) of unvaccinated hesitant respondents who did not believe they needed a COVID-19 vaccine did not endorse being a member of a high-risk group, even though they self-reported older age or a PHC in the 608 campaign. Nevertheless, Multimedia Appendix 10 shows that most respondents who indicated they were not in a risk group also planned to use protective measures other than vaccines, and infrequently indicated they did not think COVID-19 was a serious illness. Thus, while unvaccinated hesitant people in the 608 campaign groups may not be aware of their underlying COVID-19 risk, such as older age or diabetes status, they do appear to have an appreciation of the risk and an understanding of important risk mitigation measures.

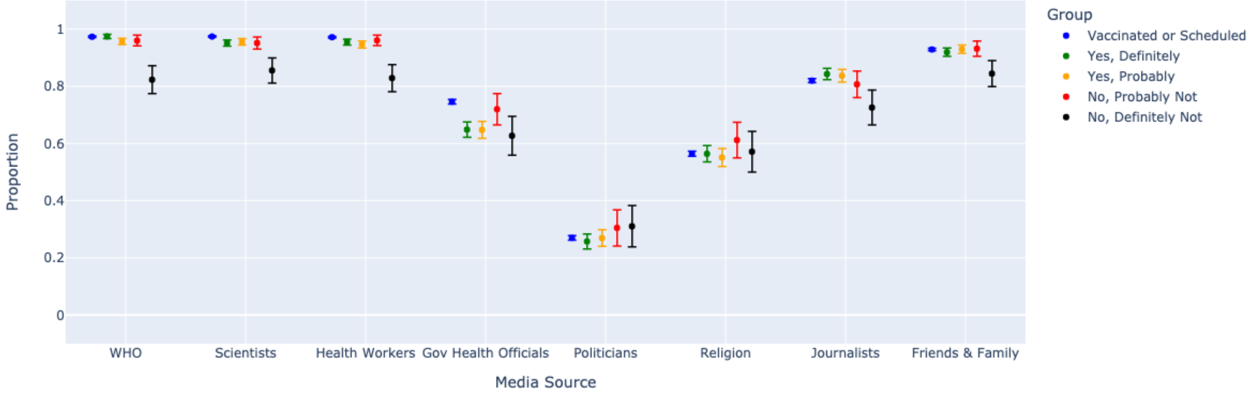
Figure 4. Frequency of selected multichoice responses for why individuals chose "I don't believe I need a COVID-19 vaccine" in the cross-sectional survey (June 14, 2021, to October 4, 2021).



Trusted Media for COVID-19 Information

Given vaccine hesitancy concerns and respondents indicating they might vaccinate later if there is more information, we sought to investigate what information sources would best reach this group. Medical and scientific representatives were the most trusted sources of information on COVID-19 among all respondents, regardless of the degree of hesitancy. Specifically, in Figure 5, we see that respondents who completed each of these questions most frequently indicated that they trust the World Health Organization (13,564/13,980, 97.0%), scientists/health experts (13,600/14,033, 96.9%), and local health workers (13,827/14,304, 96.7%) for news relating to the pandemic. Politicians (3723/13,794, 27.0%) and religious leaders (7668/13,794, 55.6%) were least frequently selected as trusted. The most hesitant respondents were less trusting overall but still trusted scientists and other health experts more than other sources.

Figure 5. Trusted sources of information on COVID-19 by grade of vaccine hesitancy. Frequency of selected multichoice options for trusted media sources, combining responses for most trusted and somewhat trusted.



Discussion

Principal Findings

Through leveraging daily online health surveys conducted among the residents of Bangkok, Thailand, we found that concerns about the risks and benefits of COVID-19 vaccines were paramount during the third wave, but trust in scientific sources remained intact. Globally, the pandemic and response polarized many populations. In many regions, this led to distrust of scientific evidence and interventions, and eroded the relationship among people, politicians, and public health officials [26]. We showed that, in contrast to the antiscience and antivaccine sentiment identified elsewhere [27], most unvaccinated hesitant respondents in Bangkok still believed in the seriousness of COVID-19, in the benefits of mitigation measures, and in the information relayed by health officials. The high professional trust in health experts and scientists in Thailand offered a valuable support mechanism for the government to effectively manage response efforts [28,29].

In a systematic review of the factors associated with vaccine hesitancy [26], the most important predictors included low perceived risk of infection or sequelae, low trust in institutions, low rates of influenza vaccination, and concerns regarding vaccine side effects. Prior surveys in Thailand identified unique concerns about the efficacy of vaccines from specific manufacturers, especially Sinovac [14,19]. Our findings of risk-benefit concerns among the unvaccinated echo these themes. Additionally, we identified that many hesitant respondents were planning to wait for additional information on vaccine safety and that the specific distrust of all vaccines is low (10% vs <20% in the United States [30]). Thus, messaging from health experts emphasizing vaccine safety and efficacy, and updates as more evidence on Thai-specific vaccine options becomes available, would be most effective in reaching the most hesitant unvaccinated respondents in our survey.

Among respondents within the ≥65 years and PHC risk groups, vaccine hesitancy and reasons for hesitancy were broadly similar to the general Bangkok population. Over half (35/60, 58%) of the unvaccinated respondents who provided reasons for not believing that they needed to be vaccinated and who self-reported older age and PHCs, however, did not self-identify as being at risk for COVID-19. While older age, pregnancy, and diabetes may be well-understood by a patient, other diagnoses may be less so. The burden of disease estimates for conditions, such as renal disease [31], may depend on access to testing (eg, biopsy) or may only be understood by the patient as a medical condition or risk factor when especially severe (eg, requiring medication or dialysis). This highlights the importance of 608 campaign messaging to educate citizens about the top priority vaccination groups, with the support of community health workers.

Being able to understand the unique needs of Bangkok in the context of the 608 campaign and third COVID-19 wave underscores the value of using insights from digital health surveys, such as the UMD-CTIS, to understand interventions, inform policy, and lessen the pandemic impact. Responses to health surveys may not be generalizable due to selection and response bias, and this may be compounded by sampling from the FAUB of social media users [32]. However, most Thai people have Facebook social media accounts [33], and we showed that the demographics of UMD-CTIS respondents aligned with the demographics of the Bangkok population. Thus, while there may be some bias toward respondents with more health access, awareness, or interest, the efficacy of daily sampling of the FAUB and the consistent survey instrument combined with the minimal need for on-the-ground infrastructure make this data stream a powerful resource. Additionally, observed slower uptake during the summer lines up with the time period when a longer gap between doses was recommended [34], which demonstrates the survey's capability to identify and measure the effects of health policy changes. This analysis provides region-specific supporting evidence of resilience and adaptability in the face of a rapidly evolving public health threat and serves as a helpful validation of government efforts with support from public health experts.

Limitations

The analyses presented here have several potential limitations. The global UMD-CTIS instrument was developed during the pandemic to measure the most critical epidemiologic measures, knowledge, attitudes, and practices in near real time. The instrument is limited by a lack of internal and external validation metrics and is thus susceptible to measurement bias [35]. Redundant questions were not included to conduct within-survey internal consistency measures. Repeat respondents could not be paired by design, and as such, the independence of observations cannot be guaranteed, which could make estimates of standard error overconfident. We found that the UMD-CTIS was consistent with 3 external benchmarks, and prior work validated other UMD-CTIS measures [36,37]. As discussed above, PHCs other than diabetes were likely undermeasured by the instrument or underrepresented in the survey sample. However, the notable variation in differences from population estimates across the PHCs suggests that other factors may also be contributing to underestimation, for example, patient understanding of the nuances of chronic kidney disease stages relative to that of the diagnosis of diabetes, which might also affect a subject's vaccine acceptance. While digital health surveys sampled from a social media platform user base may not be generalizable to all Bangkok residents, this limitation also applies to other previously used survey methods conducted in the region to understand vaccine hesitancy, such as telephone and door-to-door surveys [17]. There is possible selection bias as subgroups that are less comfortable with social media and consumer technology use, such as very elderly people, may be underrepresented, which would mean less coverage of especially vulnerable groups. In contrast, marginalized populations, such as migrant workers affected by the case surges in the third wave [38], may be fearful of in-person interviews, but may be more comfortable responding to an anonymous survey through social media. A cross-sectional survey, such as the UMD-CTIS, may be subject to ecological bias, especially if the source population changes over time or there is confounding by time of the response pairs. Because participation in public health surveys is voluntary, there may be response bias if respondents have more of an interest in public health than the population at large, and as such, attitudes may be shifted away from hesitancy or lack of interest in mitigation. We observed relatively stable trends in respondent demographics and hesitancy attitudes over time, even with continued uptake of vaccination. The sampling scheme of the UMD-CTIS, being nested within an existing social media user base, may be less susceptible to this if the membership in the FAUB and response rate are stable over the time period under investigation.

Conclusions

We showed that vaccine hesitancy in Bangkok during the third wave was connected to an interest in more health expert information about vaccine efficacy and safety. The UMD-CTIS findings were concordant with smaller studies highlighting skepticism about specific vaccine options available during rollout. Importantly, hesitancy among unvaccinated respondents in the UMD-CTIS was not associated with a broader distrust in science or the public health system. This may be a valuable resource for future studies to understand the regional landscapes of vaccine hesitancy in the context of specific policy interventions such as the 608 campaign in Thailand.

Abstract

Background: The accuracy of self-reported vaccination status is important to guide real-world vaccine effectiveness studies and policy making in jurisdictions where access to electronic vaccine registries is restricted.

Objective: This study aimed to determine the accuracy of self-reported vaccination status and reliability of the self-reported number of doses, brand, and time of vaccine administration.

Methods: This diagnostic accuracy study was completed by the Canadian COVID-19 Emergency Department Rapid Response Network. We enrolled consecutive patients presenting to 4 emergency departments (EDs) in Québec between March 24, 2020, and December 25, 2021. We included adult patients who were able to consent, could speak English or French, and had a proven COVID-19 infection. We compared the self-reported vaccination status of the patients with their vaccination status in the electronic Québec Vaccination Registry. Our primary outcome was the accuracy of the self-reported vaccination status (index test) ascertained during telephone follow-up compared with the Québec Vaccination Registry (reference standard). The accuracy was calculated by dividing all correctly self-reported vaccinated and unvaccinated participants by the sum of all correctly and incorrectly self-reported vaccinated and unvaccinated participants. We also reported interrater agreement with the reference standard as measured by unweighted Cohen κ for self-reported vaccination status at telephone follow-up and at the time of their index ED visit, number of vaccine doses, and brand.

Results: During the study period, we included 1361 participants. At the time of the follow-up interview, 932 participants reported at least 1 dose of a COVID-19 vaccine. The accuracy of the self-reported vaccination status was 96% (95% CI 95%-97%). Cohen κ for self-reported vaccination status at phone follow-up was 0.91 (95% CI 0.89-0.93) and 0.85 (95% CI 0.77-0.92) at the time of their index ED visit. Cohen κ was 0.89 (95% CI 0.87-0.91) for the number of doses, 0.80 (95% CI 0.75-0.84) for the brand of the first dose, 0.76 (95% CI 0.70-0.83) for the brand of the second dose, and 0.59 (95% CI 0.34-0.83) for the brand of the third dose.

Conclusions: We reported a high accuracy of self-reported vaccination status for adult patients without cognitive disorders who can express themselves in English or French. Researchers can use self-reported COVID-19 vaccination data on the number of doses received, vaccine brand name, and timing of vaccination to guide future research with patients who are capable of self-reporting their vaccination data. However, access to official electronic vaccine registries is still needed to determine the vaccination status in certain susceptible populations where self-reported vaccination data remain missing or impossible to obtain.

Introduction

Background

Since the beginning of the COVID-19 pandemic, vaccination campaigns have been instrumental in preventing mortality and morbidity related to COVID-19 worldwide [1]. With over 13 billion doses of vaccines administered worldwide [2], public health policy makers around the world have been relying on evidence from clinical trials to guide decision-making and develop vaccination strategies to prevent the spread and consequences of this pandemic [3]. In addition to evidence from controlled clinical trials, real-world evidence regarding vaccine effectiveness is important to guide policy making [4,5] and patient decision-making [6]. In particular, real-world evidence can help understand vaccine effectiveness against different disease severities in different susceptible populations often excluded from clinical trials [7], inform policy makers about the length of vaccine protection over time [8], and document rarer side effects [9]. Real-world data can also help understand the evolving prevalence and underlying causes of vaccine hesitancy over time [10] and shape future vaccination campaigns [11,12]. Understanding the role of herd immunity and how to promote vaccination are important questions that need reliable vaccination data [13-16]. Studying COVID-19 occupational hazards for professionals working with susceptible populations also requires timely and reliable access to vaccination data [17,18]. As new variants emerge, real-world evidence informs current and future strategies to protect against COVID-19 infection [19]. To measure real-world vaccine effectiveness and inform evidence-based health promotion strategies, researchers and policy makers alike need access to reliable vaccination data. Unfortunately, not all researchers and policy makers have access to official electronic public health vaccine registries [20-23], while others have substantial challenges in securing access to individual-level vaccination data even when they exist [24]. Many researchers and policy makers must then rely on patients' self-reported status to measure real-world vaccine effectiveness, and if this is inaccurate, it may bias vaccine effectiveness estimates in test-negative designs [25]. For these studies, not only are accurate data about vaccination status key, but, most importantly, reliable data about when vaccine doses were administered are essential to determine the effectiveness in preventing infections and health service use such as emergency department (ED) visits [26].

Objective

To inform the conduct of real-world vaccine effectiveness studies using patient self-reported vaccine information and to support the development of evidence-based public health promotion policies, this study aimed to compare the accuracy of self-reported vaccination status for COVID-19 with data from an official electronic vaccination registry in the province of Québec, Canada [27].

Methods

Study Design and Setting

The Canadian COVID-19 Emergency Department Rapid Response Network (CCEDRRN; pronounced "SED-rin") is a national collaboration created to harmonize data collection related to COVID-19 in over 50 EDs across 8 provinces in Canada (British Columbia, Alberta, Manitoba, Saskatchewan, Ontario, Québec, New-Brunswick, and Nova Scotia) [28]. The

CCEDRRN has created a national observational database of suspected and confirmed patients with COVID-19 who presented to acute care EDs. Data from this network are used in national studies to inform decision-making, emerging treatment guidelines, resource allocation, and planning in response to the pandemic. As of April 2023, CCEDRRN had captured data on over 208,000 patients across Canada [29]. In December 2020, CCEDRRN initiated data collection on vaccination status that supports this study.

This CCEDRRN study is a nested diagnostic accuracy study within the larger CCEDRRN cohort that was reported using the 2015 Standards for Reporting of Diagnostic Accuracy studies [30]. This study only used CCEDRRN data collected from 4 sites in the province of Québec because access to government electronic vaccine registries in the other provinces of Canada was unavailable. These 4 Québec CCEDRRN sites only collected data on patients with a positive COVID-19 test. The study enrolled consecutive consenting patients presenting to these 4 participating EDs between March 24, 2020, and December 25, 2021.

Vaccination in Québec started on December 14, 2020, with long-term care residents and health care workers [31]. On March 1, 2021, vaccination in the general population started in sequence based on their age group. On April 14, 2021, more than 2 million Québecers had received at least 1 dose, representing a quarter of the population. On May 18, 2021, more than half of the population had received at least 1 dose, and on June 6, more than 75% of the population aged >12 years had received at least 1 dose. On July 5, 2021, Québec reduced the dosing interval to 4 weeks to maximize 2-dose coverage, such that by September 30, 2021, a total of 75% of adults were considered fully vaccinated. On September 28, 2021, a third booster dose was recommended for residents in long-term care and assisted living. Between November 16, 2021, and December 29, 2021, the booster dose was progressively authorized for specific high-risk subgroups and then in sequence for the general population based on age groups. After each dose was administered in Québec, vaccinators were required to document the vaccine brand and the time of administration directly within the provincial electronic registry [32]. The identities of the vaccinated patients were validated using at least 2 personal identification questions. Another key public health measure to consider for this study was the mandate on September 1, 2021, to implement a mandatory vaccination passport that contained information about the number of doses, vaccine brand names, and vaccination dates to access certain public services in Québec [31].

Ethics Approval and Informed Consent

The ethics committee at the *Centre intégré de santé et de services sociaux de Chaudière-Appalaches* approved this project in February 2021 (MP-23-2021-766) with a waiver of informed consent for retrospective data collected; however, informed consent was obtained during telephone follow-up for all participants. The participants did not receive any financial compensation.

Participants

Patients were included if they had a confirmed COVID-19 infection (≥1 nucleic acid amplification tests positive for SARS-CoV-2 from specimens collected during the index ED visit, 14 days before the ED visit in the community, or within 14 days after admission) [28]. Included patients were aged ≥18 years, were able to communicate in French or English, and consented independently to telephone follow-up and the use of their health data. All included patients sought care at any of the 4 participating Québec sites (Hôtel-Dieu de Lévis, Hôpital Sacré-Coeur de Montréal, Royal Victoria Hospital, and the Montreal General Hospital). Patients were excluded if they were unable to provide consent (eg, had died since the ED encounter), were unable to communicate in French or English, could not be reached after 5 attempts, or did not have a record in the Québec Vaccination Registry (eg, out-of-province patients).

Data Collection and Outcome Measures

Trained research assistants collected data for our study from different sources and at different time periods. First, starting on July 9, 2020, we used a retrospective chart review to extract demographics, the time and date of ED visits, chief complaint, laboratory tests, treatments, admission status, and comorbidities. We retrospectively collected data for the index visits of all patients and any subsequent ED visits at least 30 days after the index visit. Second, starting on March 24, 2021, we initiated data collection from the Québec Vaccination Registry and phone follow-ups. A single research assistant at each site was designated to access the Québec Vaccination Registry to determine patients' vaccination status, vaccine brands received, the total number of doses, and dates of vaccination. Separate research assistants at each site were trained to only conduct telephone follow-ups. They were blinded to the reason for collecting self-reported vaccination data and did not access the information collected from the Québec Vaccination Registry. These research assistants contacted patients by telephone to obtain consent to use their data; to obtain additional sociodemographic data not available in their medical records (eg, income, self-identified race, and education level); and to collect their self-reported vaccination data (vaccination status, vaccine brands received, the total number of doses, and dates of vaccination). The median (IQR) time to contact the patients was 202 (108-352) days after the ED index visit. As patients were called at most 30 days after their data were consulted from the Québec Vaccination Registry, we only used self-reported vaccination data from before the date we consulted the Québec Vaccination Registry.

In accordance with CCEDRRN's national data management plan, after assigning a unique study identifier for each participant, deidentified data were collected and stored in REDCap (Research Electronic Data Capture; Vanderbilt University) at the University of British Columbia. After data verification, registry data were uploaded into CaraSpace, a secure private cloud for the storage and analysis of privacy-sensitive data [28]. Analysts accessed the cloud space via an encrypted virtual private network through a firewall and 2-factor authentication.

The primary outcome of this study was the accuracy of self-reported COVID-19 vaccination status at the time of the telephone follow-up compared with their vaccination status in the Québec Vaccination Registry. We considered the self-reporting of vaccination status via telephone as the index test and the Québec Vaccination Registry as the reference standard. The index test had 2 possible results: "no vaccine dose" (self-reported as not vaccinated) or "at least one vaccine dose" (self-reported as vaccinated). We calculated the accuracy of the self-reported vaccination status as follows:

> Accuracy = (correctly self-reported as vaccinated + correctly self-reported as not vaccinated) / (correctly self-reported as vaccinated + correctly self-reported as not vaccinated + incorrectly self-reported as vaccinated + incorrectly self-reported as not vaccinated) **(1)**

We also compared the clinical and demographic characteristics of patients with concordant and discordant self-reported vaccination status compared with the Québec Vaccination Registry.

Secondary outcomes were the sensitivity, calculated as

> (correctly self-reported as vaccinated / [correctly self-reported as vaccinated + incorrectly self-reported as not vaccinated]) **(2)**

and specificity, calculated as

> (correctly self-reported as not vaccinated / [correctly self-reported as not vaccinated + incorrectly self-reported as vaccinated]) **(3)**

of the self-reported vaccination status and vaccination status in the Québec Vaccination Registry. Relaxing the reference standard assumption about the Québec Vaccination Registry, we also measured the interrater agreement between self-reported vaccination status and vaccination status in the Québec Vaccination Registry, interrater agreement between self-reported COVID-19 vaccine brand received and the brand recorded in the Québec Vaccination Registry, and interrater agreement between self-reported number of COVID-19 vaccine doses received compared with the number of doses recorded in the vaccine registry.

An additional secondary outcome was the interrater agreement between vaccination status at the time of the index ED visit determined retrospectively by using the self-reported vaccination date compared with the vaccination status at the time of the index ED visit determined by the vaccination date in the Québec Vaccination Registry (Multimedia Appendix 1). Vaccination status was defined as fully, partially, and not vaccinated at the time of the index ED visit based on the number of doses and time since the last dose received to account for likely waning protection [33,34] (Multimedia Appendix 1). We defined fully vaccinated patients at the time of the index ED visit as patients who received ≥2 doses ≥14 days before the index ED visit but less than 6 months since the last dose. We defined partially vaccinated patients as having received only 1 dose before the index ED visit or having received their second or third dose <14 days before the index ED visit or having received their second or third dose >6 months before the index ED visit. Patients were considered not vaccinated if no doses had been received before their index ED visit. Patients who could not recall the date of their last vaccination were excluded from this analysis.

Analysis

The vaccination data in the Québec Vaccination Registry were considered the reference standard. As the interest was to compare the same information collected by telephone as in the Québec Vaccination Registry, the sample size calculations were based on a 1-sided binomial test for sensitivity [35,36]. A sample size of 613 patients was needed to achieve a 95% CI for sensitivity of half width 0.02 assuming a sensitivity of 0.98 and prevalence of at least 0.40.

Data were summarized by using descriptive statistics (eg, mean [SD], counts, and percentage). Accuracy, sensitivity, and specificity for COVID-19 vaccination status reported by patients compared with the reference standard (ie, the Québec Vaccination Registry) were calculated with associated 95% CIs. Secondary analyses relaxed the reference standard assumption and provided interrater agreement using the unweighted Cohen κ coefficient [37]. We chose to use the unweighted Cohen κ because we had 2 raters (ie, self-report by participant and report from the Québec Vaccination Registry), and we wanted disagreements to carry the same weight. All analyses were conducted in R (R Foundation for Statistical Computing) using the *rms* and *psych* packages [38-40]. To ensure patient privacy, a cell-size restriction policy prohibited us from reporting counts of <5.

Results

Participant Characteristics

During the study period, there were 5912 adult patients who presented to the Québec study sites, and 1482 met the inclusion criteria; of them, 1361 (23.02%) patients had the required data from follow-up and available in the Québec Vaccination Registry (Figure 1). Among the 4430 excluded patients, 1596 (36.03%) did not consent to participate or were not able to consent. There were also 62 (1.05%) patients who did not have any vaccination record in the Québec Vaccination Registry because they were patients from outside the province or did not have a provincial health insurance number. The baseline participant characteristics are shown in Table 1. Patients who did not or could not consent were slightly older than patients who participated (age: mean 58.6, SD 21.3 years vs mean 55.1, SD 17.4 years, respectively) and were more likely to be male individuals (nonconsenting male individuals: 871/1596, 54.57%, vs consenting male individuals: 686/1361, 50.4%). Three-quarters (1010/1361, 74.21%) of the patients presented to the ED during the second and third waves of the pandemic (August 23, 2020, to July 17, 2021).

Vaccination Status

Over two-thirds (932/1361, 68.55%) of the participants reported at least 1 dose of a COVID-19 vaccine at the time of their follow-up interview (Table 2). The most administered vaccine type was Pfizer-BioNTech (689/1361, 50.6%) followed by Moderna (158/1361, 11.6%).

Table 2. Québec Vaccination Registry information and self-reported vaccination status during the initial telephone follow-up of participants whose emergency department index visit occurred between March 24, 2020, and December 25, 2021 (n=1361).

	Québec Vaccination Registry, n (%)	Self-reported vaccination status, n (%)
Vaccination status		
Yes (at least 1 dose)	913 (67.1)	932 (68.5)
No (no dose given)	448 (32.9)	429 (31.5)

Self-Reported Vaccination Status Accuracy and Interrater Agreement Between Self-Reported Vaccination Data and Québec Vaccination Registry Data

We reported high measures of accuracy (96%), sensitivity (98%), and specificity (92%) for self-reported vaccination status compared with the Québec Vaccination Registry as the reference standard (Tables 3 and 4). Moreover, Cohen κ was 0.91 (95% CI 0.89-0.93), indicating excellent agreement between patient self-report and the Québec Vaccination Registry.

With respect to vaccine brand type, Cohen κ for dose 1 brand was 0.80 (95% CI 0.75-0.84) indicating strong agreement (Table 5). However, this estimate decreased with subsequent doses: Cohen κ was 0.76 (95% CI 0.70-0.83) and 0.59 (95% CI 0.34-0.83) for dose 2 and dose 3 brands, respectively.

Most patients reported receiving 1 dose (368/1361, 27.04%) or 2 doses (511/1361, 37.56%) of COVID-19 vaccines at the time of the follow-up interview (Table 6). Only 3.89% (53/1361) of patients reported receiving 3 doses. One-third (429/1361, 31.52%) of the patients reported not having received the COVID-19 vaccine at the time of follow-up. Cohen κ for the number of self-reported doses compared with the Québec Vaccination Registry was very strong, at 0.89 (95% CI 0.87-0.91).

Cohen κ for self-reported vaccination status at the time of ED index visit was 0.85 (95% CI 0.77-0.92). However, many patients (774/1361, 56.87%) could not recall the exact date of their latest vaccine dose and had to be excluded from this analysis. Of those who did recall their vaccination dates, most (538/587, 91.7%) reported not being fully vaccinated at the time of the ED visit, with only 16 (2.7%) patients being fully vaccinated (Table 7).

The demographic, clinical, and sociocultural characteristics of patients with discordant (n=53) and concordant (n=1308) vaccination statuses are shown in Multimedia Appendix 2. Participants with discordant self-reported vaccination status compared to those with concordant self-reported vaccination status were younger (age: mean 51.1, SD 20.5 years, vs mean 55.3, SD 17.3 years, respectively), had lower self-reported income (5/53, 9% reported current income >CAD $73,701 (US

$56,693) per year vs 294/1308, 22.48%), had lower education level (5/53, 9% with a university degree vs 444/1308, 33.94%), and had a lower vaccination rate according to the Québec Vaccination Registry (17/53, 32% vs 896/1308, 68.5%). The median time elapsed between the ED index visit and the telephone follow-up to determine the patient's self-reported vaccination status was similar for discordant (median 94, IQR 53-191 days) and concordant cases (median 126, 62-196 days). Immigration status, race, and ethnicity did not influence the accuracy of our results.

Table 3. Confusion matrix comparing self-reported vaccination status with the Québec Vaccination Registry data for all participants whose emergency department index visit occurred between March 24, 2020, and December 25, 2021 (n=1361).

Self-reported vaccination status (index test)	Vaccination status in the Québec Vaccination Registry (reference standard), n	
	Yes	No
Yes	896	36
No	17	412

Table 4. Sensitivity, specificity and accuracy of self-reported vaccination status and interrater agreement of self-reported vaccination status compared with the Québec Vaccination Registry for all participants whose emergency department index visit occurred between March 24, 2020, and December 25, 2021 (n=1361).

	Measure (95% CI)
Sensitivity	0.98 (0.97-0.99)

Self-reported vaccination status determined using the date of latest vaccination dose in relation to the ED[b] visit date[c]	Québec Vaccination Registry vaccination status determined in relation to the ED index visit date[d], n		
	Not vaccinated	Partially vaccinated	Fully vaccinated
Not vaccinated	527	5	6
Partially vaccinated	<5	29	0
Fully vaccinated	0	0	16

[a] Cohen κ: 0.85 (95% CI 0.77-0.92).

[b] ED: emergency department.

[c] Categories of vaccination status at the time of ED index visit (fully, partially, and not vaccinated) for this analysis are defined in Multimedia Appendix 1.

[d] A total of 774 (56.9%) participants were excluded from this analysis because they could not recall the date of their last dose.

Discussion

Principal Findings

We found that the participants' self-reported vaccination status was highly accurate at the time of the initial follow-up telephone call. The interrater agreement between the self-reported vaccine number of doses and the number of doses recorded in the vaccine registry was also strong. The agreement between self-reported vaccination status at the index visit and the patient's vaccination status as determined by the registry was strong when patients could provide vaccination dates. However, many patients could not recall their vaccination dates. Although there was a strong and moderate agreement for the self-reported vaccine brand for the first and second doses, respectively, the agreement dropped to weak for the vaccine brand of the third dose. A few discordant cases concerning the accuracy of patients' self-report of receiving at least 1 dose were found. The discordant cases involved patients of younger age groups, lower self-reported pre– and post–COVID-19 income, lower education levels, and lower vaccination rates in the Québec Vaccination Registry.

Our results are similar to those of a study conducted in the United States by Stephenson et al [41] that showed high levels of agreement between self-reported vaccination status and official computerized vaccination registry data (unweighted κ=0.9127, 95% CI 0.9109-0.9145). Similar to our study, they also found that discordant self-reported vaccination data were associated with lower education levels and unemployment. It could be that both studies found that lower education is associated with lower accuracy of self-reported vaccination status because information provided about vaccination status tends to be complex [42]. Comprehending and remembering this information requires certain health literacy skills [43]. Rolnick et al [44] also found that education and income level could influence the accuracy of self-reported vaccination status for 8 different vaccines (pneumococcal, influenza, tetanus diphtheria, tetanus diphtheria pertussis, human papillomavirus, hepatitis A, hepatitis B, and herpes zoster).

Contrary to our study, the study by Stephenson et al [41] found that the female sex increased the risk of discordant self-reported vaccination status. Sex and gender are important factors in understanding the real-world effectiveness of vaccines and postmarketing safety monitoring [45,46]. Sex and gender differences in vaccine hesitancy and immunization outcomes have been observed for COVID-19 and other vaccine-preventable diseases, with women typically reporting more vaccine hesitancy and higher adverse reactions than men [47-49]. Our results support the accuracy of self-reported vaccination data from both men and women.

Ulrich et al [50] studied the accuracy of the self-reported vaccination status by university students in a 2-dose meningococcal vaccine campaign. This study showed good self-reported vaccination status accuracy at 2 months (86%) and poor self-reported vaccination status at 20 months (69%). King et al [51] also reported a decrease in the agreement of patient self-reported vaccination status compared with a registry for prior season influenza vaccination (κ=0.86) versus the current season (κ=0.95). Although our study did not observe a time-dependent increase in discordant self-reported vaccination status, we did find that patients reporting a higher number of doses were more likely to forget the vaccine brand received and did not remember the dates of their latest vaccination dose. In patients who did remember the vaccine brand for each dose, the agreement with the registry was high. This limits the use of self-reported vaccination brand names for studies comparing the effectiveness of multiple doses of different types of vaccines [52].

The reliability of data on the timing of vaccination before being tested for a viral infection such as SARS-CoV-2 is essential for test-negative design vaccine effectiveness studies [53]. Our study was interested in determining the reliability of the self-reported vaccination data (ie, the date of their last vaccination and the total number of doses) used to retrospectively determine their vaccination status (not vaccinated, partially vaccinated, or fully vaccinated) at the time of their index ED visit. For patients who could remember their last vaccination date, our study found high levels of agreement between the self-reported vaccination status determined at the ED index visit date and the Québec Vaccination Registry. Unfortunately, more than half of our participants could not recall the date of their last dose, making this measure subject to an important selection bias when used in test-negative designs. This is an argument to support wider implementation and easy access to rigorous vaccination registries in all jurisdictions [21]. This is especially important to improve the care, research, and support of vulnerable populations presenting to the ED. In Canada, access to these registries is currently restricted by data custodians and administrative barriers that hinder timely knowledge creation and decision-making for a rapid-learning health system [54,55]. Although a study on the accuracy of self-reported influenza and pneumococcal vaccination status in a high-risk inflammatory bowel disease population showed high accuracy for self-reported influenza (97%) and pneumococcal (84%) vaccination status [56], our study did not find any difference between high-risk groups with different comorbidities. In concordance with Laurence et al [57], who found that older patients accurately self-reported their influenza (96%) and pneumococcal (87%) vaccine status, we also found that older adults adequately self-reported their COVID-19 vaccine status. Surprisingly, we found a higher proportion of discordant self-reported COVID-19 vaccination statuses among patients aged ≤34 years. This could be associated with the fact that COVID-19 presents a milder course in younger patients [57,58] and increased vaccination hesitancy in this age group [59-61].

There are several potential explanations for the high accuracy of self-reported vaccination status at telephone follow-up and moderate to strong agreement between the self-reported number of doses and the self-reported vaccination status determined at the time of the ED index visit. First, this high accuracy and strong agreement could have been caused by the implementation of Québec's mandatory vaccine passport, which registered dates, brands, and doses as a requirement to access the workplace and most commercial services. Although we did not ask participants to consult their passports before answering our phone questionnaire, our study personnel did not prevent participants from consulting their passports during our telephone follow-ups. Participants' recall of their own vaccination data could also have been improved by having to consult their passport frequently, as both federal and provincial governments in Canada granted substantial benefits to fully vaccinated citizens, such as lifting travel restrictions and access to event venues, fitness centers, and restaurants via the use of a vaccination passport [62]. Second, the impact of COVID-19 on the Canadian population has been substantial, and it may have improved the recall and the accuracy of the self-reported vaccination status. Third, the COVID-19 vaccination campaign; the omnipresence of the COVID-19 pandemic in the lay press; the many frequently reported statistics portraying the evolution of this pandemic (cases, hospitalizations, deaths, and population vaccination coverage); and the vigorous public debate about vaccination public health mandates may have also raised citizens' awareness of their own vaccination status. Fourth, this study only included patients with confirmed COVID-19 infections. This could have improved the recall of participants compared with patients who were not infected with COVID-19.

Our results indicate that when access to official electronic vaccination registries is not available, the reliance on patients' self-reported COVID-19 vaccination status, vaccine brand received, number of doses, and vaccination dates (when provided) can be used for research purposes. This is a substantial finding for researchers in jurisdictions that do not have access to electronic vaccine registries [20,63] and for others that have substantial challenges in securing timely access to individual-level vaccination data even when they exist [24]. Vaccine registries can also suffer from missing data for patients who have received their vaccines in different jurisdictions (as shown in our results), misclassification bias because of human error, and the timeliness of data entry into electronic vaccination registries [64]. Relying on timely and highly accurate self-reported vaccination status reduces the potential underestimation of real-world test-negative vaccine effectiveness studies introduced by vaccination-reporting bias [25]. Knowing the sensitivity and specificity of the self-reported vaccination status is also important to correct the estimation of vaccine effectiveness based on the observed risks for vaccination status misclassification [65].

This study has limitations. First, although we assumed that the Québec Vaccination Registry was the reference standard, we cannot rule out the possibility that some vaccination data were entered incorrectly. Second, our results do not apply to patients with cognitive disorders who cannot provide consent. This represents a selection bias that we could not avoid because of ethical constraints. Patients who consented to participate in our study were also more likely to be younger and female than those who did not consent or who could not consent. Understanding the impact of the pandemic on patients who cannot consent to provide their vaccination status because of cognitive issues will still necessitate access to linked vaccination registry data. Access to a vaccination registry also avoids systematic differences in the characteristics of consenting patients versus nonconsenting patients in studies that rely on self-reporting. Third, although we had many landed immigrants constituting an ethnically diverse sample, our results are potentially not applicable to patients who do not speak English or French. Other studies have shown that the self-reported vaccination status is inaccurate in certain susceptible and hard-to-follow-up racial and ethnic groups [44,50]. Although we had to exclude patients who could not speak English or French, immigration and race and ethnicity did not influence the accuracy of our results. Fourth, our study did not verify the accuracy of vaccination status provided at the time of ED care. Future prospective studies at the point of care would be needed to validate the accuracy of self-reported data for use in guiding clinical decision-making.

Conclusions

Our study found that relying on self-reported COVID-19 vaccination status is accurate for adult patients without cognitive disorders who can express themselves in English or French. Researchers can use self-reported COVID-19 vaccination data on the number of doses received, vaccine brand name, and timing of vaccination to guide future research with certain groups of patients who are capable of self-reporting their vaccination data. However, access to official electronic vaccine registries is still needed to determine the vaccination status in certain susceptible populations where self-reported vaccination data remain missing or impossible to obtain.

Acknowledgments

The authors would like to acknowledge the assistance of Ms Amber Cragg and Ms Josie Kanu in the preparation of this manuscript. The authors would like to thank the University of British Columbia clinical coordinating center staff; legal, ethics, privacy, and contract staff; and the research staff at each of the participating institutions in the network outlined in the attached supplement (Multimedia Appendix 3). In particular, the authors would like to thank Chantal Lanthier and David Iannuzzi for their support in collecting the data for this study. The network would not exist today without the dedication of these professionals. The authors would also like to thank all the patient partners who shared their lived experiences and perspectives to ensure that the knowledge we cocreate addresses the concerns of patients and the public. Creating the largest network of collaboration across Canadian emergency departments would not have been possible without the tireless efforts of emergency department chiefs, research coordinators, and research assistants at participating sites. Finally, the authors would like to express their most humble and sincere gratitude to all their colleagues in medicine, nursing, and the allied health professions who have been on the frontlines of this pandemic from day 1, staffing ambulances, emergency departments, intensive care units, and hospitals bravely facing the risks of COVID-19 to look after fellow citizens and after one another. The authors would like to dedicate this network to them. This network was funded by the Canadian Institutes of Health Research (447679, 464947, and 466880); Ontario Ministry of Colleges and Universities (C-655-2129); Saskatchewan Health Research Foundation (5357); Genome BC (COV024 and VAC007); Fondation du CHU de Québec (Octroi No. 4007); and Sero-Surveillance and Research (COVID-19 Immunity Task Force Initiative), who provided peer-reviewed funding. The BC Academic Health Science Network and BioTalent Canada provided non–peer-reviewed funding. These organizations are not for profit and had no role in conducting the study, analysis, or manuscript preparation.

The Canadian COVID-19 Emergency Department Rapid Response Network (CCEDRRN) consisted of the following members: Patrick Fok, Hana Wiemer, Samuel Campbell, Kory Arsenault, Tara Dahn, Kavish Chandra, Patrick Archambault, Joel Turner, Lars Grant, Greg Clark, Raoul Daoust, Éric Mercier, Sébastien Robert, Laurie Morrison, Steven Brooks, Ivy Cheng, Jeffrey Perry, Rob Ohle, Justin Yan, Rohit Mohindra, Megan Landes, Michelle Welsford, Tomislav Jelic, Phil Davis, Andrew McRae, Brian Rowe, Katie Lin, Stephanie VandenBerg, Jake Hayward, Jaspreet Khangura, Corinne Hohl, Daniel Ting, Maja Stachura, Frank Scheuermeyer, Balijeet Braar, John Taylor, Ian Martin, Sean Wormsbecker and Lee Graham.

Data Availability

Data are available on reasonable request. For investigators who wish to access Canadian COVID-19 Emergency Rapid Response Network data, proposals may be submitted to the network for review and approval by the network's peer review publication committee, the data access and management committee, and the executive committee as per the network's governance. Information regarding submitting proposals and accessing data may be found on the Canadian COVID-19 Emergency Department Rapid Response Network website [9].

Conflicts of Interest

None declared.

Abstract

Background: Although patients recovered from COVID-19 already have immunity gained from natural infection, they are still at risk of reinfection due to the emergence of new variants of COVID-19 and the diminishing of naturally acquired immunity over time. Vaccination is associated with efficacious protection against COVID-19 infection and could boost infection-acquired immunity; however, various COVID-19 survivors have not been vaccinated due to vaccine hesitancy.

Objective: The aim of this study was to investigate COVID-19 vaccine hesitancy and related factors among COVID-19 survivors.

Methods: A cross-sectional questionnaire survey was conducted among patients who recovered from COVID-19 infection in Wuhan, China, between June 10 and July 25, 2021. The questionnaire included sociodemographic information, items on COVID-19 infection, the COVID-19 vaccine hesitancy scale based on the 3Cs (complacency, convenience, and confidence) model, trust in vaccine manufacturers and health facilities, and reasons for the decision to accept COVID-19 vaccination. Multivariate logistic regression analysis was used to assess the factors influencing COVID-19 vaccine hesitancy.

Results: Among the 1422 participants, 538 (37.8%) were not vaccinated against COVID-19. The COVID-19–recovered patients who self-reported having a current unhealthy status expressed more hesitancy about the COVID-19 vaccine than those who perceived themselves to be healthy (odds ratio [OR] 0.45, 95% CI 0.28-0.71). Compared to the asymptomatic patients, patients with mild symptoms were more likely to receive a COVID-19 vaccine (OR 1.67, 95% CI 1.02-2.82). Regarding the 3Cs model, high complacency (P=.005) and low convenience (P=.004) were significant negative factors for COVID-19 vaccination. Trust in vaccine manufacturers and health facilities was a significant positive factor for COVID-19 vaccination (OR 1.14, 95% CI 1.09-1.19). “Self-needs” was the main reason for patients to receive the COVID-19 vaccine, whereas “already have antibodies and do not need vaccination” was the main reason for patients to not receive the COVID-19 vaccine.

Conclusions: Among the three major factors of vaccine hesitancy, complacency proved to be the most notable among COVID-19–recovered patients. Therefore, educational campaigns can focus on raising the awareness of risk of infection and the benefits of vaccination to reduce complacency toward vaccination among this population. In particular, for individuals who have recovered from COVID-19, improving factors related to convenience such as transportation, the environment of vaccination, and providing door-to-door service was also deemed necessary to facilitate their vaccination. In addition, addressing the concerns about vaccination of COVID-19–recovered patients could foster trust and promote their uptake of vaccination.

Introduction

The COVID-19 pandemic has caused a serious disease burden, as well as financial, psychological, and life hardship for people over the past 3 years. Currently, the high transmissibility, high pathogenicity, and high immune-evasion ability of the emerging new variants pose new challenges and uncertainties in preventing COVID-19 infection, as well as posing a serious threat to public health [1-3]. Previous studies have demonstrated that individuals naturally infected with COVID-19 might be at decreased future risk of COVID-19 infection due to the immunity induced by contracting COVID-19 to protect them from reinfection [4]. However, according to the World Health Organization (WHO), the presence of antibodies in recovered patients does not guarantee protection against reinfection, and the probability of protection against reinfection at 6 months was estimated to be 50.0% in people aged over 65 years [5-7]. Reinfection of COVID-19 could be as severe or even more severe than the first infection, including among patients with antibodies [6,8]. Therefore, since previous infection does not necessarily protect an individual from reinfection, it is necessary for patients who recovered from COVID-19 infection to protect against reinfection through COVID-19 vaccination [9].

Vaccination is considered to be one of the greatest achievements of public health. The ongoing COVID-19 pandemic can be mitigated by an efficacious vaccine, which reduces disease incidence, prevalence, new hospitalizations, and intensive care demand [10,11]. The COVID-19 vaccine has been shown to provide significant protection against COVID-19 infection and to significantly reduce the risk of symptomatic COVID-19 infection. Moreover, COVID-19 vaccination could boost infection-acquired immunity, and this increased immunity would remain high for more than 1 year after infection [12,13]. In 2021, five COVID-19 vaccines were approved for conditional marketing or emergency use in China, including inactivated vaccines, adenovirus vector vaccines, and recombinant protein vaccines, and the Chinese government provided nationwide COVID-19 vaccination for all populations free of charge. As of July 25, 2021, approximately 155 million cumulative doses of the COVID-19 vaccine had been administered in mainland China [14]. With the steady increase in COVID-19 vaccine supplies, vaccine hesitancy is becoming a barrier to high vaccine coverage [15]. There are still many people who delay or reject being vaccinated due to vaccine hesitancy even though they are recommended to accept the COVID-19 vaccination, including COVID-19 survivors. In the United States, vaccination coverage (>1 dose and full vaccination) was lower among those who ever had COVID-19 than among those who had no history of COVID-19 infection from July to August 2021 [16]. In Italy, 34.2% and 24.9% of COVID-19 patients were undecided or reluctant, respectively, to receive the COVID-19 vaccine from September to November 2020 [17].

The SAGE Working Group on Vaccine Hesitancy defines vaccine hesitancy as a delay in acceptance or refusal of vaccination despite the availability of vaccination services. Vaccine hesitancy is complex and context-specific, varying across time, place, and vaccines [18]. Factors such as the evolving epidemiological context and multiple waves of infection, trust in the health care system, attitudes toward vaccines, self-efficacy, and the presence of chronic disease have all been indicated to be associated with hesitancy to receive the COVID-19 vaccine [19-23]. In particular, COVID-19–recovered patients might experience not only physical disease symptoms but also psychological distress [24,25]. Some of these individuals might be hesitant to get vaccinated, fearing that they are not physically able to tolerate the vaccine. In addition, since other infectious diseases such as measles confer immunity for a longer duration or for life, some patients might consider that infection-acquired immunity with COVID-19 is the best type of immunity. Moreover, the concerns about the safety of vaccines developed in a short time might also be a factor contributing to COVID-19 vaccine hesitancy [26].

Vaccine hesitancy as a complex decision-making process has been interpreted based on various conceptual models such as the “3Cs” model, the health belief model, and the theory of planned behavior [27,28]. The “3Cs” model is one of the most widely known models, highlighting three dimensions: complacency, referring to the belief that perceived risks of vaccine-preventable diseases are low and that vaccination is not a necessary preventive action; convenience, referring to vaccine availability and accessibility; and confidence, referring to the trust in the effectiveness and safety of vaccines, the delivery system, and the motivations of vaccination policy makers [29]. Previous studies demonstrated that complacency, convenience, and confidence were equally significant factors influencing COVID-19 vaccine hesitancy [30-32].

Given the lack of data on COVID-19 vaccination status among COVID-19–recovered patients infected with the original SARS-CoV-2 strain in China, the aim of this study was to investigate COVID-19 vaccine hesitancy status and relevant factors among COVID-19–recovered patients. In particular, we focused on the role of the factors considered in the 3Cs model to identify the specific constructs that can influence COVID-19 vaccine hesitancy. In addition, the vaccination status and possible determinants of vaccine hesitancy in terms of sociodemographic information; clinical classification; history of infection in family members, relatives, and friends; and other vaccination history were investigated among COVID-19–recovered patients. This study will provide a basis for developing vaccination promotion activities and strategies for COVID-19–recovered patients to reduce their vaccine hesitancy and promote them to receive the COVID-19 vaccine.

Methods

Study Design and Sampling

This cross-sectional study was carried out among former COVID-19 patients in Jianghan District of Wuhan, China, from

June 10 to July 25, 2021. According to the electronic medical records of the Health Bureau of Jianghan District and the inclusion criteria, a total of 3059 recovered COVID-19 patients were eligible for the study who had all been infected with the original SARS-CoV-2 strain and were diagnosed between December 10, 2019, and April 20, 2020. Among them, 1601 COVID-19 survivors were invited to complete a questionnaire survey on their vaccine hesitancy status when they were receiving clinical reexamination. If they agreed to participate in this survey, they were invited to the "Survey Room" to complete the questionnaire. Self-administered electronic questionnaires were generated on Research Electronic Data Capture (REDCap), an online survey platform, from which patients could complete by themselves. To ensure the quality of the survey, our trained investigators stayed at the "Survey Room" to promptly answer the participants' questions.

The following inclusion requirements had to be met by participants: participants must be at least 18 years old, have a COVID-19 infection history, be able to work independently with the researcher to complete several scale assessments, and have access to a mobile communication device such as a cell phone with a WeChat account. People who fit one or more of the following criteria were excluded: (1) having significant cognitive impairment; (2) having life-threatening medical conditions such as heart, lung, kidney, liver diseases or cancers; and (3) finding it challenging to cooperate with the questionnaire study. In total, 1422 of the 1601 invited participants were chosen as the sample for this study based on the aforementioned standards and after discarding any incomplete questionnaires.

Ethical Considerations

Ethics approval for the study was obtained from the Ethics Review Committee of the Institute of Pathogen Biology, Chinese Academy of Medical Sciences, Beijing, China (IPB-2020-22). All individuals provided digital informed consent to ensure their voluntary participation, which also included consent that the study data could be analyzed when used anonymously. All data were deidentified. All data are stored in an account with a password and cannot be used without consent. All study participants were compensated for transportation to the questionnaire site.

Measurements

Sociodemographic Characteristics

Demographic characteristics included gender, age, place of residence, education level, marital status, smoking (whether or not they are habitual smokers), drinking (whether or not they habitually drink alcohol), and perceived current health status. We also investigated COVID-19 clinical classification by asking participants which type of diagnosis they had after their first admission (ie, asymptomatic, mild, moderate, clinically severe) and their acute-phase symptoms (ie, fever, respiratory symptoms, cardiovascular symptoms, gastrointestinal symptoms, other). Questions on COVID-19 infection and vaccination were also surveyed, including history of infection in family members, history of infection in relatives and friends, and other vaccination history (within the last 5 years).

COVID-19 Vaccine Hesitancy Scale Based on the 3Cs Model

On the basis of the flu vaccine hesitancy scale, we replaced "flu vaccine" in the items with "COVID-19 vaccine" to form the revised COVID-19 vaccine hesitancy scale. The flu vaccine hesitancy scale consists of 6 items and the 3 dimensions of the 3Cs model (complacency, confidence, and convenience) [33]. Complacency was measured by perceived necessity and importance of the vaccine, confidence was measured by perceived vaccine safety and effectiveness, and convenience was measured by perceived convenience and affordability of the vaccine. Participants rated each item on a 5-point Likert scale (1=strongly disagree; 5=strongly agree). The items were as follows: (1) necessity ("Thinking specifically about the COVID-19 vaccine, do you think the COVID-19 vaccine is necessary?"), (2) importance ("Thinking specifically about the COVID-19 vaccine, do you think the COVID-19 vaccine is important?"), (3) safety ("Thinking specifically about the COVID-19 vaccine, do you think the COVID-19 vaccine is safe?"), (4) effectiveness ("Thinking specifically about the COVID-19 vaccine, do you think the COVID-19 vaccine is effective?"), (5) convenience ("Thinking specifically about the COVID-19 vaccine, do you think the COVID-19 vaccine is convenient?"), and (6) affordability ("Thinking specifically about the COVID-19 vaccine, do you think the COVID-19 vaccine is affordable?"). The Cronbach α value for the whole scale was .92, and the Cronbach α values for the dimensions of complacency, convenience, and confidence were .92, .94, and .73, respectively. [34].

Trust

Two items were used to measure participants' trust in vaccine manufacturers and health facilities, respectively, which were each scored on a 10-point Likert scale (1=strongly disagree; 10=strongly agree). The Cronbach α value for the two items was .92.

Reasons for Accepting and Not Accepting the COVID-19 Vaccine

For participants who had received the COVID-19 vaccine, multiple-choice questions were designed to investigate the corresponding reasons, with answers including: (1) self-needs, (2) recommended by health agencies, (3) recommended by others (eg, relatives, friends, neighbors), (4) recommended by those who have been vaccinated, (5) internet information, (6) free vaccination, and (7) others.

For participants who had not received the COVID-19 vaccine, multiple-choice questions were set up to investigate the reasons, with answers including: (1) don't know how to get reliable information about COVID-19 vaccine, (2) have received negative media reports about COVID-19 vaccines, (3) have had a bad experience with the health clinic or provider, (4) have had a bad experience or adverse reactions from previous vaccinations, (5) have been told that others have had adverse reactions from some vaccines, (6) fear of injections, (7) already have antibodies and do not require vaccination, (8) long waiting time for vaccination, and (9) others.

Statistical Analysis

Confirmatory Factor Analysis of the COVID-19 Vaccine Hesitancy Scale

To validate the COVID-19 vaccine hesitancy scale, we performed a confirmatory factor analysis. Model fit was evaluated by various goodness-of-fit indices, including the root mean square error of approximation (RMSEA), comparative fit index (CFI), and Tucker Lewis index (TLI) [35-37]. RMSEA values close to 0.06 or below were regarded as a good fit, 0.07 to 0.08 as moderate fit, 0.08 to 0.10 as marginal fit, and >0.10 as poor fit [38]. For the CFI and TLI, values close to 0.95 or above were regarded as good fit, values close to 0.90 and 0.95 as acceptable fit, and values approaching 0 as poor fit [39,40]. Convergent validity was assessed by average variance extracted (AVE) and composite reliability (CR), and convergent validity was considered high if the AVE was greater than 0.50, CR was greater than 0.70, and CR was greater than AVE. Discriminant validity was considered satisfactory if the correlation between the factor scores was significant and the correlation coefficient was less than the square root of the corresponding AVE [41,42].

Univariate and Multivariate Analysis

Categorical variables are summarized as frequencies and proportions, whereas continuous variables are summarized as mean (SD). Respondents who were vaccinated against COVID-19 indicated that they were not hesitant about the COVID-19 vaccine, whereas those who were not vaccinated against COVID-19 indicated that they had COVID-19 vaccine hesitancy. To identify any differences in the distributions of variables between the vaccinated and unvaccinated groups, the χ^2 test and *t* test were used for categorical and continuous variables, respectively. Using the unvaccinated population as a reference, multiple logistic regression analysis was used to assess the association between the investigated factors and COVID-19 vaccine hesitancy. The associations between dependent and independent variables were determined using the odds ratio (OR) with 95% CI and a *P* value <.05 was deemed to indicate statistical significance of the independent variables. Data were analyzed using Stata version 16.0.

Results

Confirmatory Factor Analysis of the COVID-19 Vaccine Hesitancy Scale

Figure 1 depicts the results of the confirmatory factor analysis for the model built in the sample, including the three dimensions of the 3Cs model. Separate confirmatory factor analysis based on the original structure of the "complacency" dimension (2 items), "confidence" dimension (2 items), and "convenience" dimension (2 items) were performed. The RMSEA value (0.076) indicated a moderate fit, the CFI value (0.994) indicated a good fit, and the TLI value (0.986) indicated a good fit.

Table 1 shows the results of convergent validity and discriminant validity of the model. For convergent validity, the AVE values for all dimensions of the model were greater than 0.50 and the CR values for all three dimensions of the model were greater than 0.70. In addition, the CR values for all factors in the model were greater than the AVE. For discriminant validity, the correlation coefficients for any two dimensions were less than the square root of the corresponding AVE, except for the correlation coefficients for confidence and convenience, which were higher than the square root of the corresponding AVE.

Figure 1. Results of the confirmatory factor analysis model. Standardized covariances between dimensions are shown in bold, standardized path coefficients are italicized, and standardized variances are also shown.

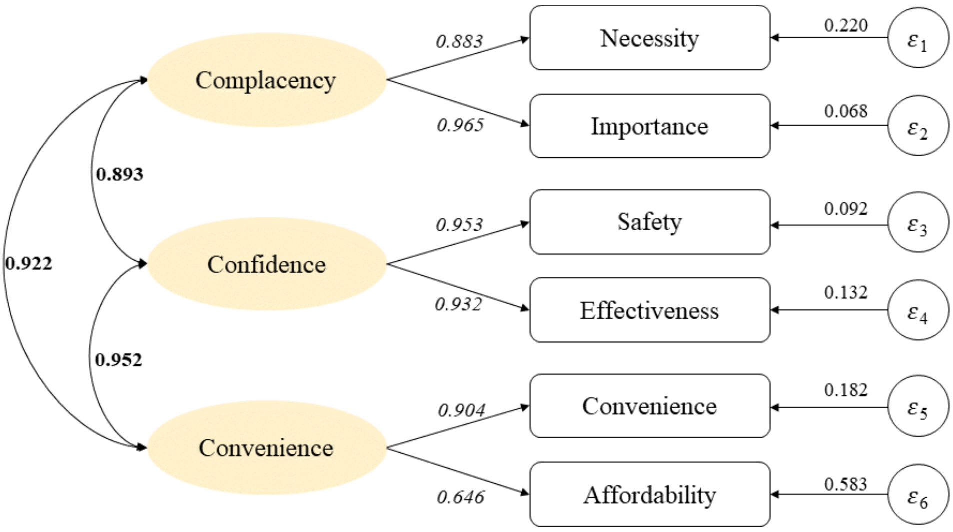

Table 1. Convergent and discriminant validity of the COVID-19 vaccine hesitancy model.

Dimensions	Pearson correlation coefficient			AVE[a]	CR[b]
	Complacency	Confidence	Convenience		
Complacency	*0.925*[c]	N/A[d]	N/A	0.855	0.922
Confidence	–0.827*	*0.942*	N/A	0.888	0.941
Convenience	–0.759*	0.796*	0.785	0.617	0.758

[a] AVE: average variance extracted.

[b] CR: composite reliability.

[c] Values on the diagonal are the square roots of each AVE value for comparison with other correlation coefficients; values in italics indicate a higher square root of the AVE value in each subscale than the correlation coefficients with other subscales.

Sociodemographic Characteristics of Participants

Among the 1422 participants, 538 (37.8%) were not vaccinated against COVID-19. There was a higher proportion of participants aged 41 to 60 years (634/1422, 45.2%), followed by the 61-80 years age group (611/1422, 43%). The great majority of the participants lived in urban areas (1245/1422, 87.6%), and 1197 (84.2%) participants were married. The majority (968/1422, 68.1%) had an education level of senior high school or below. Nearly half of the participants had a household income for 2020 lower than 60,000 Yuan (approximately US $8607) per year. Most participants self-reported that they were not current smokers (1233/1422, 86.7%) or drinkers (1038/1422, 73.0%), and 6.1% (87/1422) of the patients were asymptomatic, 70.8% (1007/1422) had mild symptoms of COVID-19, 10.3% (146/1422) had moderate symptoms, and 12.8% (182/1422) had critically severe symptoms. In the acute phase, 62.7% (891/1422) of patients had fever, 49.9% (709/1422) had respiratory symptoms, 18.2% (259/1422) had gastrointestinal symptoms, 6.4% (91/1422) had cardiovascular symptoms, and 15.5% (221/1422) had other symptoms. Overall, 24.1% (342/1422) were reinfected with COVID-19 after the first discharge, nearly half of the participants (654/1422, 46%) had family members who had been infected with COVID-19, 30.2% (429/1422) had relatives or friends who had been infected with COVID-19, and 17.2% (245/1422) of the participants had received other vaccines within the last 5 years (Table 2).

Table 2 also shows that the age gap between vaccinated and unvaccinated participants was statistically significant; participants aged ≤40 years had a higher hesitancy rate compared to the other three age groups (*P*<.001). The hesitancy rate of those living in urban areas (485/1245, 39.0%) was significantly higher than that of participants living in a village (53/177, 29.9%). Significantly, participants who were married had a lower hesitancy rate (428/1197, 35.8%) compared to that of participants who were single (23/54, 42.6%) and those with another marital status (87/171, 50.9%). Participants who perceived having an unhealthy status had a higher hesitancy rate than that of participants who self-reported being healthy (*P*<.001). Patients who had fever in the acute phase had a higher COVID-19 vaccine hesitancy rate (359/891, 40.3%) than those who did not have fever (179/531, 33.7%).

Contributions of 3Cs Model Constructs and Trust to Vaccine Hesitancy

Figure 2 shows the distribution of answers on the COVID-19 vaccine hesitancy scale based on the 3Cs model among all participants. Table 3 shows the univariate analysis results of 3Cs model components and trust in vaccinated and unvaccinated groups. The unvaccinated group scored significantly higher on “complacency” related to COVID-19 vaccination than the vaccinated group. In contrast, participants who had received the COVID-19 vaccine scored higher on “confidence” and “convenience” than those who were not vaccinated. Moreover, the vaccinated group scored significantly higher than the unvaccinated group on trust (all *P*<.001).

Figure 2. Distribution of answers on the COVID-19 vaccine hesitancy scale according to the 3Cs model (complacency, convenience, confidence).

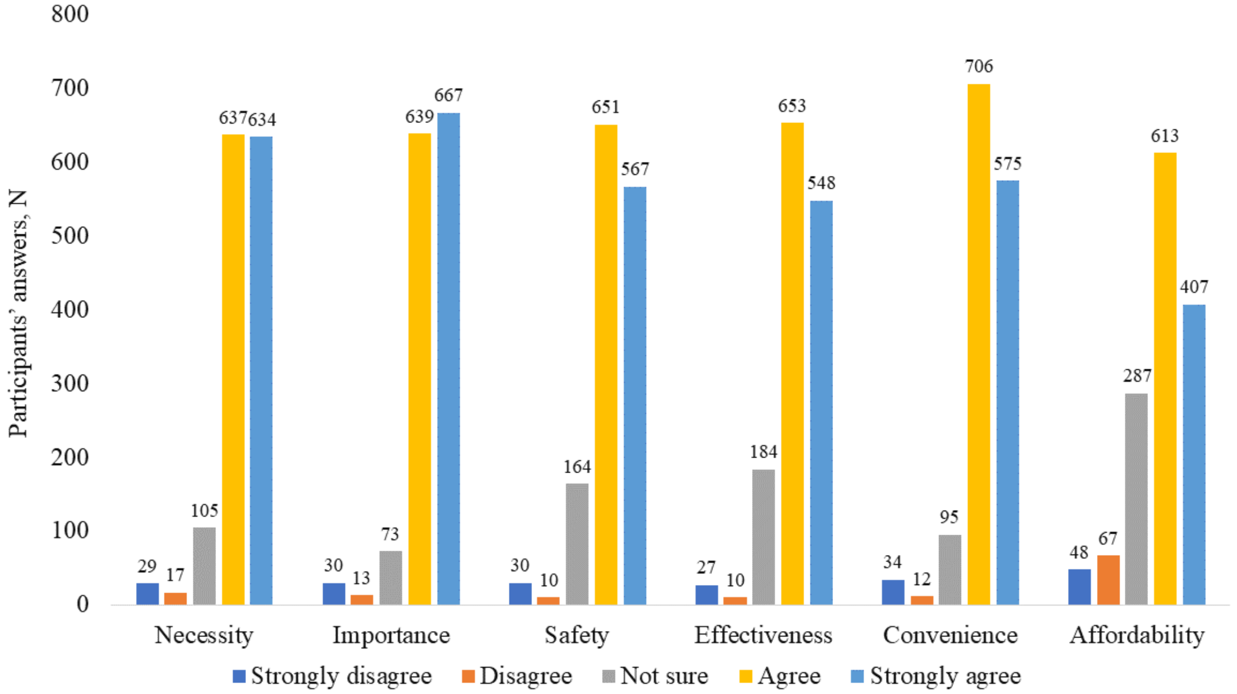

Table 3. Univariate analysis of the 3Cs (complacency, confidence, convenience) model constructs and trust in vaccinated and unvaccinated groups.

Variables	Scores, mean (SD)			*P* value
	Unvaccinated (n=538)	Vaccinated (n=884)	Total (N=1422)	
3Cs Complacency	3.82 (1.69)	3.11 (1.40)	3.38 (1.55)	<.001
3Cs Confidence	7.96 (1.65)	8.66 (1.52)	8.39 (1.61)	<.001
3Cs Convenience	7.66 (1.62)	8.43 (1.52)	8.14 (1.60)	<.001
Trust	17.02 (3.39)	18.42 (2.44)	17.89 (2.91)	<.001

Multivariate Predictors of COVID-19 Vaccine Hesitancy

Table 4 shows that participants aged 41-60 years (OR 2.12, 95% CI 1.34-3.36) and 61-80 years (OR 2.59, 95 %CI 1.56-4.30) were more likely to receive a COVID-19 vaccine than participants aged ≤40 years; however, participants aged >80 years (OR 0.14, 95% CI 0.03-0.66) were less likely to receive a COVID-19 vaccine than those aged <40 years. Participants who reported "other" marital status (ie, divorced, widowed) were more likely to be hesitant about receiving the COVID-19 vaccine than those who were single (OR 0.42, 95% CI 0.19-0.91). In addition, patients who perceived having an unhealthy status had more hesitancy about the COVID-19 vaccine than those who were healthy (OR 0.45, 95% CI 0.28-0.71). Compared to the asymptomatic patients, patients with mild symptoms were more likely to receive the COVID-19 vaccine (OR 1.67, 95% CI 1.02-2.82). Regarding the acute-phase symptoms, patients who did not have fever were less likely to receive the COVID-19 vaccine than those who had fever (OR 1.48, 95% CI 1.13-1.94). Not receiving any other vaccination within the last 5 years was negatively associated with receiving the COVID-19 vaccine (OR 0.69, 95% CI 0.50-0.95). Regarding the 3Cs model constructs, complacency was a significant negative factor for getting vaccinated for COVID-19 (OR 0.81, 95% CI 0.71-0.94), whereas convenience was a significant positive factor for COVID-19 vaccination (OR 1.21, 95% CI 1.06-1.37). Participants who had more trust were more likely to receive the COVID-19 vaccine (OR 1.14, 95% CI 1.09-1.19).

Reasons for Accepting and Not Accepting COVID-19 Vaccination

Among the reasons for getting vaccinated against COVID-19, "self-needs" was chosen most frequently (n=625), followed by "recommended by health agencies" (n=191) and "free vaccination" (n=149). The reason for "recommended by those who have been vaccinated" was selected 37 times, which was only higher than the "others" response option (n=11). Among the reasons for not getting vaccinated against COVID-19, "antibodies are already in existence and do not require vaccination" was chosen most frequently (n=88), followed by "don't know how to get reliable information about the COVID-19 vaccine" (n=53) and "others" (n=30). The reason "have had a bad experience with the health clinic or provider" was selected 4 times, which was the least frequently selected option (Table 5).

Table 5. Reasons for accepting and not accepting COVID-19 vaccination.

Reasons	Participants, n
Accepting COVID-19 vaccination	
Self-needs	625
Recommended by health agencies	191
Recommended by others (eg, relatives, friends, neighbors)	73
Recommended by those who have been vaccinated	37
Internet information	40
Free vaccination	149
Others	11
Not accepting COVID-19 vaccination	
Don't know how to get reliable information about COVID-19 vaccine	53
Have received negative media reports about COVID-19 vaccines	26
Have a bad experience with the health clinic or provider	4
Have a bad experience or adverse reactions from previous vaccinations	18
Have been told that others have had adverse reactions from vaccines	29
Fear of injections	25
Antibodies are already in existence and do not require vaccination	88
Long waiting time for vaccination	19
Others	30

Discussion

Principal Results

The WHO indicated that antibodies in COVID-19–recovered patients do not guarantee protection against reinfection, making it necessary to receive the COVID-19 vaccine after natural infection [7]. However, diverse and effective preventive measures such as wearing a mask provided an alternative to prevent COVID-19 and might undermine the perceived need for vaccination to the point of developing an attitude of COVID-19 vaccine hesitancy [43,44]. This study revealed that the rate of COVID-19 vaccine hesitancy among patients who recovered from COVID-19 was 37.8%. According to previous research, this vaccine hesitancy rate is higher than that determined in a similar time period among Chinese patients with chronic diseases, including HIV infection (27.5%), cancer (24.1%), and inflammatory bowel disease (27.4%) [45-47]. Even though COVID-19–recovered patients and patients with chronic diseases are both vulnerable to COVID-19 reinfection based on their poor health conditions, COVID-19–recovered patients have a lower perceived risk of COVID-19 reinfection due to their belief that they already have antibodies gained from previous infection compared to patients with chronic diseases. Several studies also suggested lower vaccination intention among COVID-19–recovered individuals compared to uninfected individuals [48,49]. Research has shown that acquired immunity from COVID-19 infection would diminish over 6-8 months and protection against the new variant (Omicron variant) might be inadequate [50]; thus, COVID-19–recovered patients are still at risk of reinfection. The high perceived risk of contracting diseases is an essential determinant in overcoming vaccine hesitancy; that is, individuals who perceived a high risk of COVID-19 infection were assumed to adopt more preventive health behaviors to avoid or minimize health risks [51]. As the threat of reinfection increases due to continuously emerging new mutant strains, raising COVID-19–recovered patients' awareness of the reinfection risk is essential to reduce their vaccine hesitancy.

In this study, COVID-19 patients with mild symptoms were more likely to receive the COVID-19 vaccine than asymptomatic patients. Similarly, previous studies have shown that people who have experienced severe COVID-19 disease have a lower rate of hesitancy compared to those with less severe disease [17]. Patients who have experienced the negative health effects of COVID-19 infection were willing to be vaccinated because they did not want to experience these symptoms again and would have a greater fear of reinfection. Previous studies also suggested that the severity perception of COVID-19 infection would directly affect the intention to vaccinate against COVID-19; patients who perceived COVID-19 infection to be severe were the most likely to be vaccinated [52,53]. In addition, patients with symptoms may develop sequelae symptoms and thus believe that they are vulnerable and that their perceived risk of COVID-19 infection will be higher, leading to the belief that they need to be vaccinated. Results of a cohort study showed that 61.4% of patients infected with the original SARS-CoV-2 strain had at least one sequelae symptom [54]. The significance of vaccination was not limited to preventing COVID-19 infection, as vaccination in COVID-19–recovered patients was found to also be effective at preventing sequelae symptoms [55]. Several studies have shown that the vaccinated group had a lower risk of developing sequelae symptoms compared to the unvaccinated group [56-58]. Emphasizing the benefits of vaccination among hesitant patients, such as prevention of reinfection and prevention of sequelae, will raise their awareness of the need for vaccination and thus motivate unvaccinated COVID-19–recovered patients to get vaccinated.

Complacency occurs when individuals have a lower perception of the need for a vaccination or a perceived low risk from diseases, which is influenced by general health beliefs [59,60]. Similar to other studies, complacency had a significant effect on increasing COVID-19 vaccine hesitancy in this study [61,62]. The immunity from previous infections might be one of the reasons for the complacency among the patients who recovered from COVID-19 infection. Meanwhile, misconceptions about the efficacy or safety of vaccination, misinformation in popular social media, and the perception that vaccines may not offer better protection than previous infections also could lead to complacency and result in underacceptance of the COVID-19 vaccine [63-65]. Additionally, the belief that vaccination of those around them is sufficient to prevent transmission and protect themselves from COVID-19 reinfection could result in a lower perception of COVID-19 reinfection risk among COVID-19–recovered patients. According to our study, among the reasons why COVID-19 survivors were willing to be vaccinated, most participants chose "self-needs," which could eventually lead to high vaccine uptake [66]. By reducing their beliefs about complacency, this group of COVID-19 survivors might realize that vaccination is necessary for them. Specifically, health systems and relevant authorities should provide valuable information highlighting the evidence that immunity gained from natural infection would diminish over time and the risks of failure to vaccinate to enhance their "self-needs." This would increase vaccination rates among COVID-19 survivors and ensure that they have sufficient protection against reinfection.

Convenience was a significant factor affecting vaccine hesitancy. Previous vaccination programs have shown that obstacles to vaccination include limited access to information, difficulties obtaining vaccines, unaffordable vaccine prices, and the long time (or distance) required to receive a vaccine [67-69]. Our results showed that "long waiting time for vaccination" and "have had a bad experience with the health clinic or provider" were among the convenience-related reasons participants stated for not receiving the COVID-19 vaccine. "Free vaccination" was among the reasons why participants received a COVID-19 vaccine, which is related to high convenience. Hence, to enhance COVID-19–recovered patients' convenience in getting vaccinated for COVID-19, relevant health facilities should optimize the vaccination process to shorten waiting or queueing times, further improve the vaccination environment, and train vaccination-related workers to make them knowledgeable about the vaccine and to be more patient when answering questions [65]. In addition, targeting COVID-19–recovered patients with mobility issues and offering door-to-door vaccinations to address accessibility barriers would be very effective measures to increase vaccination rates.

Trust is a strong driver in reducing vaccine hesitancy. People with a higher level of trust in health authorities would have a more positive perception of the COVID-19 vaccine [70,71]. This study utilized two questions to evaluate participants' trust, and the results also showed that trust was a motivating factor for patients who recovered from COVID-19 to get immunized. However, a crisis of trust in the COVID-19 vaccine, vaccine manufacturers, and health facilities unavoidably arose as a result of vaccine safety–related events and the dissemination of false information since the COVID-19 outbreak. Trust would build when people feel that health authorities possess knowledge and expertise; that the authorities take into account all relevant opinions; and that the authorities are transparent, honest, and open [72]. To assist in fostering trust and boosting confidence in the COVID-19 vaccine, identifying the concerns of patients who recovered from COVID-19, providing accurate information, and establishing communication channels with the health authorities are necessary. Ensuring appropriate, effective, and more specific education targeted at patients who recovered from COVID-19, while expressing the overall benefits and risks of the vaccine would also be beneficial to build trust to promote vaccination.

Since the availability of COVID-19 vaccines, we have dependable, high-quality evidence attesting to their safety, effectiveness, and value of protecting people from COVID-19 infection. However, our research has shown that patients are likely to be hesitant to receive vaccines because of complacency, convenience, trust, and other issues. In December 2022, a large-scale outbreak of COVID-19 infection occurred in China that lasted for 2-3 months, resulting in a high proportion of the population being in the category of COVID-19–recovered patients. These individuals will inevitably have to decide whether to get another dose (booster shot) if the COVID-19 epidemic persists and new variants continue to emerge. The study team conducted an online survey between January 5, 2023, and February 9, 2023, among people in seven geographic subdivisions of China regarding their willingness to receive a booster shot. A total of 7070 valid questionnaires were collected among these COVID-19–recovered patients and the COVID-19 vaccine hesitancy rate was 43.54% (data not shown). This high rate indicates that vaccine hesitancy still exists among COVID-19–recovered patients in China since the latest surge of the COVID-19 pandemic. The findings of this study may contribute to providing a research base and support for interventions to reduce future hesitancy related to COVID-19 booster shots among COVID-19–recovered patients, since future booster shots and the COVID-19 vaccination services and procedures that are currently in progress may converge.

Limitations

This study has several limitations. First, the study was conducted in Wuhan, China, and a convenience sampling approach was employed for the survey, which may result in potentially biased estimates and selection bias. Therefore, the generalizability of our results will still be limited in certain aspects. Second, this was a cross-sectional study using a self-report questionnaire, leading to the presence of information bias. Third, since these data were collected between June and July 2021, the investigation was carried out in a very dynamic and ever-changing context, and it is possible that current perceptions of vaccines have changed both in terms of the perceived disease threat to study participants and the development of the COVID-19 vaccine itself.

Conclusions

COVID-19–recovered patients may have a low perception of the risk of reinfection because they already have immunity acquired through natural infection, and this may lead to complacency, ultimately leading to COVID-19 vaccine hesitancy. Advocacy strategies based on scientific evidence to raise public awareness of the risk of reinfection and the superiority of immunity gained from vaccination over that gained from infection can be effective in reducing complacency and thus overcoming vaccine hesitancy. Improving convenience-related factors such as time, transportation, and environment to get vaccinated is also necessary to address accessibility barriers and facilitate vaccination uptake. Furthermore, education efforts targeted at individuals who recovered from COVID-19 based on solid and adequate knowledge are needed to address their concerns about vaccination, which could foster greater trust and promote their vaccination acceptance.

Acknowledgments

This research was funded by the Asian Regional Special Cooperation Fund of the National Health Commission of the People's Republic of China (BLXM01) and the Innovative Engineering Program sponsored by the Chinese Academy of Medical Sciences (2020-I2M-2-015).

Data Availability

The data sets generated during and/or analyzed during the current study are available from the corresponding author on reasonable request.

Authors' Contributions

YH, LZ, YW, and JF prepared the revised manuscript. YH and HW prepared the first draft. XS provided overall guidance and managed the overall project. WX, HW, YX, MS, JF, XC, MJ, ZL, and DC were responsible for the questionnaire survey and data management. YH analyzed the data. YH, LZ, and XS finalized the manuscript on the basis of comments from other authors. All authors read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Distributing COVID-19 vaccines to the public was an important task for the governments of each country. Because of various limitations, priority settings for vaccination were determined at the time of mass vaccination. However, trends between vaccine intention and uptake, as well as reasons for getting vaccinated or not getting vaccinated, among these groups were understudied, undermining verification of the legitimacy of priority selection.

Objective: This study aims to illustrate a trend from prior COVID-19 vaccine intention, when the vaccine was not available, to the actual uptake within 1 year when all residents had access to the vaccine, to illustrate a change of reason for getting vaccinated or not getting vaccinated and to examine whether priority settings predicted subsequent vaccination uptake.

Methods: Prospective cohort, web-based, self-administered surveys were conducted in Japan at 3 time points: February 2021, September to October 2021, and February 2022. In total, 13,555 participants (age: mean 53.1, SD 15.9 years) provided valid responses, with a 52.1% follow-up rate. On the basis of the information obtained in February 2021, we identified 3 types of priority groups: health care workers (n=831), people aged ≥65 years (n=4048), and those aged 18 to 64 years with underlying medical conditions (n=1659). The remaining patients were treated as nonpriority (n=7017). Modified Poisson regression analysis with a robust error estimated the risk ratio for COVID-19 vaccine uptake after adjusting for socioeconomic background, health-seeking behavior, attitude toward vaccines, and COVID-19 infection history.

Results: In February 2021, a total of 5182 out of 13,555 (38.23%) respondents expressed their intention to get vaccinated. In February 2022, a total of 1570 out of 13,555 (11.6%) respondents completed the third dose and 10,589 (78.1%) respondents completed the second dose. Prior vaccine intention and subsequent vaccine coverage rates were higher in the priority groups. Protection of themselves and their families from potential infection was the most frequent reason for getting vaccinated, whereas concern about side effects was the most frequent reason for hesitation across the groups. Risk ratios for received, reserved, or intended for vaccination in February 2022 were 1.05 (95% CI 1.03-1.07) for the health care worker group, 1.02 (95% CI 1.005-1.03) for the older adult group, and 1.01 (95% CI 0.999-1.03) for the preexisting conditions group compared with the nonpriority group. Prior vaccine intention and confidence in vaccines were strong predictors of vaccine uptake.

Conclusions: The priority settings at the start of the COVID-19 vaccination program had a significant impact on vaccine coverage after 1 year. The priority group for vaccination achieved higher vaccination coverage in February 2022. There was room for improvement among the nonpriority group. The findings of this study are essential for policy makers in Japan and other countries to develop effective vaccination strategies for future pandemics.

Introduction

Background

Since 2020, the wave of COVID-19 infection caused by SARS-COV-2 has affected populations intermittently around the world. To address this global challenge, COVID-19 vaccines were quickly developed, tested, licensed, and delivered worldwide in a relatively short time frame [1]. Vaccines are the most effective way to reduce the risk of COVID-19 infection, to bring herd immunity, and eventually to end the pandemic [2-4]. Being vaccinated contributes not only to preventing infection but also to reducing the severity, hospitalization, and mortality rates of COVID-19 [5-8]. In addition to the direct benefits to vaccine recipients, there are indirect benefits to those who are protected from the spread of COVID-19 infection. At the initial stage of vaccination, due to limitations in supply, logistics, and workforce, it was impossible to provide an equal opportunity for vaccination to all citizens at the same time. Prioritizing health care workers (HCWs) and people with medical vulnerabilities associated with poorer COVID-19 outcomes, such as older adults or those with chronic diseases, was common practice across countries [9-13]. Certainly, it was necessary to prioritize these populations when new vaccines were introduced to maintain the health care system and social function. However, at the same time, this practice might create artificial health disparities between priority and nonpriority groups. Attention should be paid to the manner in which the setting of priorities has affected the subsequent vaccine uptake situation.

The following paragraph describes an overview of the COVID-19 vaccine situation in Japan. Regarding countermeasures against COVID-19, there were no strict restrictions that involved penalties, such as those imposed during the lockdown in the United Kingdom. Instead, the government declared a state of emergency and called for citizens to refrain from actions that could spread the infection. It should also be noted that Japan has a universal health care system. COVID-19 vaccination was free of charge and was not mandatory. On February 14, the Pfizer vaccine was approved in Japan. The first dose of vaccination began on February 17, 2021, targeting HCWs in the National Hospital Organization, particularly those on the frontlines of COVID-19 patient care. Nationwide vaccination for HCWs began in March 2021. Mass vaccination for the following groups started in April: those aged ≥65 years at the end of March, those aged 18 to 64 years with preexisting conditions, and those who were working in nursing homes [14]. The government approved the Takeda or Moderna vaccine in May and the AstraZeneca vaccine in August. Although Japan started mass vaccination several months later than Western countries, vaccination coverage grew steadily once it began [15,16]. The third dose of vaccination for HCWs started in December 2021. As of April 2022, Japan has depended on imported vaccines supplied by Pfizer, Takeda or Moderna, and AstraZeneca that require 2-dose shots. By April 2022, more than half of the total population had received a booster dose, although vaccination rates among those in their 20s and 30s were reported to be low [17]. Those aged ≥60 years and those with underlying conditions were given the opportunity for a fourth vaccination dose, starting in May 2022, before HCWs.

Researchers have investigated the sociodemographic, psychological, behavioral, and social factors associated with vaccine intention or uptake status. In Japan, the following factors were related to vaccine intention or uptake: age [18-25], sex [18,20-25], employment status [18,22], marital status [18,19], income [18-20,22,23], educational attainment [18,19,22], underlying medical conditions [18-21,25], influenza vaccine history [19,24-26], medical checkup history [26], and COVID-19–related fear or anxiety [18-20,25,26]. Regarding attitudes toward the COVID-19 vaccine, concerns about the side effects of vaccines [25,26], confidence in vaccine effectiveness and public authorities [18,20,25], and pseudoscience [26] were linked to vaccine intention. Concern about adverse reactions is one of the most common reasons for vaccine hesitancy [21,22,25]. Although most of the existing literature relies on cross-sectional data, longitudinal studies on vaccine intention and subsequent uptake status are emerging worldwide [27-32]. These longitudinal studies demonstrate that the shift from initial intention to COVID-19 vaccination to actual uptake was influenced by the information about vaccine safety and efficacy that became available to the public. However, to date, no longitudinal studies have simultaneously observed the shift between those who are eligible for priority vaccination and those who are not. This is mainly because of the difficulty in recruiting a sufficient number of respondents in cohort studies.

Objectives

Two series of web-based, prospective cohort studies are ongoing: the Japan Society and New Tobacco Internet Survey (JASTIS) and the Japan COVID-19 and Society Internet Survey (JACSIS). We derived 1-year longitudinal data from 3 time points of these surveys to address the following objectives: (1) to illustrate a trend from prior COVID-19 vaccine intention, when the vaccine was not available, to the actual uptake within 1 year when all residents had access to the vaccine; (2) to illustrate a change of reason for being vaccinated or not being vaccinated; and (3) to examine whether priority settings predicted vaccination uptake. The results are presented focusing on 3 types of vaccination priority and nonpriority groups at the rollout of mass vaccination. This approach allowed us to identify important trends over time and to examine whether the setting of priority groups was reasonable. Our study will also provide profound information for governments, health care policy makers, and health care providers to determine the target population for public health messages intended to promote vaccine uptake and how to tailor these messages for their specific audience.

Methods

Study Setting and Design

The data were derived from JASTIS from 2015 onward and JACSIS from 2020 onward. The study profiles have been described elsewhere [18,33]. Briefly, they comprised a series of web-based, self-administered cohort surveys that shared the same survey panel. The survey panel was drawn from approximately 2.2 million panelists at a Japanese internet research company (Rakuten Insight, Inc), which comprises individuals from diverse socioeconomic backgrounds (eg, marital status, educational level, and household income) to be a nationally representative sample of Japan. In JASTIS and JACSIS, sampling was stratified by sex, age, and prefecture of residence to be as nationally representative as possible. We used 3 time points to analyze the longitudinal data from the surveys conducted from February 8 to 25, 2021 (T1); September 27 to October 29, 2021 (T2); and February 1 to 28, 2022 (T3). All the respondents received a nominal incentive for survey completion at each time point.

Study Participants

At T1, an email containing a link to the survey website was distributed to 32,827 candidates who participated in the same survey series conducted between 2015 and 2020. In total, 73.29% (24,059/32,827) of the participants answered the questionnaire. The survey continued to gather new panelists from the same internet research company until the number of respondents reached the targeted sample size (n=26,000). The respondents who answered that they were HCWs were classified as HCW group. The remaining respondents were classified into 3 groups: those who were aged ≥65 years, those who were aged 18 to 64 years with at least one preexisting condition, and those who were aged 18 to 64 years with no preexisting conditions. Preexisting conditions were defined as the following 14 conditions: hospital attendance for hypertension, diabetes mellitus, asthma, pneumonia or bronchitis, angina pectoris, myocardial infarction, stroke (including cerebral infarction and cerebral hemorrhage), chronic obstructive pulmonary disease, chronic kidney disease, chronic liver disease (excluding fatty liver and hepatitis), immune disorders and other diseases that cause immune deficiency (including steroid use), or cancer (including malignant tumor); sleep apnea identified by a medical checkup or physician; and a BMI ≥30 kg/m^2. The exclusion criteria are summarized in Multimedia Appendix 1.

Ethics Approval, Informed Consent, and Participation

Ethics approval for this study was obtained from the ethics committee of the Osaka International Cancer Institute (#20084-6) and the ethics committee of the University of Tsukuba, Institute of Medicine (#1737). All procedures were performed in accordance with the ethical standards of the institutional or national research committees and the 1964 Declaration of Helsinki and its later amendments, or comparable ethical standards. All participants provided web-based informed consent at registration. The study data were deidentified. For the research incentives, the participants earned points that could be used for shopping but the amount was not disclosed.

Measures

Assessment of COVID-19 Vaccine Intention, Uptake, and Reasons for a Decision

In each survey, COVID-19 vaccine intention and uptake were assessed using a single-item question. The details are described in Multimedia Appendix 2. According to the response at T3, the participants were dichotomized into either a hesitant group or a received, reserved, or intended group. The hesitant group included participants who expressed that they did not want to get vaccinated or they would like to get vaccinated after waiting to see how it goes. The received, reserved, or intended group included participants who answered that they wanted to get vaccinated; had reserved a vaccination; or had received the first, second, and third (booster) dose of vaccine.

Each survey asked the received, reserved, or intended group for their reasons for getting vaccinated against COVID-19. The following sentence was only asked at T1: “It was recommended by SNS or the media.” The following sentences were only asked at T2 and T3: “It was recommended by the media,” “It was recommended by SNS,” and “It was recommended by a health care worker.” Each survey also asked the hesitant group about reasons for not getting vaccinated. The following sentences were only asked at T2 and T3: “Long-term side effects are unknown,” “I’m worried about short term side effects,” “I’m worried about death by the vaccines,” and “I don’t trust the vaccines’ approval process.” Multiple answers were allowed; therefore, the sum of the proportions for each reason did not necessarily add up to 100%.

Sociodemographic and Behavioral Factors and Vaccine-Related Scales

The following variables were derived from the T1 survey: age group, preexisting conditions, employment status, sex, marital status, educational background, occupation, annual household income, and influenza vaccination in the 2019/2020 season. The following variables were derived from the T2 survey: regular medical checkups before the COVID-19 pandemic, the vaccine hesitancy scale, the vaccine conspiracy beliefs scale, and the fear of COVID-19 scale. COVID-19 infection history and vaccine supplier details were derived from the T3 survey.

The vaccine hesitancy scale modified version [34,35] was used, which comprises 9 items, such as “Vaccines are important for my health,” scored on a 5-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree). One item, “I do not need vaccines for diseases that are not that common anymore,” was omitted because COVID-19 was not convergent. The average scores for 2 subscales were calculated: 2 items for aversion to the risk of vaccination and 7 items for lack of confidence in the vaccine [36]. A higher average score, each ranging from 1 to 5, indicates a higher level of lack of confidence or risks. The Cronbach α was .62 for aversion to risk and .93 for lack of confidence.

The vaccine conspiracy beliefs scale was used, which comprises 7 items, such as “Vaccine safety data is often fabricated,” scored on a 7-point Likert scale from 1 (strongly disagree) to 7 (strongly agree) [35]. A higher average score, ranging from 1 to 7, indicates a higher level of conspiracy beliefs against the vaccine. The Cronbach α was .95.

The fear of COVID-19 scale was used, which comprises 7 items, such as “I am very afraid of coronavirus-19,” scored on a 5-point Likert scale from 1 (strongly disagree) to 5 (strongly agree) [37,38]. A higher average score, ranging from 1 to 5, indicates a higher level of fear of COVID-19. The Cronbach α was .84.

The score for the aversion to the risk of vaccination was classified into 2 groups by the median: “low” defined as a score lower than the median and “high” defined as a score equal to or higher than the median. Scores for the lack of confidence in the vaccine, conspiracy beliefs about the vaccine, and fear of COVID-19 were categorized into 3 groups by the tertile scores: “low” defined as a score below the lower tertile, “middle” defined as a score between the lower and higher tertiles, and “high” defined as a score higher than the higher tertile.

The participants were asked if they had been diagnosed with COVID-19 infection. Those who answered “Yes, within the last year” or “Yes, over a year ago” were defined as having a COVID-19 infection history. Participants were also asked if they had been hospitalized due to COVID-19.

Those who had received the vaccination at least once were asked which company supplied the vaccines they received. The possible answers were Pfizer, Takeda or Moderna, AstraZeneca, Johnson & Johnson, others, and “I don’t know.”

Statistical Analysis

To identify factors associated with COVID-19 vaccine uptake at T3, we calculated the risk ratios (RRs) and 95% CIs using a modified Poisson regression analysis with a robust error variance [39]. The objective variable was vaccine uptake; those who had received vaccination, reserved vaccination, or intended to receive vaccination were coded as 1, and the hesitant individuals were coded as 0. In model 1, unadjusted RRs were calculated for the priority setting. In model 2, the following variables assessed at T1 were used for adjustment: prior COVID-19 vaccination intention, age group, employment status, number of preexisting conditions, sex, marital status, educational background, annual household income, and influenza vaccination in the 2019/2020 season. Model 3 was additionally adjusted for the following variables assessed at T2: regular medical checkups before the pandemic, aversion to the risk of vaccination, lack of confidence in the vaccine, conspiracy beliefs about the vaccine, and fear of COVID-19. Model 4 was additionally adjusted for COVID-19 infection history at T3. A sensitivity analysis was conducted, including age group, employment status, and number of preexisting conditions instead of vaccination priority settings.

Before conducting the modified Poisson regression analysis, the multiple regression analysis confirmed that there was no multicollinearity among the explanatory variables. The 2-sided significance level was set at 5%, and SPSS Statistics (version 28; IBM Corp) was used for all the analyses.

Results

Eligible Participants for Analysis

The flowchart of selecting eligible participants for analysis is illustrated in Multimedia Appendix 3. After excluding participants who matched the exclusion criteria or were lost to follow-up at each time point, a total of 13,555 individuals (age: mean 53.1, SD 15.9 years; 6519/13,555, 48.09% female) remained for analysis. They were older and had more male individuals than the excluded 12,445 individuals (age: mean 46, SD 16.9 years; 6231/12,445, 50.1% female). The overall valid follow-up rate was 52.1%. A total of 6538 individuals were eligible for each of the 3 types of vaccination priority: 1659 (25.37%) aged <65 years with underlying medical conditions (age: mean 51.5, SD 10.2 years; 540/1659, 32.55% female), 4048 (61.91%) aged ≥65 years (age: mean 71.3, SD 4.1 years; 1965/4048, 48.54% female), and 831 (12.71%) HCWs (age: mean 44.7, SD 12.6 years; 379/831, 45.6% female). A total of 7017 individuals did not meet any of the requirements for vaccination priority (age: mean 44, SD 12.4 years; 3635/7017, 51.80% female).

Table 1 shows the characteristics of the participants according to the priority settings at T1. At T3, the proportion of the hesitant group was highest in the nonpriority group (13.3%) and lowest in the priority group (4.5%) of older adults. Table S1 in Multimedia Appendix 4 summarizes the breakdown of underlying medical conditions among the priority group of those with preexisting conditions. Hypertension (n=779) and sleep apnea (n=409) were the most common preexisting conditions. The proportion of the received, reserved, or intended group ranged from 86.5% among patients with angina pectoris to 98.7% among patients with immune deficiency. Table S2 in Multimedia Appendix 4 shows the breakdown of jobs among the priority group of HCWs. There were 110 nurses, 63 pharmacists, and 55 physicians. Midwives (n=7) exhibited relatively lower vaccine coverage of 71.4%. Tables S1 to S5 in Multimedia Appendix 5 summarize the COVID-19 vaccine coverage rate stratified by COVID-19 infection history or hospitalization over 1 year. Higher RRs indicated that those who had been infected with COVID-19 in the past were more likely to receive vaccines than those who had not been infected. Across all 4 groups, the RRs ranged from 0.90 to 1.10.

Table 2 demonstrates the kind of COVID-19 vaccines that were inoculated to the respondents by T3. Most people had been vaccinated with Pfizer vaccines.

Table 1. Characteristics of the respondents stratified by the COVID-19 vaccination priority settings at T1 (February 2021; the percentages in parentheses in each category vertically add up to 100).

Characteristics	Total (N=13,555), n (%)	Nonpriority (n=7017), n (%)	Aged 18-64 years with preexisting conditions, non-HCW[a] (n=1659), n (%)	Aged ≥65 years, non-HCW (n=4048), n (%)	HCW (n=831), n (%)

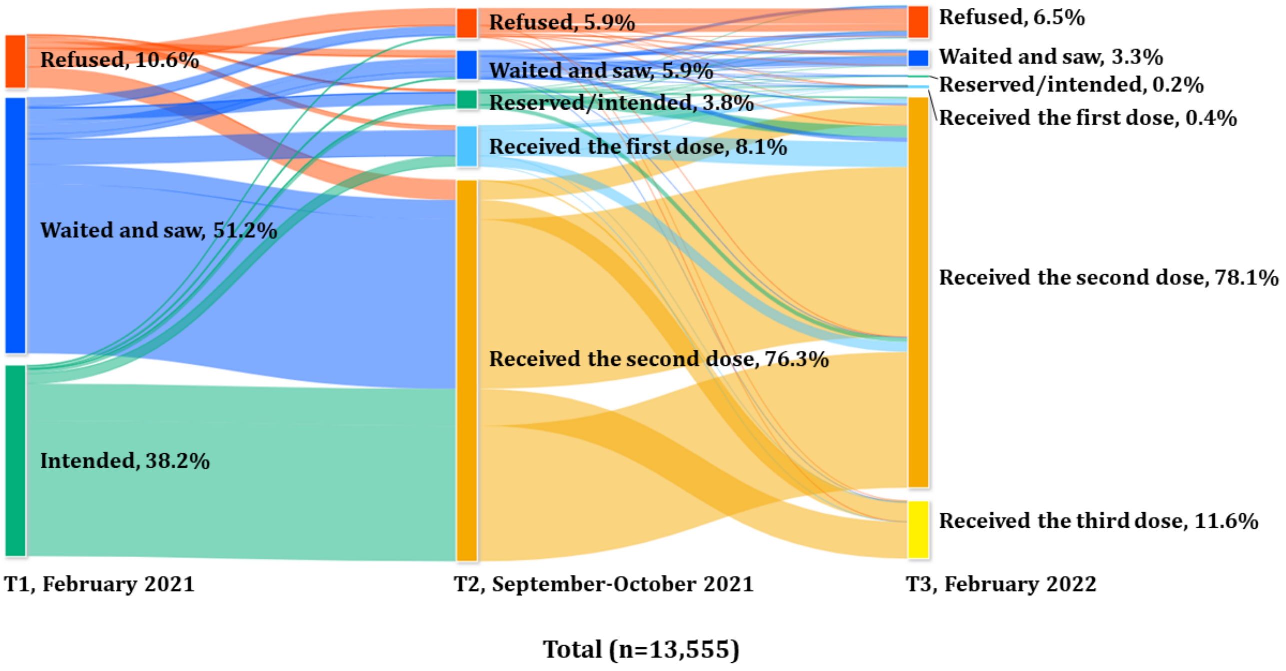
[b] HCW: health care worker.

Shift From Prior COVID-19 Vaccine Intention to Actual Vaccine Uptake 1 Year Later

As illustrated in Figure 1, at T1, a total of 6936 out of 13,555 (51.17%) respondents answered, “I would like to get vaccinated after waiting to see how it goes.” At T2, a total of 10,339 out of 13,555 (76.27%) respondents had received 2 vaccination shots. At T3, a total of 10,589 out of 13,555 (78.12%) respondents completed 2 shots and 1570 (11.58%) respondents completed a third (booster) shot of vaccination. Figures S1 to S4 in Multimedia Appendix 6 showed the results stratified by the nonpriority group and the 3 priority groups. Prior intention to get vaccinated was lowest among the nonpriority group and highest in the older adult group. At T3, the percentage of those who had received the second dose/third dose of vaccine was 82.7%/3.2% in the nonpriority group, 86.2%/4.3% in the group with preexisting conditions, 71.8%/23.6% in the group aged ≥65 years, and 54%/38.5% in the HCW group.

Figure 1. Shift from prior COVID-19 vaccine intention in February 2021 to actual vaccine uptake in February 2022, including the nonpriority group and the 3 priority groups. ChartExpo™ was used to illustrate the Sunkey diagram.



Shift in the Reasons for Receiving or Not Receiving COVID-19 Vaccination

Figure 2 summarizes the shift in the reasons for getting vaccinated among those who received vaccination, who reserved vaccination, or who were intended for vaccination. The top reasons for getting vaccinated were worry about infecting themselves, their family, or others around them, followed by social norms. The percentage of those who expressed that they were worried about contracting COVID-19 gradually declined (63.6%, 51.4%, and 46.6%, respectively). Figures S1 to S4 in Multimedia Appendix 7 show the results for each priority group and the nonpriority group. There were intergroup characteristics in the reasons for getting vaccinated: the preexisting conditions and older adult groups were more likely to get vaccinated because they thought they had a high risk of contracting severe COVID-19 infection. The HCW group had the lowest number of reasons for getting vaccinated.

The reasons for not getting vaccinated among the hesitant group are shown in Figure 3. The most common reason for not getting vaccinated among the unvaccinated people was concerns about side effects at all 3 time points. The percentages were highest when the vaccination program had not yet begun at T1, declined at T2, and remained at the same level at T3 (81.7%, 51.9%, and 53.7%, respectively). Concerns about long-term side effects were raised more frequently than those about short-term side effects. The percentage who argued that the COVID-19 vaccine was ineffective gradually increased over the course of the year (9.2%, 21%, and 29.9%, respectively). Figures S1 to S4 in Multimedia Appendix 8 show the results for the nonpriority group and each priority group. At T3, the percentage of respondents who answered "I'm worried about side effects of the vaccines" was highest in the priority group with underlying medical conditions. The proportion of those who said "I don't trust the vaccines' approval process" was highest in the priority group of adults aged ≥65 years.

Figure 2. Shift in reason for getting vaccinated against COVID-19 from February 2021 to February 2022, including the nonpriority group and the 3 priority groups. Respondents were those who had intended or reserved to receive the vaccines or those who had received the vaccines at least once at each time point. The following sentences was asked only at T1: "It was recommended by SNS or the media." The following sentences were only asked at T2 and T3: "It was recommended by the media," "It was recommended by SNS," and "It was recommended by a health care worker.".

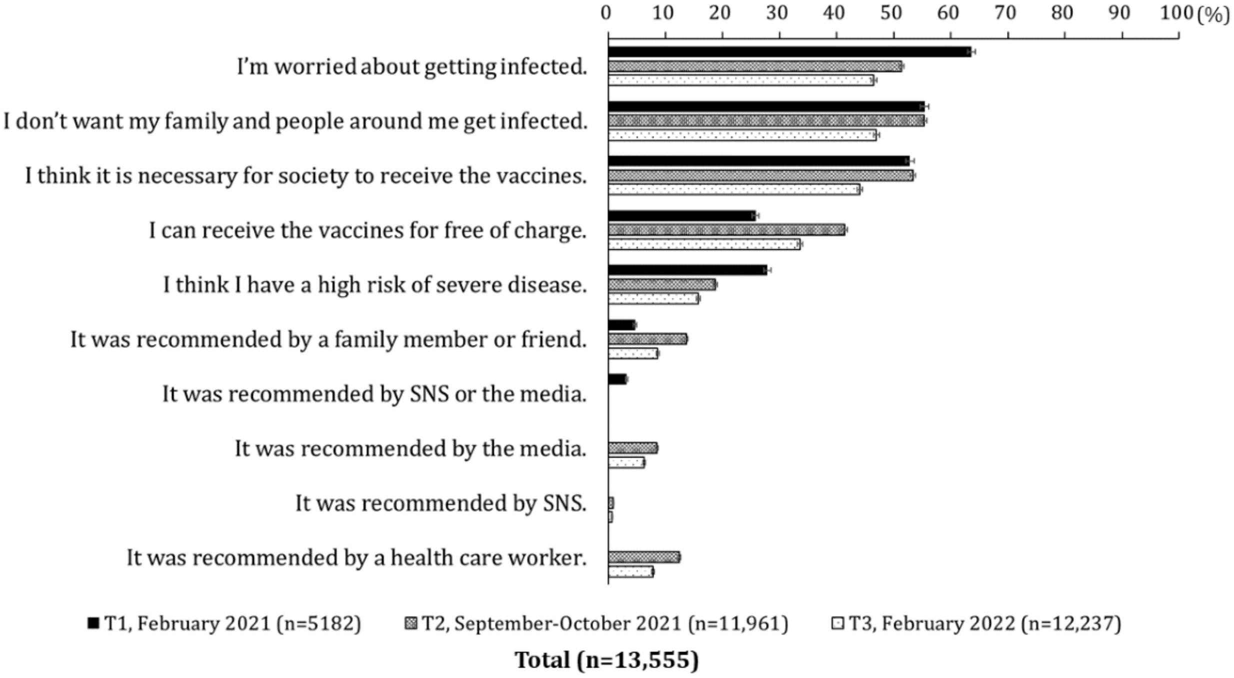


Figure 3. Shift in reason for not getting vaccinated against COVID-19 from February 2021 to February 2022, including the nonpriority group and the 3 priority groups. Respondents were those who chose to wait and see or refused to receive the vaccines at each time point.The following sentences was asked only at T2 and T3: “Long-term side effects are unknown,” “I’m worry about short term side effects,” “I’m worried about death by the vaccines,” and “I don’t trust the vaccines’ approval process.”.

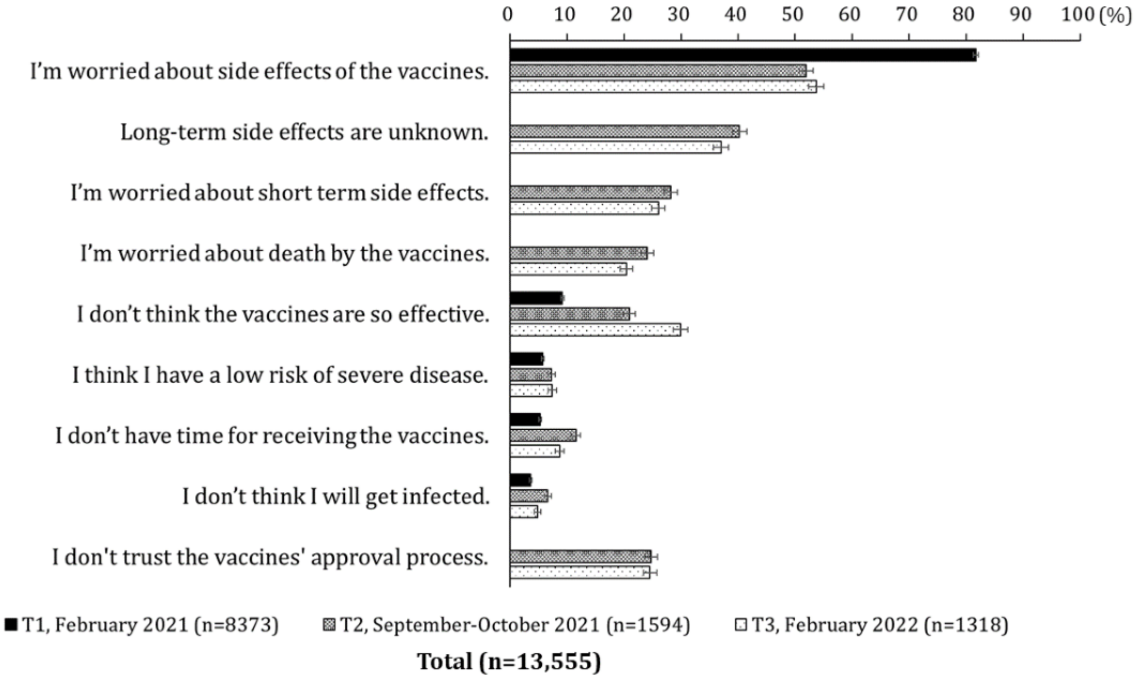

Priority Settings at the Start of Mass Vaccination and Subsequent COVID-19 Vaccine Uptake 1 Year Later

Table 3 summarizes the results of the Poisson regression analyses. In model 4, significantly higher RRs for getting vaccinated were observed in the priority group of adults aged ≥65 years (RR 1.02, 95% CI 1.005-1.03) and HCWs (RR 1.05, 95% CI 1.03-1.07).

A sensitivity analysis was performed by replacing the priority group with age group, employment status, and number of preexisting conditions. The results are shown in Multimedia Appendix 9. In model 4, prior willingness for COVID-19 vaccination, a lower level of aversion to the risk of vaccination, a higher level of confidence in the vaccine, and a lower level of conspiracy beliefs about the vaccine exhibited higher RRs, which indicated a higher likelihood of getting immunization. Those who had the following characteristics were more likely to receive COVID-19 vaccination: being older, female, higher educational level, higher household income, having received influenza vaccination in the 2019/2020 season, and regular medical checkups before the pandemic. In contrast, statistically significant lower RRs were observed in those who were unemployed or not working and those who had a lower level of fear of COVID-19.

Table 3. Risk ratios (RRs) for COVID-19 vaccination uptake status at T3 (February 2022) by priority settings at T1 (February 2021).[a]

	Nonpriority, RR (95% CI)	18-64 years with preexisting conditions, non-HCW[b], RR (95% CI)	≥65 years, non-HCW, RR (95% CI)	HCW, RR (95% CI)
Model 1	Reference	1.05 (1.03-1.07)	1.10 (1.09-1.11)	1.08 (1.05-1.10)
Model 2	Reference	1.03 (1.01-1.04)	1.05 (1.04-1.07)	1.04 (1.02-1.06)
Model 3	Reference	1.02 (0.999-1.03)	1.02 (1.004-1.03)	1.05 (1.03-1.07)
Model 4	Reference	1.01 (0.999-1.03)	1.02 (1.005-1.03)	1.05 (1.03-1.07)

[a] Modified Poisson regression analysis with a robust error variance was performed. A higher RR indicated a higher likelihood of receiving, reserving, or intending to vaccinate at T3. Model 1 was unadjusted. Model 2 was adjusted for prior vaccination intention, sex, marital status, educational background, annual household income, and influenza vaccination during the 2019/2020 season. In addition to model 2, model 3 was adjusted for regular medical checkups before the pandemic, aversion to the risk of vaccination, lack of confidence in the vaccine, conspiracy beliefs about the vaccine, and fear of COVID-19. In addition to model 3, model 4 was adjusted for COVID-19 infection history.

[b] HCW: health care worker.

Discussion

Principal Findings

Prompt distribution of COVID-19 vaccines to the public was one of the global goals to be accomplished in 2021. In this study conducted in Japan, we reported on the shift from COVID-19 vaccine intention to actual uptake and the reasons for getting or refusing vaccination in a 1-year period. In February 2021, a total of 5182 out of 13,555 (38.23%) participants expressed that they intended to take the vaccine, 6936 (51.17%) chose to wait and see, and 1437 (10.6%) refused to get vaccinated. One year later, >90% (12,216/13,555) of the participants had received at least 1 dose of the vaccine. There were considerable differences in uptake across the nonpriority group and the 3 typical vaccine priority groups. We confirmed that COVID-19 vaccination uptake rates were higher among priority groups than the nonpriority group in line with recent reports [17]. This trend continued for 1 year after the start of mass vaccination. Overall, protection against infection for themselves, their families, and the people around them was cited as the main reason for seeking vaccination. In contrast, concern about side effects was cited as the main reason for avoiding vaccination. We also elucidated the factors that predicted, or were associated with, vaccine uptake. As hypothesized, prioritized groups at the initial stage of the COVID-19 mass vaccination program exhibited a higher vaccine uptake rate after adjusting for sociodemographic background, health-seeking behavior, and attitude toward the vaccine. To our knowledge, this is the first longitudinal study to illustrate these results simultaneously by priority groups and nonpriority groups with the advantage of a large cohort sample.

The vaccination coverage rate in our sample was higher than that reported in the official Japanese vaccination statistics, which stated that approximately 75% of the total population had received at least 1 dose by the end of February 2022 [40]. Therefore, caution should be exercised when interpreting and generalizing these results. Although stratified sampling was used to get as close to a nationally representative population as possible, the participants were registered monitors of an internet research company, and sampling bias was inevitable. For example, it is difficult to reach those who have no access to the internet, such as the institutionalized, poor, or homeless. In addition, the follow-up rate was slightly higher than 50%. It is also possible that the participants at the baseline died of COVID-19 and dropped out. Our current sample may comprise more older and health-oriented people than the actual population. These factors could lead to the overestimation of vaccination coverage. Nevertheless, a web-based survey targeting registered monitors was a feasible and frequently used research method during the COVID-19 pandemic. It should also be noted that this study focused on priority settings at the start of vaccination in the spring of 2021. Governments around the world made changes to their priority conditions as the vaccines became more widely distributed; for instance, lowering the age threshold for the older adult group [11]. The Japanese government did not set a priority for the third (booster) vaccination, which started in December 2021.

Overall, almost all of those who intended or chose to wait and see to receive the vaccine before the vaccine rollout actually received the vaccine after it became available. A large intention-to-action gap was observed in the past in relation to vaccination against H1N1 influenza [41,42]; however, the gap appears to be much smaller for COVID-19 vaccines [27,29,31]. Approximately half of those who had initially refused the vaccine continued to refuse, whereas the other half changed their intentions and accepted vaccination. The persistent refusers across the 3 time points were found more in the nonpriority group and the priority group with preexisting conditions. It should be noted that, among the hesitant individuals in these 2 groups, the percentage of those who refused vaccination increased between T2 and T3. Whether they remain unvaccinated or change their mind afterward remains to be observed. The highest vaccination coverage rates were found among the priority groups of older adults and HCWs. More than 90% of participants in these groups completed 2-dose vaccination within half a year. This tendency was also confirmed by the multivariable analysis. The older adult group was considered one of the most susceptible groups to severe COVID-19 infection, and participants in this group were the most eager to get vaccinated, even before the vaccination program began. This finding is in line with previous studies that have reported that older age groups were more willing to get vaccinated [18-26].

Concerns about side effects in general remained the most common reason for vaccine hesitancy or resistance within the year. This result is in line with previous studies in Japan [21,22,25] and in other countries [43-46]. We demonstrated that this trend continued from before the start of mass vaccination to 1 year later. We further illustrated that the number of participants who thought the COVID-19 vaccine was ineffective increased gradually in the vaccine hesitant group. This may be because the COVID-19 pandemic has not yet settled despite increased vaccination rates. This may also be due to outbreaks of the omicron variants, which were reported to be highly infectious and resistant to currently available vaccines [47,48]. There were some intergroup differences among the groups. In the older adults and preexisting conditions groups, more respondents cited fear of severe COVID-19 and awareness of the need for vaccination as their reason for getting vaccinated. Despite having the second highest coverage rate, the HCW group cited the fewest reasons for vaccination. This group might have benefited from the availability of vaccines at their workplace, although the current survey did not provide information on where they were vaccinated. Future studies should consider the convenience of time and location for vaccination, which can affect vaccine hesitancy [49,50].

There were slight differences in subsequent vaccine uptake between those who had a history of COVID-19 infection and those who had no history at T1. The same was true for a history of COVID-19 infection at T3. It should be noted that during the surveyed period, from February 2021 to February 2022, it is unclear from the current data which came first, the infection or vaccination. There would have been both prevaccination and breakthrough infections during the surveyed period. The current results do not support the existing literature in other countries

[31,51], which suggested that those who had previously been infected were less anxious about reinfection and had less interest in vaccination. However, vaccination after recovery from COVID-19 is reported to still be effective in preventing reinfection [52]. This inconsistency could be due to the small number of infected individuals in the current data set. Indeed, despite being a superaging society, Japan's COVID-19 mortality rate is among the lowest in the world [53,54]. In our sample, the highest percentage of COVID-19 infection history was found in the HCW group, who were considered to have the most frequent contact with patients with COVID-19 and also the most frequent infection testing. This finding underlines the need to prioritize vaccination for HCWs [55]. In contrast, the older adults group had the lowest percentage of COVID-19 infection history. Together with high vaccination coverage, it is fair to say that the vaccination campaign targeting the older adult population was successful. The nonpriority group had the largest number of infected cases, although the percentage was smaller than that of the HCW and preexisting conditions groups.

Those who were younger, were unemployed, were unmarried, had lower educational attainment, had lower income, had a presence of underlying medical conditions, had not had an influenza vaccination, and had not attended regular health checkups before the start of mass vaccination exhibited a lower vaccine uptake rate 1 year later. The current results corroborate a number of cross-sectional studies in Japan that have reported an association between these factors with vaccine hesitancy [18-26]. Our findings were consistent with a number of studies in other countries that have elucidated factors related to vaccine intention and uptake [56-58]. We have demonstrated the importance of conducting vaccine promotion campaigns for these populations. Prior favorable vaccine intention and more positive attitudes about the safety and effectiveness of the vaccine significantly improved the likelihood of COVID-19 vaccine uptake. Those who believed that there was a conspiracy behind vaccines had a lower incidence of immunization. The low level of fear of COVID-19 was also associated with being vaccine hesitant. These results were congruent with previous studies [27,29,31,56,57,59]. In particular, prior intention for vaccination and confidence in vaccines were the strongest predictors of subsequent vaccine uptake. These findings support the idea that bridging the vaccination intention-to-action gap could be accomplished by overcoming concerns regarding vaccine safety [1,60].

Clinical Implications

This study has important clinical implications. The public authorities need to start by acknowledging the disparities in vaccine uptake in the nonpriority group, including younger healthy adults. In Japan, the largest percentage of confirmed cases of COVID-19 was among individuals aged under 30 years [61], highlighting their significance as key players in COVID-19 transmission. Matrajt et al [62] claimed that switching the vaccine allocation target to the high-transmission groups from the high-risk groups would achieve high vaccine effectiveness, as is the case with influenza vaccines [63,64]. In other words, it is possible to reduce the number of patients with COVID-19 in the older adults group by controlling the number of patients in the young adults group. Therefore, it is essential to keep examining whether the vaccine priority settings were appropriate for maximizing vaccine effectiveness. In promoting vaccine uptake, the content of the message should be tailored to each population group, taking into account their attitudes toward vaccines. When targeting young and healthy groups, those responsible for delivering the message should recognize the concerns of these groups about vaccine safety and effectiveness. Changing the perception of vaccine risk would be a key strategy in promoting vaccination. Needless to say, the development of new vaccines that have fewer side effects and are more effective against new types of mutation is expected. Our results also suggest that it is important to begin the promotion of vaccine acceptance before the introduction of new vaccines. Even after COVID-19 has converged, other emerging infectious diseases could lead to pandemics in the future. One possible way to reduce vaccine hesitancy in introducing new vaccines is to increase the number of people who receive influenza vaccination or undergo medical checkups regularly. These behaviors would reduce the barriers to vaccination if a new virus emerged for which vaccines are required [65].

Limitations

Despite the abovementioned strengths of this study, there are some limitations that should be noted. First, vaccine-related scales such as the vaccine hesitancy scale were only assessed at T2. At that time, some respondents had already received vaccination, while others had not. Therefore, we were unable to draw conclusions regarding the direction of causality between these variables. Second, due to the nature of self-administered surveys, recall bias and reporting bias may have occurred. Third, the classification of the priority groups was not completely accurate. For example, although the severity of each disease was set as a condition for priority, information on this was not obtained. As a proxy, a hospital visit for the disease was used to define the group. In addition, individuals who reached the age of 65 years in March 2021 were misclassified into the nonpriority group; however, the number of relevant participants was estimated to be small enough to affect the result. Participants working in a nursing home, one of the vaccination priority groups, could not be identified. Finally, we could not distinguish within-group differences in vaccine priority, such as frontline workers or office workers in a hospital.

Conclusions

Our findings demonstrate that the priority settings at the start of the COVID-19 vaccination program had a significant impact on vaccine coverage 1 year later. Japan achieved a high rate of vaccine uptake, resulting in a low COVID-19 mortality rate at the start of 2022. However, things took a drastic turn in 2022 with the outbreak of the omicron variant, which was a complete change from the year 2021. At its peak in August 2022, there were >250,000 cases and >300 deaths per day. Japan experienced another surge in infections in January 2023. After its peak had passed, the government downgraded COVID-19 to category 5 of infectious disease, the same rank as seasonal influenza, in May 2023. Although the threat of COVID-19 appears to have subsided for the moment, there remains the possibility that new emerging infectious diseases will arise and cause unprecedented situations. Further research is necessary to determine the effectiveness of vaccine distribution procedures in preventing COVID-19 from 2022 to 2023. Such efforts are essential for reducing the impact of the next pandemic on individuals and society.

Abstract

Background: COVID-19 vaccine hesitancy reduces vaccination rates, which is detrimental to building herd immunity and halting the spread of COVID-19 and its variations. Most researches have simply identified the reasons affecting COVID-19 vaccination reluctance without delving into its dynamics, which makes forecasting future trends difficult.

Objective: This study aimed to examine the current COVID-19 vaccine booster hesitancy rate in Chinese adults as well as the dynamics of vaccine hesitancy and its influencing factors. The results of this study will have practical implications for policy responses in mainland China, and effective COVID-19 booster vaccination in specific populations.

Methods: The web-based survey was completed by creating questionnaires and using a stratified random sampling method to collect information from adults (≥18 years old) among 2556 households in 4 geographical regions of China. We collected sociodemographic information, health status, awareness of COVID-19 and its vaccine, self-perceptions, trust in medical staff and vaccine developers, and so on. The odds ratios and 95% CI for the statistical associations were estimated using logistic regression models.

Results: Overall, 6659 participants (females: n=3540, 53.2%; males: n=3119, 46.8%) responded. In total, 533 (8%; 95% CI 7.4%-8.7%) participants presented a clear hesitancy in receiving the COVID-19 booster vaccination, while 736 (11.1%; 95% CI 10.3%-11.8%) expressed hesitancy in regular booster vaccination. A higher prevalence of vaccine hesitancy in both booster vaccination and regular booster vaccination was observed among participants with a history of allergies, experiencing chronic disease, lower levels of public health prevention measures or susceptibility or benefits or self-efficiency, higher levels of severity or barriers, and lower trust in both medical staff and vaccine developers ($P<.05$). The females and participants with higher education levels, higher levels of barriers, lower levels of susceptibility, and lower trust in vaccine developers preferred to have attitudinal changes from acceptance to hesitancy, while people with higher education levels, lower self-report health conditions, experiencing chronic disease, history of allergies, and lower trust in medical staff and developers were all positively associated with constant COVID-19 booster hesitancy.

Conclusions: The prevalence of COVID-19 vaccine booster hesitancy is not high in mainland China. However, there is a slight increment in hesitancy on regular booster vaccination. Conducting targeted information guidance for people with higher education levels and chronic diseases, as well as improving accessibility to booster vaccination and increasing trust in medical staff and vaccine producers may be highly effective in reducing vaccine hesitancy.

KEYWORDS

COVID-19 vaccine; vaccine hesitancy; COVID-19 booster vaccination; influencing factors; China

Introduction

Vaccinating a sufficient proportion of the population against COVID-19 is one of the most effective methods for achieving "herd immunity," lowering morbidity, and increasing population survival. It is also the most cost-effective and straightforward intervention to prevent the COVID-19 pandemic [1,2]. Prevention of the COVID-19 virus and its variants through COVID-19 vaccination can confer benefits related to morbidity and mortality [3], mainly including the protection of immunocompromised populations such as infants, young children, and the elderly [4,5]. According to the latest reports from the World Health Organization (WHO), two-thirds of the world's population is vaccinated, including 75% of health workers and older people. However, there are still wide disparities in vaccination rates [6]. The COVID-19 booster vaccination is an important tool for consolidating herd immunity and responding to the COVID-19 pandemic and deaths [7], and receiving the COVID-19 booster vaccine is essential to achieve adequate immunization coverage to control the global pandemic [8,9]. Understanding people's attitudes to COVID-19 booster vaccination aids in developing COVID-19 booster vaccination plans, which ensure the consolidation of herd immunity and minimize health inequalities.

Since the global outbreak of the COVID-19 epidemic, several vaccines have been developed, such as inactivated vaccines, live-attenuated vaccines adenovirus vector vaccines, and recombinant protein vaccines [10,11]. Although these multiple vaccines are considered safe and effective [3,4], and countries around the world are increasing the supply of vaccines, waiving vaccination fees [12], and actively promoting the COVID-19 booster vaccination, there are still concerns about vaccine hesitancy, which affects the vaccination rates of COVID-19 vaccines as well as booster vaccination. This situation may not be helpful to bolster herd immunity in order to prevent the further spread of COVID-19 and its variations. According to the WHO, "Vaccine hesitancy" has been considered as one of the top 10 public health problems across the world [13-15]. It refers to the delay or refusal to receive safe vaccination services, which can accompany the use of vaccines [3,15-17]. The danger of vaccine hesitancy is that it can lead to immunization of populations below the herd immunity threshold and ultimately fail to protect the populations. This is particularly true for people whose immunity is very weak to be vaccinated, such as infants, the elderly, or patients with serious illnesses, who are the first to be exposed to infectious diseases if the herd immunity barrier is breached [4,18]. The COVID-19 vaccine booster hesitancy is a type of vaccine hesitancy and is a continuation of people's hesitancy about the COVID-19 vaccine. Therefore, what factors influence people's hesitancy to receive the COVID-19 booster vaccine? An in-depth study of this issue would be of great relevance in guiding the next phase of the COVID-19 booster vaccination program.

The reasons for vaccine hesitancy are thought to be complex and case specific. The existing literature cites concern about COVID-19 vaccine safety and efficacy, vaccination accessibility, the severity of the regional epidemic, experience with routine vaccination, and guardians' willingness to vaccinate their children as the primary reasons for hesitancy. For example, in a study of Canadians, individuals with vaccine hesitancy had a higher prevalence of being concerned about vaccine side effects [19]. The antecedents of vaccine hesitancy range from a lack of knowledge and awareness to culturally rooted reservations [20]. The most commonly reported reasons parents chose not to vaccinate their child against COVID-19 were concerns about long-term adverse side effects and a negative reaction [21]. At the same time, concern about side effects is also the most common reason for COVID-19 vaccine hesitancy in low- and middle-income countries [3]. In addition, misinformation and disinformation can substantially result in vaccine hesitancy [22] and might influence the vaccine advice of health care providers [23]. These factors will probably influence people's hesitancy about the COVID-19 booster vaccination.

Understanding local barriers to vaccination and concerns about vaccination is critical to developing tailored interventions [24]. The current basic vaccination rate of COVID-19 vaccine in China exceeds 89% [12], which is probably one of the leading countries in the world not only because of its large population but also its extensive exchanges and closer cooperation with other regions [25,26]. However, the coverage of booster vaccination in China is not widespread, which is still a significant gap compared with the basic vaccination rate. Furthermore, compared to other countries around the world, the epidemic prevention and control policies in mainland China are adequate, and vaccines are supplied for free and in sufficient quantities [27], but the problem of vaccine hesitancy remains unresolved. Focusing on the problem of vaccine hesitancy in COVID-19 booster vaccination in mainland China will be highly representative. The existing research on booster vaccination hesitancy is limited, and hence, we designed a multicenter study focusing on COVID-19 vaccine booster vaccination and regular booster vaccination in mainland China. This study aimed to understand the current COVID-19 vaccine hesitancy in booster vaccination of the Chinese population and analyze the dynamic trend of vaccine hesitancy as well as its influencing factors.

Methods

Procedures and Participants

From June 29, 2022, to July 2, 2022, we used a self-designed questionnaire to perform a preliminary survey by recruiting web-based volunteers. We conducted The Dynamic Evolution of COVID-19 Vaccination Study, a national, multicenter, observational household tracking survey from China using a stratified random sampling method. Eastern, Central, Western, and Northeast geographical regions within mainland China were selected to form the sample for this study. Therefore, 4 cities were selected from the Eastern (Changzhou and Jiangsu), Central (Zhengzhou, Henan), Western (Xi’ning and Qinghai), and Northeast (Mudanjiang and Heilongjiang) regions.

We calculated the minimum sample size of each region according to the population proportion of China’s Seventh National Population Census. In each province, the sample size of urban and rural areas was determined according to the proportion of population in the Seventh National Population Census, more than 2 cities and 2 rural areas were randomly selected for sampling. For all of the cities and families in the sample, coding was carried out followed by random sampling. Finally, all members of the selected family have been involved in this survey (age≥18 years) and completed the web-based or offline questionnaire with the assistance of the investigators. A total of 2556 households from 4 geographic regions of China were enrolled in the survey.

The study was designed as a 4-stage survey. For the first stage, we conducted the survey from August 3, 2022, to August 14, 2022. Data collection is still ongoing for the second, third, and fourth stages. Here, we describe the results from the first stage of the study only.

Ethics Approval

Participants were informed of the benefits and risks of participating in this study, and they provided informed consent. All data were used merely for research purposes. This study was approved by the Life Science Ethics Review Committee of Zhengzhou University (2021-01-12-05).

Questionnaire Design and Data Collection

Web-based questionnaires were designed to collect data through a survey conducted through the Wenjuanxing platform. We also conducted a face-to-face interview with participants who cannot use a smartphone. The questionnaire covered five thematic areas: (1) sociodemographic characteristics: age, gender, nation, religion, marital status, educational status, subjective social status in China or community, smoking status, drinking status, and physical activity; (2) health conditions: chronic disease, the history of allergies, self-report health condition (measured by EuroQol 5 Dimensions Questionnaire [28-30]); (3) perception of COVID-19 and its vaccine: public health prevention measures, awareness of COVID-19 vaccines, the channel of accessing information, the way of accessing information, the risk of COVID-19 infection, the history of COVID-19 infection, the convenience of vaccination, and the uptake of COVID-19 vaccine; (4) self-perception (Kaiser-Meyer-Olkin=0.796): perceived severity (Cronbach α=.879), perceived susceptibility (Cronbach α=.865), perceived benefits (Cronbach α=.907), perceived barriers (Cronbach α=.927), and self-efficiency (Cronbach α=.913; Kaiser-Meyer-Olkin=0.886); and (5) trust in medical staff and developers. All questionnaires are shown in Multimedia Appendix 1.

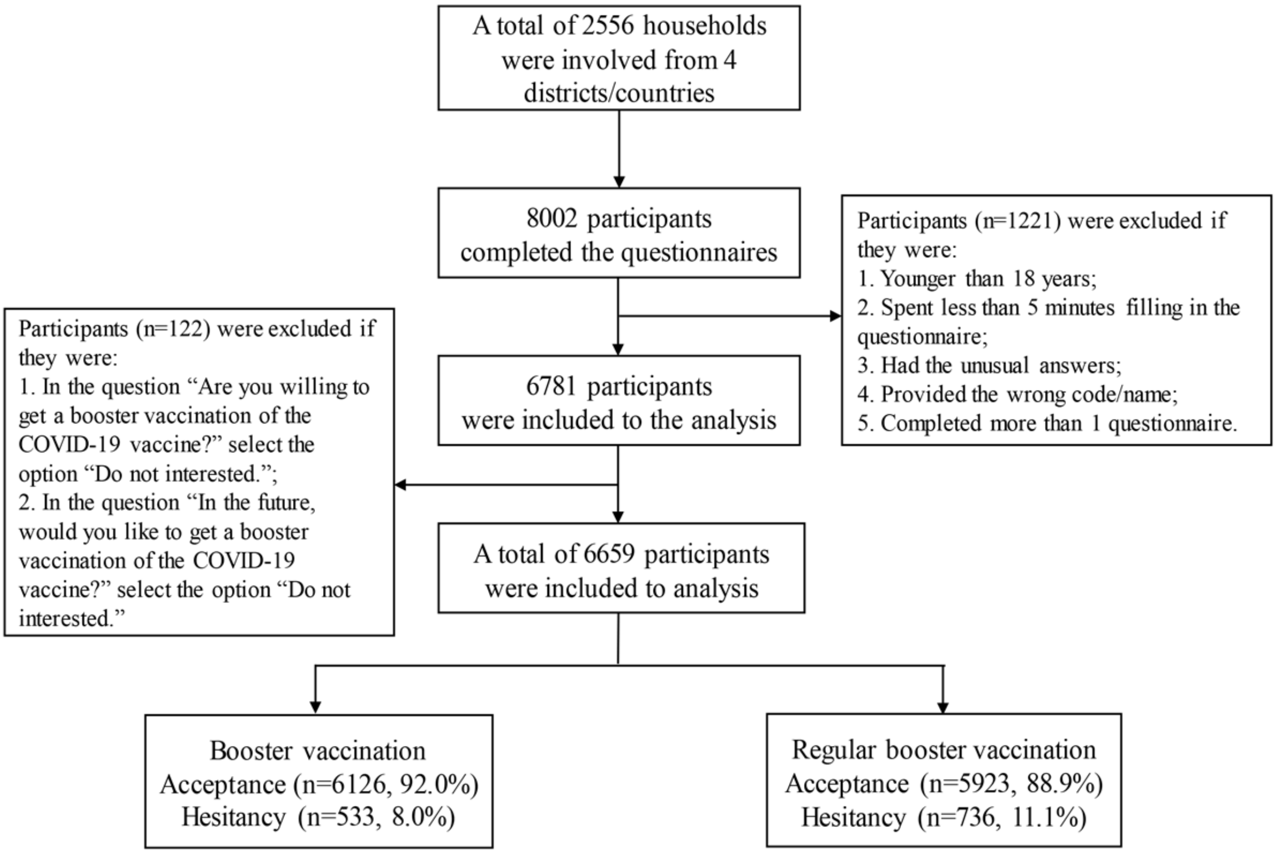
Assessments

Questionnaires with abnormal answers (contradictions and inconsistencies, eg, inconsistency or contradictions of sex) were excluded. In addition, we also excluded the participants who spent less than 5 minutes completing this questionnaire. Moreover, the remaining questionnaires were carefully reviewed by trained staff, and finally, 6659 questionnaires were deemed eligible for inclusion. The flowchart of participants is shown in Figure 1.

The primary outcome was COVID-19 vaccine hesitancy in both booster and regular booster vaccination, assessed by asking participants “Are you willing to get a booster vaccination of the COVID-19 vaccine?” and “In the future, would you like to get a booster vaccination of the COVID-19 vaccine?” Participants could choose 1 response from the options “(1) willing,” “(2) hesitant or delayed,” “(3) refused,” and “(4) do not interested” from the 2 questions. According to the definition of vaccine hesitancy, option 1 was regarded as “acceptance,” and options 2 and 3 were merged into “hesitancy.” In addition to this, participants were excluded if they selected the option “do not interested” (n=122).

A booster vaccination is a shot that is given after a period of time (which may be 6 months or more) after a population has completed a standard immunization program, and due to the gradual decay of antibodies in the body, the specific immunity in the body needs to be boosted with another booster vaccination. Regular booster vaccinations are administered after a period of booster vaccination to strengthen the immune system.

Figure 1. Flowchart of data processing and analysis.



Statistical Analysis

Chi-square tests were used to test differences in vaccine hesitancy between groups. Binary logistic regression analyses were carried out to examine factors associated with COVID-19 vaccine hesitancy in both booster and regular booster vaccination. A sensitivity analysis was performed by excluding the participants aged ≥80 years to test the robustness of results and assess the source of uncertainty. In stratified multistage sampling, post hoc stratification was used to weight the sample and the corresponding variables so that the sample's estimate of the total was unbiased. Odds ratios, 95% CI, and *P* values were calculated for each independent variable. All statistical analyses were carried out using SPSS (version 21.0; IBM Corp) and STATA (version 16.0; StataCorp). Differences were regarded as statistically significant if *P* values were less than .05.

Results

Characteristics of COVID-19 Vaccine Hesitancy in Booster Vaccination

Among the 8002 participants who completed the questionnaire, a total of 1343 participants who did not meet the inclusion criteria were subsequently excluded. Importantly, no statistically significant differences were found between the final 6659 participants included in the analysis and the overall sample of 8002 (*P*>.05) (Multimedia Appendix 2). The sociodemographic characteristics, awareness of COVID-19 vaccine, trust in the health care system as well as COVID-19 vaccine hesitancy in booster vaccination and regular booster vaccination of all study participants are displayed in Table 1. Overall, 533 adults (8%; 95% CI 7.4%-8.7%) showed a clear COVID-19 vaccine hesitancy in booster vaccination, while 6126 adults (92%; 95% CI 90.3%-94.2%) indicated that they were willing to vaccinate. Meanwhile, 736 participants (11.1%; 95% CI 10.3%-11.8%) expressed their hesitancy about regular booster vaccination of COVID-19 vaccine. Furthermore, we can see clearly that the participants of all ages are evenly distributed, the proportion of female participants (53.2%) is more than male (46.8%), and most of the participants (87.5%) were married.

A higher prevalence of vaccine hesitancy in both booster vaccination and regular booster vaccination was observed among participants with a history of allergies, experiencing chronic disease, lower levels of public health prevention measures or susceptibility or benefits or self-efficiency, higher levels of severity or barriers, and lower trust in both medical staff and vaccine developers (all *P*<.05; Figure 2).

Table 1. The characteristics and COVID-19 vaccine booster hesitancy of all study participants in China (n=6659).

Covariates	Total, n (%)	*P* value[a]	Vaccine hesitancy in booster vaccination (95% CI)[b]	*P* value	Vaccine hesitancy in regular booster vaccination (95% CI)	*P* value

[b] Row percentages derived from the total number in the corresponding row.

[c] Levels 1-4 indicate progressively higher degrees. The higher the degree, the higher level of social status in China or community, the better the self-assessment of health status, the more awareness of COVID-19 vaccine, the more severe or more barriers, the greater the susceptibility or benefits, the higher the self-efficacy and the more trust in medical staff and developers.

[d] EQ-5D: EuroQol 5 dimensions.

Factors Associated With COVID-19 Vaccine Hesitancy in Booster Vaccination

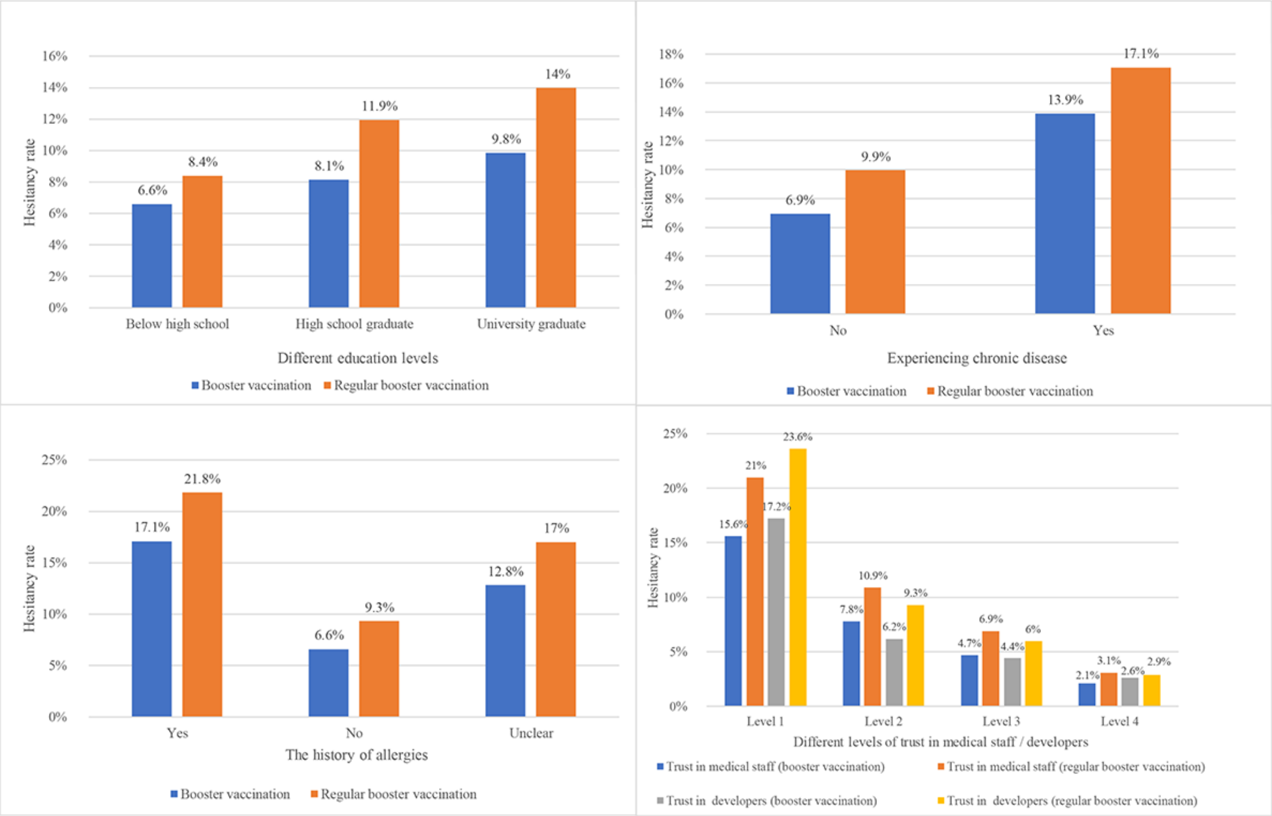
In the binary logistic regression model, subjective social status in China or community, chronic disease, history of allergies, drinking status, physical activity, public health prevention measures, awareness of COVID-19 vaccines, severity, susceptibility, benefits, barriers, self-efficiency, and trust in medical staff or developers were found to be all independently associated with COVID-19 vaccine hesitancy in both booster vaccination and regular booster vaccination (all *P*<.05).

After adjusting for potential confounders, we found that unmarried, experiencing chronic disease, history of allergies, low level of physical activity, lower level of public health prevention measures or susceptibility or benefits or self-efficiency, higher level of severity or barriers, and lower trust in medical staff or developers were all positively associated with COVID-19 vaccine hesitancy in booster vaccination (all

P<.05). Meanwhile, we observed that participants who were female, with higher educational level, higher level of subjective social status in community, experiencing chronic disease, history of allergies, lower level of public health prevention measures or susceptibility or benefits or self-efficiency, higher level of severity or barriers, lower trust in both medical staff and developers were all positively associated with COVID-19 vaccine hesitancy in regular booster vaccination after adjusting for potential confounders (all *P*<.05). Detailed results are all shown in Figure 2 and Multimedia Appendix 3.

In particular, participants with higher levels of education and lower levels of trust in medical staff or developers showed stronger COVID-19 vaccine hesitancy and higher rates of hesitancy at the following regular booster vaccination. The same trend could be observed in participants with a history of vaccination allergy and those with chronic disease (Figure 3).

Figure 3. COVID-19 vaccine hesitancy rates for different influencing factors in both booster and regular booster vaccination.



Dynamic Fluctuations of COVID-19 Vaccine Hesitancy in Booster Vaccination

The COVID-19 vaccine hesitancy rate among Chinese residents shows a trend of raising, which was from 8% (533/6659) to 11.1% (736/6659) between the booster vaccination and regular booster vaccination. In addition, some participants' attitudes toward COVID-19 vaccine booster vaccination were shown to change. There were 5870 and 480 participants who remained vaccinated and hesitant about routine booster vaccination respectively, while there were still 256 participants who would switch from acceptance to hesitancy.

Multimedia Appendix 4 lists 4 attitudinal changes toward COVID-19 booster vaccination, such as acceptance to acceptance, acceptance to hesitancy (ATH), hesitancy to acceptance, and hesitancy to hesitancy (HTH). The results demonstrated that participants who were female, with higher educational level, higher level of barriers, lower level of susceptibility or self-efficiency, and lower trust in developers were positively associated with ATH (all *P*<.05). Participants with higher levels of physical activity and self-efficiency as well as not experiencing chronic disease expressed their willingness from hesitancy to acceptance (all *P*<.001). Furthermore, participants who had higher educational level, lower self-report health condition, having from chronic disease, history of allergies, lower level of public health prevention measures or susceptibility or benefits or self-efficiency, higher level of barriers, lower trust in both medical staff and developers were all positively associated with HTH after adjusting for potential confounders (all *P*<.05). Detailed results are all presented in Figures 4 and 5.

Figure 4. Relevant influences on acceptance to acceptance and acceptance to hesitancy for all participants.

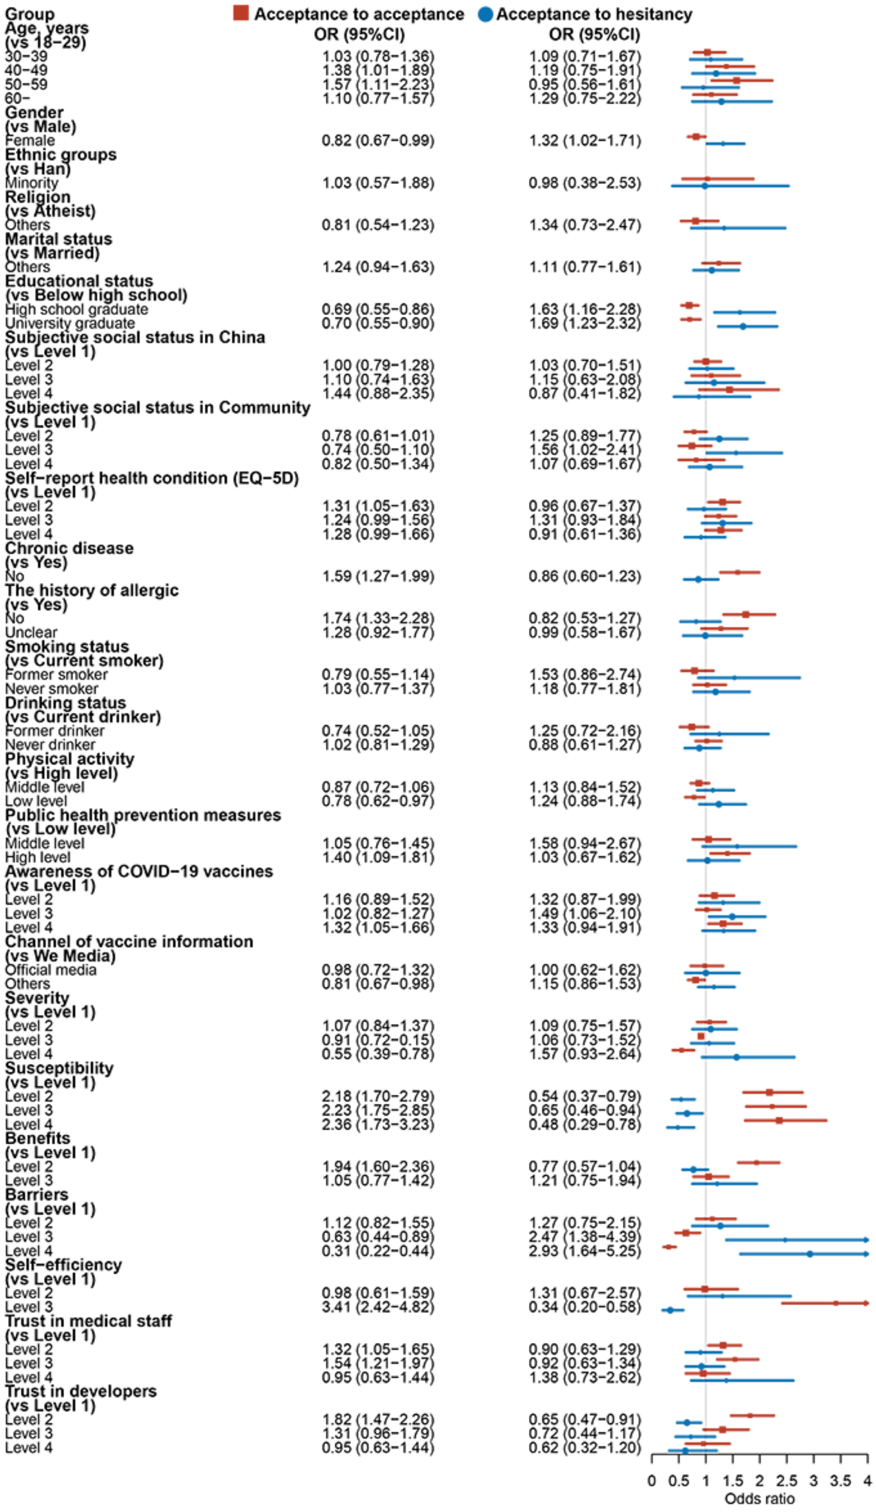


Figure 5. Relevant influences on hesitancy to acceptance and hesitancy to hesitancy for all participants.

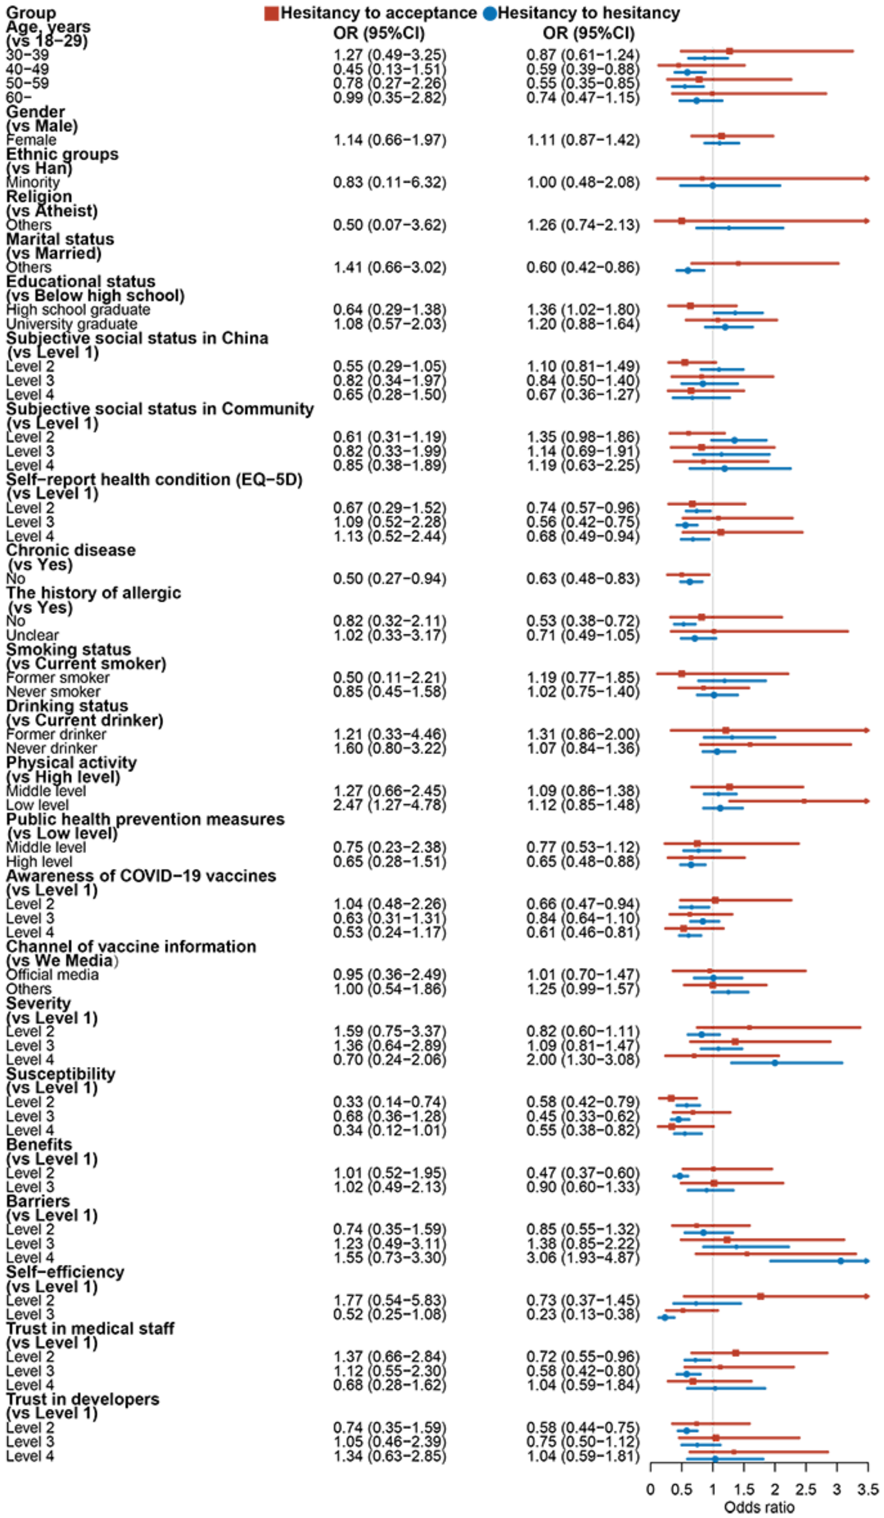

Sensitivity Analysis

In sensitivity analyses, the exclusion of participants aged >80 years did not significantly alter the outcome of COVID-19 vaccine hesitancy. Effect estimates for the primary outcome remained similar (Multimedia Appendix 5).

Discussion

Principal Findings

This study focused on the hesitancy rate of COVID-19 vaccine booster in the sample from 4 provinces in mainland China, namely Heilongjiang, Jiangsu, Henan, and Qinghai. The vast majority of participants (6126/6659, 92%) indicated a willingness to receive the COVID-19 booster vaccine, with an additional 8% (533/6659) expressing vaccine hesitancy. The higher vaccination rate and lower vaccine hesitancy rate may be attributed to the following reasons: first, China has continued to strengthen postmarketing surveillance of vaccines, emphasizing their safety and efficacy while continuously tracking the incidence of vaccine-preventable diseases and public acceptance of vaccines [26]. Second, the Chinese government has increased the supply of COVID-19 vaccines and set up reasonably designated medical institutions to carry out booster vaccinations, which has improved the accessibility of vaccination services [31]. Finally, the government and communities have used instant communication media such as television, news, and radio to promote the idea that the overall benefits of COVID-19 vaccination outweigh the risks, and disseminated scientific knowledge about vaccination to reduce people's doubts. At the same time, community staff actively carried out door-to-door campaigns to mobilize residents actively participate in the booster vaccination.

Nevertheless, the hesitancy rate altered dynamically, increasing from 8% (533/6659) to 11% (736/6659) at the next regular COVID-19 booster vaccination. This may be related to the rapid mutation of the COVID-19 virus [10,32] and spot outbreaks in some cities such as Shanghai, Hainan, Zhengzhou, and so forth in mainland China [33]. People are beginning to wonder about the necessity of the COVID-19 booster vaccination and whether it is effective and safe. This result suggests that repeated outbreaks or spot outbreaks are destroying confidence in the COVID-19 vaccine, which will not be conducive to the control of the epidemic. Therefore, it would be relevant to explore the main influences on vaccine hesitancy and its dynamic fluctuations.

Previous studies have indicated that participants with a lower education level expressed a higher level of COVID-19 vaccine hesitancy in a global survey of 17 countries [34], adults in Ontario with less than a bachelor degree were more likely to report unwillingness to COVID-19 vaccination [35], as well as Chinese adults with lower education level endorsed clear vaccine hesitancy response in primary COVID-19 vaccination [26]. However, our findings suggest the opposite view. Those participants with higher levels of education were more reluctant to participate in the regular COVID-19 booster vaccination, showing a clear vaccine hesitancy. Previous studies have demonstrated similar results [36,37]. Likewise, a similar trend was observed in the regular and the booster vaccination attitude conversion (ATH and HTH). The reason for the contrary findings could be attributed to the fact that individuals with a higher level of education may have greater access to information regarding the COVID-19 outbreak and vaccine. This may lead them to believe that the epidemic will come to an end soon and that they will no longer require a booster shot for COVID-19 [5,20]. Alternatively, the highly educated population may have more resources to combat the risk of the COVID-19 epidemic [38,39].

It is worth noting that there was a significant association between experiencing chronic disease, history of previous vaccination allergies, and participants' hesitancy to receive booster vaccinations. This hesitancy was also found in the conversion of attitudes from booster vaccination to regular booster vaccination. Participants with chronic diseases (hypertension, diabetes, etc) expressed clear hesitancy to receive booster vaccinations and were consistently hesitant to receive regular booster vaccinations. The reason for this consequence may be that people with chronic disease were concerned about whether people with immunodeficiency and immunosuppression should be vaccinated [40,41]. They are confused as to whether having a chronic disease can exacerbate adverse reactions to COVID-19 booster vaccination [42,43]. The same trend can be observed in participants with a history of vaccination allergy. Previous experiences with vaccination allergies have made people wary of the COVID-19 vaccine [44]. They are unsure if they will develop allergic injuries after the COVID-19 booster vaccination [45], so hesitancy about the booster is inevitable. Consequently, widespread education of people would be essential to reduce vaccine hesitancy.

In this study, we found that participants with higher levels of epidemic severity, barriers, and lower levels of susceptibility, benefits, and self-efficacy were more hesitant to receive a booster vaccination. The severity of the epidemic influenced people's choice, with higher levels of severity instead promoting vaccine hesitancy, which is inconsistent with previous findings [12,46]. This may be due to people being more aware of self-protection, taking more adequate self-protection measures, going out less, or participating in timely nucleic acid testing when the epidemic is severe [47,48]. Although most people have confidence in the vaccine, this attitude does not automatically translate into vaccine use, as there are a variety of other barriers to vaccination [49,50]. While barriers to vaccination (eg, inconvenience and long queues) affect booster vaccination rates, a reasonable number of booster vaccination sites can facilitate vaccination [38], and the current high rate of COVID-19 vaccination in China can be attributed to a large number of vaccination sites. Therefore, in order to increase the booster vaccination rate, it is important to improve the accessibility of vaccination services. Besides, effective measures can be taken simultaneously, including ensuring the supply of vaccines, increasing the number of vaccination staff, improving the vaccination experience, and providing appointment services to reduce the waiting time for vaccination [26,50,51]. Consistent with the results of Włodarczyk and Ziętalewicz [52], higher self-efficacy and the benefits of COVID-19 vaccination influenced people to take part in vaccination, suggesting that we need to expand the perception that the benefits of vaccination outweigh the disadvantages and guide people positively to take part in vaccination with full self-efficacy.

Mistrust of medical staff and vaccine developers is an important factor influencing hesitancy in receiving COVID-19 booster vaccination. This has been demonstrated in previous studies of vaccine hesitancy [53-55]. Low levels of trust in medical staff and developers can lead to hesitancy in receiving COVID-19 booster vaccinations, even regular booster vaccinations. Both experiences of adverse reactions to vaccinations and even the influence of counterfeit vaccines in society have led to suspicion of medical staff and developers [56,57], which directly influences the COVID-19 booster vaccination. Therefore, it is imperative to strengthen the regulation of vaccine development, production, transportation, and vaccination. Strict adherence to industry guidelines and ethical standards will strongly ensure the standardization, safety, and efficacy of vaccines [16,58]. At the same time, it is necessary to strengthen the training of medical staff to enhance the communication between medical staff and residents, which aims to improve the quality of vaccination services. In addition, enhanced screening of patients with contraindications to COVID-19 vaccination is necessary [24,59], and avoiding or delaying vaccination of contraindicated patients will effectively reduce the occurrence and adverse effects of allergic events.

Strengths and Limitations

This is the first multicenter nationwide household-based survey to assess the hesitancy of COVID-19 booster vaccination, influencing factors, and its dynamic fluctuation trend with the help of a saturation sample, which is highly innovative and forward-looking. Throughout the survey process, dedicated staff were assigned to follow-up the survey sites in each of the 4 centers, and strict quality control was carried out to ensure that the survey data were complete and authentic. However, there are still several limitations of this study. First, this study is a cross-sectional observational study, the causality association of vaccine hesitancy cannot be established, and it needs to be supported by data from the follow-up surveys. Second, it may introduce reporting bias in the collecting data on COVID-19 booster vaccination. Finally, this survey was conducted on a household-based sample with a population of permanent residents, and the findings may not be applicable to the floating population.

Conclusions

The prevalence of COVID-19 vaccine booster hesitancy is not high in mainland China. However, there is a slight increment in hesitancy on regular booster vaccination. To reduce vaccine hesitancy, targeted information guidance for people with higher education levels and chronic diseases would be fruitful. Furthermore, improving the accessibility of booster vaccination and enhancing people’s trust in medical staff and vaccine developers would be highly effective in reducing vaccine hesitancy.

Abstract

Background: As the SARS-CoV-2 attenuates and antibodies from the COVID-19 vaccine decline, long-term attention should be paid to the durability of primary booster administration and the preventive effect of the second or multiple booster doses of the COVID-19 vaccine.

Objective: This study aimed to explore the durability of primary booster administration and the preventive effect of second or multiple booster doses of the COVID-19 vaccine.

Methods: We established a bidirectional cohort in Guizhou Province, China. Eligible participants who had received the primary booster dose were enrolled for blood sample collection and administration of the second booster dose. A retrospective cohort for the time of administration was constructed to evaluate antibody attenuation 6-12 months after the primary booster dose, while a prospective cohort on the vaccine effect of the second booster dose was constructed for 4 months after the second administration.

Results: Between September 21, 2022, and January 30, 2023, a total of 327 participants were included in the final statistical analysis plan. The retrospective cohort revealed that approximately 6-12 months after receiving the primary booster, immunoglobulin G (IgG) slowly declined with time, while immunoglobulin A (IgA) remained almost constant. The prospective cohort showed that 28 days after receiving the second booster, the antibody levels were significantly improved. Higher levels of IgG and IgA were associated with better protection against COVID-19 infection for vaccine recipients. Regarding the protection of antibody levels against post–COVID-19 symptoms, the increase of the IgG had a protective effect on brain fog and sleep quality, while IgA had a protective effect on shortness of breath, brain fog, impaired coordination, and physical pain.

Conclusions: The IgG and IgA produced by the second booster dose of COVID-19 vaccines can protect against SARS-CoV-2 infection and may alleviate some post–COVID-19 symptoms. Further data and studies on secondary booster administration are required to confirm these conclusions.

Introduction

Since the end of 2019, COVID-19 has been the cause of a global pandemic, placing a heavy burden on the global public health system [1]. With the widespread and continuous evolution of SARS-CoV-2, many variants of concern (VOCs), such as Alpha (B.1.1.7), Beta (B.1.351), Gamma (P.1), Delta (B.1.617.2), and Omicron (B.1.1.529), have emerged globally and have led to several infection waves [2-5]. At present, the Omicron variant, which has a higher transmissibility and immune escape ability, is the dominant variant in the world [6]. Previous studies have shown that the Omicron variant not only has resistance to serum antibodies of convalescent patients but also has certain resistance to the serum of individuals who have been fully vaccinated against COVID-19 [7-12]. Therefore, Omicron poses a serious threat to the control of the COVID-19 pandemic and disease treatment.

China has administered 3.491 billion doses of the COVID-19 vaccine. The coverage rate of the first dose and second dose for the entire population reached 92.9% and 90.6%, respectively [13], and more than 771 million booster injections have been administered [14]. In November 2022, China adjusted and optimized the prevention and control measures for COVID-19. The local epidemic quickly climaxed, which led to a depletion of medical resources. Febrifuge, antitussive, and other COVID-19–related drugs could not meet the exponential increase in the number of patients in the short term, and the more serious concern was overwhelming the availability of hospital beds [15,16]. Therefore, long-term attention should be paid to the preventive effect and clinical value of the second or multiple booster doses of the COVID-19 vaccine.

In China, the most commonly used vaccines for both primary and booster immunization against COVID-19 are inactivated vaccines produced by the China National Biotec Group and Sinovac Biotech. Inactivated vaccines are prepared by cultivating SARS-CoV-2 in vitro to render the virus noninfectious while preserving its antigenicity. Although homologous boosting is generally considered a standard practice, heterologous regimens have been proposed as a COVID-19 vaccine strategy to elicit stronger and broader, or longer-lasting, immunity [17,18]. A recombinant COVID-19 vaccine using adenovirus type 5 as a vector for inhalation was developed by CanSino Biologics (inhalant Ad5-nCoV). Ad5-nCoV inhalation involves the recombination of the spike glycoprotein gene of SARS-CoV-2 into the replication-deficient human type 5 adenovirus gene, which induces an immune response in the body. This inhalant is easy to administer and can stimulate mucosal immunity. In a previous phase 1 trial, Ad5-nCoV inhalation was found to be well tolerated. Further, compared with intramuscular vaccination, aerosol vaccination could trigger a higher ratio of neutralizing antibodies to total antibodies [19].

Few real-world studies have demonstrated the effect of a fourth dose of heterologous booster on Omicron, especially using inhalation vaccines. Here, we aimed to reveal the immunogenicity and persistence of the primary booster dose and the real-world immune effect of the secondary inhalation booster to assess immunogenicity and persistence and prevent sequelae of booster administration in the real world.

Methods

Study Design

Overview

A bidirectional cohort was established to investigate the efficacy of booster administration between September 21, 2022, and January 30, 2023, in Guiyang City, Guizhou Province, China. The cohort was retrospectively tracked to determine the effect and durability of primary booster administration and prospectively followed up to assess the immunogenicity and real-world protective effect of secondary booster heterologous immunization, with the time of receiving the second booster as the node.

Retrospective Study

Blood samples were collected from individuals for antibody testing at the time of enrollment. A questionnaire covering basic characteristics and immunization programs was required to evaluate the durability and effectiveness of the third booster dose.

Secondary Booster Administration

All enrolled individuals received the inhalant, Ad5-nCoV, as part of a secondary booster immunization program (the fourth dose).

Prospective Study

About 4 weeks (21-35 days) after receiving the second booster dose, blood samples were collected for antibody testing. After about 16 weeks (84-140 days), information on the infection and sequelae of COVID-19 was collected from participants through follow-up phone calls.

Participants

Participants were recruited by the Guizhou Center for Disease Control and Prevention. These individuals were aged 18 years or older and had received 3 doses of the COVID-19 vaccine before 6 months or above. The main exclusion criteria were individuals with a history of clinically or laboratory-confirmed COVID-19 or SARS-CoV-2 infection within the first 6 months of enrollment, a history of vaccination (any administration, including COVID-19 baseline or booster dose) within the first 6 months of enrollment, or an allergy to any component of the vaccine.

Procedures

Individuals from Guanshanhu District, Qingzhen City, and Baiyun District of Guiyang City were recruited for this study. All individuals completed the basic and primary booster immunization procedures with the inactivated vaccine from the China National Biotec Group or Sinovac Biotech.

Eligible participants received 1 dose of inhalant Ad5-nCoV (0.1 mL per dose) through a specific atomization device. Venous blood samples (5 mL) were collected before inhalation and 28 days after inhalation to detect immunoglobulin G (IgG) and immunoglobulin A (IgA) antibodies against SARS-CoV-2 in serum. Antibody detection was performed by the receptor-binding domain antibody test kit produced by Vazyme Biotech Co Ltd. The kit detects receptor-binding domains IgA and IgG antibodies against SARS-CoV-2 that are produced during incubation through an indirect enzyme-linked immunosorbent assay (ELISA). After processing and color development, the absorbance of the sample was measured at a wavelength of 450 nm. The absorbance of the sample was positively correlated with the antibody titers.

Survey Tool

Telephone follow-up was conducted with the participants to assess their status and the timing of contracting SARS-CoV-2 after inhalation and evaluate the persistent symptoms of post–COVID-19 using a scale. The scale comprised 49 items and was used to assess the severity of the post–COVID-19 impact using 8 indicators: fatigue, shortness of breath, brain fog, impaired coordination, physical pain, impaired sleep quality, depression, and impaired quality of life. These indicators were selected based on the common symptoms of post–COVID-19 condition (PCC), that is, a set of signs and symptoms that emerge during or after an infection consistent with COVID-19 and are not explained by an alternative diagnosis [20].

Each item was rated as “never occurred,” “slightly affected,” “moderately affected,” and “severely affected,” with scores of 0, 1, 2, and 3, respectively. The Cronbach α values of the 8 indicators ranged from .79 to .94, indicating acceptable reliability [21]. The detailed questionnaire and Cronbach α values are provided in Multimedia Appendix 1.

Statistical Analyses

The baseline characteristics are presented as means (SDs) for continuous variables and percentages for categorical variables. Missing values were treated and reported in all analyses.

The attenuation curves of the antibody and time were fitted through locally weighted scatterplot smoothing (LOWESS), a nonparametric method used in the analysis of local regression. The sample was divided into short intervals, and weighted polynomial fitting to the sample in each interval was conducted. Linear regressions were constructed to fit the curve stratified according to the preceding immune program.

Comparisons of geometric mean titers (GMTs) and geometric mean increases (GMIs) between the groups were performed using logarithmic conversion values. The differences in antibodies before and after administration were compared using a paired Student 2-tailed *t* test, and linear regression was used to compare GMIs among different groups. For positive seroconversion, the antibodies after administration should increase by 4-fold or more, according to the literature [19,22]. A logistic regression was used to compare the seroconversion rate. On the basis of the marginal forecast rates of each category estimated by the regression, we used the weighted average of the standard population to calculate the direct standardized seroconversion rate and GMI. All test criteria to confirm the hypothesis were bilateral, with a significance level of .05. The adjusted α was reduced to .017 when pairwise comparisons were made between the 3 groups.

Kaplan-Meier analysis was used to plot the uninfected curves and cumulative hazard curves of different antibody levels, and the log-rank test was used to compare the difference in infection time among individuals with different levels. A multivariate Cox proportional hazard regression model was used to adjust for the effects of confounding factors on the results. Finally, a linear regression model was constructed to analyze the correlation between different sequelae scores and antibodies.

All statistical analyses were performed using R (version 4.2.0; R Development Core Team) and Stata (version 17.0; Stata Corporation).

Ethics Approval

The protocol was approved by the institutional review board of the Guizhou Center for Disease Control and Prevention (approval number Q2023-03) and was performed in accordance with the Declaration of Helsinki and the Good Clinical Practice guidelines. All participants provided written informed consent before enrollment.

Results

Basic Characteristics of the Participants

A total of 327 participants who completed the vaccination and blood sampling were enrolled in the final statistical analysis. The specific participant entry and exit processes are outlined in Multimedia Appendix 1. A total of 234 female and 93 male participants were enrolled, with a mean age of 39.4 (SD 9.5) years. All participants received 3 doses of the COVID-19 vaccine before the survey, including 2 doses for basic immunization and 1 dose for booster immunization. Of the 327 participants, 166 received the BBIBP-CorV inactivated vaccine (SinoBio Pharmaceutical Ltd) and 161 received the CoronaVac inactivated vaccine produced by Sinovac Ltd. Among them, 233 participants worked in hospitals, 84 worked in nonhospital institutions, and the remaining 10 were reluctant to report their occupations and workplaces. Detailed information is provided in Table 1.

Table 1. The characteristics of participants (N=327).

Characteristics	Participants
Age (years), mean (SD)	39.4 (9.5)
Age (years), n (%)	
<30	63 (19.3)
30-40	94 (28.7)

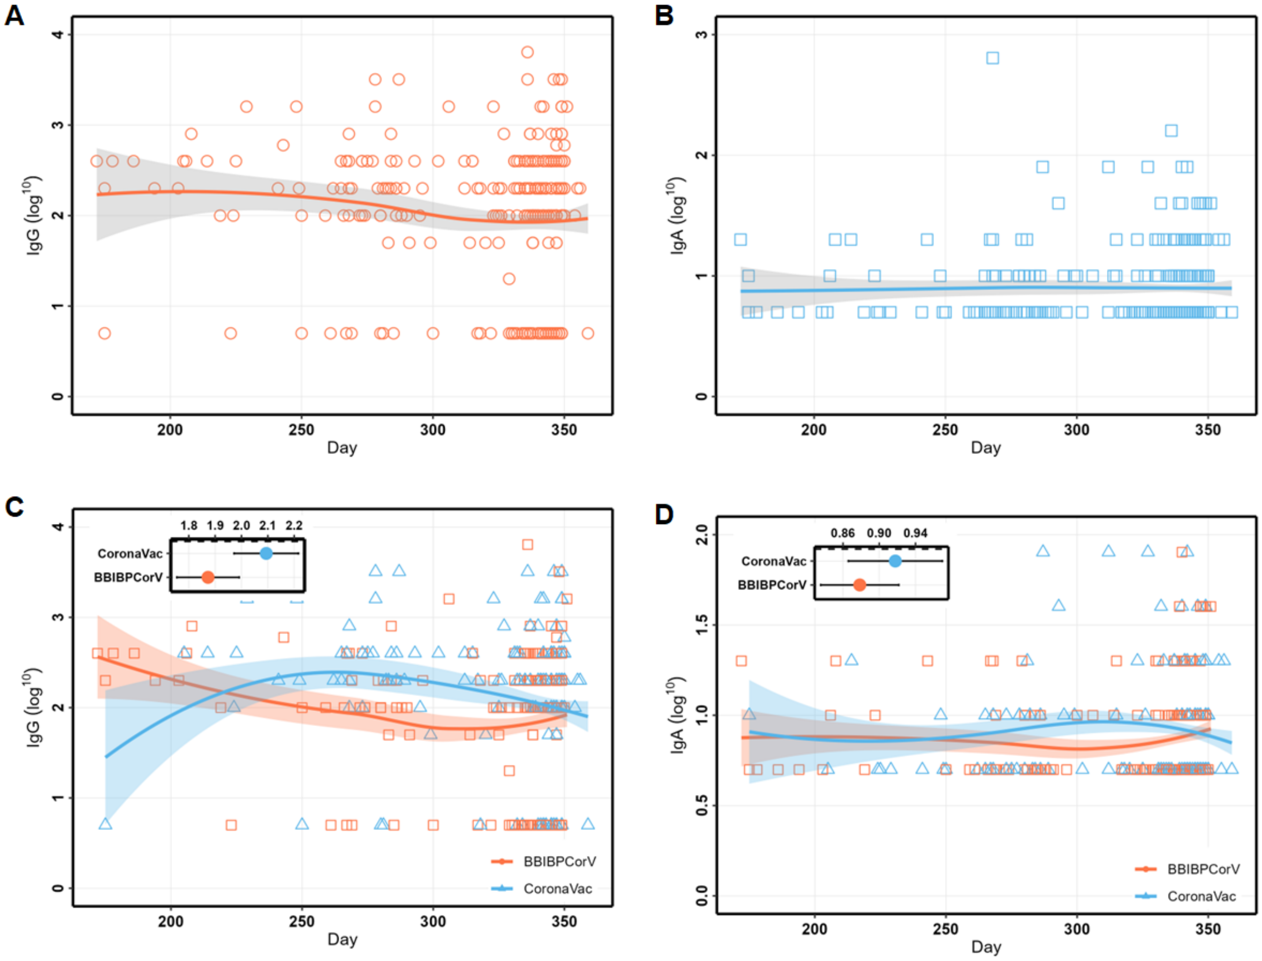
Long-Term Durability of the Antibodies After Primary-Booster Administration (Third Dose)

Before receiving the second booster (fourth dose), we measured the antibody levels of the participants. Approximately 6-12 months after receiving the booster, the GMT of the IgG antibody was 95.9 (95% CI 78.8-116.7), while that of the IgA antibody was 7.9 (95% CI 7.3-8.5). The time interval between the last booster immunization and antibody detection was used as the independent variable, while the antibody level was used as the dependent variable for LOWESS segmented curve fitting. The fitting results showed that the IgG antibody level slowly declined with time after the primary booster, while the IgA antibody level remained almost constant (GMT 7.9; Figure 1A and B).

We proceeded to stratify the results based on the different immunization programs and perform linear fitting. Figure 1C shows that the declining trend for the IgG antibody level of participants administered the CoronaVac vaccine and those administered the BBIBP-CorV vaccine was consistent after 6 months of immunization, with the IgG antibody titer of CoronaVac (GMT 124.2; 95% CI 93.8-164.3) vaccine recipients being slightly higher than that of the BBIBP-CorV vaccine recipients (GMT 74.7; 95% CI 56.9-97.9). Figure 1D shows that the levels and trends of the 2 are almost identical.

Figure 1. The locally weighted scatterplot smoothing (LOWESS) curves of IgG and IgA over time during 6-12 months after primary booster administration. (A) The curves of IgG over time. (B) The curves of IgA over time. (C) The changing curves of IgG stratified by a booster vaccine (third dose). (D) The changing curves of IgA stratified by a booster vaccine (third dose). IgA: immunoglobulin A; IgG: immunoglobulin G.



Immunogenicity of the Second Booster (Fourth Dose)

At 28 days after receiving the inhalant vaccine as the second booster, the GMT of the IgG antibody was 5066.5 (95% CI 4418.1-5810.1), while that of the IgA antibody was 108.6 (95% CI 95.4-123.5). The GMI of IgG was 52.8 (95% CI 42.6-65.6), and the seroconversion rate reached 94.5% (95% CI 92-97). The GMI of IgA was 13.7 (95% CI 12-15.7), and the antibody seroconversion rate was 89.3% (95% CI 85.9-92.7).

The antibody levels of individuals with different sociodemographic characteristics and prevaccination programs showed significant improvement after vaccination. The line graphs of the pre and postvaccination GMTs for the IgG and IgA antibodies of different groups are shown in Figure 2.

We explored the crude and adjusted changes in antibody (GMI and seroconversion rate) among different groups based on age, sex, ethnicity, workplace, and type of primary booster vaccine, as detailed in Table 2. There was no difference in postvaccination GMI or seroconversion of IgG antibodies among the different demographic groups. However, for participants who received BBIBP-CorV (adjusted rate 97.4%; 95% CI 94.9-99.9) as their initial booster, the seroconversion rate of the IgG antibody was higher than that of those who received CoronaVac (adjusted rate 91.4%; 95% CI 87.2-95.7) after the secondary booster immunization.

Figure 2. The differences of the pre- and postvaccination GMTs for the IgG and IgA antibodies of different groups. (A-E) GMTs for the IgG. (A) Group by age. (B) Group by sex. (C) Group by ethnicity. (D) Group by type of primary booster vaccine. (E) Group by workplace. (F-J) GMTs for the IgA. (F) Group by age. (G) Group by sex. (H) Group by ethnicity. (I) Group by type of primary booster vaccine. (J) Group by workplace. GMT: geometric mean titer; IgA: immunoglobulin A; IgG: immunoglobulin G.

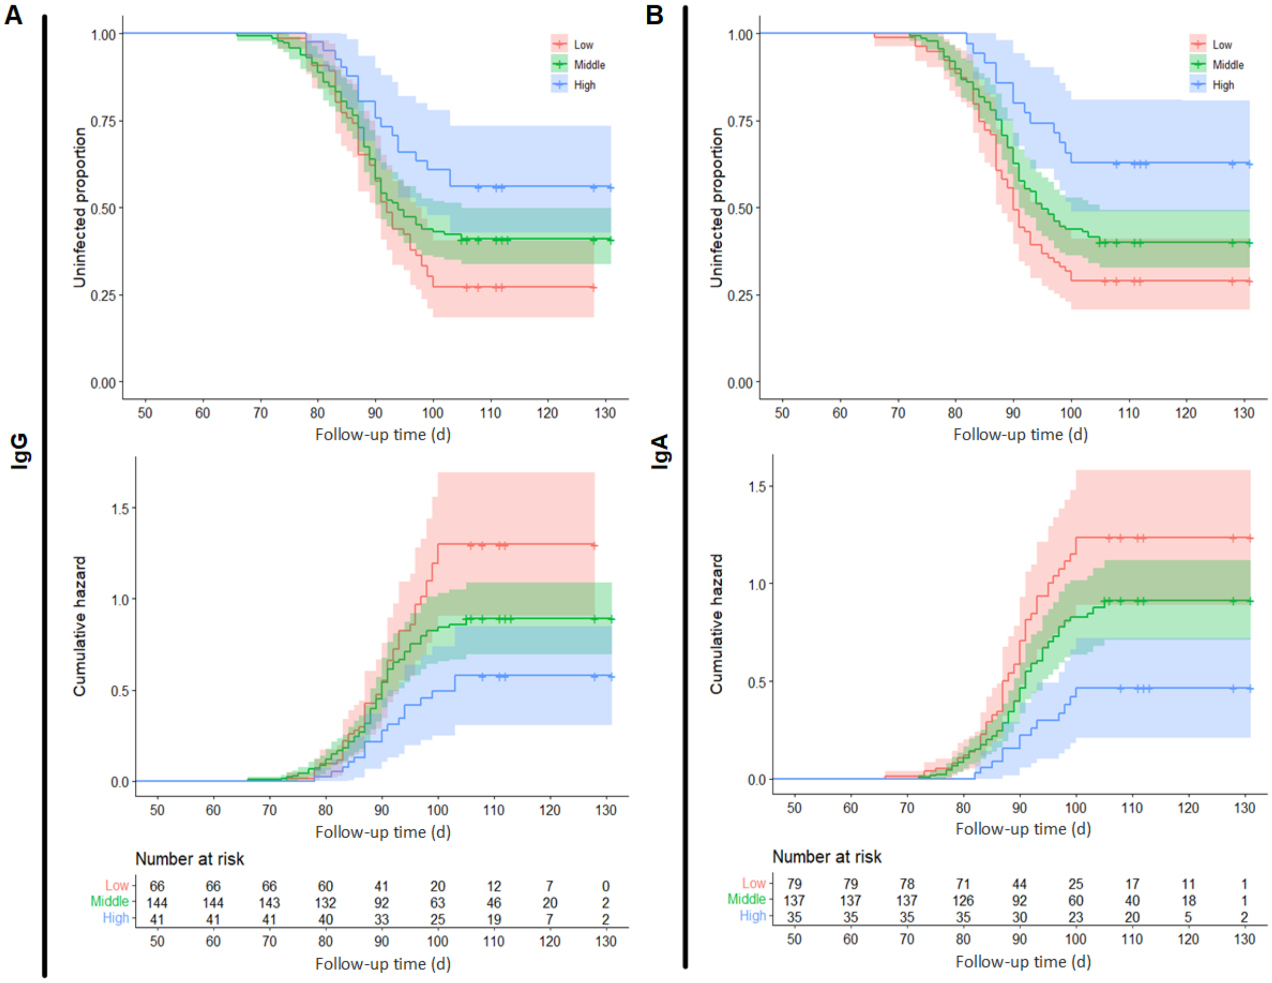
Real-World Protective Effect of Secondary Booster Administration Against Infection

After the second booster, we continued to track and follow up with the participants to derive the breakthrough infection rates. As of January 30, 2022, we followed up with 251 participants; the breakthrough infection rate was 60.2% (151/251).

After adjusting for confounding factors, Cox regression analysis revealed a significant correlation between postimmunization IgG antibody levels and breakthrough COVID-19 infection (hazard ratio 0.60; 95% CI 0.45-0.79); the same result was obtained for IgA antibody levels (hazard ratio 0.55; 95% CI 0.39-0.78). This result suggests that both IgG and IgA antibodies after the second booster can provide a certain degree of protection against COVID-19 and prevent infection. We categorized postimmunization IgG and IgA antibodies into 3 levels, high, medium, and low, based on 25th percentile and 75th percentile. Survival and cumulative risk curves were plotted for each level, as shown in Figure 3. Higher levels of postimmunization IgG antibodies were associated with better protection against COVID-19 infection and a lower cumulative risk for vaccine recipients (Figure 3A). Similarly, higher levels of postimmunization IgA antibodies were associated with better protection against COVID-19 infection and a lower cumulative risk for vaccine recipients (Figure 3B).

Kaplan-Meier curves for the risk of COVID-19 infection for age and sex subgroups were plotted, as shown in Figure 1. Differences between age groups were found: participants between 30 and 40 years of age had a higher hazard risk than other age groups. The differences were insignificant after adjusting for other sociodemographic factors. Women appear to have a higher risk of infection than men, but this did not reach statistical significance (*P*=.051).

Figure 3. The Kaplan-Meier and cumulative hazard curve of COVID-19 infection grouped by antibody levels. (A) Curves grouped by IgG levels (low, middle, and high). (B) Curves grouped by IgA levels (low, middle, and high). IgA: immunoglobulin A; IgG: immunoglobulin G.



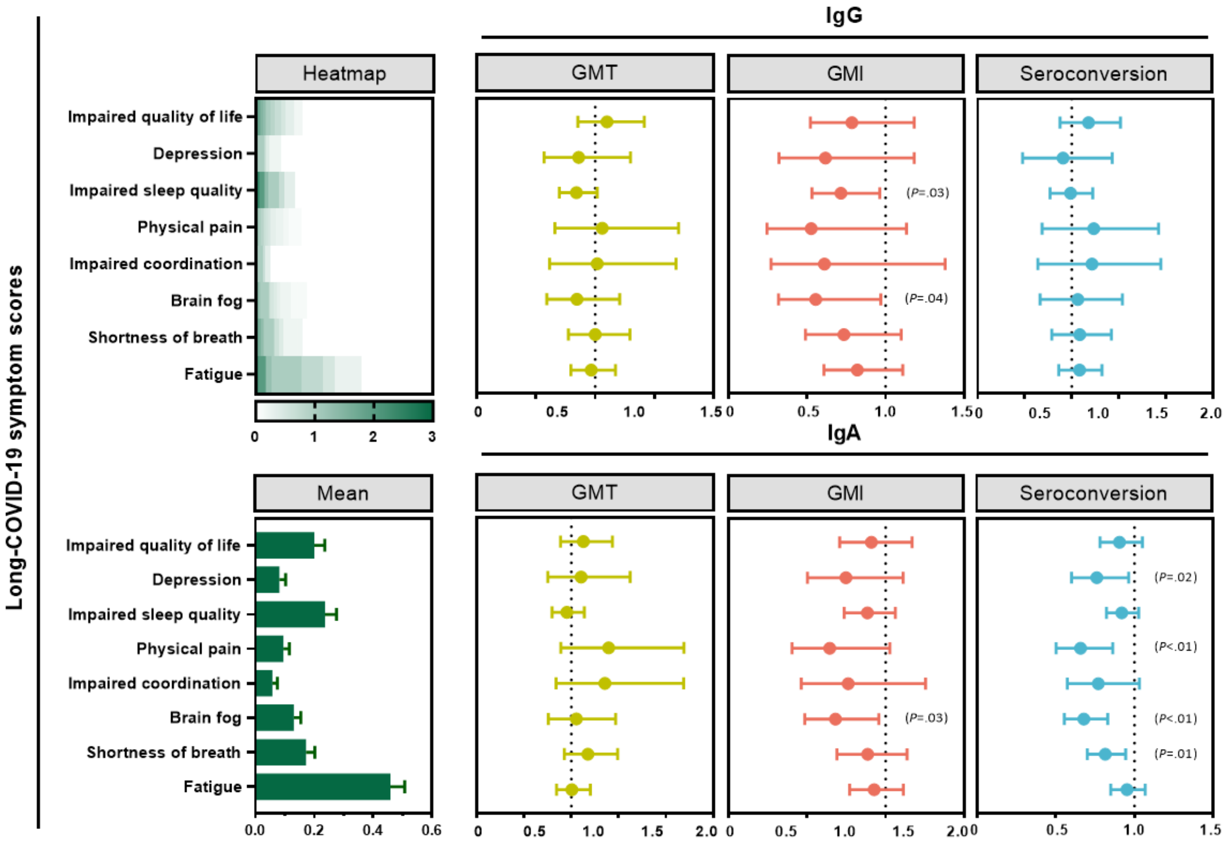
Real-World Protective Effect of Secondary Booster Administration Against Post–COVID-19 Symptoms

Finally, a questionnaire was used to evaluate the post–COVID-19 symptoms of 151 participants who experienced breakthrough infections, including fatigue, shortness of breath, brain fog, impaired coordination, physical pain, impaired sleep quality, depression, and impaired quality of life. The most common symptoms were fatigue, impaired sleep quality, and impaired quality of life, with mean scores of 0.46, 0.24, and 0.20, respectively.

We constructed a regression model with postimmunization antibody levels as the independent variable and questionnaire scores as the dependent variable. Based on the results, the GMI levels of postimmunization IgG antibodies had a protective effect on brain fog (odds ratio [OR] 0.56; 95% CI 0.32-0.97) and sleep quality (OR 0.71; 95% CI 0.53-0.96). The GMI levels of postimmunization IgA antibodies had a protective effect on brain fog (OR 0.68; 95% CI 0.49-0.96). Additionally, participants who were IgA antibody seropositive after infection had milder symptoms of shortness of breath (OR 0.81; 95% CI 0.7-0.95), brain fog (OR 0.68; 95% CI 0.55-0.83), impaired coordination (OR 0.66; 95% CI 0.50-0.86), and physical pain (OR 0.76; 95% CI 0.60-0.96; Figure 4).

The age-stratified protective effect of IgG and IgA after secondary enhancement on post–COVID-19 symptoms was reported. Unfortunately, no differences between age groups were found, and detailed results can be seen in Figure 2.

Figure 4. The adjusted regression models of antibodies on post–COVID-19 scores. The heatmap and bar chart on the left represent the discrete and central trends of the post–COVID-19 scores, and the scores of each subitem entered the model as a dependent variable. The 3 graphs on the top right are the results of entering different metrics of IgG (ie, GMT, GMI, and seroconversion rate) into the regression model as independent variables. The 3 graphs on the bottom right are the results of entering different metrics of IgA (ie, GMT, GMI, and seroconversion rate) into the regression model as independent variables. Each regression adjusted for basic sociodemographic characteristics. GMI: geometric mean increase; GMT: geometric mean titer; IgA: immunoglobulin A; IgG: immunoglobulin G.



Discussion

Overview

Based on existing evidence, there is a significant decline in neutralizing antibody titers 4-5 months after completion of the routine vaccination program [23,24]. The immune protection induced by the vaccine declines continuously with time, highlighting the urgent need for booster vaccination to enhance protection. According to statistics from the National Health Commission, approximately 850 million people in China have received their booster vaccine as of February 2023 [16]. The administration of a third dose of the same vaccine has been demonstrated to significantly increase neutralizing antibody levels and effectively reduce the symptomatic infection rate of the SARS-CoV-2 variant [25,26].

The literature suggests a decline or even disappearance of antibody levels within a short period of 3-6 months [27-30]. In this study, we tracked the antibody level owing to the first booster for 6-12 months without the interference of natural infection to evaluate long-term immunogenicity. We found that the decline in antibody level was slow after 6 months and maintained at a relatively low level, with a GMT of approximately 96 for IgG and approximately 8 for IgA. In confirmatory research, vaccine effectiveness was estimated to decline from approximately 70% one week after the booster dose to approximately 40% at 15 weeks or more [31].

The titers of postadministration antibodies vary according to the vaccine type. In China, inactivated vaccines are the most commonly used vaccines for basic and booster immunizations owing to their safety and stability. Based on evidence from the Chinese Center for Disease Control and Prevention, the GMTs owing to BBIBP-CorV were 25 at 1 month and 4 at 12 months, while those owing to CoronaVac were 20.2 and 4.1, respectively [32]. In this study, ELISA revealed that the IgG antibody titers from CoronaVac were slightly higher than those from BBIBP-CorV at 6-12 months after administration but converged at 12 months.

Breakthrough infections have become more common with the decline in antibody levels and the development of new VOCs with strong immunologic escape, despite the remarkable effect of primary boosting [33]. A fourth dose of the COVID-19 vaccine can boost cellular and humoral immunity, and the peak responses were found to be similar to the peak responses after the third dose [34]. According to some clinical trials, the adenovirus vector booster dose based on an inactivated vaccine could lead to higher neutralization antibodies than homologous boostering [35,36]. In China, nearly 47 million residents have now completed the sequential booster immunization since the start of its dissemination in November 2022 [14].

Based on the available evidence, a prospective study was conducted to evaluate heterologous secondary booster administration. To our knowledge, this study is the first real-world evaluation of the effectiveness of the second booster dose in China. Herein, the inhalant Ad5-nCoV vaccine was administered as a second booster dose. Inhalant Ad5-nCoV is homologous to injectable Ad5-nCoV but achieves protection through mucosal immunization through inhalation. Mucosal immunity is a critical component of the human immune system, with more than 90% of infections occurring in the mucosa, which comprises numerous dendritic cells with strong T-cell activation capacity that can induce an immune response. ELISA to detect the serum antibodies revealed that the GMT of the IgG antibody was 4978.2 and that of the IgA antibody was 107.8 at 28 days after inhalation. The seroconversion rates for IgG and IgA were 93.8% and 86.9%, respectively. The antibody titers of the primary booster against the Omicron variant were attenuated relative to those of other virus strains, such as the wild type and other VOCs. Therefore, the use of heterogeneous vaccines for the second-booster procedures is a concern for the prevention of the Omicron variant [37].

China suffered a COVID-19 epidemic between December 2022 and January 2023 owing to changes in health policies and the impact of the Omicron variant, with a peak in cases on December 22, 2022 [13]. In this study, we followed up with participants for 4 months after receiving their fourth vaccine dose to assess their real-world COVID-19 infection status. As of January 30, 2023, 60.2% (151/251) of participants self-reported that they had been infected with COVID-19. Notably, IgG and IgA provided strong protection against COVID-19 infection, as demonstrated by the high antibody titers after the fourth dose.

In addition to infection prevention, the long-term effects of COVID-19 are also concerning. Studies from high-income countries suggest that vaccination may alleviate post–COVID-19 or PCC [38]. However, based on other evidence, COVID-19 vaccination is not associated with improvement in PCC [39,40]. We sought to assess some nonspecific post–COVID-19 symptoms. Based on our results, the GMI and seroconversion rates of IgG and IgA may alleviate some of the symptoms after secondary booster administration, including sleep quality, shortness of breath, brain fog, impaired coordination, and physical pain. The GMTs had no statistical relationship, which may be explained by the insufficient statistical efficacy induced by the small sample size. However, its clinical value is still worth exploring. The varying levels of IgG and IgA suggest the mechanisms of immune protection after infection, suggesting that further tracking and research are warranted.

Our study had some limitations. First, the SARS-CoV-2 infection of participants was self-reported, which may have led to recall and reporting biases. Further, asymptomatic patients may not have been identified. Second, the antibody detection method used was an ELISA quantitative assay rather than the neutralization test. However, the results of both tests are highly correlated according to the literature. ELISA can be used as a substitute for the gold standard to assess immunogenicity [22]. Third, there was no control group setting without a second booster dose for estimating the vaccine effect of the second booster dose. Their use of antibody levels was reasonable in accordance with previous trials, however [41]. Finally, only follow-up data collected within approximately 1 month after infection were reported in this study. These findings may offer suggestions for future populations with post–COVID-19. Further studies are needed, including appropriate control measures for unvaccinated individuals, to confirm the trajectory of persistent symptoms after COVID-19 vaccination.

Conclusions

The IgG and IgA antibodies did not decrease significantly but remained at a relatively low level after administration of the second booster dose. The antibodies generated significant immunogenic protection against breakthrough infections and might partially alleviate post–COVID-19 symptoms. Further studies on secondary booster administration are needed to validate these correlations.

Acknowledgments

The authors would like to thank professors Fengcai Zhu and Aihua Zhang (Guizhou Medical University) for their great support and expertise in this study. We would also like to thank the following organizations for their full support in the implementation of the project: Guiyang Bureau of Health, Jinhua Community Healthcare Center of Guanshanhu District, Century-City Third Community Healthcare Center of Guanshanhu District, Qingzhen Center for Disease Control and Prevention, Baihua Community Healthcare Center of Qingzhen, Hongta Community Healthcare Center of Qingzhen, Baiyun Branch of Guizhou Provincial People's Hospital, the Affiliated Hospital of Guizhou Medical University (Baiyun Branch), Kaiyang Center for Disease Control and Prevention, Kaiyang COVID-19 Vaccination Site, Xifeng Bureau of Health, Xifeng Maternity and Child Healthcare Hospital, Xiuwen Center for Disease Control and Prevention, Baixin Hospital of Xiuwen, Center for Disease Control and Prevention of Yunyan District, and Qianling Hospital of Yunyan District. Abstract

Background: The COVID-19 pandemic, caused by SARS-CoV-2, has triggered a global public health crisis of unprecedented proportions. SARS-CoV-2 vaccination is a highly effective strategy for preventing infections and severe COVID-19 outcomes. Although several studies have concluded that COVID-19 vaccines are unlikely to affect fertility, concerns have arisen regarding adverse events, including the potential impact on fertility; these concerns are plagued by limited and inconsistent evidence.

Objective: This review aims to provide a recent assessment of the literature on the impact of COVID-19 vaccines on male sperm quality. The possible impact of COVID-19 vaccines on fertility potential was also examined to draw a clearer picture and to evaluate the effects of COVID-19 on male reproductive health.

Methods: PubMed, Scopus, Web of Science, Embase, and Cochrane databases were searched from their inception to October 2023. Eligible studies included articles reporting SARS-CoV-2 vaccination and human semen quality and fertility, as well as the impact of vaccination on assisted reproductive technology treatment outcomes. The quality of cohort studies was assessed using the Newcastle-Ottawa Scale, and the quality of cross-sectional studies was assessed using the quality evaluation criteria recommended by the Agency for Healthcare Research and Quality. The systematic review followed PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines.

Results: The initial literature search yielded 4691 records by searching 5 peer-reviewed databases (PubMed, Scopus, Web of Science, Embase, and Cochrane). Finally, 24 relevant studies were selected for our study. There were evident research inequalities at the regional level, with the United States and Western European countries contributing 38% (9/24) of the studies, Middle Eastern countries contributing 38% (9/24), China accounting for 21% (5/24), and Africa and South America accounting for none. Nonetheless, the overall quality of the included studies was generally good. Our results demonstrated that serious side effects of the COVID-19 vaccine are extremely rare, and men experience few problems with sperm parameters or reproductive potential after vaccination.

Conclusions: On the basis of the studies published so far, the COVID-19 vaccine is safe for male reproductive health. Obviously, vaccination is a wise option rather than experience serious adverse symptoms of viral infections. These instances of evidence may help reduce vaccine hesitancy and increase vaccination coverage, particularly among reproductive-age couples. As new controlled trials and prospective cohort studies with larger sample sizes emerge, the possibility of a negative effect of the COVID-19 vaccine on sperm quality must be further clarified.

KEYWORDS

COVID-19 vaccine; SARS-CoV-2; reproductive system; fertility; sperm quality

Introduction

Background

The COVID-19 pandemic, caused by SARS-CoV-2, has severely affected global public health, economics, and social life since 2019 [1-3]. To establish herd immunity and effectively reduce the risk of COVID-19 infection, the medical and research community conducted many research studies within a short period to develop the SARS-CoV-2 vaccines. Impressively, these efforts have ultimately led to the development of multiple efficacious vaccines in a short period, which is an unprecedented and important accomplishment [4]. Vaccination is proven to be an effective tool for reducing the risk of infection and severe COVID-19 outcomes and is now a global priority [5,6].

Earlier reports have confirmed that the testis is one of the tissues with the highest expression of angiotensin-converting enzyme 2 messenger RNA (mRNA) and protein, both of which are key targets for SARS-CoV-2 to enter host cells [7]. The inflammatory state caused by COVID-19 may undermine the integrity of the blood-testis barrier and further promote the infiltration of the virus. Therefore, in the early stages of the COVID-19 epidemic, some researchers argued that the testes might be susceptible to SARS-CoV-2. In fact, a series of studies have confirmed a short-term reduction in testosterone production and semen quality in patients with COVID-19. Semen parameters, including semen volume, sperm concentration, total sperm count, total sperm motility, and progressive sperm motility, were negatively affected by SARS-CoV-2 infection [8,9]. On the basis of the aforementioned potential damage to the reproductive system following SARS-CoV-2 infection, some researchers suspected that vaccines that mimic the virus could also affect fertility via a similar mechanism. Numerous types of disinformation and misinformation have emerged on social media, including questioning the relationship between COVID-19 vaccination and male fertility [10-12]. This public fear is partly owing to a lack of understanding of the newly developed COVID-19 vaccine [13,14].

It is also important to note that the current authoritative evidence on the impact of COVID-19 vaccines on male fertility is still limited, and the results are controversial. The lack of evidence for a definitive conclusion could discourage the public, fuel concerns about the potential impact of the vaccine on male fertility, and lead to vaccine hesitancy [15-17].

Objectives

As the pandemic continues to evolve, the number of newly approved vaccines and scientific studies will continue to increase [18]. In this study, we systematically reviewed the latest data and theoretical considerations on the impact of COVID-19 vaccines on semen quality in men to provide more conclusive information for policy makers, health care providers, media, and the public.

Methods

Search Strategy and Selection Criteria

According to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, we conducted a systematic review of empirical articles on SARS-CoV-2 vaccination, human semen quality and fertility, and the impact of vaccination on assisted reproductive technology (ART) treatment outcomes. The PRISMA checklist is provided in Multimedia Appendix 1. The PubMed, Scopus, Web of Science, Embase, and Cochrane databases were used to identify all relevant literature published up to October 2023. A keyword search strategy was developed with the following terms: “COVID-19,” “COVID19,” “covid19,” “covid-19,” “coronavirus,” “novel coronavirus,” “new coronavirus,” “SARS Coronavirus 2 Infection,” “2019 Novel Coronavirus Disease,” “2019 Novel Coronavirus Infection,” “SARS-CoV-2,” “severe acute respiratory syndrome coronavirus 2,” “COVID-19 Virus Disease,” “COVID-19 Virus Infection,” “Coronavirus Disease-19,” “Vaccines,” “vaccine,” “vaccination,” “COVID-19 Vaccines,” “COVID-19 Vaccines/adverse effects,” “SARS-CoV-2 Vaccine,” “Coronavirus Disease 2019 Vaccine,” “2019-nCoV Vaccine,” “SARS Coronavirus 2 Vaccine,” “BNT162b2 mRNA vaccine,” “COVID-19 mRNA Vaccine,” “Fertility,” “Fecundability,” “Fecundity,” “Infertility, Male,” “Infertility, Female,” “sterility,” “IVF,” “Fertilization in Vitro,” “reproductive function,” “ART,” “sperm,” “spermatozoa,” “semen analysis,” “spermatogenesis,” and “semen parameter.” The search strategies are provided in detail in Multimedia Appendix 2.

The search was restricted to articles on humans, published in any language, without additional restrictions. With regard to publication type, original studies were selected. Abstracts, comments, reviews (narrative or systematic), modeling only, case reports, case series (reporting data for <10 patients), and editorials were excluded. We evaluated the relevance and quality of the text. Two independent reviewers (GL and BS) screened all the studies by title, abstract, and keywords to identify potentially relevant articles. All articles obtained through the search strategy were imported into Rayyan (Qatar Computing Research Institute), and duplicates were removed. Papers that did not meet the inclusion criteria for the full-text evaluation were excluded. Subsequently, the full texts were screened to collect the data. Furthermore, the reference lists of the included studies were manually searched to identify additional eligible studies and to ensure that relevant studies were not missed.

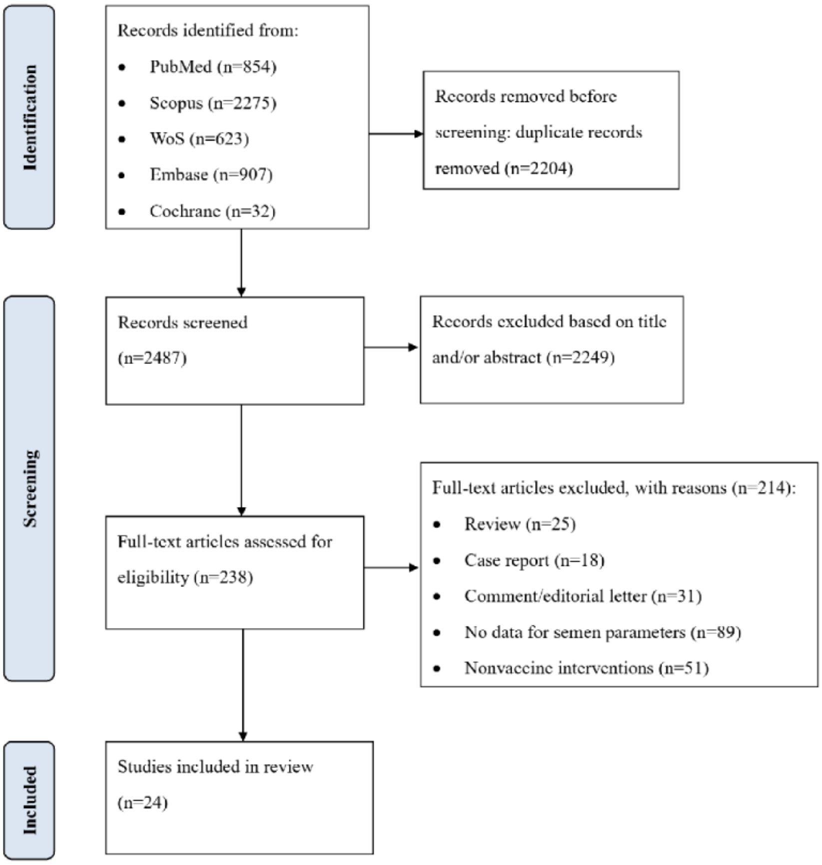
Eligible studies that were chosen to be included in this study were those evaluating the impacts of the COVID-19 vaccine on semen quality and male reproduction. Articles related to female vaccination and those without information on male vaccination were excluded. Data on the effect of the SARS-CoV-2 on male fertility were also excluded. The inclusion and exclusion criteria are presented in Table 1. Any disagreements were resolved through discussion among the study team members. The flow and results of the literature search are summarized in a PRISMA flowchart (Figure 1). Ethics approval was not required for this study because the data were derived from previously published studies.

The initial literature search yielded 4691 records. Of these, 2204 duplicate articles were removed, 2249 records were further excluded based on title or abstract screening, and 214 were excluded based on full-text assessment. Finally, 24 studies were selected for evaluation. We extracted the data using a pretested data extraction form created in Microsoft Excel 2019 (Microsoft Corporation). Article information (eg, PubMed Identifier, first author, year of publication, and country); study design; vaccine type; side effects; and changes in semen parameters were extracted from the articles.

Table 1. Summary of the inclusion and exclusion criteria.

Parameter	Inclusion criteria	Exclusion criteria
Article or study type	• Population-based original research studies	• Abstracts, comments, and editorials • Reviews and book chapters • Protocols and modeling only • Case reports and case series • Animal experiment
Language	• Any language	• Without additional restrictions
Publication period	• November 1, 2019, to October 1, 2023	• All dates outside the span from November 2019 to October 2023
Study content	• Studies assessing the impact of COVID-19 vaccines on semen quality and male reproduction	• Studies related to female vaccination without information on male vaccination • Data on the effects of COVID-19 on male fertility

Figure 1. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the screening and selection process. WoS: Web of Science.



Characteristics of the Included Literature

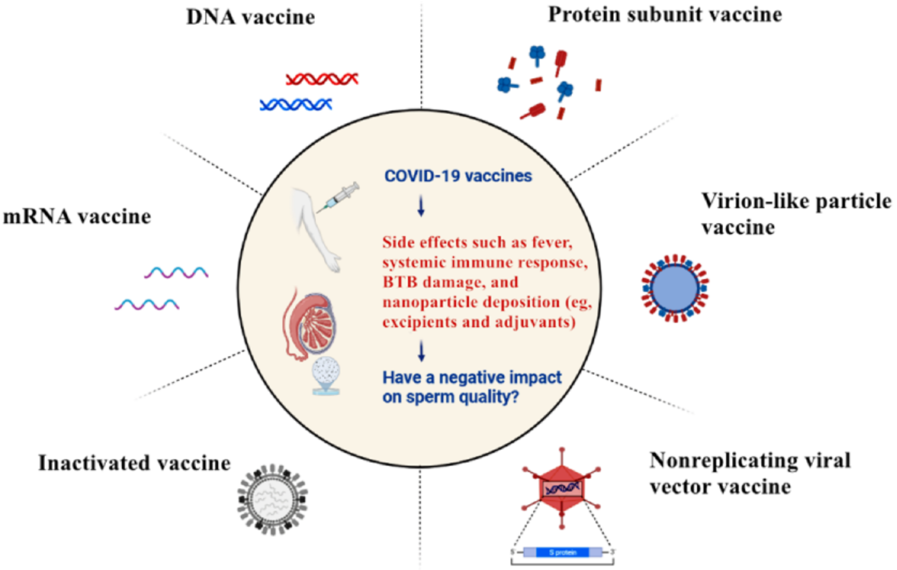
The methodological quality of the included studies was evaluated according to study design. Cohort studies were assessed using the Newcastle-Ottawa Scale, which provides a score between 0 and 9 and assesses the following quality parameters: comparability of study groups, selection of study groups, and ascertainment of outcomes [19]. Cross-sectional studies were evaluated using 11 entries from the quality evaluation criteria recommended by the Agency for Healthcare Research and Quality [20]. Each entry contained options "Yes," "No," and "Unclear." "Yes" was rated as 1 point, while "No" and "Unclear" were counted as 0. Scores of 0 to 3, 4 to 7, and 8 to 11 were considered as low-, medium- and high-quality studies, respectively.

Results

COVID-19 Vaccine Platform

Vaccines are critical and cost-effective tools to control the COVID-19 pandemic. Since the onset of the COVID-19 pandemic, research groups from various countries have made significant progress in developing vaccines in a short period using a variety of platform technologies, with >100 vaccine candidates currently undergoing preclinical development worldwide [21]. These vaccine platforms range from protein-based (eg, subunits and virus-like particles) and virus-based (eg, attenuated live and inactivated vaccines) strategies to gene-based strategies [22,23]. The different types of vaccine platforms are shown in Figure 2. In this study, we focused on several widely used vaccines that have been reported to affect semen quality.

Figure 2. Different platform types of COVID-19 vaccines and the possible mechanisms affecting semen quality. BTB: blood-testis barrier; mRNA: messenger RNA.



mRNA Vaccines

Several large biotechnology companies such as Pfizer, BioNTech, and Moderna have developed COVID-19 vaccines using advanced mRNA vaccine platforms. In the United States, the Food and Drug Administration approved emergency authorizations for the BNT162b2 (Pfizer-BioNTech) and mRNA - 1273 (Moderna) vaccines in December 2020 [24-26]. mRNA vaccines involve an innovative approach, borrowing the cell's transcriptional machinery to produce the desired set of particles. Vaccine mRNA can enter cells and can be converted into SARS-CoV-2 glycoproteins (spike proteins). The spike proteins elicit an immune response by activating helper T and B cells, eventually establishing immunity against SARS-CoV-2 [27]. These mRNA-based vaccines are noninfectious. They do not contain any live viral particles and are synthesized by in vitro transcription in the absence of microbial molecules.

Recombinant Viral-Vectored Vaccines

Recombinant viral-vectored vaccines use a bioengineered viral vector that can express and clone antigens from the target pathogen [28]. Lentiviruses, retroviruses, adenoviruses, and adeno-associated viruses are the common vectors used in this platform. Nonreplicating viral vaccines have been extensively studied and have a well-established track record for preventing infectious diseases because of their genetic malleability, safety, and ability to stimulate strong cellular immune responses without the use of adjuvants. Furthermore, a single dose of viral vector–based vaccines may provide adequate protection. Several COVID-19 vaccines based on recombinant viral vector technology including Sputnik V (Gamaleya Institute), ChAdOx1 (Oxford Astra Zeneca), and Ad26. COV2. S (Johnson & Johnson Janssen) have been approved for emergency use worldwide [29].

Inactivated Vaccines

Chemically or physically inactivated viral vaccines are among the oldest vaccine design approaches and have been used successfully against a variety of human viral infections such as hepatitis A, polio, and influenza [30]. This method involves injecting an inactivated virus into the host, inducing an immune response and promoting strong immunity against the virus. In contrast to their live attenuated counterparts, inactivated viral vaccines pose few safety concerns and deliver a wide range of native viral antigens, including surface antigens with conserved epitope conformations, which can stimulate conformation-dependent antibody responses. As completely inactive viruses do not replicate, repeated administration and adjuvants are required to stimulate the immune system and ensure that these vaccines work properly [31]. Currently, several vaccines, including CoronaVac (Sinovac) and BBIBP-CorV (Sinopharm), are being widely used in several countries, including China.

Effects of SARS-CoV-2 Vaccination on Semen Quality: Available Evidence

All available COVID-19 vaccines had acceptable efficacy and safety profiles in phase 3 clinical trials [32]. As of January 2023, >13 billion doses of the vaccine had been administered worldwide, with an excellent safety and efficacy profile. However, as reproductive toxicity has not been evaluated in clinical trials, one reason for vaccine hesitancy is its potential negative effects on fertility [33].

As shown in Table 2, we identified 24 studies that evaluated the effects of different COVID-19 vaccines on semen quality (some studies simultaneously evaluated >1 vaccine). All the studies were published between March 2020 and October 2023. The overall quality of both the cross-sectional and cohort studies is shown in Table 2.

All the studies were of reasonable quality. Of 24 studies, 9 (38%) studies were conducted in the United States and Western European countries [34-42], 5 (21%) in China [43-47], 1 (4%) in Indonesia [48], and 9 (38%) in the Middle Eastern countries [49-57]. In total, 3 (12%) studies used inactivated COVID-19 vaccines, 4 (17%) studies used viral-vectored vaccines, 8 (33%) studies used mRNA vaccines, and 3 (12%) studies included a combined analysis of multiple types of vaccines. A total of 11 (46%) studies involved patients with infertility undergoing ART, 11 (46%) involved healthy volunteers or sperm donors, and 2 (8%) involved other male populations with type 2 diabetes and nonserious chronic conditions. All studies described standard methods for sample collection and processing and followed the fifth edition of the World Health Organization laboratory manual. ’The study design, study population, vaccine type, result analysis, and adverse reaction reports of all 24 studies are listed in Table 3. These studies reported a variety of semen parameters: 9 (38%) reported total sperm count, 23 (96%) reported sperm concentration, 7 (29%) reported sperm morphology, 19 (79%) reported total sperm motility, 17 (71%) reported progressive sperm motility, and 11 (46%) reported total motile sperm count (TMSC).

Table 2. Summary of the inclusion and exclusion criteria.

Table 3. The effect of COVID-19 vaccines on semen parameters.

Source	Country	Vaccine type	Sample size; population	Age (y)	Semen test before vaccination	Semen test after vaccination, days	Outcomes	Side effects
Diaz et al [34], 2021-2022	United States	58% Moderna vaccines and 42% Pfizer vaccines	12; normal volunteers	Mean 26; range 25-30	Before the first dose of vaccine	T1[a]: 3 months after the first dose and T2[b]: at least 9 months after the second dose	No significant differences	Not reported
Gonzalez et al [35], 2020-2021	United States	21 received BNT162b2 and 24 received mRNA-1273	45; normal volunteers	Mean 28; range 25-31	Before the first dose of vaccine	75 (IQR 70-86) days after the second dose	After vaccination, the median sperm concentration, median TMSC[c], semen volume, and sperm motility were significantly increased	Not reported
Wang et al [43], 2021	China	Inactivated vaccine: CoronaVac (Sinovac)	153; patients with infertility undergoing IVF[d] treatment	Mean 33; range 29-37	Before the first dose of vaccine	Median 71 (IQR 38-102) days after the second dose	After vaccination, the amount of semen increased, the vitality decreased, and the normal morphology of sperm decreased	Not reported
Huang et al [44], 2021-2022	China	Inactivated vaccine: BBIBP-CorV (Sinopharm) or CoronaVac (Sinovac)	128; men with previous semen examination in the medical center	Mean 31; range 29-35	Before the first dose of vaccine	Median 87.5 (IQR 52.0-137.5) days after the second dose	No significant differences	Not reported
Zhu et al [45] (2020-2021)	China	Inactivated vaccine	43; semen donors from sperm bank	Mean 28.6 (SD 5.9)	Before the first dose of vaccine	T1: mean 9.1 (SD 8.1) days after the first dose and T2: mean 30.1 (SD 23.3) days after the second dose	No significant differences	A sore arm for both the first and second injections (nearly 13.9% and 4.7%, respectively). One donor reported feeling tired
Xia et al [46], 2021	China	Inactivated vaccine: BBIBP-CorV (Sinopharm) or CoronaVac (Sinovac)	Vaccine group (n=105) and control group (n=155); patients undergoing IVF treatment	Vaccine group: mean 33.9 (SD 4.7) and control group: mean 33.3 (SD 4.4)	Not tested	Unvaccinated group and vaccinated group: average 80.6 days after the first dose	No significant differences	Pain at the injection site (11.43%), followed by fatigue (6.67%), headache (1.90%), nausea (0.95%), and low-grade fever (0.95%)
Dong et al [47], 2023	China	Inactivated vaccine	519; fertile men	Mean 35.3 (SD 4.3)	Not tested	Unvaccinated group and vaccinated group: ≤90 days or >90 days after the first dose	No significant differences	The main adverse effect was injection site pain or redness; percentage of participants with fever (first dose: 0.3%, second dose: 0.6%, and booster dose: 1.9%)
Abd et al [51], 2022	Iraq	Pfizer-BioNTech (BNT162b2)	60; men undergoing IVF treatment (infertility due to clear female factors)	Mean 37.2 (SD 5.3)	Before the first dose of vaccine	Mean 101 (SD 37) days after the first dose	Both total motility and progressive motility were slightly reduced after vaccination	Not reported

Source	Country	Vaccine type	Sample size; population	Age (y)	Semen test before vaccination	Semen test after vaccination, days	Outcomes	Side effects
Al-Alami et al [50], 2021	Jordan	Pfizer (44.1%), Sinopharm (31.4%), Astra Zeneca (7.9%), and Moderna (0.3%)	354; participants who visited 1 infertility unit	Mean 35.6 (SD 7.9)	Not tested	Unvaccinated group and vaccinated group: clear data were not available	The sperm concentration was higher among vaccinated participants than unvaccinated participants	Not reported
Alenzi et al [49], 2021	Saudi Arabia	Pfizer-BioNTech (44%), Oxford and Astra Zeneca (32%), and mixed (24%)	100; normal volunteers	Mean 37.89 (SD 10.3)	Before the first dose of vaccine	1 month after the second dose	There was a significant increase in progressive sperm motility: prevaccination motility: median 55.03 (IQR 42-61.75) vs postvaccination motility: median 56.5 (IQR 42.25-63)	Not reported
Lestari et al [48], 2020-2022	Indonesia	CoronaVac (Sinovac), Astra Zeneca, and Moderna: proportion is not clear	70; patients with infertility	Vaccine group: mean 29.8 (SD 3.5) and control group: mean 29.3 (SD 4.5)	Before the first dose of vaccine	2 to 4 weeks after the second dose	The viral-vector vaccine caused a decrease in morphology as well as an increase in DFI[e]	Not reported
Karavani et al [52], 2021-2022	Israel	Pfizer-BioNTech (BNT162b2)	58; men undergoing IVF treatment	Mean 38.0 (SD 6.1)	Before the first dose of vaccine	6 to 14 months after vaccination	No significant differences	Not reported
Gat et al [53], 2021-2022	Israel	Pfizer-BioNTech (BNT162b2)	37; semen donors from sperm banks	Mean 26.1 (SD 4.2)	Before the first dose of vaccine	T1, T2, and T3[f]: included 1 to 3 semen samples per donor who provided the samples 15 to 45 days, 75 to 125 days, and >145 days after vaccination	Compared with sperm concentration at T0[g], the concentration at T2 decreased by 15%, and total motor count decreased by 22%. Subsequently, T3 evaluation showed that the damage had recovered	Not reported
Lifshitz et al [54], 2021	Israel	Pfizer-BioNTech (BNT162b2)	75; normal volunteers, 40% of whom were medical staff	Mean 38.6 (SD 4.3)	Not tested	On average, 37 days after the second dose	Compared with the WHO[h] reference range, there are only 2 borderline sperm specimens	Fatigue (34.7%), pain at the injection site (13.3%), fever (9.3%), and chills (8%)
Safrai et al [55], 2021	Israel	Pfizer-BioNTech (BNT162b2)	72; patients undergoing IVF treatment	Mean 35.7; range 33-43	Before the first dose of vaccine	Median 71.0 (IQR 40.5-104.8) days after the first dose	No significant differences	Not reported
Barda et al [56], 2020-2021	Israel	Pfizer-BioNTech (BNT162b2)	33; semen donors from sperm banks	27	Before the first dose of vaccine	The average sperm parameters of multiple samples were used for comparison. For each donor, at least 1 sample was received ≥72 days after the second dose	Total sperm count and TMSC increased after the second dose of vaccine	Pain at injection site: 79% (T1) and 88% (T2) of participants, lethargy: 9% (T1) and 48% (T2) of participants, and fever: 1 case (T1)

Source	Country	Vaccine type	Sample size; population	Age (y)	Semen test before vaccination	Semen test after vaccination, days	Outcomes	Side effects
Orvieto et al [57], 2021	Israel	Pfizer-BioNTech (BNT162b2)	36; patients with infertility undergoing IVF treatment	Mean 40.1 (SD 4.8)	Before the first dose of vaccine	Mean 33.3 (SD 14.9) days after the second dose	No significant differences	Not reported
Olana et al [36], 2021	Italy	Pfizer-BioNTech (BNT162b2)	47; normal volunteers	Mean 29.3 (SD 6.0)	Before the first dose of vaccine	70 days from the second dose	No significant differences	Not reported
Reschini et al [37], 2022	Italy	Pfizer-BioNTech (69%), Moderna (19%), Oxford and Astra Zeneca (9%), Johnson & Johnson's Janssen (1%), and mixed (2%)	106; fertile men undergoing ART[i] programs	Mean 39; range 36-42	Before the first dose of vaccine	Median 75 (IQR 38-112) days after the first dose	No significant differences	45% of the patients reported mild, self-resolving adverse events after the vaccine, including pain at injection site, fever, fatigue, nausea, muscle pain, and diarrhea
Massarotti et al [38], 2021	Italy	76% received mRNA vaccines, 20% viral-vector vaccines, 2% a mixed formulation, and 2% were not clear about the type	101; men undergoing fertility treatments	Mean 37.5 (SD 5.5)	Before the first dose of vaccine	Mean 2.3 (SD 1.5) months after the second dose	After vaccination, the median volume of the sample decreased from 3.0 to 2.6 ml. Sperm concentration, progressive motility, and TMSC increased	Not reported
Chillon et al [42], 2021	Germany	Pfizer-BioNTech (not reported)	86; normal volunteers	Vaccine group: mean 38 (SD 5.5) and control group: mean 36 (SD 6.5)	Not tested	Unvaccinated group and vaccinated group: clear data were not available	SARS-CoV-2 vaccination parameters and vaccine-induced antibodies were not associated with sperm parameters	Not reported
Drapkina et al [39], 2021	Russia	Viral-vector vaccine: Sputnik V	45; normal volunteers	Mean 36; range 30-44	Before the first dose of vaccine	90 days after the first dose	No significant differences	Not reported
Esaulenko et al [40], 2021	Russia	Viral-vector vaccine: Sputnik V	30; patients with type 2 diabetes	Mean 46; range 42-48	Before the first dose of vaccine	90 days after the first dose	No significant differences	19 (63%) patients demonstrated a temperature rise and 26 (87%) patients reported tenderness at injections site

Source	Country	Vaccine type	Sample size; population	Age (y)	Semen test before vaccination	Semen test after vaccination, days	Outcomes	Side effects
Elagin et al [41], 2021-2022	Russia	Viral-vector vaccine: (Sputnik V)	44; normal volunteers	Mean 22.4 (SD 4.7)	Before the first dose of vaccine	10-12 days after the first dose and 32-36 days after the second dose	No significant differences	A total of 5 and 7 participants exhibited fever with headache after the first and second vaccine doses, respectively

Discussion

Principal Findings

Safrai et al [55] published the first study on the impact of the COVID-19 vaccine on sperm parameters, demonstrating that the BNT162b2 mRNA vaccine (Pfizer or BioNTech) was not associated with a decrease in sperm quality. The study enrolled 72 individuals (57 of whom had normal sperm parameters). Sperm parameters in men with normal and abnormal sperm analysis did not change significantly after vaccination. The authors noted that after COVID-19 vaccination, none of the sperm parameters changed significantly [55]. In February and March 2021, Lifshitz et al [54] evaluated the effects of the Pfizer COVID-19 vaccine in 75 men with proven fertility [54]. The primary outcome was the percentage of abnormal sperm parameters in men 1 to 2 months after the second injection of the COVID-19 vaccine, including abnormal sperm morphology, reduced percentage of motile spermatozoa, and oligozoospermia rates. The results showed that the semen parameters after COVID-19 vaccination were mostly within the normal reference ranges established by the World Health Organization and did not indicate any causative negative effects of the COVID-19 vaccination. However, the participants in this study were a relatively homogeneous group, consisting of fertile male individuals from high socioeconomic groups. Moreover, participants were only followed up for 1 to 2 months after receiving the second dose of vaccine; therefore, long-term results have not yet been reported. In contrast, in a retrospective, longitudinal, multicenter study recently published in *Andrology*, the effects of the COVID-19 BNT162b2 vaccine on semen parameters were evaluated in 37 semen donors at different time points, before and after immunization [53]. Compared with the prevaccination levels, there was a selective decrease in sperm concentration and TMSC 75 to 125 days after vaccination (P=.01 and P=.007, respectively). Normal levels of these parameters were restored 145 days after vaccination, and no changes in sperm volume or motility were observed. Similarly, Abd et al [51] observed that the total motility and progressive sperm activity decreased significantly after BNT162b2 injection. Notably, considering that all semen parameters were still within the normal range, the investigator considered that the vaccine had no deleterious effects on semen parameters [51]. An additional prospective cohort study evaluated the effects of an inactivated vaccine (CoronaVac) on semen quality and in vitro fertilization (IVF) outcomes. A total of 542 patients undergoing IVF were divided into the unexposed group (nonvaccination) and the exposed group (vaccination), and it was found that the semen parameters seemed to fluctuate in the vaccinated men, including increased semen volume, decreased normal forms of sperm, and lower motility, whereas the motile sperm counts were similar. In addition, all semen parameters were above the lower reference limit. Therefore, researchers jointly believed that inactivated vaccines may not negatively affect sperm indicators or embryo development potential in men [43]. However, although this was a cohort study with a relatively large sample size, the male participants were all infertile, limiting the generalizability of the findings.

Surprisingly, significant improvements in some sperm parameters were noted after the COVID-19 vaccination. Massarotti et al [38] conducted a prospective study in which 101 vaccinated men (who were undergoing fertility treatments) had semen testing before vaccination and 2.3 (SD 1.5) months after the second dose of vaccine (76% of the participants were vaccinated with mRNA vaccine and 20% with viral-vectored vaccine). The investigators found a significant reduction in the median volume of the sample (from 3.0 to 2.6 mL), whereas sperm concentration, progressive motility, and TMSC increased (from 25.0 to 43.0 million/mL, from 50% to 56%, and from 34.8 to 54.6 million, respectively) [38]. In another prospective cohort study published in JAMA, Gonzalez et al [35] evaluated the effect of mRNA vaccines in 45 healthy volunteers (21 Pfizer and 24 Moderna) and found no significant decrease in sperm parameters. Semen samples were collected before the first dose and a median of 75 days after the second dose [35]. The baseline median sperm concentration was 26 million/mL, and the TMSC was 36 million. After the second vaccine dose, the median sperm concentration increased to 30 million/mL, and the median TMSC concentration increased to 44 million. Sperm motility and semen volume also increased significantly. The authors suggested that the increase in sperm parameters might be explained by known individual variations in sperm and increased abstinence time before postvaccine sample collection. Similarly, Barda et al [56] evaluated the effect of 2 doses of the vaccine (BNT162b2) on the sperm parameters of 33 sperm donors who donated sperm on multiple occasions. Compared with the percentage of motile sperm in the sample before vaccination, the percentage after the second dose of the vaccine did not change. However, the total sperm and motile counts increased unexpectedly.[56]. One possible explanation is that some participants changed their lifestyle habits or were more health conscious than the retrospectively enrolled infertile population, which acted as a confounding factor and positively affected sperm quality [58].

Two previous meta-analyses examined the effect of COVID-19 vaccination on sperm parameters based on published data [59,60]. Both studies suggested that the vaccination had no discernible negative impact on sperm quality. However, the 2 meta-analyses had nonnegligible limitations: the included studies used different types of vaccines, administered different doses of vaccines, had mostly unknown time intervals from vaccination to sperm analysis, had large differences in the participating populations, and had a small sample size for each group after the subgroup analysis. In other words, the methodological quality of meta-analyses assessing the impact of COVID-19 vaccination on semen parameters is currently unsatisfactory. As new controlled trials and prospective cohort studies with larger sample sizes emerge, the possibility of a negative effect of the COVID-19 vaccine on sperm quality must be further clarified.

Commonly reported side effects of the COVID-19 vaccine in premarketing clinical trials and postmarketing surveillance programs include systemic reactions (eg, fatigue, headache, and muscle pain) as well as injection site reactions (eg, pain, redness, and swelling), with rare serious adverse events [61,62]. Furthermore, fever is considered one of the most common side effects of vaccination [63]. According to the literature, fever can temporarily impair sperm parameters, causing a decline in sperm count, quality, and DNA integrity [64]. It should be noted that a range of studies have demonstrated fever to be a common adverse effect following multiple vaccine injections including mRNA vaccines (eg, BNT162b2), inactivated vaccines (eg, CoronaVac), and viral-vector vaccines (eg, Ad26. Sputnik V). Therefore, male patients who experience fever after receiving the COVID-19 vaccine may experience fluctuations in their sperm parameters. However, this effect is similar to that caused by fever due to other registered vaccines [41,47,54].

According to a study by Gat et al [53], the systemic immune response following BNT162b2 immunization may contribute to the deterioration of selective temporary sperm concentration and TMSC; however, the long-term prognosis remains favorable [53]. It is important to note that similar studies did not have data on the detailed health and immune status of the participants before vaccination. Therefore, their conclusions should be interpreted with caution. Carto et al [65] examined data from a large US electronic health record database on the risk of orchitis, epididymitis, or both in men vaccinated against COVID-19 [65]. They discovered that the serum levels of antisperm antibodies and antiphospholipid antibodies against cardiolipin, phosphatidylserine, annexin V, and 2-glycoprotein-1 did not differ significantly before and after vaccination. Furthermore, the levels of these autoimmune antibodies did not correlate with the sperm parameters. Their findings even suggested that COVID-19 vaccination was linked to a lower risk of orchitis, epididymitis, or both (odds ratio 0.568, 95% CI 0.497-0.649). More directly, Chillon et al [42] examined antibody concentrations in the seminal plasma of 86 men vaccinated with the new Crown pneumonia vaccine and showed that the antibody levels in seminal plasma after COVID-19 vaccination were correlated with serum antibody titers, but not with sperm parameters.

In addition, BNT162b2 and mRNA-1273 are lipid nanoparticle-formulated vaccines against SARS-CoV-2. These excipients, adjuvants, or both may act as vehicles for therapeutic content delivery while also increasing the intensity of the immune response [22]. Several studies have shown that these nanoparticles can cross biological barriers and can be deposited in reproductive organs, such as the testes, impairing sperm quality by increasing inflammation, damaging DNA structure, decreasing mitochondrial function, and inducing apoptosis [66]. Therefore, some researchers are concerned that vaccine excipients, adjuvants, or both may induce testicular damage. However, Olana et al [36] found no significant differences in the levels of reactive oxygen metabolites, electrolytes, or interleukin-6 in the seminal plasma of participants before and after the BNT162b2 vaccination [36]. Indeed, the current basic research evidence and clinical data supporting the idea that a systemic immune response after COVID-19 vaccination can lead to impaired sperm quality are insufficient.

Although semen analysis serves as the foundation for evaluating male fertility, it should be noted that it is an imperfect predictor of fertility potential. Further persuasive evidence comes from ART and artificial insemination by partner outcomes in couples after receiving the COVID-19 vaccine [57,67]. In a prospective cohort study involving 735 infertile couples, Dong et al [47] demonstrated that the quality of the embryos and the pregnancy rate in IVF treatment were unaffected by the couples' vaccination status or vaccine type. Similarly, no differences in fertility or pregnancy outcomes were observed in the study by Orvieto et al [57]. In another multicenter prospective study of 4185 couples, Wang et al [68] found no association between COVID-19 vaccination status (eg, inactivated, adenoviral, and recombinant vaccines) and pregnancy rates in artificial insemination by partner treatment [68].

More directly, using data from an internet-based preconception cohort study, Wesselink et al [69] investigated the relationship between COVID-19 vaccination and SARS-CoV-2 infection with fertility in couples attempting spontaneous pregnancy [69]. Their results suggested that male SARS-CoV-2 infection may be associated with a short-term decline in fertility, whereas COVID-19 vaccination had no effect on fertility in either partner.

Limitations

It is important to acknowledge that this review has a few limitations. First, data from most relevant studies were observational and lacked complete follow-up and analysis of missing data. All the included studies assessed vaccination based on self-reports or with no descriptions. Although previous influenza vaccination validation studies found 97% agreement between self-report and medical records, the conclusion may not be directly generalizable to COVID-19 vaccination, and misclassification risk may still exist [70]. Second, there is a need for more robust studies, with more precise eligibility criteria, appropriate sample sizes, and a more representative population, not focusing only on specific groups, such as those undergoing IVF. Third, despite the transient alterations in sperm parameters found in some studies, these findings were often not well supported by histological or pathophysiological data. Furthermore, the potential implications for sperm biology, including mitochondrial function, and the possible effects on the regulatory systems of epigenetic changes have received little attention.

However, given the widespread and ongoing spread of COVID-19, the available data on decreased semen quality in survivors of COVID-19 outweigh concerns about the potential negative effects of the COVID-19 vaccine on sperm parameters [71,72]. From the perspective of reproduction, vaccination against COVID-19 is preferable for severe adverse symptoms of the SARS-CoV-2 infection. Large-scale prospective cohort studies and randomized controlled trials of existing COVID-19 vaccines and newly developed vaccines are needed to further confirm this review's conclusion.

Conclusions

In summary, the data in this review show that the COVID-19 vaccine is safe for male reproductive health. Serious side effects of the COVID-19 vaccine are extremely rare, and men experience few problems with sperm parameters or reproductive potential after vaccination. Considering that SARS-CoV-2 infection itself may be associated with impaired fertility, vaccination could serve as a potential tool to preserve male fertility by preventing COVID-19. Therefore, vaccination should be clearly recommended for all men wishing to have children unless there are additional contraindications.

Abstract

Background: The 2022 multicountry mpox outbreak positioned the condition as a public health emergency of international concern. By May 2023, Brazil ranked second globally in the cumulative number of mpox cases and deaths. The higher incidence of mpox among gay and other men who have sex with men in the current mpox outbreak deepens the stigma and discrimination against sexual and gender minorities (SGM). This might worsen the structural barriers impacting access to health services, which ultimately leads to undertesting and underreporting of cases. There are no data available on mpox knowledge and stigma in Latin America.

Objective: We aimed to evaluate mpox knowledge, stigma, and willingness to vaccinate for mpox among SGM, and to describe sociodemographic and behavioral characteristics according to self-reported mpox diagnosis.

Methods: A cross-sectional, internet-based survey was conducted in a convenience sample of adults (aged >18 years) living in Brazil recruited through advertisements on dating apps, social media, referral institutions for infectious diseases websites, and mass media (October-November 2022). We compared participants' characteristics according to self-reported mpox diagnosis using chi-square test or Fisher exact test for qualitative variables and Kruskal-Wallis test for quantitative variables.

Results: We enrolled 6236 participants: 5685 (91.2%) were cisgender men; 6032 (96.7%) were gay, bisexual, or pansexual; 3877 (62.2%) were White; 4902 (78.7%) had tertiary education; and 4070 (65.2%) reported low or middle income. Most participants (n=5258, 84.4%) agreed or strongly agreed that "LGBTQIA+ individuals are being discriminated and stigmatized due to mpox." Mpox awareness was 96.9% (n=6044), and 5008 (95.1%) were willing to get vaccinated for mpox. Overall, 324 (5.2%) reported an mpox diagnosis. Among these, 318 (98.1%) reported lesions, 178 (56%) local pain, and 316 (99.4%) sought health care. Among participants not reporting a diagnosis, 288 (4.9%) had a suspicious lesion, but only 158 (54.9%) of these had sought health care. Compared to participants with no diagnosis, those reporting an mpox diagnosis were younger ($P<.001$), reported more sex partners ($P<.001$), and changes in sexual behavior after mpox onset ($P=.002$). Moreover, participants diagnosed with mpox reported more frequently being tested for HIV in the prior 3 months ($P<.001$), living with HIV ($P<.001$), currently using HIV pre-exposure prophylaxis ($P<.001$), and previous sexually transmitted infection diagnosis ($P<.001$).

Conclusions: Our results point to high mpox knowledge and willingness to vaccinate among SGM in Brazil. Participants self-reporting mpox diagnosis more frequently reported to be living with HIV, STI diagnosis, and current pre-exposure prophylaxis use, highlighting the importance of an mpox assessment that includes comprehensive sexual health screenings. Efforts to decrease stigma related to mpox among SGM are necessary to avoid mpox underdiagnosis.

(JMIR Public Health Surveill 2023;9:e46489) doi:10.2196/46489

Introduction

The 2022 multicountry mpox outbreak positioned the condition as a public health emergency of international concern, as declared by the World Health Organization on July 23, 2022 [1]. Previously, mpox had been barely identified outside specific African countries with a known endemic epidemiology [2]. The first cases in nonendemic countries were announced in the United Kingdom, in May 2022, with over 87,000 confirmed mpox cases worldwide by May 23, 2023 [3,4]. The outbreak has disproportionally burdened vulnerable groups, especially gay, bisexual, and other cisgender men who have sex with men (MSM) [2,5]. Brazil ranked second globally in the cumulative number of mpox cases and deaths, with 10,941 confirmed diagnoses and 16 deaths as of May 23, 2023 [4]. Confirmed mpox cases in Brazil mostly occurred among cisgender MSM, with a potential role of sexual contact in the transmission dynamics [6-8].

Unfortunately, the higher incidence of mpox among vulnerable groups in the current mpox outbreak deepens the stigma and discrimination against MSM and other sexual and gender minorities (SGM) and might worsen the structural barriers impacting access to health services, which ultimately leads to undertesting and underreporting of cases [9-12]. Furthermore, the shame and fear related to societal judgment about individuals’ sexuality combined with the need for prolonged self-isolation have a significant impact on a person’s professional and daily life, thus undermining the mental health of the most vulnerable [13]. Moreover, this phenomenon might not be restricted to the current outbreak. Mpox-related stigma against SGM could be underestimated in countries with endemic mpox, as many of these still criminalize same-sex relationships, and data on cases among MSM might be inaccurate [14].

Efforts are in course to mitigate the impact of an mpox outbreak on the most vulnerable groups, and a stigma-free message that embraces sexual and gender-diverse people is key to establishing strong links connecting health services to the community. For this purpose, it is essential to analyze the knowledge among vulnerable populations about mpox so that communication and health actions can be tailored accordingly. A cross-sectional survey among 1932 respondents in the United Kingdom showed that, despite a vaccine acceptability rate as high as 96%, only 29% would seek a health service in case of mpox symptoms [15]. In the United States, 50% of MSM who responded to a web-based survey reported a 50% reduction in the number of sex partners, 1-time sexual encounters, group sex, and sex with a partner they met on a dating app or at a sex venue after the onset of the current mpox outbreak, although there was no change in condom use [16].

There are no data available on mpox knowledge in Latin America. This is the first survey in Brazil aiming to evaluate mpox knowledge, stigma, and willingness to vaccinate for mpox among SGM, and to describe sociodemographic and behavioral characteristics of study participants according to self-reported mpox diagnosis.

Methods

Study Design

This was a cross-sectional internet-based survey conducted in a convenience sample of adults (aged ≥18 years) living in Brazil, who were recruited through advertisements on dating apps (Grindr and Scruff), social media (Facebook and Instagram), referral institutions for infectious diseases websites or social media (Instituto Nacional de Infectologia Evandro Chagas and Fundação Oswaldo Cruz), radio, and mass media from October to November 2022. Banners in Scruff and Grindr and boosted posts on Facebook and Instagram, as in prior work [17,18], were used to recruit individuals to complete a voluntary open survey in Portuguese, with all items including a nonresponse option. The survey was programmed on Alchemer. Respondents were able to change or review answers and did not receive any compensation. Usability and technical functionality in different personal computers and mobile phone operating systems were confirmed before survey administration. We excluded respondents who did not reach the end of the survey and those who incorrectly answered any of the 5 attention questions [19]. Only 1 response per IP address was allowed.

Variables

Sociodemographic

Recruitment was categorized in Grindr, Scruff, Instagram, Facebook, and others (eg, WhatsApp and other websites). Age at the time of the survey was categorized in 4 intervals: 18-24; 25-30, 31-40, and >40 years. Gender categories were cisgender man, transgender man, cisgender woman, transgender woman, nonbinary or gender fluid, queer, and not declared. Sexual orientation categories were lesbian, gay, bisexual, pansexual, heterosexual, or other (eg, asexual and demisexual). Race was categorized as Asian (Japanese, Chinese, Korean, and among others), Black, Indigenous, Pardo (mixed race), White, or not declared. For schooling, the highest degree attained is considered (primary, secondary, or tertiary). Income reporting was based on the monthly income of the household in Brazilian minimum wages (MWs): low (up to 2 MW), middle (>2-6 MW), and high (>6 MW), in accordance with previous studies [18,20]. In 2022, MW per month was BRL 1212 (US $230). Participants were also asked whether they received any social support (eg, conditional cash transfers such as Auxílio Brasil) and the number of persons living in the same house (median, IQR). Brazilian regions were defined according to the Brazilian administrative division: North (7 states), Northeast (9 states), Central-west (3 states and Federal District), South (3 states), and Southeast (4 states). The state region was stratified into capital, metropolitan area, and other cities.

Mpox Awareness, Knowledge, Symptoms, and Contact

We defined mpox awareness as a positive answer to the question: “Have you ever heard about mpox?” Knowledge of mpox lesions was assessed with the question: “Do you know, or have you seen pictures of suspected mpox wounds/lesions?” Participants answered where they obtained information about mpox (eg, television, radio, Grindr, Hornet, Scruff, Google, other) and if they would follow social distancing if diagnosed with mpox (yes or no).

The survey also included questions about the participant’s health as it relates to any suspicious lesions related to mpox since the onset of mpox outbreak in Brazil (June 2022) (yes or no), location of the potential lesions, number of legions per location, if attended health facility to investigate lesions (yes or no), if lesions were painful, and graduation of pain from 0 (no pain) to 100 (worst pain). Participants were also asked if they had symptoms possibly related to mpox (predetermined list) since June 2022, and in case of any symptoms, if they attended a health facility to investigate them (yes or no).

Participants were asked about contact (sexual or nonsexual) with persons with suspected or confirmed mpox diagnosis, if traveled within Brazil or abroad since June 2022. Finally, for those self-reporting an mpox diagnosis, we inquired if they adhered to social distancing after receiving the diagnosis.

Sexual Behavior

Participants answered questions about their sexual behavior since June 2022, including gender of sex partners, number of sex partners (stratified in 0, 1, 2-5, 6-10, and >10), steady partners (yes or no and if only 1 steady partner), sex practices (insertive or receptive vaginal sex, anal sex, and oral sex), condomless sex for these sex practices, transactional sex, and frequency in sex venues (yes or no). Participants were also questioned about the changes in sexual behavior due to the mpox outbreak (“Have you changed your sexual behavior since mpox cases started in Brazil [June 2022]?”). If yes, they were asked about risk reduction measures adopted from a predetermined list, including the reduced number of sex partners and avoided sex parties.

Substance Use and Chemsex

Participants answered questions on substance use since June 2022. Binge drinking was evaluated with the question “Since June 2022, did you drink 5 or more drinks in a couple of hours?” (yes or no) [21]. Participants answered questions about illicit drug use from a predetermined list and an open field option for other substances, later dichotomized into yes or no. Individuals who reported binge drinking or any illicit drug use were inquired about use before or during sex (“binge drinking before or during sex” and “chemsex”) [21,22].

HIV Testing, Treatment, and Prevention, and Other Sexually Transmitted Infections

HIV self-reported status was derived from the question “Have you ever had an HIV test?” with potential responses positive, negative, or never (“unknown”). Participants were asked when the last HIV test was (≤3, >3-6, and >6 months). People living with HIV answered questions about the time since the diagnosis (≤6, >6-12, and >12 months), about antiretroviral therapy (ART) use, ART adherence using a validated scale [23], and if they currently had an undetectable HIV viral load (yes or no). Participants self-reporting negative or unknown status were asked about HIV pre-exposure prophylaxis (PrEP) use (never, current, or past) and adherence (rated from 0 [missed all doses in past 30 days] to 100 [no missing dose]). We dichotomized complete PrEP adherence (rating=100) into yes or no.

Participants were asked about syphilis, gonorrhea, and chlamydia diagnoses since June 2022 (yes or no), hepatitis B vaccination (no, 1-2 doses, 3 doses, and did not remember), and ever tested positive for hepatitis C (yes or no).

Adherence to Vaccination Campaigns, and Willingness to Use Vaccines and Treatment for Mpox

Participants responded to questions regarding participation in vaccination campaigns (always, sometimes, or never) and whether they had been vaccinated for COVID-19 and mpox. We used a 4-point Likert scale to access the willingness to use an mpox preventive vaccine, which was defined as responding highly likely to the question: “Would you vaccinate against mpox?” following other studies evaluating the willingness to use biomedical technologies [24,25]. We also accessed willingness to participate in research studies to evaluate: (1) mpox preventive vaccine; (2) mpox preventive drug; and (3) mpox therapeutic drug.

Internalized Lesbian, Gay, Bisexual, Transgender, Queer, Intersex, Asexual, Plus Phobia, Stigma, and Discrimination

The Reactions to Homosexuality Scale (RHS), originally developed to measure internalized homonegativity among MSM, includes 7 items measured on a 7-point Likert scale from strongly disagree to strongly agree, with total scores ranging from 0 to 42 [18,26]. For this analysis, we adapted the scale to allow completion by all SGM, as described in Table S1 in Multimedia Appendix 1. Higher RHS scores indicate higher internalized lesbian, gay, bisexual, transgender, queer, intersex, asexual, plus (LGBTQIA+) phobia. We also asked participants to rate mpox stigma toward LGBTQIA+ people on a 7-point Likert scale from strongly disagree to strongly agree: “LGBTQIA+ individuals are being discriminated and stigmatized due to mpox.”

Main Outcome

Our main outcome was self-reported mpox diagnosis, defined as a positive answer to the question: "Have you been diagnosed with mpox by a health professional?"

Spatial Analysis

We performed an exploratory analysis based on the kernel estimator, with adaptive radius and Gaussian function, to obtain an overview of the spatial distribution of the points corresponding to individuals with confirmed and nonconfirmed mpox diagnosis and identifying potential outbreaks of occurrence. The zip codes were considered for georeferencing.

Statistical Analysis

Continuous variables were described by their median and IQR and mean and SD. We compared sociodemographic, behavior, and clinical characteristics according to self-reported mpox diagnosis (yes vs no) using a chi-square test or Fisher exact test for qualitative variables and a Kruskal-Wallis test for quantitative variables. All analyses were performed using R software (version 4.2.2; R Foundation for Statistical Computing).

Ethics Approval

This study received approval from the institutional review board at the Instituto Nacional de Infectologia Evandro Chagas, Fundação Oswaldo Cruz (#CAAE 61290422.0.0000.5262). All study participants provided electronic informed consent before survey initiation.

Results

A total of 9798 individuals accessed the survey and 1219 (12.4%) did not meet the inclusion criteria (Figure 1). Of the 8579 individuals who initiated the survey, 6236 (72.7%) reached the final survey page and were included in this study. Recruitment mostly occurred on Instagram (n=2331, 37.4%), followed by Scruff (n=1561, 25.0%), Grindr (n=1246, 20.0%), and Facebook (n=692, 11.1%) (Table 1). Median age was 36 (IQR 31-44) years; 91.2% (n=5685) were cisgender men, 83.3% (n=5197) gay, 62.2% (n=3877) White, 78.7% (n=4902) had completed tertiary education, 41.2% (n=2571) reported middle income, 68.3% (n=4259) were from the Southeast region of Brazil, and 67.6% (n=4217) were living in a state capital city.

[a] Female gender construction, which is identified in social, family, cultural, and interpersonal life through this identity.

Most participants had heard of mpox (n=6044, 96.9%), reported knowing how mpox lesions appear (n=5298, 85.0%) (Table 2), and that they would follow social distancing if diagnosed with mpox (n=6051, 97.0%). Information about mpox was mostly obtained on the internet (n=4793, 76.9%) and television (n=4519, 72.5%) (Table S2 in Multimedia Appendix 1).

Overall, 324 (5.6%) individuals reported an mpox diagnosis; 44.4% (n=144) of mpox cases were from São Paulo state, followed by 15.7% (n=51) in Rio de Janeiro (Table S3 in Multimedia Appendix 1). Hotspots of participants reporting an mpox diagnosis were concentrated in the metropolitan areas of São Paulo and Rio de Janeiro (Figure 2). A total of 304 (93.8%) respondents reported social distancing after mpox diagnosis. Compared to those with no diagnosis, participants reporting an mpox diagnosis were younger (age median 34, IQR 30-39.2 vs median 37, IQR 31-44 years; *P*<.001), more frequently cisgender men (314/324, 96.2% vs 5371/5912, 90.8%; *P*=.02), gay (292/324, 90.1% vs 4905/5912, 83%; *P*<.001), Black (52/324, 16% vs 611/5912, 10.3%; *P*=.008), and living in a state capital city (239/324, 73.8% vs 3978/5912, 67.3%; *P*=.003) (Table 1).

Among participants reporting an mpox diagnosis (n=324), 318 (98.1%) reported lesions, 178 (56%) had local pain, and 316 (99.4%) sought health facilities for diagnosis. The most common lesion sites were genital region (n=155, 48.7%), face (n=128, 40.3%), and anal region (n=118, 37.1%) (Table S4 in Multimedia Appendix 1). Sites with the highest mean numbers of lesions were anal region (4.4, SD 4.3), back (3.7, SD 4.4), genital region (3.2, SD 4.3), and arms (3.2, SD 3.1) (Table S5 in Multimedia Appendix 1). Mpox symptoms were reported by 95.4% (n=309/324) of the participants who reported mpox diagnosis. Among them, 96.8% (n=299/309) attended medical facilities to investigate these symptoms (Table 2), of which the most frequent were headache (n=211, 65.1%) and asthenia (n=205, 63.3%) (Table S6 in Multimedia Appendix 1).

Among participants with no mpox diagnosis, 4974 (84.1%) were aware of mpox lesions, 288 (4.9%) had a suspicious mpox lesion, and 4009 (67.8%) reported potential mpox symptoms. Among individuals with no diagnosis, only 54.9% (n=158/288) and 34.9% (n=1399/4009) attended a health facility to investigate a lesion or any symptoms, respectively (Table 2).

Participants with an mpox diagnosis compared to those with no diagnosis more frequently reported sex partners with suspicious or confirmed mpox (112/324, 34.6% vs 206/5912, 3.5%; *P*<.001), sex with a cisgender man (320/324, 98.8% vs 5132/5912, 86.8%; *P*<.001), more sexual partners (median 10, IQR 5-20 vs median 4, IQR 1-10; *P*<.001), and insertive or receptive anal or oral sex, including condomless sex (*P*<.001 for all) (Table 3). Binge drinking before or during sex (115/324, 35.5% vs 1565/5912, 26.5%; *P*<.001), chemsex (118/324, 36.4% vs 1429/5912, 24.2%; *P*<.001), and any illicit drug use (160/324, 49.4% vs 2354/5912, 39.8%; *P*<.001) were more frequent among those self-reporting an mpox diagnosis. Changes in sexual behavior after the outbreak onset were reported frequently regardless of mpox diagnosis but were higher among participants with a diagnosis (186/324, 57.4% vs 2878/5912, 48.7%; *P*=.002) (Table 4).

Table 2. Mpox awareness, knowledge, symptoms, and possible contact according to self-reported mpox diagnosis.

Characteristics	No (n=5912)	Yes (n=324)	Total (N=6236)	*P* value
Mpox awareness, n (%)	5724 (96.8)	320 (98.8)	6044 (96.9)	.048

Asked partners about mpox symptoms	749 (12.7)	50 (15.4)	799 (12.8)	.15
Anal sex only with condoms	742 (12.6)	50 (15.4)	792 (12.7)	.13
Sex abstinence or avoided any type of sex	644 (10.9)	36 (11.1)	680 (10.9)	.90
Avoided kissing	409 (6.9)	26 (8.0)	435 (7.0)	.45
Web-based sex	382 (6.5)	12 (3.7)	394 (6.3)	.047
Washed bed linen and other (eg, towels) after sex	284 (4.8)	26 (8.0)	310 (5.0)	.009
Self-masturbation with partner in the space without touching him or her or they	90 (1.5)	2 (0.6)	92 (1.5)	.19
Wear face masks during sex	79 (1.3)	5 (1.5)	84 (1.3)	.75
Dated people only using clothing	80 (1.4)	2 (0.6)	82 (1.3)	.26
Oral sex with condoms only	63 (1.1)	2 (0.6)	65 (1.0)	.44
Used gloves for anal fisting or fingering	20 (0.3)	1 (0.3)	21 (0.3)	.93

HIV prevalence (122/324, 37.7% vs 1353/5912, 22.9%; *P*<.001), hepatitis C (ever tested positive; 23/324, 7.1% vs 238/5912, 4%; *P*=.007), and any diagnoses of sexually transmitted infections (STIs) (81/324, 25% vs 628/5912, 10.6%; *P*<.001) differed by mpox diagnosis report (Table 5). Among HIV-negative or unknown individuals, HIV testing in the prior 3 months (234/316, 74.1% vs 2335/5545, 42.1%; *P*<.001) and current PrEP use (96/201, 47.8% vs 1106/4537, 24.4%; *P*<.001) were higher among those reporting an mpox diagnosis (Table 5).

Most participants were willing to receive an mpox vaccine (n=5008, 95.1%). When asked about mpox research studies, 74.1% (n=4621) responded that they would participate in prevention vaccine trials, 69.2% (n=4288) in prevention drug trials, and 68.7% (n=4263) in therapeutic trials. In addition, 92% (n=5735) reported frequent participation in vaccination campaigns, with 95.8% (n=4734/4946) coverage of at least 3 doses of the COVID-19 vaccine. Nevertheless, only 47 (0.7%) participants received an mpox vaccine, which is not available in Brazil (Table 2).

Overall, 5258 (84.4%) participants agreed or strongly agreed with the statement: “LGBTQIA+ individuals are being discriminated and stigmatized due to mpox.” Median score of internalized LGBTQIA+ phobia measured by the adapted RHS scale was lower among participants reporting mpox compared to those with no diagnosis (6, IQR 2-11 vs 7, IQR 2-12; *P*<.001).

Table 5. HIV testing, treatment, and prevention, and other sexually transmitted infections according to self-reported mpox diagnosis.

Characteristics	No (n=5912), n (%)	Yes (n=324), n (%)	Total (N=6236), n (%)	*P* value

[a] ART: antiretroviral therapy.

[b] PrEP: pre-exposure prophylaxis.

[c] STI: sexually transmitted infection.

Discussion

Principal Findings

This analysis describes the results of a large web-based survey in Brazil conducted during the mpox surge in 2022. Respondents were mostly MSM from metropolitan regions, with a 5.6% prevalence of self-reported mpox diagnosis, which is slightly higher than Brazilian surveillance numbers. This indicates that our survey may have reached populations most affected by mpox by the current outbreak [2,5,6]. There were no reported cases among transgender women, which highlights the low mpox burden in this group, in agreement with Brazilian official data available, disaggregated by gender [8,27]. Our findings point to a high awareness of mpox among SGM, with the internet and television as the most frequent information sources. This underscores the importance of adequate science communication through traditional and innovative means of communication and the need to stop fake news that contributes to misleading information as well as reinforces stigma [28]. Most participants agreed or strongly agreed that LGBTQIA+ individuals are being discriminated against and stigmatized due to mpox. To our knowledge, this is the first study to describe mpox awareness, willingness to vaccinate for mpox, and self-reported prevalence of mpox in Latin America.

Willingness to Use Mpox Vaccine

Willingness to use mpox vaccine and to follow social isolation if required were high, suggesting an adequate understanding of the importance of public health measures to successfully mitigate the impact of the mpox outbreak among SGM. While countries in North America and Western Europe initiated mpox vaccination of the most affected population (MSM) by mid-2022, mpox vaccination in Brazil only started in March 2023. Due to the low number of vaccine units available, vaccination in the country is restricted to very few groups such as people living with HIV, health professionals working with *Orthopoxvirus* (pre-exposure vaccination), and those who had contact with fluids and secretions of persons with suspected mpox (postexposure vaccination) [29].

Participants' Characteristics According to Self-Reported Mpox Diagnosis

In our study, individuals with self-reported mpox diagnosis more frequently referred to mucocutaneous, genital or anal lesions, coinfection with hepatitis C, and local pain. These clinical characteristics are in agreement with global and national data [2,6,30]. Local pain was the most frequent reason for hospitalization in a cohort in Rio de Janeiro State, Brazil [6]. This is critical in the context of poor outcomes related to pain control according to gender, sexual orientation, and race, which might deepen mpox-related stigma and increase the gap between the most vulnerable populations and health services [31,32].

Among respondents with no mpox diagnosis, a substantial proportion did not seek health care assistance despite reporting mpox suspicious lesions or symptoms. Avoidance of health services is common among SGM and directly linked to stigma, discrimination, and structural barriers faced by these groups [33,34]. This might lead to the underreporting of mpox cases in highly discriminatory settings, such as Brazil. In addition, participants with a self-reported mpox diagnosis also reported following a higher frequency of health measures (eg, HIV care and testing, STI diagnosis, and PrEP use) and lower rates of internalized LGBTQIA+ phobia. This might indicate that individuals who sought an mpox diagnosis most commonly have access to health services in general. Furthermore, these participants might have previous links with gender-competent health care services and more access to health information, all potentially related to a lower perceived gender and sexual orientation–based discrimination.

Although participants with an mpox diagnosis reported a higher number of sexual partners, binge drinking before sex, chemsex, substance use, and higher frequency to sex venues, they also adopted more changes in sexual behavior after the mpox outbreak, possibly due to higher awareness and feelings of fear and hopelessness related to mpox. This finding is in agreement with previous surveys conducted in the United States among the most vulnerable populations [16,35]. Moreover, most individuals with an mpox diagnosis in our survey also reported sex with other cisgender men, reinforcing the role of highly interconnected and dense sexual networks in the mpox transmission dynamics [36]. Even among participants who self-reported an mpox diagnosis, only a small proportion reported a partner with suspected or confirmed mpox. Although this observation might be related to underdiagnosed cases, it raises concerns about the potential role of subclinical infections in mpox transmission dynamics, while it also reflects the well-known challenges in STI network mapping [37-39].

People living with HIV enrolled in the current analysis reported low ART adherence (895/1473, 60.8%). Regardless of mpox diagnosis, this reinforces the urgent need to better monitor the HIV care continuum. In the context of mpox, advanced immunosuppression and poor ART adherence have been associated with worse mpox clinical outcomes, including mpox-related hospitalization and death [40]. The high rates of other STIs occurring concomitantly with mpox highlight the importance of a comprehensive screening at mpox assessment, in accordance with the well-established rationale that 1 STI diagnosis implies a higher likelihood of coinfection with an additional one [41].

Limitations

Our study has some limitations. First, the cross-sectional study design hinders identifying causal associations. In addition, all responses were self-reported, thus introducing the possibility of recall, response, or social desirability bias. Moreover, our sample constitutes a highly educated, middle or high socioeconomic status subset of Brazilian persons with access to a device compatible with GSN apps, although cellphones and internet connection have been shown to be widely available in all socioeconomic strata in Brazil [42]. Transgender women are often a highly vulnerable group in Brazil with lower access to the internet, which may have impacted their recruitment using web-based strategies as previously observed [17].

Conclusions

Our results point to high mpox knowledge and willingness to vaccinate for mpox among SGM in Brazil. Participants self-reporting mpox diagnosis more frequently reported to be living with HIV, STI diagnosis, and current PrEP use. Our findings highlight the importance of an mpox assessment that includes comprehensive sexual health screenings. Efforts to decrease stigma related to mpox among SGM is necessary to avoid mpox underdiagnosis.

Acknowledgments

Parts of these results were presented at CROI Conference in Seattle in February 2023. We would like to thank study participants and Leandra Sobral, Cláudio Nascimento, Gerson Santos, Priscila Cristine, Alexandre Castilho, Daniel RB Bezerra, and Ronaldo

M Ismerio. TST, PML, and BG are supported by Conselho Nacional de Desenvolvimento Científico e Tecnológico and Fundação Carlos Chagas Filho de Amparo à Pesquisa do Rio de Janeiro.

Data Availability

The study's final deidentified data set and dictionary will be made available with the publication upon reasonable request. A proposal should be submitted to the corresponding author's email, who will evaluate and approve the request. No other additional documents will be available.

Authors' Contributions

TST, MSTS, CC, BH, VGV, and BG conceived this study. TST and BH drafted the questionnaire. MSTS, CC, EMJ, JM, VGV, and BG reviewed the questionnaire. TST, CC, and PML conceived and supervised the current analysis. TST supervised data acquisition. TST performed statistical analysis and MAM performed the spatial analysis. TST and MSTS drafted the manuscript. BH, EMJ, SWC, JM, MAM, PML, VGV, and BG revised the manuscript for important intellectual content. All authors read and approved the final manuscript.

Abstract

Background: Childhood cancer survivors are at a high risk of medical consequences of their disease and treatment. There is growing information about the long-term health issues of childhood cancer survivors; however, there are very few studies describing the health care utilization and costs for this unique population. Understanding their utilization of health care services and costs will provide the basis for developing strategies to better serve these individuals and potentially reduce the cost.

Objective: This study aims to determine the utilization of health services and costs for long-term survivors of childhood cancer in Taiwan.

Methods: This is a nationwide, population-based, retrospective case-control study. We analyzed the claims data of the National Health Insurance that covers 99% of the Taiwanese population of 25.68 million. A total of 33,105 children had survived for at least 5 years after the first appearance of a diagnostic code of cancer or a benign brain tumor before the age of 18 years from 2000 to 2010 with follow-up to 2015. An age- and gender-matched control group of 64,754 individuals with no cancer was randomly selected for comparison. Utilization was compared between the cancer and no cancer groups by χ^2 test. The annual medical expense was compared by the Mann-Whitney *U* test and Kruskal-Wallis rank-sum test.

Results: At a median follow-up of 7 years, childhood cancer survivors utilized a significantly higher proportion of medical center, regional hospital, inpatient, and emergency services in contrast to no cancer individuals: 57.92% (19,174/33,105) versus 44.51% (28,825/64,754), 90.66% (30,014/33,105) versus 85.70% (55,493/64,754), 27.19% (9000/33,105) versus 20.31%

(13,152/64,754), and 65.26% (21,604/33,105) versus 59.36% (38,441/64,754), respectively (all *P*<.001). The annual total expense (median, interquartile range) of childhood cancer survivors was significantly higher than that of the comparison group (US $285.56, US $161.78-US $535.80 per year vs US $203.90, US $118.98-US $347.55 per year; *P*<.001). Survivors with female gender, diagnosis before the age of 3 years, and diagnosis of brain cancer or a benign brain tumor had significantly higher annual outpatient expenses (all *P*<.001). Moreover, the analysis of outpatient medication costs showed that hormonal and neurological medications comprised the 2 largest costs in brain cancer and benign brain tumor survivors.

Conclusions: Survivors of childhood cancer and a benign brain tumor had higher utilization of advanced health resources and higher costs of care. The design of the initial treatment plan minimizing long-term consequences, early intervention strategies, and survivorship programs have the potential to mitigate costs of late effects due to childhood cancer and its treatment.

Introduction

The survival of children diagnosed with cancer has dramatically improved over the last 4 decades [1,2]. This improvement is primarily the result of advancements in the conventional treatment of the cancers with chemotherapy, surgery, and radiotherapy. Unfortunately, these therapeutic modalities have significant short- and long-term morbidities [3-5]. More recently, advances in the understanding of the biology of the cancers in children promise to allow more targeted therapy and tailored treatment regimens that will reduce the duration and toxicity of the therapy [6-8]. Unfortunately, these targeted therapies and tailored treatments are only beginning to be incorporated into the initial therapy of children with a malignant or brain tumor. Despite the 80% survival rate currently seen among children with cancer, a recurrence of the primary cancer remains the main important concern for most children with malignancy [1,2,9,10]. Some malignancies with good risk features and low stage at diagnosis have a very low recurrence rate and can be expected to be cured. Reduction in short- and long-term morbidities is a major strategy for these malignancies. Other malignancies have a higher recurrence rate and lower survival, and thus, require further improvement in therapy.

Disease- and therapy-related complications that result in long-term disabilities have increased over recent years as the cure rate has increased. An example of this is the physical disabilities associated with limb-sparing procedures for bone tumors as improvements in surgical techniques and equipment have been made. Further, as an increasing number of children are cured of brain tumors, many have long-term health issues including seizure disorders, other neurologic effects of the primary tumor [11-13], and endocrinologic abnormalities [14,15]. These complications are primarily cognitive and neurologic effects of chemotherapy and radiation therapy [11-13,16-18]; endocrinologic complications resulting from surgery, radiation therapy, alkylating agents, certain tyrosine kinase inhibitors, and immune system modulators [14,15,19-24]; organ system toxicity [22-32]; and psychologic and emotional effects [33-37].

Estimates [38,39] suggest that there are currently 16.9 million cancer survivors in the United States. The average out-of-pocket spending each year for cancer survivors aged 18-64 years was recently reported to be approximately US $1000, compared with US $622 for people without a history of cancer [38]. Although there is now a growing body of knowledge about the long-term effects on children who survived cancer, only little information is available on the long-term costs of health care for these children [40-45]. This is especially true for the long-term costs of health care not directly related to the primary cancer. This report evaluates the utilization of health care resources and their costs for long-term survivors of childhood cancer in Taiwan.

Methods

Research Database

We analyzed the national databases of the Health and Welfare Data Science Center (HWDC) in Taiwan including the death registry of the Taiwanese population and claims data of the National Health Insurance (NHI) from the Bureau of National Health Insurance. In Taiwan, the NHI is a single-payer compulsory social insurance plan enrolling more than 99% of its residents [46,47], a population of 25.68 million covered individuals at the end of 2005. After deidentification by the HWDC, the database is open to researchers in Taiwan for research applications.

Study Design

This is a nationwide, population-based, case-control study of individuals who had a diagnostic code of cancer (ICD-9-CM [International Classification of Diseases, Ninth Revision, Clinical Modification] code 140-208) or a benign brain tumor (ICD-9-CM code 225) and who had survived for more than 5 years. The study included all survivors of childhood cancer who appeared in the national database between 2000 and 2010 and aged less than 18 years at the time of first appearance in the database. Survivors who were diagnosed between 1983 and 1999 were included in the data set as long as they were younger than 18 years when they first appeared in the database during years 2000-2010. The study population included cases whose birthday was as early as 1983 because they could have first appeared in the database beginning in the year 2000 at the age before 18. We defined the index date of follow-up as the date 5 years after the initial coding of cancer or a benign brain tumor in the claims data. To evaluate the costs of health care in long-term survivors of childhood cancer, we compared the utilization and costs of health care between children with cancer or a benign brain tumor who survived their disease more than five years and children without a history of cancer or brain tumor. Patients who died within 5 years of first diagnosis or first coding of cancer or a benign brain tumor in the database, who had no follow-up records beyond 1 year after the index date, or who had used antineoplastic and immunomodulating agents (Anatomical Therapeutic Chemical [ATC] class L) during the follow-up period were excluded from analysis.

Case Group

The case group of childhood cancer survivors (cancer group) consisted of 33,105 patients who were diagnosed with cancer at an age less than 18 years. The age at entry to the study was defined by the year of first coding of cancer or a benign brain tumor in the database minus the birth year. All the survivors in the case group had at least 6 years of tracking records (5 years after initial appearance in the database plus 1 year of follow-up). The survivors were further classified as having/had hematologic cancer (ICD-9-CM codes 200-208), brain cancer (including all central nervous system [CNS] cancers; ICD-9-CM codes 191-192), benign brain tumor (including low-grade CNS tumors; ICD-9-CM code 225), and non-CNS solid tumor (ICD-9-CM codes 140-190 and 193-199).

The index date for the initiation of tracking health care utilization and costs was 5 years after the first date of cancer coding for each case and their matched comparison individuals. The date of the latest medical claims in the database was the endpoint of tracking health care utilization and costs.

Comparison Group

An age- and gender-matched comparison group was included for comparison. To identify a matched comparison group, we randomly selected children without cancer or a benign brain tumor from the claims database; 2 comparison individuals were enrolled for each survivor of cancer or a benign brain tumor. A total of 64,754 comparison group individuals were selected by matching the propensity score of age and gender for each case [48,49]. As each survivor in the cancer groups was matched by 2 individuals with no cancer, the index date for each of the 2 individuals in the comparison group was set to be the same as their matched survivor in the cancer groups.

Outcomes of Interest

The proportion of individuals utilizing health care services, annual outpatient visits, and the annual medical expense per person were calculated for each group. The annual medical expenses were the total medical cost between the index date and the last day of follow-up in this study divided by the years of follow-up. The utilization and cost in each domain of health care (ie, outpatient, inpatient, and emergency) and in each level of health care (ie, community clinic, regional hospital, and medical center) were calculated respectively and compared across groups.

Statistical Analysis

The proportion of categorical variables such as sex, age, and health care utilization status was analyzed by the χ^2 test. Continuous variables including age, years of follow-up, and annual medical expenditure were expressed as the median and IQR; the Mann-Whitney *U* test was used for 2-group comparisons and the Kruskal-Wallis rank-sum test for multiple-group analyses. We demonstrated the annual outpatient medical expenditures (by gender and stratified age groups) graphically by radar plots and box plots. The expenses were converted from Taiwan dollars to United States dollars at the exchange rate of 30:1. All data processing in this study was performed using SAS 9.3 (SAS Institute), and statistical analysis and graphing were performed using R 3.6.1 (R Foundation for Statistical Computing). Two-sided *P* values <.05 were considered statistically significant.

Ethics Approval

This study was approved by the Joint Institutional Review Board of Taipei Medical University (TMU-JIRB N201911023), which agreed that informed consent can be waived when using these administrative data for analyses.

Results

Demographics

A cohort of 33,105 patients surviving 5 years after the first appearance of childhood cancer or a benign brain tumor in the database were identified (cancer group) and a comparison group of 64,754 individuals was selected from the deidentified national claims database of the HWDC in Taiwan from 2000 to 2015 (Table 1). The median follow-up starting from 5 years after the first appearance in the database (cancer group) or the index date of enrollment for the comparison group was 7 years. The cancer groups consisted predominantly of solid tumors (29,171/33,105, 88.12%); approximately two-thirds of the solid tumors were outside the CNS, whereas one-third originated in the CNS. The hematologic cancers comprised 11.88% (3934/33,105) of the cancer groups. The gender distribution of the cancer and no cancer groups was comparable with a slight male predominance (male:female=1.2:1) in both groups. The age distribution among the cancer and comparison groups was similar, with median ages between 11 and 14 years (Table 1).

Table 1. Demographics of the cancer and comparison groups.

Demographics	Childhood cancer survivors (n=33,105)	Cancer groups (ICD-9-CM[a])					Comparison group	
		Hematologic cancer (200-208) (n=3934)	Brain cancer (191-192) (n=2241)	Benign brain tumor (225) (n=7825)	Non-CNS[b] solid tumor (140-190; 193-199) (n=19,105)	*P* value[c]	No cancer individuals (n=64,754)	*P* value[d]
Gender, n (%)								
Male	18,377 (55.51)	2211 (56.20)	1209 (53.95)	4091 (52.28)	10,866 (56.88)	<.001	35,803 (55.29)	.52
Female	14,728 (44.49)	1723 (43.80)	1032 (46.05)	3734 (47.72)	8239 (43.12)	N/A[e]	28,951 (44.71)	N/A

Years of follow-up, median (IQR)	7.23 (3.58-10.01)	7.73 (4.73-10.53)	8.59 (5.25-10.90)	7.60 (4.73-10.00)	6.54 (3.07-9.76)	<.001	7.16 (3.53-9.98)	.04

[a] ICD-9-CM: International Classification of Diseases, Ninth Revision, Clinical Modification.

[b] CNS: central nervous system.

[c] Compared among the cancer groups and the no cancer group.

[d] Compared between all cancer survivors versus no cancer individuals.

[e] N/A: not applicable.

Utilization of Medical Services

We examined the difference in medical service utilization between cancer survivors and no cancer individuals (Table 2). Cancer survivors had a higher utilization of medical center, regional hospital, inpatient, and emergency services in contrast to individuals without cancer: 57.92% (19,174/33,105) versus 44.51% (28,825/64,754), 90.66% (30,014/33,105) versus 85.70% (55,493/64,754), 27.19% (9000/33,105) versus 20.31% (13,152/64,754), and 65.26% (21,604/33,105) versus 59.36% (38,441/64,754), respectively (all *P*<.001), with more cancer survivors using medical center services (19,174/33,105, 57.92%, vs 28,825/64,754, 44.51%). We then examined the difference in service utilization among the cancer and no cancer groups. Brain cancer and benign brain tumor survivors demonstrated a different pattern of utilization, that is, more brain cancer and benign brain tumor survivors used inpatient and emergency services in contrast to hematologic and non-CNS solid tumor survivors. A higher proportion of benign and malignant brain tumor survivors also utilized secondary and tertiary care services, including hospital outpatient, inpatient, and emergency services. Of note, the utilization of emergency services was high among both the survivors and no cancer individuals (21,604/33,105, 65.26% and 38,411/64,754, 59.32%), reflecting societal patterns of seeking medical advice (Table 2).

Table 2. Utilization of medical services of the cancer and comparison groups.

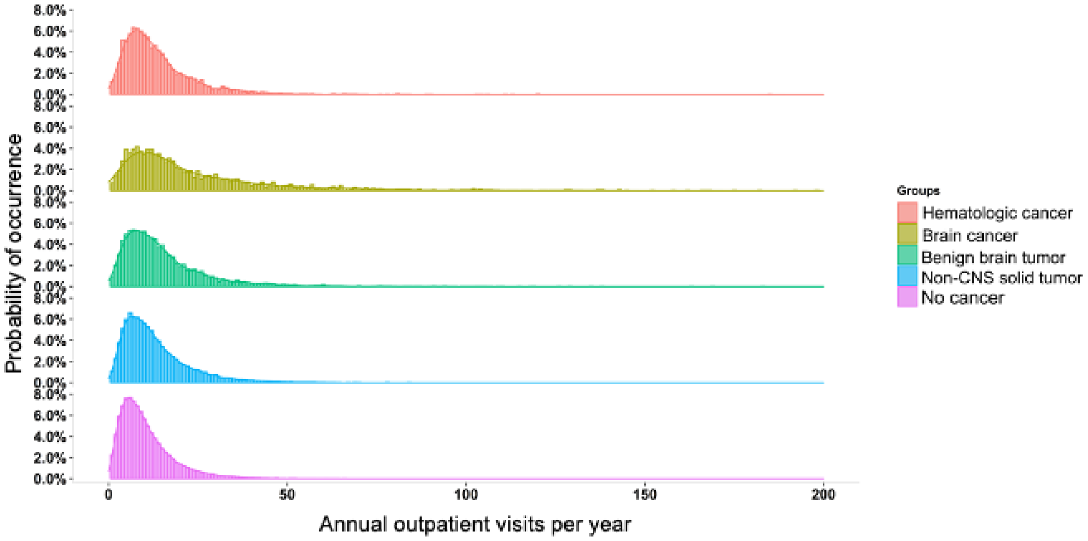
[e] Compared between all cancer survivors and no cancer individuals.

Distribution of Annual Outpatient Visits

The outpatient visit frequency showed a markedly right-skewed distribution with a long tail in all the 4 cancer groups and the comparison group, suggesting that there were a number of individuals in each group with high utilization of outpatient services (Figure 1). The median frequency (IQR) of annual outpatient visits of all childhood cancer survivors was 11.38 (6.88-18.27) visits/year, which was significantly higher than 8.63 (5.20-13.71) visits/year of the comparison group (*P*<.001). The median frequency (IQR) of outpatient visits of the 4 cancer groups was different from that of the comparison group: 11.20 (6.95-17.46) for hematologic cancer, 16.54 (9.22-30.60) for brain cancer, 12.33 (7.29-19.69) for a benign brain tumor, and 10.72 (6.52-17.03) for a non-CNS solid tumor (*P*<.001). The shape of the distribution curve was different among the cancer groups; the long tails of the distribution curves tapered off more gradually in the brain cancer and benign brain tumor groups. The results suggest that the frequencies of annual outpatient visits were the highest in the brain cancer and benign brain tumor groups, and that there were some extreme users in these 2 groups (Figure 1).

Figure 1. Distribution of annual outpatient visits in the cancer and comparison groups. The probability distribution of the annual outpatient visit frequencies in each group is summarized in a histogram. The area under the curve of each group is 100% of probability. Note the long tails in the brain cancer and benign brain tumor groups. CNS: central nervous system.



Medical Expense

The cost of medical services for childhood cancer survivors was higher than that for the comparison group (Table 3). The median total annual expense was 1.4-fold higher in childhood cancer survivors than in the comparison group (US $285.56, IQR US $161.78-US $535.80 per year vs US $203.90, IQR US $118.98-US $347.55 per year; *P*<.001); the median annual hospital outpatient cost and community clinic cost were also higher, 2.48- and 1.15-fold, respectively (*P*<.001). Moreover, childhood cancer survivors showed a different pattern of costs, with higher median annual expenses in medical centers (US $6.35 vs US $0 per year; *P*<.001) and regional hospitals (2.09-fold; *P*<.001) in contrast to no cancer individuals. Among the cancer groups, brain cancer and benign brain tumor survivors had a different pattern of costs, with higher median annual total and outpatient expenses, especially in emergency services (2.69- and 1.98-fold more over the comparison group, respectively; *P*<.001) and medical center services (US $68.37 vs US $0 and US $13.52 vs US $0 per year; *P*<.001) compared with hematologic and non-CNS solid tumor survivors (Table 3).

Annual Outpatient Expense

The median outpatient expense per person of each cancer group was higher than that of the comparison group. Importantly, the median outpatient expense of the brain cancer group was approximately 2 times higher than that of the other cancer groups (Figure 2A). The pattern of annual outpatient expense of the cancer and comparison groups was the same for both genders (Figures 2B and 3A and 3B). To further examine the annual outpatient expense across different ages at entry, we stratified the age into 4 intervals, namely, 0-2, 3-5, 6-11, and 12-17 years. We found that the pattern of annual outpatient expense of the cancer and comparison groups was the same across all age groups (Figures 2C and 3C-3F). Interestingly, female childhood cancer survivors and comparison individuals had a higher annual outpatient expense than their male counterparts (Table 4). In addition, infants and children up to the age of 2 years had a higher annual outpatient expense than older individuals (Table 5). The annual outpatient expense of brain cancer survivors was similar across gender and ages; however, the brain cancer survivors had a higher annual outpatient expense compared with the other cancer groups and with the no cancer group across both genders and all ages at entry (Tables 4 and 5).

Brain cancer survivors had the highest mean and median annual outpatient expenses, in contrast to other cancer groups and the comparison group ($P<.001$). The IQR of outpatient expense per person per year of the brain cancer group was greater than that of the other cancer groups and the no cancer group (Figure 2D).

Figure 2. The median annual outpatient expense in each cancer and comparison group is shown (A) and compared by gender (B) and age at entry (C). The distribution of annual outpatient expense per person was compared across the cancer and comparison groups in a box plot (D) (circles, mean annual outpatient expense; boxes, the 25th, 50th, and 75th percentile of each group; solid vertical lines, 1.5 box length, ie, 1.5 interquartile range; dots, outliers). The average outpatient medical expense per person-year in each cancer and comparison group was compared (E). Color bars represent the Anatomical Therapeutic Chemical (ATC) Classification of medications and the lowest brown bars represent nonmedication costs of medical services. CNS: central nervous system.

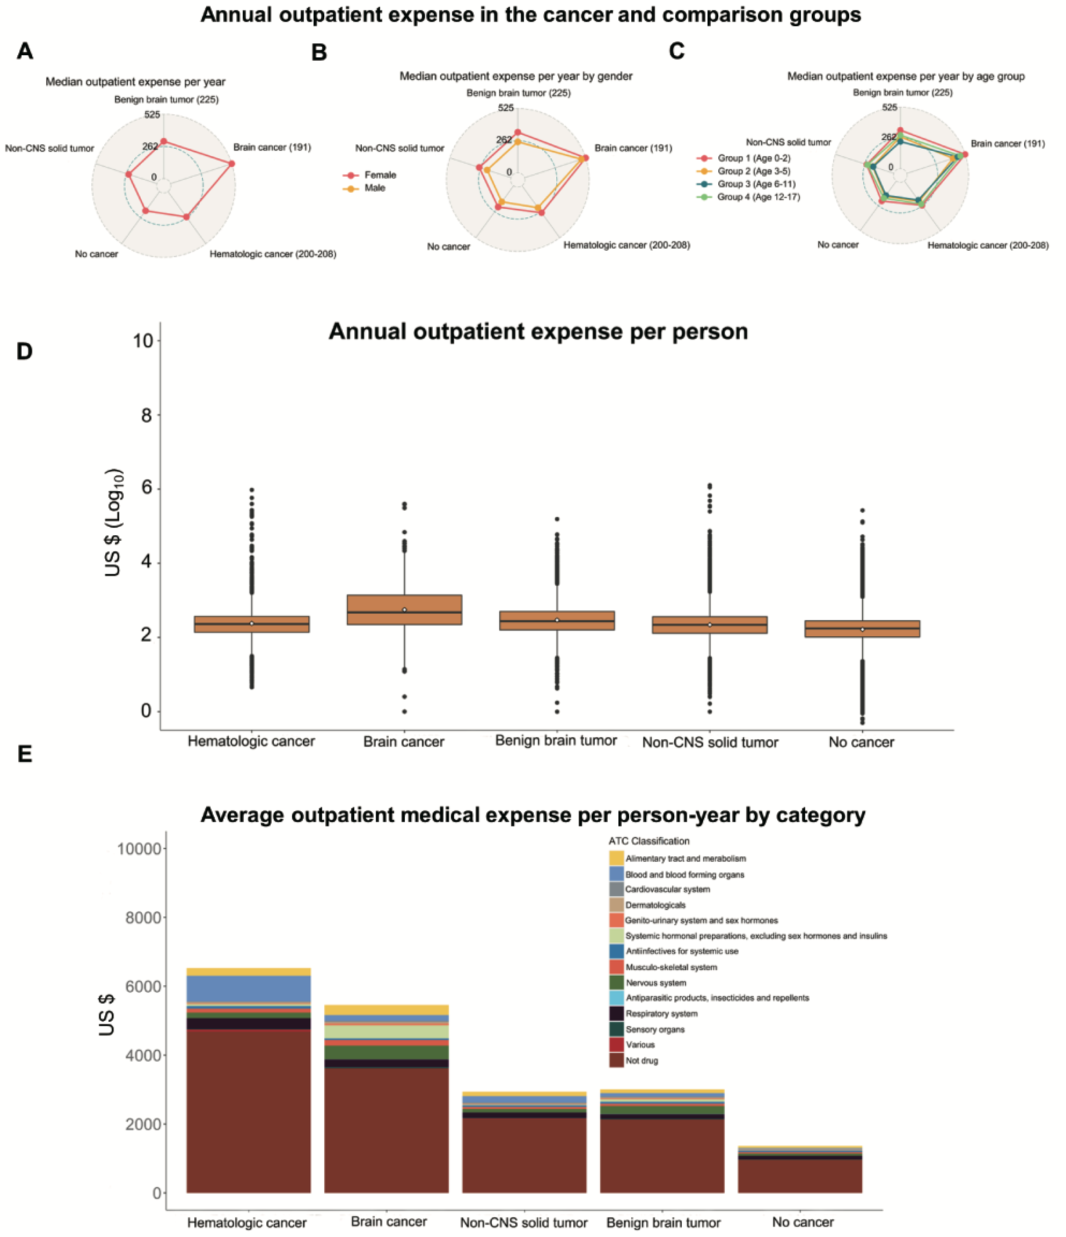

Figure 3. The annual outpatient expense in each cancer and comparison group was compared by male (A), female (B) and the age at entry of 0-2 years (C), 3-5 years (D), 6-11 years (E) and 12-17 years (F). Circles, mean annual outpatient expense; boxes, the 25th, 50th, and 75th percentile of each group; solid vertical lines, 1.5 box length, i.e., 1.5 interquartile range; dots, outliers.

[a] Data represent the median expense in US $ per person per year (IQR).

[b] ICD-9-CM: International Classification of Diseases, Ninth Revision, Clinical Modification.

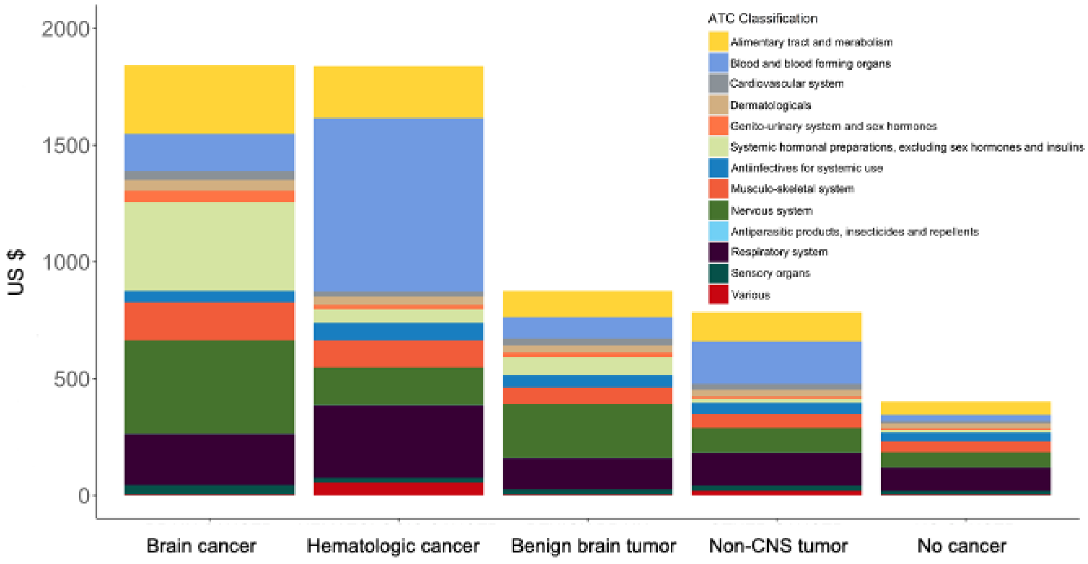
[c] Compared with the age of 0-2 years in each group.

[d] CNS: central nervous system.

To evaluate the composition of cost, we calculated the average outpatient medical expense per person-year of the cancer groups that was much higher than that of the no cancer group (Figure 2E). The hematologic and brain cancer groups had the highest average outpatient medical expense per person-year (4.79- and 4.01-fold of the no cancer group, respectively). The average outpatient medical expense per person-year of nonmedication service of hematologic and brain cancers was much higher (Figure 2E, brown bars). Moreover, the average outpatient medication expense per person-year was the highest in hematologic and brain cancers (Figure 4). Further, the cost was lower in medication than nonmedication services across all groups (Figure 2E). The proportion of medication cost was significantly higher in brain cancer survivors compared with no cancer individuals (33.79% vs 29.55%; *P*=.003), whereas the proportion of medication cost for survivors of hematological cancer (28.18% vs 29.55%; *P*=.31), benign brain tumor (29.16% vs 29.55%; *P*=.79), and non-CNS solid tumor (26.75% vs 29.55%; *P*=.06) was not significantly different than in the no cancer group (Figure 2E). In the brain cancer and benign brain tumor groups, medication costs for hormonal therapy, nervous system, alimentary tract, and metabolism were the major classifications of medication costs (Figures 2E and 4).

Figure 4. The average outpatient medical expense of medications per person-year in each cancer and comparison group was compared. Color bars represent the ATC Classification of medications. ATC: Anatomical Therapeutic Chemical.



Discussion

Principal Findings

In children aged 0-14 years, the annual incidence of newly diagnosed cancers (excluding benign CNS tumors) is 178 cases/million in the United States and 125 cases/million in Taiwan [50-52]. With the advent of multidisciplinary care and multimodality treatments, the 5-year survival rate of childhood cancer has now exceeded 80% [1,2], especially with leukemias and lymphomas [53-55]. Because of this success, every year the number of childhood cancer survivors continues to rise. It is now estimated that in the next 10-20 years 1/1000 individuals in Taiwan aged 20-30 years will be a survivor of childhood cancer. In the United States, the number of individuals surviving their cancer and treatments is projected to reach more than 22.1 million by 2030 [38,39].

It has been reported that 62% of survivors of childhood cancer develop a long-term health problem and 27% have a serious or life-threatening condition [56]. As a result, only 1 in 3 survivors of childhood cancer remains free of long-term health problems related to the cancer and its treatment. Thus, the treatment outcomes of childhood cancer should be not only the survival rate but also the long-term health care issues that include medical service utilization and the medical costs of the services.

There is growing information about the long-term health issues of childhood cancer survivors; however, there are very few studies describing the utilization and costs of health care for this unique population. Although the average cost of childhood cancer treatment varies among countries, estimated to be US $32,157 in Korea [57-60], the long-term health care costs of survivors remain unknown. Our data demonstrate that the utilization and costs of medical service during long-term follow-up for childhood cancer survivors are greater than those for the comparison group without a previous cancer diagnosis. In addition, the patterns of health care services that are utilized by the cancer survivors and individuals without a history of cancer are very different, with cancer survivors utilizing more hospital care and advanced care.

Comparing childhood cancer survivors with individuals without a diagnosis of cancer, the former not only had higher utilization of health care but also had much higher medication and nonmedication costs. Although the cancer survivors had much higher medication cost, the main categories of medication costs of both groups were respiratory, gastrointestinal, and neurological. The nonmedication costs were the major component of costs in both groups.

When we evaluated the health care utilization and cost of each cancer group, it was clear that children with both malignant and benign brain tumors had unique medical needs in long-term follow-ups. Specifically, brain cancer survivors had the highest utilization and costs; similarly, benign brain tumor survivors also had high utilization and costs. This was also seen in a recent publication from the French Childhood Cancer Survivor Study and the French Network of Cancer Registries where the highest median annual health care expenditure was seen in survivors of a childhood CNS tumor [61]. Regarding outpatient medication costs for these subgroups, hormonal and neurological medications comprised the 2 largest proportions of costs in brain cancer and benign brain tumor survivors. Notwithstanding, all groups of survivors have an increased annual medical cost during long-term follow-up compared with the no cancer group.

In the analysis of costs, we noted that females had significantly higher costs than their male counterparts in both the cancer survivor and no cancer groups, similar to the findings from the French study [61]. The difference was especially large in survivors of a benign brain tumor. However, the cause of cost disparities between genders could not be determined by our data and thus needs further investigation.

Our data also suggest that cancer survivors who were diagnosed at younger ages, especially those with brain tumors, will require more services in their long-term care. These data are similar to those from the French study, where the annual health care expenditures were higher in children diagnosed at older ages or with a CNS tumor [61]. Likewise, in our study, the higher cost associated with brain cancer was seen in all age groups. To address the unique medical needs of these patients, a specialized, multidisciplinary team with individualized surveillance programs needs to be established to promote health and prevent future illness. Our data also support the attempt to mitigate the long-term effects of very young children with brain tumors by reducing, delaying, or eliminating radiation therapy [16-18].

Further study is needed to define the health issues that contribute to the increased health care cost and health care burden of childhood cancer survivors. The goals for the health care system are (1) to understand the extent of the health issues that survivors of childhood cancer face; (2) to understand the specific types of health issues that survivors of childhood cancer face; (3) to develop interventions to improve the health of the survivors of childhood cancer; (4) to decrease the health care costs of survivors of childhood cancer; and (5) to reduce the health care burden of survivors of childhood cancer to the health system. The goals for the survivors of childhood cancer are (1) to mitigate the extent of their health problems; (2) to mitigate the severity of their health problems; and (3) to improve their quality of life. Further, the design of the treatment plan for children with cancer needs to minimize long-term consequences. In addition, early intervention strategies to overcome potential disabilities caused by the cancer should be implemented at the time of diagnosis.

Strengths and Limitations

There are several limitations of this study. First, this is a retrospective analysis of childhood cancer survivors in Taiwan. The proportion of hematologic cancer survivors is smaller than that of other survivorship cohorts [9,10], probably due to the relatively lower survival rate of those with acute leukemias in Taiwan during the early years of the study [62,63]. Second, we used claims data that were not directly linked to the nationwide cancer registry. The ICD-9 diagnostic codes, which were determined by physicians, could not be validated. We believe there were also a number of benign brain tumors representing tumors that are not typically considered in the benign brain tumor registries. We also believe there were a large number of benign solid tumors included in the "non-CNS solid tumor" group, which was intended to only include malignant diseases. In addition, the specific causes of costs for each cancer group could not be defined in this study and will require further analysis. Further, the history of treatment with stem cell transplantation or radiotherapy, which is known to be associated with late effects and increased medical costs, could not be analyzed in this study. The effects of these therapies should thus be evaluated in future studies. The strengths of this study are that it is a nationwide, population-based design; that the study cohort is relatively large, with the case group of childhood cancer survivors; and that there is a comparison group determined by matching the propensity score of age and gender from the claims data of the NHI that covers 99% of the Taiwanese population. Therefore, the results represent a real-world scenario, rather than assumptions and projections.

Conclusions

The cost of health care of children in Taiwan surviving childhood cancer or a brain tumor was higher than that of an age- and gender-matched comparison group of children without a history of cancer. The utilization of health care resources among children in Taiwan surviving childhood cancer and its treatment was also higher than that among an age- and gender-matched comparison group without a history of cancer. The types of health care expenditures and issues for children surviving a malignant or a benign brain tumor were different from those of the normal population. Thus, these children require coordinated follow-up and comprehensive, specialized care to optimize outcomes and quality of life. To reduce these health care costs and utilization, a careful prospective analysis of the costs and patterns of utilization will be needed. Further, preventive strategies with effective interventions will be required.

Acknowledgments

YWK, WLH, and BCS had full access to all of the data in the study and were responsible for the integrity of the data and the accuracy of the data analysis. JSM, YLL, YWK, WLH, and BCS were responsible for the concept and design of the study. JSM, YLL, YWK, SYC, and WLH acquired, analyzed, or interpreted the data. JSM, YLL, YWK, and WLH drafted the manuscript. YWK performed the statistical analyses. WLH and BCS provided administrative, technical, or material support. Abstract

Background: Inappropriate use of inhaled corticosteroids (ICSs) for asthma impairs control and may cause exacerbation, including asthma-related hospitalization (ARH). In prospective studies, ICS use peaked around ARH, but information on routine care use is limited. Since ARH is a major outcome, controller therapy use in routine care before and after ARH should be documented.

Objective: This study aimed to distinguish ICS use typologies (trajectories) before and after ARH, and assess their relationships with sociodemographic, disease, and health care characteristics.

Methods: A retrospective cohort study was performed using a 1% random sample of the French claims database. All patients hospitalized for asthma between January 01, 2013, and December 31, 2015, were classified as either children (aged 1-10 years) or teens/adults (aged ≥11 years). Health care resource use was assessed between 24 and 12 months before ARH. ICS use was computed with the Continuous Measures of Medication Acquisition-7 (CMA7) for the 4 quarters before and after ARH. Initially, the overall impact of hospitalization on the CMA7 value was studied using a segmented regression analysis in both children and teens/adults. Then, group-based trajectory modeling differentiated the groups with similar ICS use. We tested different models having 2 to 5 distinct trajectory groups before selecting the most appropriate trajectory form. We finally selected the model with the lowest Bayesian Information Criterion, the highest proportion of patients in each group, and the maximum estimated probability of assignment to a specific group.

Results: Overall, 863 patients were included in the final study cohort, of which 447 (51.8%) were children and 416 (48.2%) were teens/adults. In children, the average CMA7 value was 12.6% at the start of the observation period, and there was no significant quarter-to-quarter change in the value (*P*=.14) before hospitalization. Immediately after hospitalization, the average CMA7 value rose by 34.9% (*P*=.001), before a significant decrease (*P*=.01) of 7.0% per quarter. In teens/adults, the average CMA7 value was 31.0% at the start, and there was no significant quarter-to-quarter change in the value (*P*=.08) before hospitalization. Immediately after hospitalization, the average CMA7 value rose by 26.9% (*P*=.002), before a significant decrease (*P*=.01) of 7.0% per quarter. We identified 3 and 5 trajectories before ARH in children and adults, respectively, and 5 after ARH for both groups. Trajectories were related to sociodemographic characteristics (particularly, markers of social deprivation) and to potentially inappropriate health care, such as medical management and choice of therapy.

Conclusions: Although ARH had an overall positive impact on ICS use trajectories, the effect was often transient, and patient behaviors were heterogeneous. Along with overall trends, distinct trajectories were identified, which were related to specific patients and health care characteristics. Our data reinforce the evidence that inappropriate use of ICS paves the way for ARH.

Introduction

Asthma is a major public health concern, and over 5% of the total population in high-income countries live with the condition [1]. Both adults and children cover the asthma demographic [2], and it not only affects quality of life but also causes significant morbidity (and in some instances mortality). It is responsible for high financial burden at both the individual and societal levels, particularly as a result of acute exacerbation [3,4].

The risk of exacerbation increases when asthma is poorly controlled, and severe exacerbation can lead to asthma-related hospitalization (ARH) [5,6]. A common cause of poor control is the inappropriate use of inhaled corticosteroids (ICSs) in monotherapy or as fixed-dose combinations (FDCs), as well as the inappropriate use of long-acting beta agonists (LABAs) in monotherapy [7,8].

In a prospective cohort study of ARH, a rapid decrease was shown in the use of ICSs and oral corticosteroids (OCSs) after hospital discharge [9]. Information on preadmission use, however, was not available. Another study clarified the overall relationship between adherence to ICSs and the occurrence of severe exacerbations, including ARH, with the use of ICSs increasing shortly before the exacerbation and further increasing afterward [10].

Nonetheless, asthmatics are likely heterogeneous in that regard, and their behaviors, particularly ICS use, may differ in real-life conditions compared with that during prospective field studies, where medication use is regularly assessed. Since ARH is a major outcome, the use of controller therapy in routine care before and after ARH should be documented. This information would incite health care professionals to adjust modifiable patient and care characteristics in order to prevent recurring exacerbations. The objectives of this study were to distinguish the typology of ICS use before and after ARH in the routine care of a representative sample of the overall asthma population, and to identify sociodemographic, disease, and health care characteristics related to ICS trajectories.

Methods

Data Source

The data source of this study was the Echantillon Généraliste des Bénéficiaires (EGB; General Sample of Beneficiaries), which is a 1/97th representative random sample of the French national health system (Système National des Données de Santé [SNDS]; National Health Data System) that covers more than 90% of the French population. It contains comprehensive, anonymized individual information on sociodemographic characteristics, date of death, out-of-hospital reimbursed health care expenditures (from both public and private health care providers), and hospital discharge summaries using the International Classification of Diseases 10th Revision (ICD-10) codes [11].

Study Population

We included all patients who were hospitalized for asthma (ICD-10 codes: J45 and J46) as the singular main diagnosis between January 1, 2013, and December 31, 2015. The first recorded date of ARH was defined as the index date. We selected patients with continuous follow-up during the period between 24 months before and 12 months after the index date. Patients hospitalized for asthma-related reasons in the 12 months before the index hospitalization were excluded. Two subgroups were defined: children (1-10 years old) and teens/adults (≥11 years old).

Study Variables

For children and teens/adults separately, we described the sociodemographic characteristics (age, gender, free access to care status as a proxy of social deprivation [given on a means-tested basis; this status supports the health expenses of more modest patients], and chronic disease status [patients who benefit from this status for a diagnosed condition are totally reimbursed for care related to that condition, ie, asthma in our study]), health care resource utilization (general practitioner visits, pediatrician visits, respiratory physician visits, emergency room [ER] visits for any cause, pulmonary function testing, and hospital admission for asthma), and initiation of asthma therapy (ICSs, LABAs, FDCs of ICSs/LABAs, leukotriene receptor antagonists [LTRAs], short-acting β2 agonists [SABAs], OCSs, and antibiotics for respiratory infections). We also described the therapeutic ratio or the “controller to total asthma medication ratio” as a proxy of the quality of asthma care. Studies have shown that patients with high therapeutic ratios (≥50%) experience fewer asthma exacerbations than those with low ratios [12-15].

Description of ICS Use

The baseline period started at T0, 365 days before the date of the index ARH (Multimedia Appendix 1). For both children and teens/adults, ICS use (in monotherapy or FDCs) was separately assessed by computing the Continuous Measures of Medication Acquisition-7 (CMA7) for 4 quarters, before the hospital admission (from T0 to the index ARH date) and after hospital discharge. CMA7 is a standard method to assess adherence to medication, calculated as the cumulative days’ supply obtained over a series of intervals divided by the total days from the beginning to the end of the study period [16,17].

Statistical Analysis

Descriptive statistics were used to describe the sociodemographic characteristics, health care utilization, and asthma therapy over the period between 24 and 12 months before the index ARH. The categorical variables of patient characteristics were described by providing the sample size within each modality and the relative percentages. We described the quantitative variables of health care utilization to determine the sample size and relative percentages for patients (with at least one care item) to calculate the mean and SD of the number of care items in all patients.

Initially, the overall impact of hospitalization on the CMA7 value was studied using a segmented regression analysis in both children and teens/adults [18]. Then, group-based trajectory modeling (the SAS proc traj function) was used to distinguish different groups of patients regarding the typologies of the trajectories of CMA7 for ICSs [19,20] both before and after ARH. We tested different models having 2 to 5 distinct trajectory groups before selecting the most appropriate form of the trajectories. We finally selected the model with the lowest Bayesian Information Criterion, the highest proportions of patients in each group, and the maximum estimated probability of assignment to a specific group. The chi-square test, Fisher test, and Kruskal-Wallis test were used to compare patient characteristics (including asthma therapy) across trajectory groups over the baseline period for children and teens/adults as separate groups.

The statistical analysis was performed using SAS Version 9.4 (SAS Institute).

Ethical Considerations

This observational study was conducted on anonymized data. The Commission Nationale de l'Informatique et des Libertés (CNIL; National Informatics and Liberty Committee) provided authorization for the use of the EGB data for research purposes, and approval was obtained from the French Institute for Health Data (Institut des Données de Santé) under number 133 (granted on June 9, 2015).

Results

Study Population

In total, 1473 patients were hospitalized for asthma from January 1, 2013, to December 31, 2015. We excluded 411 patients whose claims did not span the 2 years prior to their hospitalization, 34 patients who were hospitalized for asthma in the year before the index date, and 165 patients who had no continuous follow-up. In the end, 863 patients were included, of which 447 (51.8%) were children aged 1 to 10 years and 416 (48.2%) were teens/adults aged over 11 years (Figure 1). Regarding ICS use, similar trends were observed in both the children and teens/adults (segmented regression analysis) (Figure 2).

Figure 1. Study flowchart.

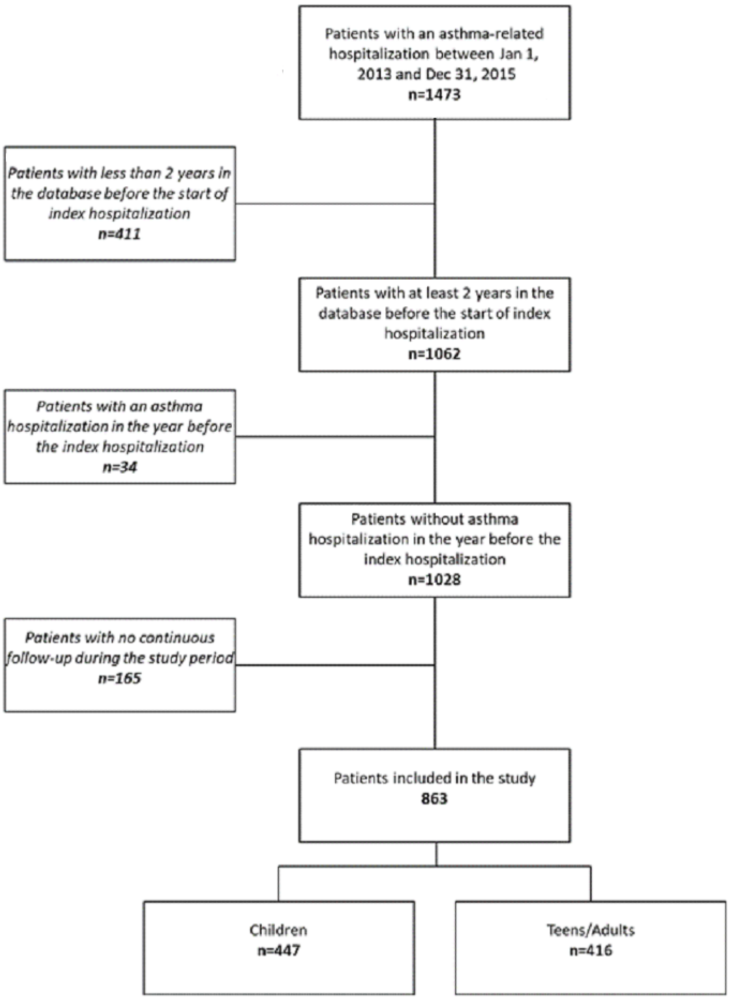

Figure 2. Inhaled corticosteroid use by children and teens/adults before and after asthma-related hospitalization (ARH). CMA7: Continuous Measures of Medication Acquisition-7.

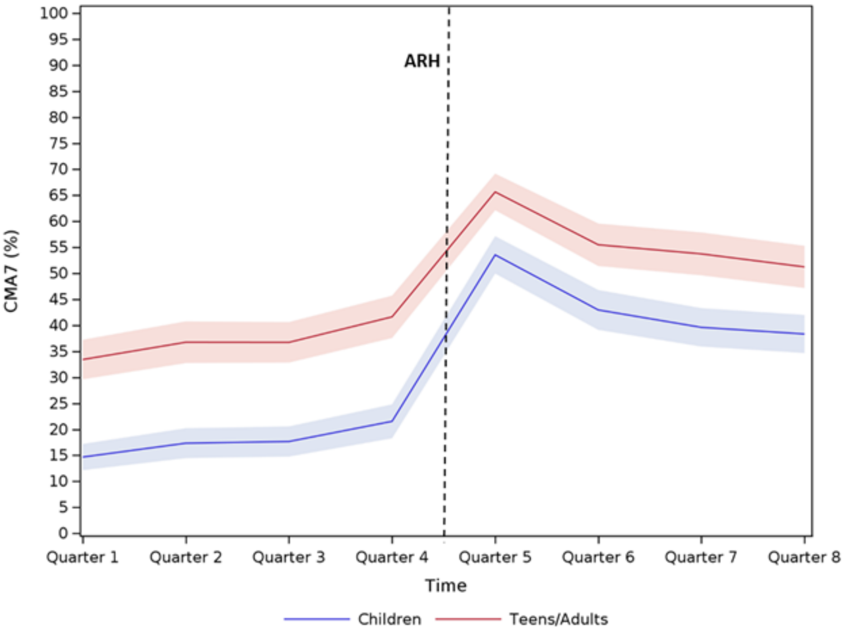

In the children, at the start of the observation period, the average CMA7 value was 12.6%, and there was no significant quarter-to-quarter change in the value (*P*=.14) before hospitalization. Immediately after hospitalization, the average CMA7 value rose by 34.9% (*P*=.001), before a significant decrease (*P*=.01) of 7.0% per quarter.

In the teens/adults, at the start of the observation period, the average CMA7 value was 31.0%, and there was no significant quarter-to-quarter change in the value (*P*=.08) before hospitalization. Immediately after hospitalization, the average CMA7 value rose by 26.9% (*P*=.002), before a significant decrease (*P*=.01) of 7.0% per quarter.

Population Characteristics Before ARH in the Children

At baseline, the mean age of the children was 4.2 years, and most were male (291/447, 65.1%). A quarter (112/447, 25.1%) had free access to health care. Almost half of the children (213/447, 47.7%) visited a pediatrician, whereas a quarter (115/447, 25.7%) visited a respiratory physician at least once. OCSs were dispensed to 60.9% (272/447) of the children at a mean annual dose (MAD) of 240 mg, while respiratory antibiotics were administered to 75.2% (336/447) of the children, with 4 annual dispensing events on average (Table 1). Altogether, few children (119/447, 26.6%) had high therapeutic ratios (≥0.5).

Table 1. Characteristics of the children at baseline (T0) overall and in the different preasthma-related hospitalization trajectories.

[a] ICS: inhaled corticosteroid.

[b] FDC: fixed-dose combination.

[c] LABA: long-acting beta agonist.

[d] N/A: not applicable.

[e] LTRA: leukotriene receptor antagonist.

[f] SABA: short-acting β2 agonist.

[g] OCS: oral corticosteroid.

[h] R03: group of medications used in the treatment of obstructive airway diseases (Anatomical Therapeutic Chemical classification).

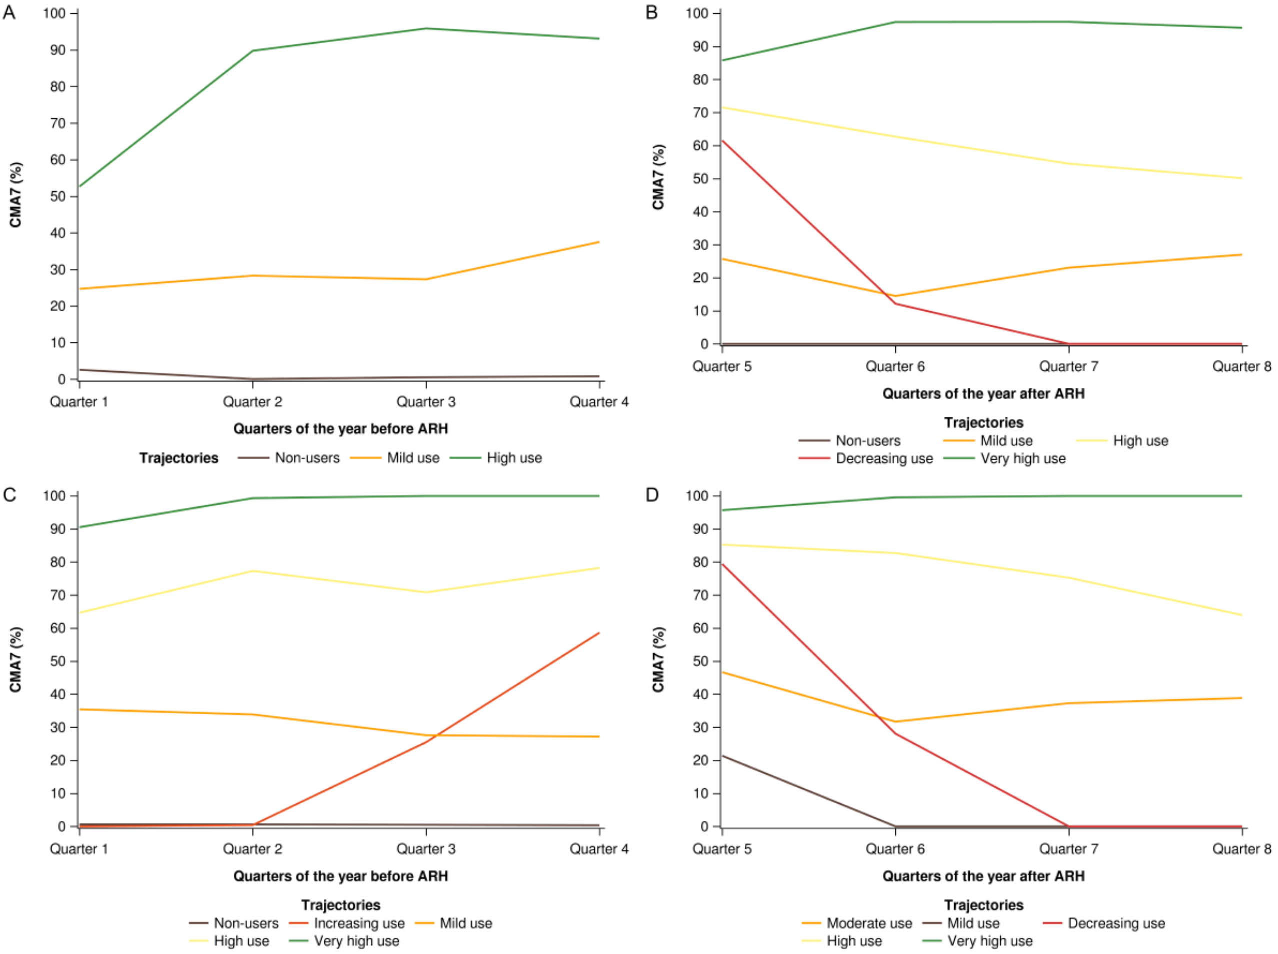
[i] Patients not receiving any respiratory therapy.

ICS Trajectories Before ARH in the Children

Three trajectories of ICS use were distinguished before ARH in the children: (1) no use (CMA7 value around 0%), (2) mild use (CMA7 value of 15%-40%), and (3) high use (CMA7 value of >80% during at least 3 quarters of the year before ARH) (Figure 3A). Just over half of the children (243/447, 54.4%) had a no-use typology, 38.5% (172/447) had a mild-use typology, and 7.2% (32/447) had a high-use typology during the last 3 quarters before ARH.

The no-use group comprised a larger percentage of males (167/243, 68.7%) compared to the mild-use (107/172, 62.2%) or high-use (17/32, 53.1%) group. There was extensive use of OCSs, with rates of 48.6% (118/243; MAD of 223 mg), 73.3% (126/172; MAD of 414 mg), and 87.5% (28/32; MAD of 675 mg) among the no-use, mild-use, and high-use groups, respectively. Respiratory antibiotics were dispensed to 72.8% (177/243), 76.7% (132/172), and 84.4% (27/32) of the children in the no-use, mild-use, and high-use groups, respectively (Table 1). The children in the mild-use (141/172, 82.0%) and high-use (29/32, 90.6%) groups had more visits to the respiratory physician or pediatrician than those in the no-use group (158/243, 65.0%).

Figure 3. Inhaled corticosteroid trajectories of children (n=447) and teens/adults (n=416), before (A and C, respectively), and after (B and D, respectively) asthma-related hospitalization (ARH). CMA7: Continuous Measures of Medication Acquisition-7.



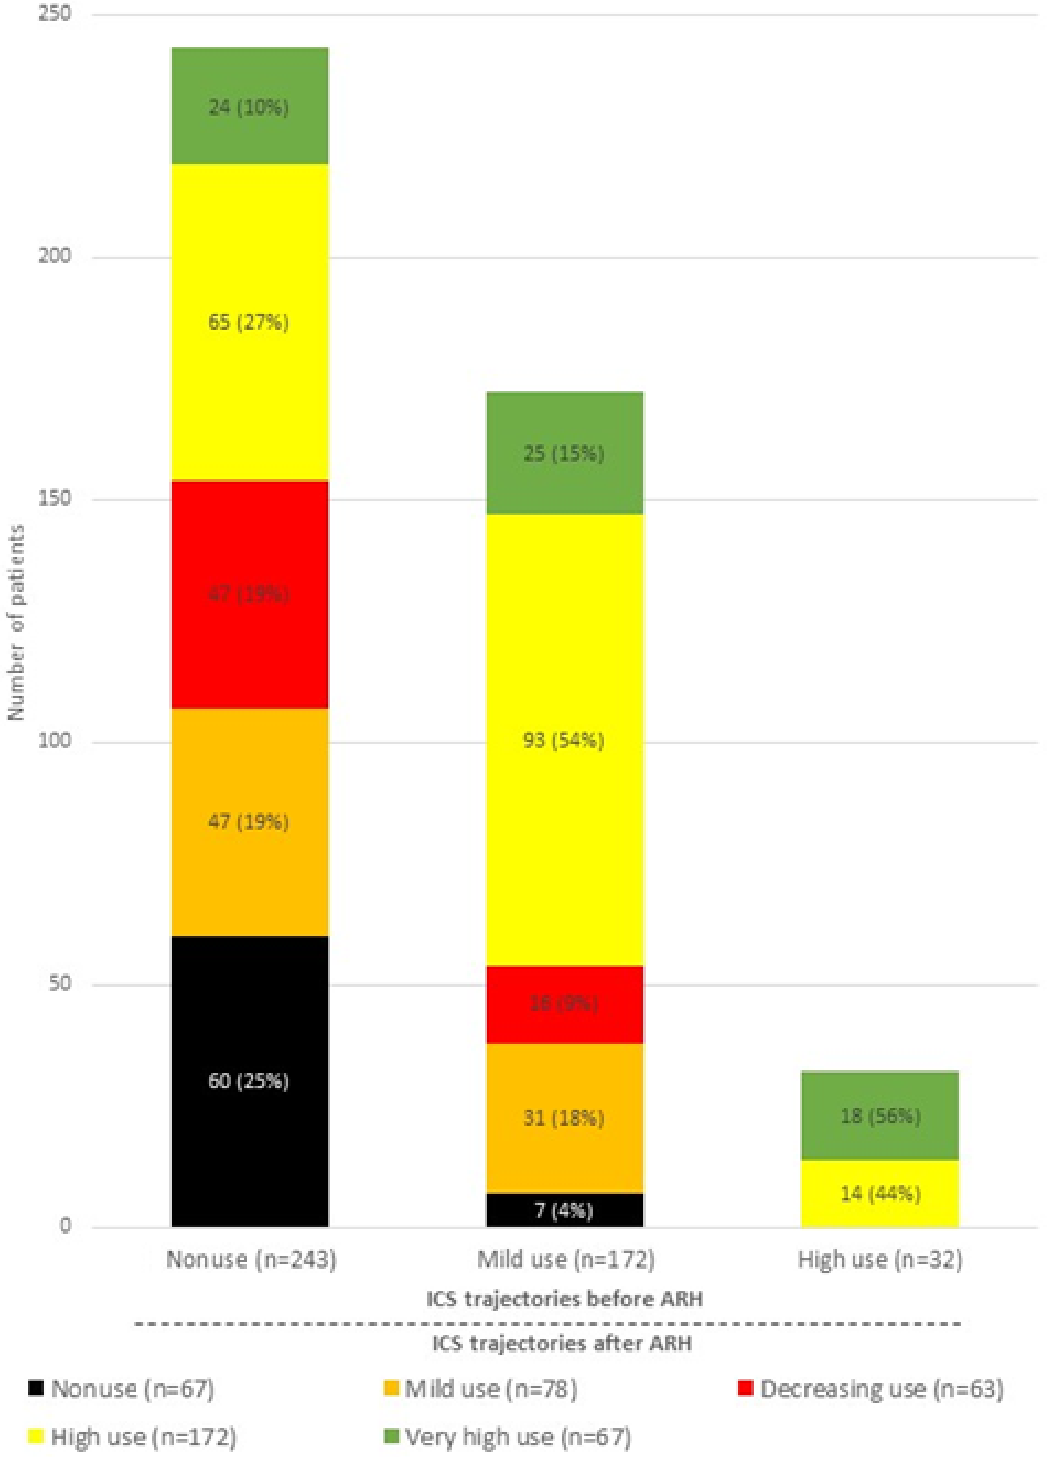
ICS Trajectories After ARH in the Children

In the year following ARH, 5 trajectories were distinguished in the children (Figure 3B). More than half of the children (239/447, 53.5%) had CMA7 values >50%. These included either very high users (n=67) with CMA7 values of >80% throughout the year or high users (n=172) with CMA7 values declining from 70% to 50% throughout the year. Nonusers (CMA7=0) corresponded to 15.0% (67/447) of all children. Mild users (n=78) had stable CMA7 values (20%-30%) throughout the following year, whereas decreasing users (n=63) had CMA7 values of 60% at the beginning of the year, which declined to zero by the end of the year.

Changes in Trajectories (Before-After ARH) in the Children

All children in the high-use group before ARH maintained a high-use profile during the year after hospitalization (Figure 4). Almost a quarter (60/243, 24.7%) of nonusers before ARH remained unchanged in the following year, whereas one-third (89/243, 36.6%) of nonusers switched to the high-use group after ARH. More than two-thirds (149/243, 61.3%) of mild users before ARH increased their use of ICSs after ARH, with 54.1% (93/172) becoming high users and 14.5% (25/172) becoming very high users. Graphs presenting the between-group interchange of individual patients are presented in Multimedia Appendix 2.

Figure 4. Distribution of inhaled corticosteroid (ICS) trajectories of children before and after asthma-related hospitalization (ARH) (n=447).



Population Characteristics Before ARH in the Teens/Adults

At baseline, the mean age of the teens/adults was 45.7 years, and most patients were female (254/416, 61.1%). Moreover, 13.5% (56/416) had free access to care, 15.4% (64/416) had a chronic disease status for asthma, and 38.5% (160/416) had visited a respiratory physician or pediatrician. Almost one-third (137/416, 32.9%) of the patients had one or more ER visits, and 30.0% (125/416) underwent pulmonary function testing (Table 2). At the time of the study, 11.8% (49/416) of the teens/adults were using LABAs in monotherapy, 70.4% (293/416) received respiratory antibiotics, and 55.5% (231/416) received OCSs. Additionally, few patients (112/416, 26.9%) had high therapeutic ratios (≥0.5).

Table 2. Characteristics of the teens/adults at baseline (T0) overall and in the different preasthma-related hospitalization trajectories.

ICS Trajectories Before ARH in the Teens/Adults

Among the teens/adults, 5 ICS trajectories were distinguished before ARH. These were as follows: (1) no use (CMA7 value of about 0; 134/416, 32.2%), (2) mild use (CMA7 value of 30%-35%; 100/416, 24.0%), (3) increasing use over time (CMA7 value rising from 0% 1 year before ARH to 60% at the time of ARH; 45/416, 10.8%), (4) high use (CMA7 value of 60%-80%; 82/416, 19.7%), and (5) very high use (CMA7 value of >90%; 55/416, 13.2%) (Figure 3C). More than half of nonusers (75/134, 56.0%) were aged between 11 and 35 years, whereas almost two-thirds of high (49/82, 59.8%) or very high (36/55, 65.5%) users were older than 50 years. The sex ratios also differed between groups, with males representing 41.8% (56/134) of nonusers versus 32.9% (27/82) of high users (Table 2). A chronic disease status for asthma was more frequent among high and very high users (21/82, 25.6% and 21/55, 38.2%, respectively) than among nonusers (4/134, 3.0%). Nonusers and very high users had fewer visits to a respiratory physician (37/134, 27.6% and 18/55, 32.7%, respectively) compared with the other groups (>40%). In terms of asthma therapy, very high users were frequently treated with FDCs, LABAs (in monotherapy), SABAs (10 units per year), respiratory antibiotics (91% of users receiving 10 units per year on average), and OCSs (total annual dose of 1282 mg), while their therapeutic ratios were low overall (40/55, 72.7%).

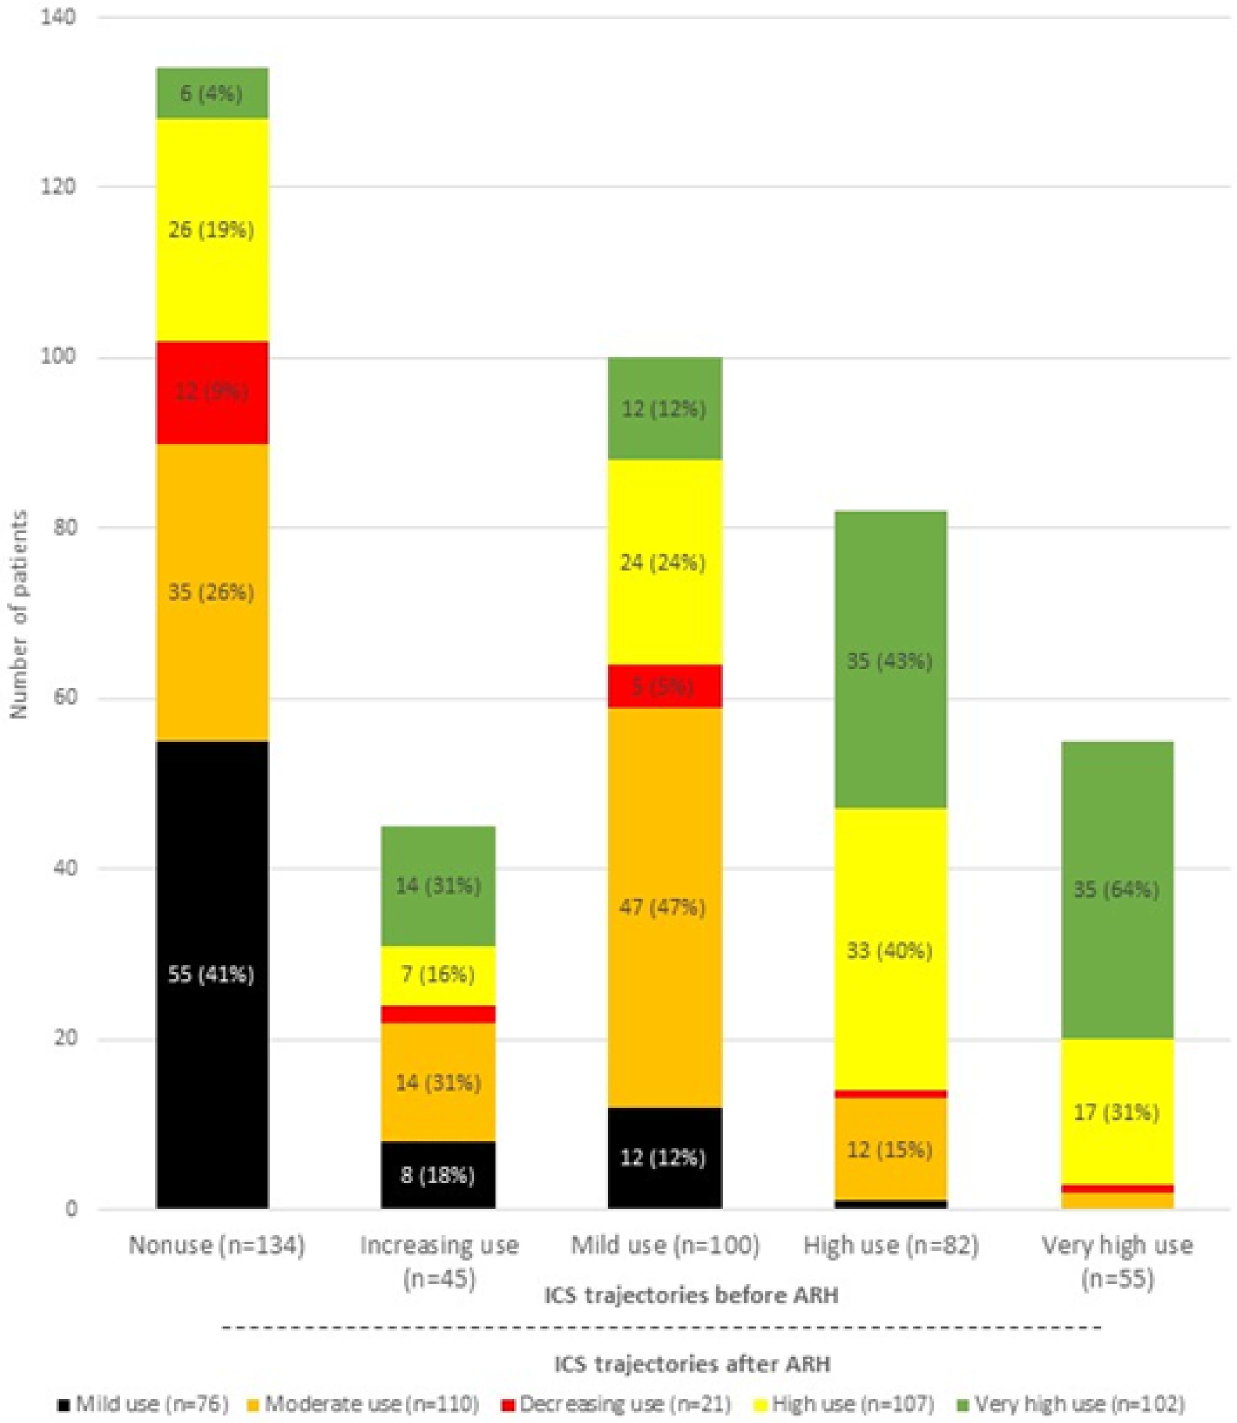
ICS Trajectories After ARH in the Teens/Adults

These patients were also distributed across 5 groups in the year following ARH. Half of them (209/416, 50.2%) were very high (CMA7 value of >90%) or high (CMA7 value of >65%) users, whereas 44.7% (186/416) were mild (CMA7 value of <20%) or moderate (CMA7 value of 30%-50%) users. The last group included a few patients (21/416, 5.1%) with decreasing use during the year following ARH, from 80% shortly after ARH to zero after the third quarter of the subsequent year (Figure 3D).

Changes in Trajectories (Before-After ARH) in the Teens/Adults

While 23.9% (99/416) of nonusers before ARH started to use ICS regularly after ARH, most patients in that group remained in an irregular use profile in the year following their hospital stay, with 41.0% (55/134) in the mild use group and 9.0% (12/134) in the decreasing use group (Figure 5). Another quarter (32/134, 26.1%) of nonusers increased their use constantly throughout the subsequent year and were thus transferred to the moderate use group.

Figure 5. Distribution of inhaled corticosteroid (ICS) trajectories of teens/adults before and after asthma-related hospitalization (ARH) (n=416).



In the group with increasing ICS use before ARH, 31.1% (14/45) stayed at a similar CMA7 level and 31.1% (14/45) switched to the very-high-use group. Lastly, most patients in the other 3 groups (mild, high, and very high use) exhibited a similar profile of ICS use after ARH compared with the year prior to ARH. Patients with CMA7 values of >60% either stayed in the same profile group or switched to the closest similar profile group (high-use to very-high-use group at 42.7% [35/82] and very-high-use to high-use group at 30.9% [17/55]). Patients in the mild-use group before ARH mostly stayed in this profile group, while 47.0% (47/100) of them joined the moderate-use group during the year after ARH. The overall trajectories of the teen/adult patients switching from groups are presented in Multimedia Appendix 3.

Discussion

Our study of the long-term routine care of pediatric and adult patients admitted to the hospital for asthma exacerbation (ARH) showed major temporal changes in ICS use before and after ARH. ARH seems to have similar effects on the typology of use in children and teens/adults. Indeed, in both populations, segmented regression analyses showed 3 contrasting segments:

pre-ARH segment (Q1-Q3) with stable use, ARH segment (Q4-Q5) with increasing use, and post-ARH segment (Q6-Q8) with use decreasing again. Interestingly, for children, the post-ARH levels of ICS use did not appear to decline to the pre-ARH levels. As a rule, trajectories were related to patient sociodemographic characteristics, health care pathways, and asthma therapy, in the context of overall poor quality of care.

Overall, our study identified 3 sets of behaviors regarding the impact of ARH on ICS use. First, in terms of improved typology, 46.3% (207/447) of nonusers or mild users before ARH increased their ICS use after hospital stay. This was the case for 46.5% (208/447) of children and 39.9% (166/416) of teens/adults with low ICS use before ARH. This may correspond to a recent or reconfirmed diagnosis of asthma.

Second, in terms of the limited impact of ARH on typology, most regular users (high-use and very-high-use groups) before ARH remained in the high or very-high-use group after ARH. These patients likely had been identified as experiencing more severe or difficult asthma before ARH and remained regularly treated. This assumption is supported by patient characteristics, such as a high rate of a chronic disease status, which is typically allocated to more severe patients, in addition to a high proportion of OCS users.

Lastly, in terms of decreased use, a minority of patients from the high-use or very-high-use group shifted to the decreasing-use or low-use group.

In all trajectories, a majority of the children had visited a pediatrician or a respiratory physician, and many children had visited the ER, suggesting that asthma was suspected before ARH, despite the low age of the pediatric sample population [21]. The use of OCSs and respiratory antibiotics was also very common before ARH, with a large majority of patients receiving respiratory antibiotics and OCSs among high ICS users. In this group, the annual dose of OCSs far exceeded the dose considered to be the threshold for OCS severe side effects [22]. The therapeutic ratio in this group was also of concern since almost half (14/32, 44%) of the children had a low ratio during the baseline period, implying an overuse of SABAs [23]. Overall, the data may reflect severity, but they do also suggest an overall poor quality of asthma care in the pediatric population.

Among teens/adults, the ratios were low (<0.5) in many teens/adults in the baseline period, which again reflects inappropriate care of asthma. The use of OCSs was also high in all teens/adults, and was particularly high (MAD of >1000 mg) in the very-high-use group, in addition to very high use of SABAs and respiratory antibiotics. More than one in 10 teens/adults inappropriately received LABAs in a separate canister [24].

Overall, the data show that although the clustering-derived typologies differed between children and teens/adults in the pre-ARH period, the global trajectories of these 2 independent samples were similar, supporting the validity of our results. A major finding is that ARH occurred in the context of low quality of care and overuse of medical resources in a population largely affected by social deprivation, as already pointed out by prior studies [25]. Our study does indeed illustrate the high proportion of patients visiting ERs before ARH (more than one-third of children [171/447, 38.3%] and teens/adults [137/416, 32.9%]), the low therapeutic ratios, and the extensive use of OCSs and respiratory antibiotics.

Regarding existing literature, studies assessing ICS use in asthma over an extended period are scarce [26]. This is particularly the case outside the context of specific prospective cohorts and thus limits the comparison with other data. In a prospective study, Krishnan et al [9] showed a rapid decrease in the use of ICSs and OCSs by asthmatic patients after hospital discharge, but no information was provided on their use before admission. Another study showed inappropriate use in children after ARH; however, again, there was no assessment of their use before ARH [27]. Similarly, Williams et al [10] clarified the overall relationship between changing ICS use and the occurrence of severe exacerbations, including ARH. Prior data on the relationship between ICS use and exacerbations may however not be generalizable since asthmatics are heterogeneous in their use of therapy and their behaviors may differ in routine care compared to investigational conditions. Of interest, a recent Danish study investigated the effect of hospital admissions for acute exacerbation on the adherence rate to controller medication in 241 adults with asthma. Their results were similar to ours in that an initial improvement in adherence to ICSs after hospital admission occurred in patients who had previously shown poor adherence. The study also showed that the improvement was transient and decreased over time during the 6 months after discharge [28]. International comparisons are however complex since patient behaviors toward therapy also depend on the local organization of health care with, for instance, the level of care co-payments, or the accessibility to health care professionals, which may affect the relationship between ICS use and exacerbation. This underlines the need to replicate investigations in different settings.

Our study had several strengths. It was a population-based study, and it was conducted with a random sample originating from data compiled from the health care consumption information of almost all French citizens (over 67 million inhabitants), without distinction of age, gender, ethnicity, residency, income, and social status, in a large country with a single universal health care system. These strengths allowed us to overcome the limitations of other studies on asthma care, such as distinct health care coverage for different patient groups or missing information as a result of fragmented care [29].

The study also had some limitations. There was no information on the education level of the patients and whether this had an impact on their trajectory. There was also no information on smoking status, pulmonary function, or BMI that may have impacted the effects of ICSs. We used CMA7 to assess ICS use. Considering that claims information provides medicine dispensing data, CMA7 measures were based on the dispensing number and frequency but did not reflect actual medication use or provide data on the quality of the inhaler technique. Additionally, we included all patients undergoing ARH during the study period independent of their ICS use and asthma diagnosis before ARH. As an alternative, we could have restricted the inclusion to patients who received an initial diagnosis of asthma during their hospital stay. Such cases were however rare among both children and teens/adults, as evidenced by the high percentage of visits to a respiratory specialist (115/447, 25.7% and 160/416, 38.5%, respectively), and by the common records of pulmonary function tests performed during the baseline period. Consequently, the impact on the results should be limited. Another limitation may have been due to the exclusion of patients who did not have continuous follow-up information recorded in the database either before or after ARH. However, those patients were excluded for administrative reasons, that is, they were affiliated to rare insurance schemes not included in the database. We feel confident that there is no reason why those patients would differ in their typologies compared with the patients included in the cohort. Finally, it may be of interest to reproduce a similar analysis in a larger population, as our sample was limited to 447 children and 416 teens/adults.

Overall, our study demonstrated inappropriate ICS use in routine care before ARH, which transiently improved shortly before and after discharge in the context of overall poor quality of care, in a largely socially deprived population experiencing persistent asthma. Our results suggest that interventions are urgently needed to improve the use of controller therapy for asthma in routine care [30], particularly during or after ARH [31]. These interventions should be based on specific patient profiles and trajectories of use before ARH. For instance, therapeutic education with action plans [32,33] or the setup of maintenance and relief therapy [34] could be a priority for some trajectories. As a rule, clinicians should emphasize the need to make regular use of controllers at appropriate doses and to make parsimonious use of relievers and OCSs. The findings are consistent with those of a recent study on care for persistent asthma that showed a decrease in primary care physician involvement and an increase in the incidence of ER visits between 2006 and 2016 [35].

In conclusion, we showed that although ARH had an overall positive impact on the trajectories of ICS use, this effect was often transient, patient behaviors were heterogeneous, and several distinctly different trajectories were identified. Additional patient and care characteristics could further improve the understanding of our findings and help more efficiently target patients in need of preventive interventions. Our data reinforce the evidence that inappropriate use of ICSs paves the way for ARH, and thus, the findings should galvanize health service efforts to keep individual ICS use at optimal levels.

Acknowledgments

The authors would like to thank the Caisse Nationale de l'Assurance Maladie for providing data, as well as Marty Brucato and Sarina Yaghobian from AcaciaTools for their medical writing and reviewing services. This work was supported by PELyon.

Data Availability

Owing to National Health Service and Système National des Données de Santé (National Health Data System) rules, no data sharing is possible, as access to data is restricted to habilitated and qualified researchers (MN and FJ are habilitated and qualified).

Authors' Contributions

MB and EVG designed the study and were responsible for producing the initial draft of the paper. CMM was responsible for producing a comprehensive version of the paper and for integrating all author comments to produce the final version. MN and FJ carried out the primary statistical analysis, constructed the figures and tables, and reviewed the manuscript to produce a finalized version.

Abstract

Background: The reported incidence of acute hepatitis C virus (HCV) infection is increasing among persons of childbearing age in the United States. Infants born to pregnant persons with HCV infection are at risk for perinatal HCV acquisition. In 2020, the United States Preventive Services Task Force and Centers for Disease Control and Prevention recommended that all pregnant persons be screened during each pregnancy for hepatitis C. However, there are limited data on trends in hepatitis C testing during pregnancy.

Objective: We estimated hepatitis C testing rates in a large cohort of patients with Medicaid and commercial insurance who gave birth during 2015-2019 and described demographic and risk-based factors associated with testing.

Methods: Medicaid and commercial insurance claims for patients aged 15-44 years and who gave birth between 2015 and 2019 were included. Birth claims were identified using procedure and diagnosis codes for vaginal or cesarean delivery. Hepatitis C testing was defined as an insurance claim during the 42 weeks before delivery. Testing rates were calculated among patients who delivered and among the subset of patients who were continuously enrolled for 42 weeks before delivery. We also compared the timing of testing relative to delivery among patients with commercial or Medicaid insurance. Multivariable logistic regression was used to identify factors associated with testing.

Results: Among 1,142,770 Medicaid patients and 1,207,132 commercially insured patients, 175,223 (15.3%) and 221,436 (18.3%) were tested for hepatitis C during pregnancy, respectively. Testing rates were 89,730 (21.8%) and 187,819 (21.9%) among continuously enrolled Medicaid and commercially insured patients, respectively. Rates increased from 2015 through 2019 among Medicaid (from 20,758/108,332, 19.2% to 13,971/52,330, 26.8%) and commercially insured patients (from 38,308/211,555, 18.1% to 39,152/139,972, 28%), respectively. Among Medicaid patients, non-Hispanic Black (odds ratio 0.73, 95% CI 0.71-0.74) and Hispanic (odds ratio 0.53, 95% CI 0.51-0.56) race or ethnicity were associated with lower odds of testing. Opioid use disorder, HIV infection, and high-risk pregnancy were associated with higher odds of testing in both Medicaid and commercially insured patients.

Conclusions: Hepatitis C testing during pregnancy increased from 2015 through 2019 among patients with Medicaid and commercial insurance, although tremendous opportunity for improvement remains. Interventions to increase testing among pregnant persons are needed.

Introduction

Chronic hepatitis C virus (HCV) infection is a leading cause of liver disease and liver-related mortality in the United States. Approximately 2.4 million persons in the United States were living with chronic hepatitis C during 2013-2016 [1,2]. These patients are at increased risk of progression to liver fibrosis, cirrhosis, liver failure, hepatocellular carcinoma, and death [3]. HCV can be transmitted during pregnancy or delivery—an estimated 5.8% of infants born to women with HCV infection become infected [4]. Perinatal infection can result in liver disease during adulthood and sequelae such as cirrhosis and hepatocellular carcinoma [5]. The incidence of acute HCV infection in the United States increased annually from 2009 to 2019, with rates highest among adults 20-29 and 30-39 years of age, including women of childbearing age [6,7]. These increases are concurrent with increases in the nation's opioid crisis [8]. Recent studies have documented an increasing prevalence of HCV infection among pregnant persons [9]. In 2018, 0.5% of all live births nationally were among mothers with hepatitis C [10]. The rate of maternal HCV infection as recorded on US birth certificates increased by 89% between 2009 and 2014, and rates were highest in Appalachia [11]. Hepatitis C antibody testing among pregnant persons from a large national commercial laboratory increased from 5.7% to 13.4% and test positivity increased from 2.6% to 3.6% from 2011 to 2016, respectively [12].

While chronic HCV infection can be cured with direct-acting antiviral therapy, direct-acting antiviral therapies have not been approved for use during pregnancy by the US Food and Drug Administration [13]. However, identifying hepatitis C during pregnancy offers several advantages, including referral for care and treatment for the pregnant person and referral for testing for the exposed infant and can inform clinical decision-making during prenatal and intrapartum care [14]. Since 2012 and 2013, the Centers for Disease Control and Prevention (CDC) and the United States Preventive Services Task Force (USPSTF), respectively, have recommended 1-time hepatitis C testing for all persons born from 1945 through 1965 and testing adults with risk factors for HCV infection [15]. In 2018, the American Association for the Study of Liver Diseases and the Infectious Diseases Society of America recommended hepatitis C screening during each pregnancy [13]. In 2020, the USPSTF and CDC recommended that all pregnant persons be screened during each pregnancy for hepatitis C [14]. However, there are limited data on trends in hepatitis C testing during pregnancy. We estimated hepatitis C testing rates in a large cohort of patients with Medicaid and commercial insurance who gave birth during 2015-2019 and described demographic and risk-based factors associated with testing.

Methods

Overview

Data for persons with commercial, Medicare Supplemental, and Medicaid insurance were obtained from the Merative MarketScan Research Databases. These data include demographics, insurance enrollment information, inpatient and outpatient, and prescription drug claims. The commercial and Medicare Supplemental databases include US persons with employer-sponsored health insurance coverage and their dependents. The MarketScan Multi-State Medicaid database includes claims for patients enrolled in Medicaid fee-for-service and managed care plans in multiple states; the number and names of states are proprietary and were not disclosed. Data from January 1, 2014, to December 31, 2019, were used to allow for a 42-week baseline enrollment period prior to delivery between 2015 and 2019.

Cohort Selection

We constructed a cohort of female patients aged 15-44 years who gave birth from January 1, 2015, to December 31, 2019. Birth claims were identified using Current Procedural Terminology (CPT) and Diagnosis-Related Group codes specific to vaginal or cesarean delivery (Table S1 in Multimedia Appendix 1). Only the earliest claim for delivery during the study period was retained; the service date of this claim was the patient's index delivery date. As hepatitis C testing during every pregnancy was not recommended during the study period, patients whose HCV infection was identified in the first pregnancy may not have been tested in subsequent pregnancies. Thus, persons with multiple births during the study period were counted once at their earliest delivery.

Measures

Claims for hepatitis C testing were identified using CPT codes for any anti-HCV antibody, RNA, and genotyping tests. The anti-HCV antibody test indicates past or current HCV infection, while HCV RNA or genotyping test identifies or characterizes current HCV infection. Screening with the HCV antibody test is recommended [14]. Hepatitis C testing during pregnancy was defined as the earliest hepatitis C testing claim in the 42 weeks prior to the index delivery date. Demographic characteristics included age, race or ethnicity (Medicaid only), and region of residence (commercial only). Clinical characteristics (alcohol use disorder, opioid use disorder, severe mental illness, obesity, HIV infection, gestational diabetes, preeclampsia, preterm labor, and singleton or multiple pregnancy) were identified using the International Classification of Diseases, Ninth/Tenth Revision, Clinical Modification (ICD-9/10-CM) codes associated with a claim in the 42 weeks prior to the index delivery date. Additional prenatal care characteristics included an obstetric test panel (including complete blood count, hepatitis B surface antigen, rubella antibody, nontreponemal syphilis test, ABO blood group and Rh typing, and red blood cell antibody screen) claim and influenza and tetanus-diphtheria-acellular pertussis (Tdap) vaccination during the 42 weeks before the index delivery date and were defined using CPT codes (Table S1 in Multimedia Appendix 1).

Statistical Analysis

Due to incomplete follow-up during the 42 weeks before the index delivery date, we estimated the rate of hepatitis C testing during pregnancy using two methods: (1) percent tested among all patients who gave birth during the study period regardless of baseline enrollment criteria and (2) percent tested among patients continuously enrolled for 42-week period prior to the index delivery date. In sensitivity analyses, we explored the impact of (1) changing the continuous enrollment criteria (12, 24, and 36 weeks, and median time to hepatitis C test), (2) restricting the sample to patients who had an obstetric panel test claim in the 42 weeks before the index delivery date, and (3) restricting the sample to patients who had any inpatient or outpatient service claim in the 42 weeks prior to the index delivery date on the estimated testing rate. The cumulative incidence of testing among patients continuously enrolled for at least 7 days before the index delivery date was also estimated using the Kaplan-Meier method. The Kaplan-Meier method can be used to estimate testing incidence in the presence of censoring (ie, incomplete follow-up). We included a 7-day enrollment minimum to exclude outliers and ensure some demographic and clinical data would be available.

We estimated the testing rate by year of delivery for each cohort and tested for statistically significant trends using the Cochran-Armitage test or for cumulative incidence estimates, and the Gray test for equality of cumulative incidence functions. Additionally, we examined the distribution of time between hepatitis C testing and index delivery date by year of delivery and insurance type. Demographic and clinical characteristics for cohorts constructed using both methods (no enrollment constraint and continuously enrolled for 42 weeks) were described by insurance type and hepatitis C testing status. Multivariable adjusted associations between demographic and clinical characteristics were estimated using logistic regression with the outcome defined as a claim for hepatitis C testing during the 42-week period prior to the index delivery date. We included all variables in multivariable models because our analysis was primarily exploratory and causal relationships between these variables and hepatitis C testing are poorly understood. Odds ratios and 95% CIs are provided. Adjusted marginal probabilities were also estimated. In a sensitivity analysis, logistic regression was performed for patients who had an obstetric panel test insurance claim. Analyses were performed in SAS (version 9.4; SAS Institute).

Ethical Considerations

This analysis of deidentified data did not require institutional review board approval.

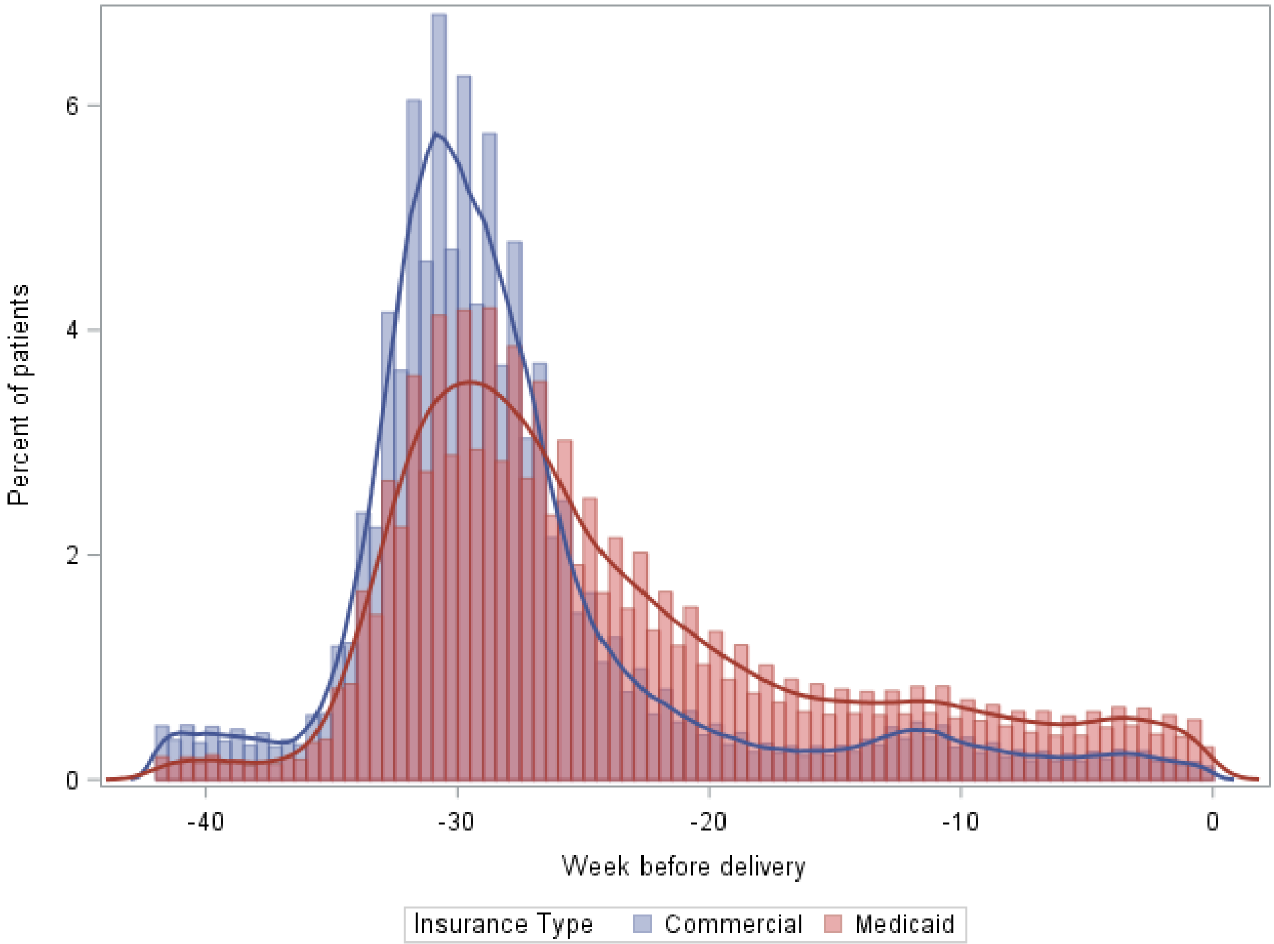
Results

Overview

We identified 1,152,283 patients with Medicaid and 1,217,686 patients with commercial insurance who had delivery claims between 2015 and 2019. Among these persons, 1,142,770 (99.2%) Medicaid patients and 1,207,132 (99.1%) commercially insured patients had valid demographic and enrollment information. When restricting the analyses to patients who were continuously insurance enrolled for 42 weeks prior to the index delivery date, 411,795 (36%) Medicaid patients and 857,618 (71%) commercially insured patients remained. Among all Medicaid patients, 175,223 (15.3%) were tested for hepatitis C in the 42 weeks prior to the index delivery date; among the continuously enrolled subset, 89,730 (21.8%) were tested. Among all commercially insured patients, 221,436 (18.3%) were tested for hepatitis C before the index delivery date, and among the continuously enrolled subset, 187,819 (21.9%) were tested.

A majority of tested Medicaid (162,868/175,223, 93%) and commercially insured (217,969/221,436, 98.5%) patients were tested for HCV antibody only. The median time between hepatitis C testing and index delivery date for Medicaid patients was 186 (IQR 137-211) days (Figure 1). For commercial insurance patients, the median time between hepatitis C testing and index delivery date was 206 (IQR 184-222) days, suggesting they were tested on average 20 days earlier than Medicaid patients.

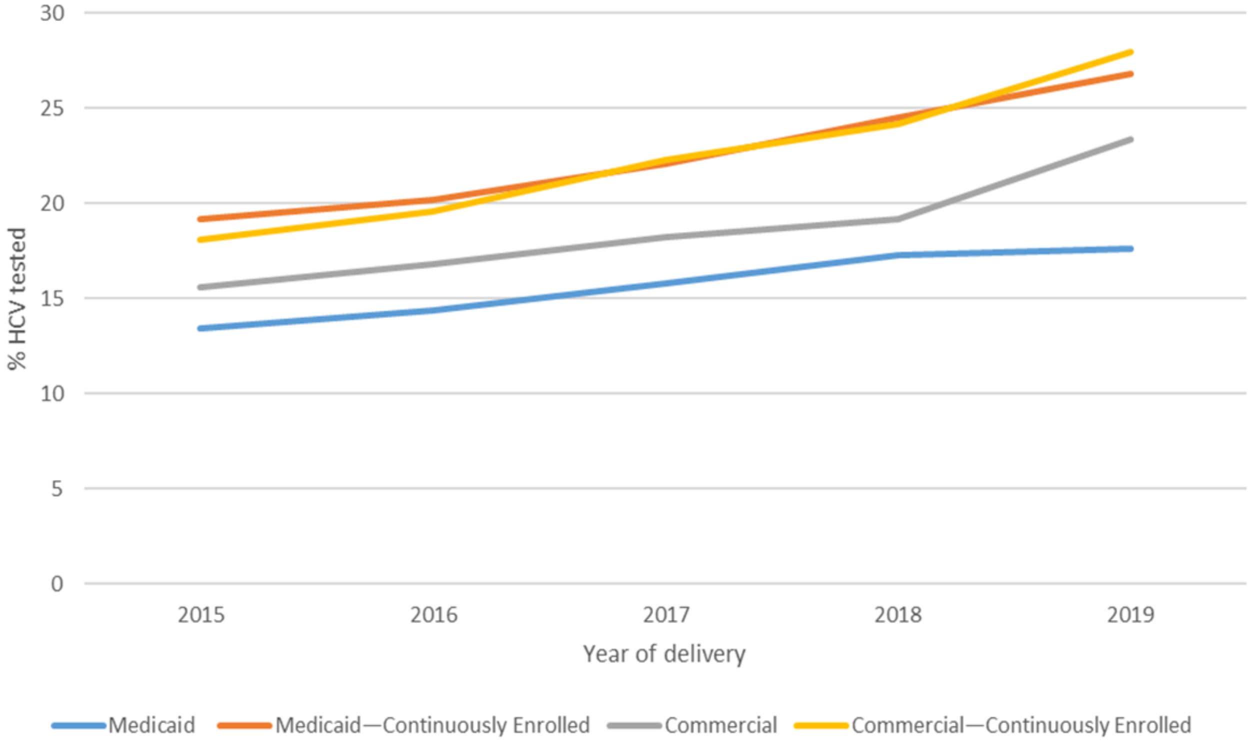
Figure 1. Distribution of weeks between hepatitis C test and delivery date, MarketScan Medicaid and Commercial.



Trends in Hepatitis C Testing

The hepatitis C testing rate increased from 2015 to 2019 for both Medicaid and commercially insured patients (Figure 2). Among Medicaid patients, testing rates increased from 13.4% (40,351/301,849) in 2015 to 17.6% (31,123/177,004) in 2019, and among continuously enrolled persons, testing rates increased from 19.2% (20,758/108,332) in 2015 to 26.8% (13,971/52,230) in 2019. Among commercially insured patients, the testing rates increased from 15.6% (43,941/281,007) in 2015 to 23.4% (45,930/296,344) in 2019, and among continuously enrolled persons, the testing rates increased from 18.1% (38,308/211,555) in 2015 to 28% (39,152/139,972) in 2019. Trends in testing were similar in the sensitivity analysis using different continuous enrollment thresholds and testing rate estimation methods: testing rates increased between 2015 and 2019 across all methods. Among patients with Medicaid insurance, the average annual change in testing rate varied from 0.8% for the cohort with no enrollment constraints to 1.7% for the cohorts with an obstetric panel claim. Among patients with commercial insurance, the average annual change in testing rate varied from 1.6% for the cohort with no enrollment constraints to 2% for the Kaplan-Meier estimate (Table S3 in Multimedia Appendix 1).

Figure 2. Hepatitis C testing by year of delivery and insurance type. HCV: hepatitis C virus.



Characteristics of Continuously Enrolled Cohorts

Demographic characteristics of patients by insurance type and hepatitis C testing status for the continuously enrolled cohorts are included in Table 1. Patients with Medicaid insurance in the continuously enrolled cohort were predominantly aged 19-29 years (265,421/411,795, 64.5%) followed by those aged 30-39 years (107,665/411,795, 26.2%). The distribution of race and ethnicity was as follows: 48% (196,441/411,795) of Medicaid patients were non-Hispanic White, followed by non-Hispanic Black (152,700/411,795, 37.1%), other race and ethnicity (44,891/411,795, 10.9%), Hispanic, all races (15,347/411,795, 3.7%), and unknown race or ethnicity (2416/411,795, 0.6%). High-risk pregnancy (202,584/411,795, 49.2%), obesity (78,781/411,795, 19.1%), preterm labor (63,219/411,795, 15.4%), severe mental illness (52,133/411,795, 12.7%), and gestational diabetes (35,249/411,795, 8.6%) were the most frequently occurring underlying conditions (Table 2). Forty-three percent (175,695/411,795) of patients received an obstetric panel test; 28.7% (117,969/411,795) and 15.7% (64,433/411,795) received Tdap and influenza vaccinations, respectively.

On average, commercially insured patients in the continuously enrolled cohort were older than the Medicaid patients. Among patients with commercial insurance, those aged 30-39 years (494,564/857,618, 57.7%) represented the largest age group, which is followed by those aged 19-29 years (315,311/857,618, 36.8%). In terms of geographic distribution, patients resided in the south (387,766/857,618, 45.2%), north central (177,013/857,618, 20.6%), west (148,048/857,618, 17.3%), and northeast (142,531/857,618, 16.6%). The distribution of underlying conditions also differed for the commercial sample relative to those with Medicaid: high-risk pregnancy (361,659/857,618, 42.2%), obesity (103,780/857,618, 12.1%), gestational diabetes (90,884/857,618, 10.6%), and preterm labor (73,004/857,618, 8.5%) were the most frequently occurring underlying conditions. Opioid use disorder (2443/857,618, 0.3%) and alcohol use disorder (1656/857,618, 0.2%) were less common than among Medicaid patients (14,069/411,795, 3.4% and 4973/411,795 1.2%, respectively). Claims for an obstetric panel test (470,404/857,618, 54.9%), Tdap vaccination (455,485/857,618, 53.1%), and influenza vaccination (258,427/857,618, 29.1%) were more common among commercially insured patients.

Factors Associated With Testing Among Continuously Enrolled Patients

Hepatitis C testing status varied by patient characteristics. Adjusted associations between patient characteristics and hepatitis C testing status are presented in Table 3. Among the continuously enrolled Medicaid patients, patients aged 40-44 years (odds ratio [OR] 0.85, 95% CI 0.80-0.90) were less likely to be tested than younger patients. Relative to non-Hispanic White patients, Hispanic patients (OR 0.53, 95% CI 0.51-0.56), non-Hispanic Black (OR 0.73, 95% CI 0.71-0.74), and other race (OR 0.90, 95% CI 0.88-0.92) were less likely to be tested among Medicaid patients.

Patients with opioid use disorder (OR 3.75, 95% CI 3.62-3.89) or HIV infection (OR 5.40, 95% CI 4.71-6.20) claims were significantly more likely to be tested than those without these conditions. Patients with severe mental illness claims or alcohol use disorder were 1.28 (95% CI 1.25-1.30) and 1.29 (95% CI 1.21-1.37) times more likely to be tested than those without these conditions. High-risk pregnancy (OR 1.46, 95% CI 1.44-1.48) was associated with higher odds of testing, whereas multiple gestations (OR 0.91, 95% CI 0.86-0.96) was associated with lower odds of testing compared to patients without these characteristics.

Among patients with commercial insurance, patients living in the north central (OR 0.40, 95% CI 0.39-0.40), west (OR 0.49, 95% CI 0.48-0.50), and south (OR 0.79, 95% CI 0.78-0.80) were less likely to be tested compared to patients residing in the northeast region. Patients with opioid use disorder (OR 2.33, 95% CI 2.15-2.53), HIV infection (OR 1.96, 95% CI 1.70-2.27), and alcohol use disorder (OR 1.36, 95% CI 1.22-1.51) were more likely to be tested than patients without these conditions. High-risk pregnancy (OR 1.23, 95% CI 1.22-1.25), obesity (OR 1.15, 95% CI 1.13-1.17), and multiple gestations (OR 1.11, 95% CI 1.08-1.14) were associated with higher odds of testing compared to patients without these characteristics. Among the cohort of commercially insured patients with no enrollment constraint, effect estimates were higher relative to those with the constraint but overall consistent in the direction of effects. Adjusted marginal probabilities of hepatitis C testing are shown in Table S6 in Multimedia Appendix 1.

Sensitivity Analyses

In the sensitivity analysis of testing rate by inclusion criteria and estimation method, the estimated testing rates increased as the length of the continuous enrollment period increased. The Kaplan-Meier method yielded higher estimates relative to naïve estimates. In addition, patients with an obstetric panel test had higher HCV testing rates relative to those who did not. Overall, differences in estimates across methods and inclusion criteria were larger for the Medicaid patients relative to the commercially insured patients (Table S2 in Multimedia Appendix 1).

In the sensitivity analyses of adjusted associations for HCV testing that included demographic and clinical characteristics, estimates for the Medicaid sample with an obstetric panel test were similar to those who were continuously enrolled for 42 weeks (Table S5 in Multimedia Appendix 1). Among commercially insured patients, the effect estimate for HIV infection was larger (OR 2.61 vs 1.96) for individuals with an obstetric panel test compared to patients enrolled for 42 weeks, although CIs overlapped, and gestational diabetes and preterm labor were not associated with higher odds of testing.

Discussion

Principal Findings

We estimated the rates of testing for hepatitis C during pregnancy in a large national sample of patients with Medicaid and commercial insurance using multiple methods. These estimates could serve as a baseline for understanding and monitoring the impact of CDC's hepatitis C screening recommendations on testing rates during pregnancy. Our results also suggest that patients who are pregnant are most often tested for hepatitis C early in pregnancy. However, Medicaid patients were more likely to be tested closer to the delivery date than commercially insured patients. This is likely linked to later entry into prenatal care as evidenced by the smaller proportion of Medicaid patients continuously enrolled in the 42 weeks prior to delivery, more frequent changes in insurance enrollment (ie, "churn"), or systematic differences in prenatal care practices among providers serving Medicaid patients. It may also be impacted by ongoing risk behaviors (eg, injection drug use) for HCV infection, which might trigger testing when disclosed to the provider. Testing rates for both Medicaid and commercially insured patients increased annually during 2015-2019. As national recommendations for testing during pregnancy did not change during the study period, these trends might reflect the increasing prevalence of or improved ascertainment of hepatitis C risk factors among pregnant persons and increasing awareness among clinicians.

Multiple factors associated with receipt of hepatitis C testing were identified. Results were largely similar for Medicaid and commercially insured patients. Younger patients were more likely to be tested than patients in the oldest age group. Among Medicaid patients, lower rates of testing were identified among Hispanic, non-Hispanic Black, and other non-White non-Hispanic patients. Lower access to prenatal care and quality of prenatal care among racial and ethnic minorities have been extensively reported in the literature [16]. Among commercially insured patients, those residing in the northeast were most likely to be tested. This might reflect regional differences in risk factor prevalence and providers' testing practices.

Patients with opioid use disorder and HIV infection were approximately 2 to 5 times more likely to be tested. Risk-based testing guidelines recommend testing for these patients; however, current CDC guidance recommends screening all pregnant persons during every pregnancy. Other observed associations such as those with alcohol use disorder and severe mental illness might also reflect unidentified injection drug use. Associations with an obstetric panel test and maternal vaccinations might be due to better retention in or quality of prenatal care. Preterm labor, high-risk pregnancy, obesity, and preeclampsia were also associated with higher odds of testing; these conditions might lead to more intensive prenatal care and inclusive testing practices. Associations with small effect sizes (eg, preterm labor) might also be due to residual confounding.

A single-center study conducted in an urban medical center in 2016 found that only 7% of pregnant patients were tested for hepatitis C [17]. Our estimates were substantially higher and may reflect differences in inclusion criteria (eg, pregnancies versus deliveries) and study populations. Low testing rates might result from a lack of assessment of hepatitis C risk factors and limited reporting of risk factors by pregnant individuals. Previous studies have reported that 10% to 59% of anti-HCV–positive pregnant persons reported no risk factors and that approximately two-thirds of patients who are pregnant reporting risk factors were not tested for hepatitis C [17,18]. A recent study of commercial laboratory test data found that 18% and 25% of obstetric panels for commercial and Medicaid patients, respectively, also had an HCV antibody test within a year [19]. Estimates of the hepatitis C testing rate were sensitive to inclusion criteria (eg, continuous enrollment thresholds). This was particularly evident for Medicaid patients for whom testing rates ranged from 15.3% to 23.9%. Continuously enrolled Medicaid and commercially insured patients had similar testing rates. Validation studies are required to assess which method is most accurate. However, the estimates of testing rate trends were robust to different methods of defining the study sample and estimating the testing rate.

Limitations

This study has several limitations. Administrative data for a very large convenience sample of pregnant persons were used, but we could not evaluate whether this population was representative of all persons who gave birth in the United States. While patients with private insurance and Medicaid were included, women with other forms of insurance or women who were uninsured were not included. The study was also limited to patients who gave birth and did not include pregnancies that ended in spontaneous abortion or termination. Incomplete follow-up was common for this sample and may have resulted in underestimation of testing prevalence if women were tested and then lost to follow-up. Insurance change is relatively common among pregnant persons in the United States; approximately 30% change insurance plans between the preconception period and delivery [20]. We were unable to validate the administrative codes used to identify pregnant persons. Some persons might have been misclassified. The prevalence of obstetric panel testing was lower than expected and might be due to misclassification of pregnancy or testing status (ie, due to missing test panel claims).

These data did not include a measure of socioeconomic status other than insurance type and race or ethnicity (Medicaid only), and variation in testing rate by income, rural and urban status, and so on were not examined. Although procedure codes were used to identify hepatitis C testing, the reason for testing (ie, screening or diagnostic testing) could not be ascertained nor whether testing was motivated by risk factor assessment. Finally, ICD-9/10-CM codes were used to define several clinical characteristics, but we could not assess the sensitivity or specificity of these codes. Additionally, patients with known chronic HCV infection were not excluded from the analysis; this could lead to underestimation of screening rates as these patients should not be included in the denominator.

Despite increases during the study period, testing for hepatitis C remained low in this large national sample of pregnant persons with commercial insurance and Medicaid. The USPSTF and CDC 2020 recommendations for universal hepatitis C screening during each pregnancy might lead to higher rates of testing. Education of providers to ensure testing during each pregnancy, and additional screening for high-risk behaviors that may necessitate repeat testing during pregnancy, are crucial to prevent perinatal transmission of HCV infection. Interventions to increase hepatitis C screening in other populations, such as electronic health record alerts or targeted patient outreach, could be adapted to the prenatal care setting and merit further study [21]. Racial and ethnic disparities in screening rates could be addressed through communication campaigns using trusted messengers to reach racial and ethnic minorities and prenatal care providers that serve these populations. Unrestricted timely treatment of hepatitis C among persons who are of childbearing age would also reduce perinatal transmission [22]. Interventions to increase testing are needed to address perinatal hepatitis C and eliminate hepatitis C in the United States.

Abstract

Background: The COVID-19 pandemic has led to an increase in known risk factors for mental health problems. Although medical information available through the internet and smartphones has greatly expanded, people’s ability to seek, eschew, and use reliable web-based medical information and services to promote their mental health remains unknown.

Objective: This study aims to explore the associations between coronaphobia and 4 frequently reported mental health problems, loneliness, irritability, depression, and stigma, during the COVID-19 pandemic and to assess the moderating effects of eHealth literacy (eHL) on the adjustment of these relationships in Chinese young adults.

Methods: The data used in this study were collected from a web-based survey of the general Chinese population, aged between 18 and 30 years, conducted in China between December 2022 and January 2023. A nonprobability snowball sampling method was used for data collection. A Bayesian structural equation model (BSEM) using parameter expansion was used to estimate the moderating effect of eHL on the relationship between coronaphobia and psychological problems. The posterior mean and 95% highest density intervals (HDIs) were estimated.

Results: A total of 4119 participants completed the questionnaire and provided valid responses. Among them, 64.4% (n=2653) were female and 58.7% (n=2417) were rural residents. All measures showed statistically significant but minor-to-moderate associations (correlation coefficients ranged from −0.04 to 0.65). Significant heterogeneity was observed between rural and urban residents at the eHL level, and coronaphobia was observed. The BSEM results demonstrated that eHL was a significant moderator in reducing the negative effects of coronaphobia on loneliness (posterior mean −0.0016, 95% HDI −0.0022 to −0.0011), depression (posterior mean −0.006, 95% HDI −0.0079 to −0.004), stigma (posterior mean −0.0052, 95% HDI −0.0068 to −0.0036), and irritability (posterior mean −0.0037, 95% HDI −0.0052 to −0.0022). The moderating effects of eHL varied across the rural and urban subsamples.

Conclusions: Using BSEM, this study demonstrated that improving eHL can significantly mitigate the negative effects of coronaphobia on 4 COVID-19–related mental health problems in Chinese young adults. Future eHL initiatives should target rural communities to ensure equal access to information and resources that can help protect their mental health during the pandemic.

Introduction

The COVID-19 pandemic, which originated in China and spread worldwide, has continued its impact for more than 3 years. This has led to an increase in the known risk factors for mental health problems, such as social isolation, loneliness, inactivity, and limited access to health and social care services [1,2]. Studies have indicated that more than half of those interviewed have experienced moderate-to-severe psychological effects caused by fear of COVID-19, and approximately three-quarters have expressed concern about the health of their family members [3-5].

Experiencing strong fear is normal under uncertain circumstances [6]. However, the COVID-19 pandemic has disrupted people’s ability to lead normal lives. Unlike previous flu epidemics, the fear associated with COVID-19 extends beyond the virus itself, impacting mental health in various ways. This excessive fear response to contracting COVID-19 has led to extreme concern over physiological symptoms, significant stress regarding personal and occupational loss, and avoidance of public places and situations [7]. Along with social distancing and strict quarantine policies worldwide, these fears have generated unprecedented stress on individuals, mentally and emotionally. This uncontrolled and persistent fear has resulted in a new and specific type of anxiety called coronaphobia, exacerbating the consequences on mental health [8].

The COVID-19 pandemic has triggered changes in people’s health care–seeking behavior because of restrictions on social contact, highlighting the importance of digital networks and web-based service platforms [9]. The availability of medical information through the internet and smartphones has greatly expanded the sources for people to seek mental health knowledge and web-based services without leaving their homes during the pandemic. Examples include web-based consultations [10], prescriptions [11], and wireless sensors to monitor the medical conditions of patients [12]. However, the quality of web-based information and services can vary in terms of verifiability, bias, and source. To efficiently navigate the internet, possessing good eHealth literacy (eHL) is particularly important. eHL is an essential skill that ensures people can access reliable web-based medical information and care [13]. Studies have shown that eHL can be useful in alleviating health disparities and improving patient experiences. Equipped with advanced eHL, individuals can search, evaluate, and apply massive amounts of information available on the internet, leading to a significant reduction in their psychological stress [14,15].

The relationship between eHL and psychological status has been widely discussed but is limited in the context of the COVID-19 pandemic. Yang et al [16] found that high eHL was significantly associated with lower levels of depression, insomnia, and posttraumatic stress disorder in 15,000 Chinese individuals. Xu et al [17] also discovered that young people with high eHL who use web-based mental health–related information tend to have a more positive attitude toward seeking mental health services and reporting better mental well-being. Another study demonstrated that rural residents with high eHL were more willing to use telemedicine and had better health status, including mental health, at the beginning of the COVID-19 pandemic [18]. The psychological impact of the pandemic has been moderate to severe because of isolation or quarantine measures. Given the rise of the digital era, understanding how people use the internet to manage their mental health during a pandemic is vital.

Research indicates that eHL can help mitigate the negative impact of COVID-19 fear on the quality of life during the pandemic among diverse populations, including patients [19] and university students [20,21]. Higher levels of eHL are associated with better adherence to preventive measures and improved psychological well-being. Additionally, abundant evidence exists regarding the relationship between coronaphobia and mental health during pandemics. Amin [22] demonstrated that coronaphobia persists among health care professionals and results in psychological symptoms that affect mental health. Yayla and İlgin [23] and Labrague and De Los Santos [24] indicated that nurses’ psychological well-being was significantly affected by coronaphobia. Although a recent study found that health literacy benefits the management of coronaphobia [25], the impact of eHL on coronaphobia during the pandemic has not been sufficiently studied. Considering that the pandemic has profoundly altered how people seek, use, and evaluate health care services, the role of eHL in this transformation should receive more attention.

However, alongside the pandemic, numerous rumors, hoaxes, and misinformation regarding the prevalence, outcomes, and prevention of COVID-19 have circulated on social media at an alarming rate [3-5]. These false claims have generated mass hysteria and panic regarding COVID-19, leading to unexpected and enduring psychological problems for the public [26]. Research has demonstrated that unreliable web-based information about the pandemic has led to heightened anxiety and even lethal mental health ramifications [27,28], which are potentially more detrimental in the long term than the virus itself. Despite this, evidence regarding the role of eHL in managing the impact of coronaphobia on psychological problems and mental illnesses during the pandemic is lacking.

This study aims to provide empirical evidence of the moderating effects of eHL on the relationship between coronaphobia and a wide range of mental health problems frequently reported during the pandemic in young adults in China. Exploration in young adults is particularly important because they are highly exposed to smartphones and the internet, which increases the likelihood of experiencing web-related psychological problems. Research has confirmed the profound impact of the pandemic on young adults, disrupting their education, routines, and peer interactions, thereby raising concerns about potential long-term mental health outcomes in this population [29].

Methods

Data and Participants

The data used in this study were obtained from a web-based survey conducted in China between December 2022 and January 2023. The study included participants who met the following criteria: (1) participants aged between 18 and 30 years, (2) participants able to read Chinese, and (3) participants able to provide informed consent. The survey was conducted at a medical university in Guangzhou, China. The research team contacted university officers in charge of student affairs and discussed the data collection plan. A link containing the study introduction and questionnaire was sent to all the students through the university's internal network using WeChat software (Shenzhen Tencent Computer Systems Company Limited), a multipurpose messaging app. To improve the diversity of the samples, a nonprobability snowball sampling method was used for recruitment. This method is commonly used in quantitative studies [30,31]. The research team did not directly recruit participants other than appointed university students but encouraged them to contact their peers and invited them to join the survey through their personal social networks. To maintain the momentum of the snowball sampling, the research team collaborated with university officials and sent 4 reminders to all students, encouraging them to further disseminate the survey link.

The questionnaire was created using the web-based platform of a professional surveying company (Wenjuanxing), with an informed consent statement appended to it. Interested participants accessed the questionnaire by clicking on the provided link. The first page of the questionnaire focused on obtaining informed consent. Participants had to read, scroll down to the end, click the agree button, and electronically sign it before proceeding to the actual survey. Once participants confirmed their participation, they were presented with a structured questionnaire containing questions about their demographics, socioeconomic status, mental health status, and eHL. Participants required approximately 15 minutes to complete the entire questionnaire.

Measures

eHealth Literacy

The eHealth Literacy Scale (eHEALS) was used to measure participants' knowledge and perceived skills in finding, evaluating, and applying eHealth information to manage health problems [32]. It was developed based on a framework comprising 6 dimensions to understand and use eHealth information. The eHEALS has 8 items (eg, I know how to find helpful health resources on the internet) rated on a 5-point Likert scale. The total eHEALS scores range from 8 to 40. Higher scores indicate greater perceived eHL. Its psychometric properties in the Chinese population have been confirmed by Xu et al [33].

Coronaphobia

Coronaphobia was assessed using the COVID-19 Phobia Scale (C19P) [34]. This self-report instrument was developed and validated to measure COVID-19 phobia levels. C19P includes 4 factors (psychological, somatic, social, and economic) with 20 items (eg, the fear of coming down with COVID-19 makes me very anxious) rated on a 5-point Likert scale from "strongly disagree" to "strongly agree." The total C19P score ranges from 20 to 100, with a high score indicating severe coronaphobia. The psychometric properties in the Chinese population have been reported by Chi et al [35].

Loneliness

The University of California, Los Angeles (UCLA) 3-item loneliness scale (ULS-3) was used to determine the perception and degree of loneliness [36]. It comprises 3 items (eg, how often do you feel that you lack companionship?) to assess an individual's feelings of companionship, being left out, and being isolated. Each item is rated on a 3-point Likert scale. The total ULS-3 score ranges from 3 to 9, with a higher score indicating a higher level of perceived loneliness. The psychometric properties of the Chinese ULS-3 have been reported by Liu et al [37].

Irritability

The brief irritability test (BIT) developed by Holtzman et al [38] was applied to assess irritation. This brief self-report scale for irritability demonstrates strong reliability and validity in both healthy and clinical populations. It includes 5 items (eg, I have been feeling like I might snap) rated on a 6-point Likert scale (1 to 6). A higher score indicates a higher level of irritation. In this study, the research team translated the BIT from English to Chinese using a standard process (2 forward and 2 backward translations). The Chinese version of the BIT is presented in Multimedia Appendix 1. In this study, the Cronbach α for the Chinese BIT was .89 indicating good internal consistency. Confirmatory factor analysis supported a one-factor structure (comparative fit index=0.99 and root mean square error of approximation=0.03).

Depression

Depressive symptoms were assessed using the Patient Health Questionnaire-9 (PHQ-9). The PHQ-9 is one of the most widely used instruments for screening, diagnosing, monitoring, and measuring depression severity. It consists of 9 items (eg, little interest or pleasure in doing things) rated on a 4-point Likert scale (0-3). A total score between 5 and 9 indicates mild depression, 10 and 14 indicates moderate depression, and 15 and above indicates moderately severe depressive symptoms. The psychometric properties of the Chinese version of the PHQ-9 have been reported in different populations [39].

Anticipated Stigma

COVID-19–related stigma was measured using the revised Chronic Illness Anticipated Stigma Scale (r-CIASS) [40]. It has 6 items (eg, [if I was to get coronavirus...] a friend or family member would be angry with me), reflecting how individuals would be treated if they were to become infected with COVID-19, which are rated on a scale from very unlikely (1) to very likely (4). Higher scores indicate a higher degree of stigma. In this study, the research team translated the r-CIASS from English to Chinese using a standard process (2 forward and 2 backward translations). The Chinese version of the r-CIASS is presented in Multimedia Appendix 2. In this study, Cronbach α for the Chinese r-CIASS was .92. Confirmatory factor analysis supported a one-factor structure (comparative fit index=0.99 and root mean square error of approximation=0.04).

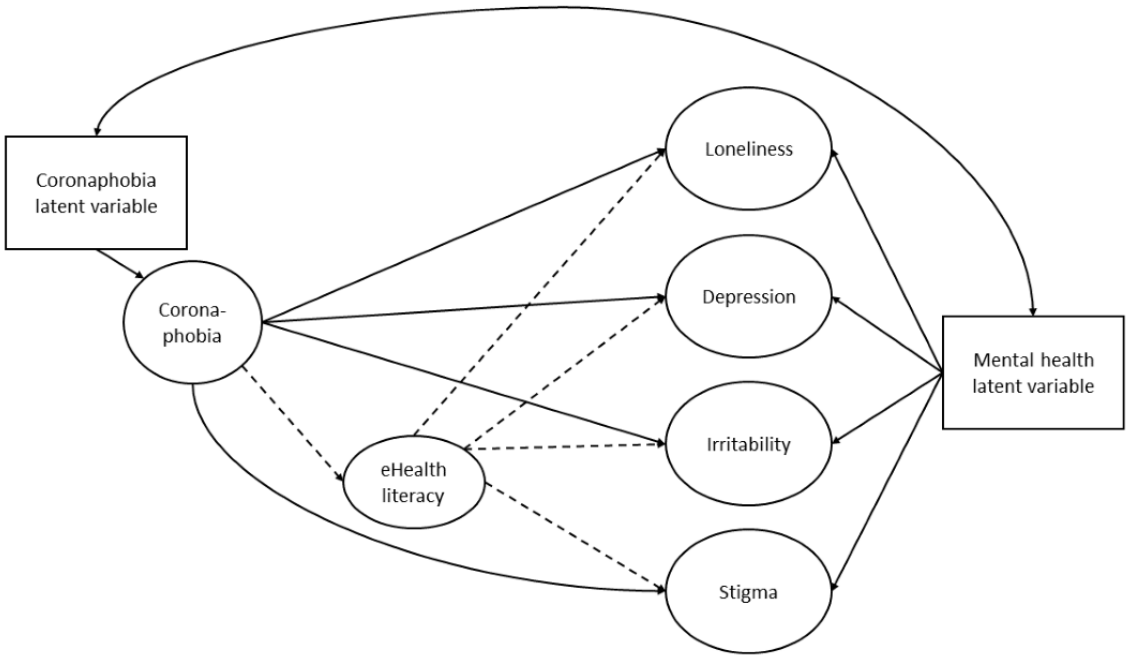
Statistical Analysis

A descriptive analysis was conducted to examine the participants’ background characteristics and mental health statuses. The min-max normalization method was applied to perform a linear transformation of the original data to then scale the data in the range between 0 and 100.

To assess the moderating effect of eHL on the relationship between coronaphobia and the 4 psychological problems, the Bayesian structural equation model (BSEM) via parameter expansion was used [41].

Bayesian methods are becoming increasingly popular in various fields because they enable the simultaneous estimation of all cross-loadings and residual correlations in a particular model, a task that is not possible with a maximum-likelihood (ML)–based estimation. Traditionally, ML estimation considers parameters as constants and aims to identify the best-fitting models for certain parameters using research data. However, Bayesian estimation involves combining data likelihoods and prior distributions to construct a posterior distribution. This combination has led researchers to apply the Bayes theorem to the estimation processes [42]. Using BSEM can improve the estimation of parameter and latent variables, enable statistics for model comparison, and provide more reliable results for smaller samples [43]. In this study, the BSEM incorporates 2 latent variables: one representing coronaphobia and the other encompassing loneliness, depression, stigma, and irritation. These 2 latent variables exhibit correlated residuals. Figure 1 illustrates the conceptual framework of the BSEM.

Figure 1. Conceptual framework of Bayesian structural equation model analysis.



Given the reparameterization of the covariances, the prior distributions on the working model parameters were specified. A subset of 800 participants was randomly selected from the full data set to calculate the prior probability. Their demographics are presented in Multimedia Appendix 3. For the BSEM, we ran 2 chains, each with 21,000 burn-in iterations and 4000 inference iterations. We verified the convergence of the trace plots for all variables and reported the statistics of the latent and regression variables. Information about the posteriors was summarized in terms of the mean and SD, and a 95% highest density interval (HDI) of the posterior mean was calculated. We focused on the direct effects of the 4 aforementioned relationships involving the coronaphobia variable. The 4 indirect effects were calculated using Sobel test [44]. To calculate the indirect effect of the eHL variable on the direct effect of coronaphobia on loneliness, we denote the coefficients of coronaphobia for eHL and eHL for loneliness as $c_{Coronaphobia,eHL}$ and $c_{eHL,loneliness}$, respectively. Their SDs are denoted as $SDc_{Coronaphobia,eHL}$ and $SDc_{eHL,loneliness}$, respectively.

Using the following formula derived from the Sobel test, we calculate the posterior mean $c_{indirect(Coronaphobia,eHL,loneliness)}$ and $SDc_{indirect(Coronaphobia,eHL,loneliness)}$ of the indirect effect. The same method was used to calculate the posterior mean and SD of the indirect effects of the other 3 variables. R software was used for all statistical analyses. The significance level was set as <.05.

$$c_{indirect(Coronaphobia,eHL,loneliness)}=c_{Coronaphobia,eHL}\cdot c_{eHL,loneliness} \quad \textbf{(1)}$$

Ethics Approval

The study protocol and informed consent were approved by the Human Research Ethics Committee of Hong Kong Polytechnic University (Ref No.: HSEARS-20210328002). Written informed consent was obtained from all the participants. All study data were collected anonymously and no compensation was provided to any participant.

Results

Participants' Characteristics

Table 1 shows that 4119 participants joined the survey and completed the questionnaire (completion rate=94.9%). Among them, 64.4% (n=2653) were female, 58.7% (n=2417) were rural residents, and nearly one-third reported a perceived family income lower than the local average (n=1220). Regarding COVID-19–related characteristics, approximately 70% (n=3024) had been infected with COVID-19. Approximately 86.6% (n=2567) and 90.6% (n=3733) reported having experienced a lockdown and working or studying from home because of COVID-19, respectively.

Table 1. Background characteristics of participants (n=4119).

Characteristics	Values, n (%)
Gender	
Male	1466 (35.6)
Female	2653 (64.4)
Age	
22 years or younger	2120 (51.5)
Older than 22 years	1999 (48.5)
Educational attainment	
Undergraduate or below	3115 (75.6)
Postgraduate or above	1004 (24.4)
Residence registry	
Rural resident	2417 (58.7)
Urban resident	1702 (41.3)
Perceived family income	
Lower than average	1220 (29.6)
Equal to average	2601 (63.1)
Higher than average	298 (7.2)
People infected with COVID-19	
No	1175 (30)
Yes	3024 (70)

Profiles of and Correlations Between Measures

In terms of eHL, the participants reported a mean eHEALS score of 28.6 (8-40). After normalization, the participants demonstrated a slightly higher level of phobia (C19P's mean 44; IQR 0-100) than other types of mental health problems (mean 24-40.2; IQR 0-100). The correlation analysis revealed a statistically significant but minor-to-moderate association between the measures (Table 2).

Table 2. Profiles of measures and the correlations between them.

	Mean (SD)	Median (IQR)	Normalized mean (0-100)	1	2	3	4	5

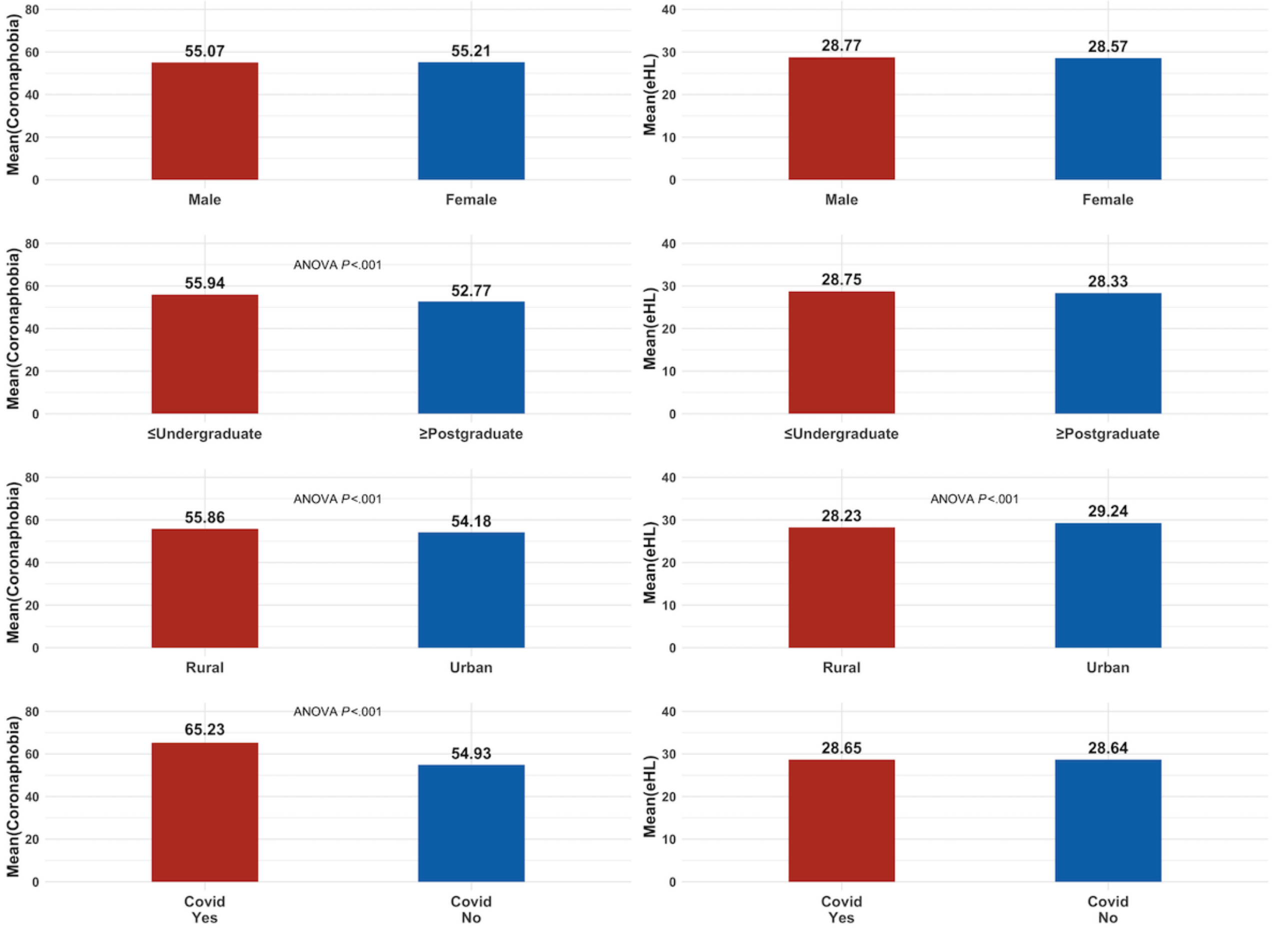
Coronaphobia and eHL in Different Socioeconomic and COVID-19–Related Status Groups

Rural residents reported a higher level of coronaphobia but a lower level of eHL than their urban counterparts. Participants with a higher perceived family income tended to have a high level of eHL, but a low level of coronaphobia. Additionally, participants with COVID-19 demonstrated high levels of coronaphobia (Figure 2).

Figure 2. Mean scores of COVID-19 Phobia Scale (C19P) and eHealth Literacy Scale (eHEALS) in subgroups. eHL: eHealth literacy.



Direct Effect and the Moderating Effect of eHL

Using the Bayesian approach, we report the results in terms of the posterior distribution. Table 3 shows a significantly strong and positive effect of latent variable 2 on depression, stigmatization, and irritation (with longlines set as the reference). This suggests the presence of a latent variable linked to these 4 variables. Considering the significant difference in eHL and coronaphobia between rural and urban residents, separate analyses were conducted for these 2 subsamples.

The posterior mean and posterior SD of the direct effects of coronaphobia on the 4 psychological problems are presented in Table 4. The coefficients are all statistically significant, as indicated by the 95% HDI. The direct effect of coronaphobia on depression was stronger than that on the other 3 psychological problems. Compared to rural residents, coronaphobia was more likely to lead to a higher level of depression and loneliness but lower levels of stigma and irritability among urban residents. Table 5 shows that eHL was a significant moderator in reducing the negative effect of coronaphobia on loneliness (posterior mean −0.0016, 95% HDI −0.0022 to −0.0011), depression (posterior mean −0.006, 95% HDI −0.0079 to −0.004), stigma (posterior mean −0.0052, 95% HDI −0.0068 to −0.0036), and irritability (posterior mean −0.0037, 95% HDI −0.0052 to −0.0022). The trace plot shows a random scatter around the mean value. Thus, our model results suggest that the chains mixed well and that the model converged (Figure 3). Other trace plots are presented in Multimedia Appendix 4.

Discussion

Principal Findings

The results of the BSEM showed that Chinese young adults with high eHL levels were less likely to report a negative impact of coronaphobia on their mental health. While previous studies have indicated that digital tools and mobile technologies played a vital role in helping people manage their mental health during the pandemic, our study adds to the knowledge that the effectiveness and efficiency of web-based interventions or programs may depend on users' eHL. This study provides empirical evidence that simply offering web-based mental health services may not be sufficient to enhance the mental health outcomes of young adults; thus, improving their eHL is essential. For policy makers, comprehending and developing an eHealth strategy that creates an interactive relationship between mental health providers, partners, and users and empowers them to use web-based resources to reduce the effect of coronaphobia on their mental health is critical.

Research has demonstrated that the fear of COVID-19 can reduce the use of health care services. For example, one study found that COVID-19–related stigma can cause people to underreport symptoms and avoid health facilities [45]. Moreover, the fear of COVID-19 can cause people to delay or avoid seeking medical attention for non–COVID-19–related illnesses, which can lead to negative health outcomes [46]. Fear can also affect mental health and lead to poor outcomes. Although eHL interventions can help reduce fear and anxiety related to COVID-19, low eHL affects a large percentage of the global population. Naeem and Boulos [47] indicated that low eHL directly contributes to the spread of COVID-19-related web-based misinformation. Lee et al [48] found that 68% of adults were exposed to COVID-19–related misinformation through social networking services or instant messaging. The widespread dissemination of misinformation through social media can render distinguishing between accurate information and falsehoods difficult for people, which can further increase anxiety and fear regarding COVID-19.

Our study identified that people's ability to find and use health information from digital sources is essential, given the increasing number of people turning to the internet for health information to improve their coping skills against mental health stressors. Participants with high eHL were more likely to find accurate and trustworthy information and resources that could significantly reduce the negative impact of coronaphobia on their mental health. By improving eHL, individuals can better manage their COVID-19–related fear and anxiety and prevent them from developing into a phobia [49]. This can have positive effects on their overall mental health and well-being and complement the efforts to prevent the spread of the virus. Improving eHL can be an important step in this process as it can help people access accurate information and resources that can help them manage their fear and anxiety related to COVID-19.

In China, the COVID-19 pandemic has impacted both urban and rural residents, although not necessarily equally [50]. Our study revealed that rural residents reported significantly higher levels of coronaphobia than urban residents. This finding partially aligns with previous findings that rural residents have been disproportionately affected by the COVID-19 pandemic [50]. Empirical evidence confirms that the expansion of telehealth services is a potential solution for bridging the gap in health care access between rural and urban areas. However, our study suggests that compared to urban residents, rural residents showed a lower level of eHL, which may undermine the efficiency of the intervention to improve mental health during the pandemic, resulting in increased disparity and inequality. This finding is consistent with those of previous studies. For example, Rush et al [18] indicated that rural Canadian residents experienced challenges with telemedicine access because of unreliable internet access and found the service impersonal. Witten and Humphry [51] reported that the eHL of rural community residents was insufficient for the proper understanding and use of technology. Initiating public health campaigns targeting rural communities is vital to improve their eHL and ensure adequate resources and support are provided to these areas to mitigate the impact of the pandemic on their mental health.

Our findings confirmed the positive role of eHL in mitigating the negative impact of the pandemic on mental health. However, this conclusion specifically applies to the populations aged between 18 and 30 years. Although this age group comprises a high proportion of internet users in China, with approximately 1.01 billion active users, further research is needed to explore these associations in other age cohorts. Obtaining empirical evidence across different age groups can provide valuable insights for policymaking in future pandemics, as the threat of COVID-19 persists and new public health crises may emerge.

Strength and Limitations

A significant advantage of our study is the use of BSEM to estimate the associations. BSEM allows for the incorporation of prior information into the model estimation process and provides a more efficient approximation of the model compared to the standard ML approach [52].

However, this study also has certain limitations. The primary limitation is the use of a snowball sampling method for data collection, which has several disadvantages. First, it is a nonprobabilistic technique that relies heavily on existing relationships between respondents, which can lead to insufficient diversity in respondents' characteristics. Second, the quality of the data received from the respondents depends on their relationship with the introducer. If the introducer has a good relationship with the respondent, the purpose of the survey can be clearly expressed, which can enhance the likelihood of obtaining valid responses. Finally, unlike other sampling methods, the snowball sampling method shifts the recruitment efforts to the respondents themselves, leading to a loss of control for the research team. In this study, given the nature of the web-based survey, we did not record the recruitment process. Thus, this method may not accurately represent the target population, leading to potential problems with the generalizability of our findings. Another limitation is that the data used in this study were collected during the most severe wave of the COVID-19 pandemic in China. Respondents may, in turn, have experienced strong coronaphobia, which may have led to recall bias.

Conclusions

This study provides evidence that coronaphobia has a significant negative impact on the mental health of Chinese young adults. However, the findings also highlight the potential of improving eHL to mitigate these negative effects. By improving individuals' ability to access reliable web-based information about the virus and resources for web-based health services, they may feel more confident and in control of their health, thereby reducing their phobia about COVID-19. Moreover, eHL initiatives should specifically target rural communities to ensure equal access to information and resources and protect their mental health during the pandemic.

Abbreviations

BIT: Brief Irritability Test
BSEM: Bayesian structural equation model
C19P: COVID-19 Phobia Scale
eHEALS: eHealth Literacy Scale
eHL: eHealth literacy
HDI: highest density intervals
ML: maximum-likelihood
PHQ-9: Patient Health Questionnaire-9
r-CIASS: Revised Chronic Illness Anticipated Stigma Scale
UCLA: University of California, Los Angeles

ULS-3: UCLA 3-Item Loneliness Scale

Edited by A Mavragani, T Sanchez; submitted 24.03.23; peer-reviewed by N Mungoli, Y Jeem; comments to author 08.05.23; revised version received 21.05.23; accepted 24.08.23; published 29.09.23.
