Our study revealed that the incidence of OID in Fujian Province exhibits a distinct distribution across populations, seasons, and regions. Notably, males and children aged >2 years are the most susceptible to OID. Moreover, our analysis demonstrated a shift in the seasonal peak of OID from autumn to winter or spring between 2005 and 2020. Our findings indicated that maximum temperature, atmospheric pressure, relative humidity, and precipitation positively influence the short-term incidence of OID. Zhangzhou City and Xiamen City were identified as the major hot spots for OID in Fujian Province. Therefore, it is essential to prioritize prevention and control efforts in these identified hot spots and among highly susceptible groups. Our findings provide valuable scientific evidence for policy makers to develop targeted intervention measures for OID, considering the specific disease pattern and geographical context.

Abstract

Background: Cameron County, a low-income south Texas-Mexico border county marked by severe health disparities, was consistently among the top counties with the highest COVID-19 mortality in Texas at the onset of the pandemic. The disparity in COVID-19 burden within Texas counties revealed the need for effective interventions to address the specific needs of local health departments and their communities. Publicly available COVID-19 surveillance data were not sufficiently timely or granular to deliver such targeted interventions. An agency-academic collaboration in Cameron used novel geographic information science methods to produce granular COVID-19 surveillance data. These data were used to strategically target an educational outreach intervention named “Boots on the Ground” (BOG) in the City of Brownsville (COB).

Objective: This study aimed to evaluate the impact of a spatially targeted community intervention on daily COVID-19 test counts.

Methods: The agency-academic collaboration between the COB and UTHealth Houston led to the creation of weekly COVID-19 epidemiological reports at the census tract level. These reports guided the selection of census tracts to deliver targeted BOG between April 21 and June 8, 2020. Recordkeeping of the targeted BOG tracts and the intervention dates, along with COVID-19 daily testing counts per census tract, provided data for intervention evaluation. An interrupted time series design was used to evaluate the impact on COVID-19 test counts 2 weeks before and after targeted BOG. A piecewise Poisson regression analysis was used to quantify the slope (sustained) and intercept (immediate) change between pre- and post-BOG COVID-19 daily test count trends. Additional analysis of COB tracts that did not receive targeted BOG was conducted for comparison purposes.

Results: During the intervention period, 18 of the 48 COB census tracts received targeted BOG. Among these, a significant change in the slope between pre- and post-BOG daily test counts was observed in 5 tracts, 80% (n=4) of which had a positive slope change. A positive slope change implied a significant increase in daily COVID-19 test counts 2 weeks after targeted BOG compared to the testing trend observed 2 weeks before intervention. In an additional analysis of the 30 census tracts that did not receive targeted BOG, significant slope changes were observed in 10 tracts, of which positive slope changes were only observed in 20% (n=2). In summary, we found that BOG-targeted tracts had mostly positive daily COVID-19 test count slope changes, whereas untargeted tracts had mostly negative daily COVID-19 test count slope changes.

Conclusions: Evaluation of spatially targeted community interventions is necessary to strengthen the evidence base of this important approach for local emergency preparedness. This report highlights how an academic-agency collaboration established and evaluated the impact of a real-time, targeted intervention delivering precision public health to a small community.

Introduction

The SARS-CoV-2 pandemic made the dearth of resources and experience to address the situation in local health departments (LHDs) alarmingly apparent. Aggregated data at the state and national levels are insufficiently granular for real-time strategic local interventions. Small communities in particular suffer from limited support and a long turnaround time for obtaining key information needed to conduct effective surveillance and intervention [1]. Texas-Mexico border counties, such as Cameron County, with high burdens of underlying chronic conditions, were heavily impacted by COVID-19 hospitalizations and deaths [2]. By the end of April 2020, Cameron County reported 2.9% case fatalities, exceeding that of its neighboring county, Hidalgo, reporting 0.8%, assuming similarly accurate data for the 2 counties [3]. The LHD of the City of Brownsville (COB), the largest city within Cameron County, accounting for 43% of its total population, recognized specific needs for COVID-19 information dissemination and the resources for assessing community response. The large percentage of the population without insurance, high poverty rates, and elevated rates of type 2 diabetes and obesity (27% and 50%, respectively) contributed substantially to high morbidity and mortality [4,5]. An added obstacle was the cultural and language barriers, given that 85.7% of households speak a language other than English (usually Spanish) and 93.8% are of Hispanic heritage [4]. The COB public health department recognized the limited resources and approached UTHealth Houston School of Public Health, Brownsville (UTHealth), with whom they had a long relationship, to form a partnership to leverage each entity’s strengths to better serve the community [6]. The collaboration began in early April 2020 and had UTHealth faculty and staff helping COB staff conduct COVID-19 case reports and contact tracing tasks. Additionally, weekly sharing of COB in-house COVID-19 case and testing data were accessed by a UTHealth research team to provide census tract-level data and reports to the COB. This team’s innovative acquisition and use of local surveillance data provided the opportunity to strategically target the efforts of the community intervention named “Boots on the Ground” (BOG).

LHDs are the first line of public health action in emergency situations [7]. Their community interventions and actions result in the most immediate response to public health crises. However, resources to effectively implement real-time interventions and assess their impact are rarely available. The “natural experiment” nature of these interventions presents challenges for their evaluation [8]. Experimental methods, such as randomized controlled trials, are considered the gold standard of evaluation. Randomized controlled trials require the random selection of intervention and control groups, which would be costly, impractical, and time-consuming, and raise ethical concerns in regard to respecting community autonomy in crisis situations [9]. Other valuable methods, such as interrupted time series (ITS) studies have been pivotal in health and public policy for evaluating the effects of community-based interventions [10]. ITS studies are used to establish the time series trend of a particular outcome that has been interrupted by an intervention at a specific point in time resulting in self-controlled study units [11]. To our knowledge, there are currently no studies in relation to spatially targeted community interventions for COVID-19 and very few for infectious diseases in general. A 2021 systematic review of spatially targeted community interventions for infectious diseases identified only 10 studies conducted since 1993, none of which properly addressed the evaluation of the intervention [12].

We conducted a study to evaluate the impact of a targeted community COVID-19 education outreach intervention on the SARS-CoV-2 daily test counts by means of an ITS. These findings could help public health professionals and policy makers make authoritative, evidence-based decisions when responding to similar public health crises.

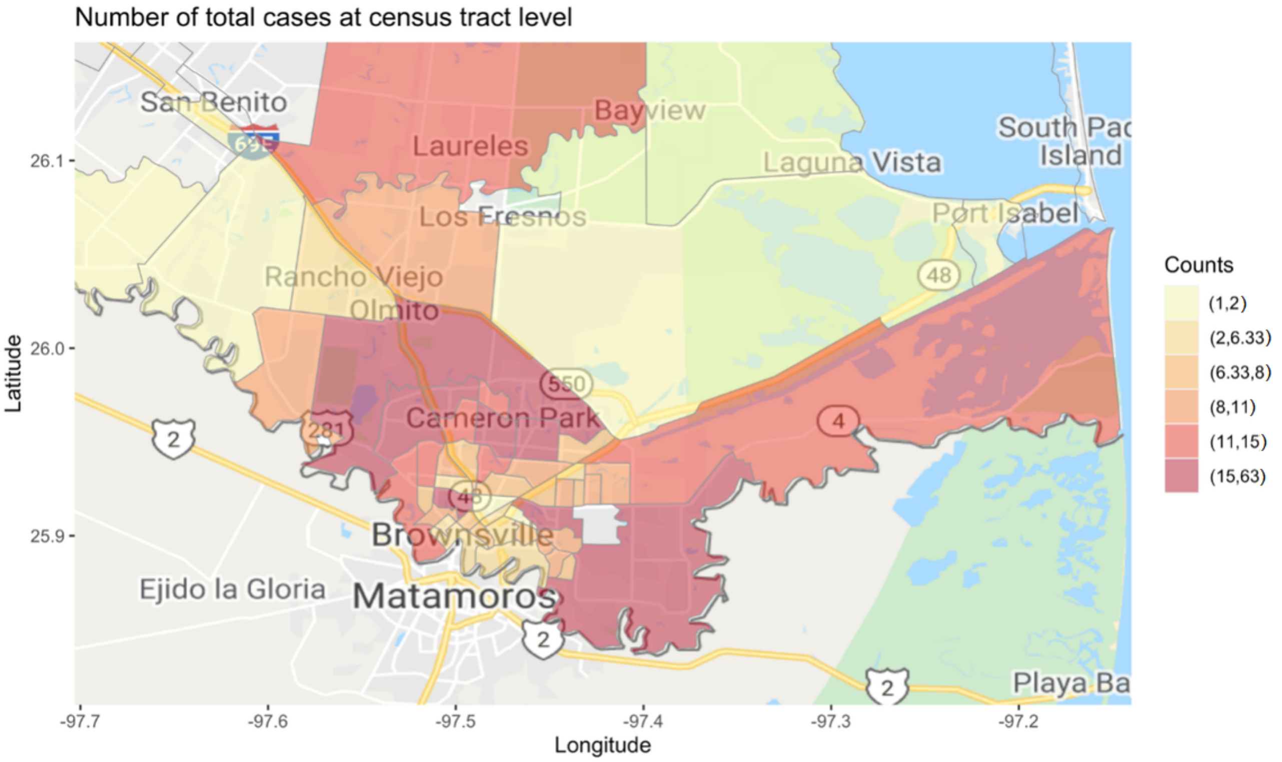
Methods

Boots on the Ground

The first official confirmed COVID-19 case report in the COB was on March 21, 2020. The city opened a municipal SARS-CoV-2 testing site and began its BOG efforts to deliver COVID-19 information to COB residents 2 days later [13]. The initial delivery method of BOG was through blanket events opened to all Brownsville residents at the city public libraries. In early April, the COB joined efforts with epidemiological and advanced statistical expertise at UTHealth, which gave rise to the COVID-19 collaborative working group. Locally collected COB COVID-19 case and testing data included geo-codable but otherwise deidentified data and were securely shared among these 2 working groups on a weekly basis. Applying geospatial science methods, the UTHealth partners used these data to deliver granular COVID-19 maps to the COB (48 census tracts). By April 17, 2020, the first COB census tract COVID-19 case maps (Figure 1) were uploaded by the UTHealth team, and on a weekly basis thereafter.

The COB public health department then used these maps to strategically target their BOG efforts at specific census tracts. The COB epidemiologist selected the census tracts with the highest case counts each week for BOG delivery. If census tracts had similar case counts, the tract with higher obesity prevalence was used to determine which tract was selected. The obesity rates were obtained from the 2019 American Community Survey 5-year estimates [14]. A total of 8 bilingual (English and Spanish) COB public health staff members went door-to-door in the streets of selected census tracts, speaking to residents and leaving packets of COVID-19 information at each house. The information packets were provided in English and Spanish and contained educational information on COVID-19 signs and symptoms as well as details regarding free local SARS-CoV-2 polymerase chain reaction testing sites and available testing opportunities. This delivery method reached a total of 17,170 houses in 18 census tracts. Subsequently, on June 23, delivery efforts shifted to broadcasting methods such as radio, social media, vans with loudspeakers, and news outlets.

Figure 1. COVID-19 case count maps for City of Brownsville census tracts.



Data Sources

The outcome measures chosen to evaluate the impact of BOG were the daily SARS-CoV-2 testing counts. COB COVID-19 testing sites immediately shared all their positive and negative SARS-CoV-2 polymerase chain reaction testing data, which included address information, with the COB. UTHealth experts geocoded addresses to obtain census tract information for each SARS-CoV-2 test, which was then aggregated each day for each of the 18 census tracts. Given the duration of the targeted BOG, from April 21 to June 8, we limited the ITS to only 14 days before and after BOG delivery for each census tract. To avoid a potential spillover effect in our results given the change in BOG delivery method in the last census tract receiving targeted BOG, we limit our time series to only 14 days before and after targeted BOG. For the exposure information, we used the electronic log of BOG efforts maintained by the COB epidemiologist. This log contained the date of targeted BOG delivery for each of the 18 selected census tracts. Based on the log, we created indicator variables representing the pre- and post-BOG day (0 and 1, respectively) status for each tract. An additional variable was created for the time elapsed since BOG delivery for each census tract for the 14 days before and after. We also obtained census tract population size in R Studio's (R Foundation for Statistical Computing) *tidycensus* package using 2015-2019 American Community Survey data [14,15]. This completed the data necessary to conduct the ITS analysis on each of the census tracts.

Ethical Considerations

Data user agreements between the COB and UTHealth were approved by city officials. Data privacy protocols were outlined in the agreement. This study was approved by the UTHealth Committee for the Protection of Human Subjects (HSC-SPH-21-1089). This study was exempt from informed consent given that aggregate level and not subject information was being used.

Statistical Analysis

We hypothesized that the pre- and post-BOG COVID-19 daily test count trend line slope and intercept would significantly increase in BOG-targeted census tracts. For each census tract, we have a series of count data with a known interruption point, which makes piecewise Poisson regression the most suitable model to test our hypothesis [16]. We fit a least squares regression line to each time segment (ie, pre and post) of COVID-19 daily counts, where the change point of the regression line was the day the census tract received targeted BOG, including an offset term of the log of the total population for the census tract. The coefficients of interest in the model were β_2, which estimates the level or intercept (immediate) change in the number of tests per day after the intervention, and β_3, which estimates the change in slope (sustained) trend post BOG compared to the pre-BOG trend along with the P values of the coefficients. Significance for the coefficients was set at a P value of <.05. All statistical analyses were performed in R Studio using the *segmented* package [17,18].

Additional Analysis

To supplement the interpretation of the 18 census tract results, we conducted an additional analysis. The analysis mentioned above was applied to the 30 census tracts in the COB that did not receive BOG during the targeted BOG phase. For these census tracts, we set a date in the middle of the targeted BOG phase as time 0 (May 18, 2020). This additional analysis provided a comparison group to which we compared our targeted BOG subset analysis results.

Results

During the targeted phase of BOG, which lasted from April 21 to June 8, 2020, a total of 18 of the 48 census tracts in the COB received BOG outreach, as shown in Figure S1 in Multimedia Appendix 1. To understand the distribution of the daily test counts for each targeted BOG tract, we included Table S1 in Multimedia Appendix 2 for reference. We obtained the 2 parameters of interest (β_2 and β_3) and their *P* values for each of the piecewise models of the 18 BOG-targeted census tracts. Using a significance *P* value threshold of <.05, significant intercept change (β_2) in testing was observed in 2 census tracts, and significant slope (β_3) change was observed in 5 census tracts. A total of 4 of the 5 tracts with significant slope change had an increase in the slope of the 2-week post-BOG COVID-19 daily test count compared to the pre-BOG slope. A summary of the results is found in Tables 1 and 2.

In the additional analysis of the remaining 30 census tracts in the COB that did not receive BOG outreach during the targeted intervention period, 10 tracts had significant slope changes. A total of 8 of the 10 significant slope changes seen in these census tracts decreased, opposite to what was seen in the slope changes in BOG-targeted census tracts. Table 3 shows the summary of the significant findings and the direction of the coefficients for both groups.

Discussion

Principal Findings

The use of local COVID-19 surveillance data, along with collaboration between local public health departments and academia to target a COVID-19 educational outreach intervention, resulted in significant impacts on daily COVID-19 test counts. Most notable was the increase in the sustained trend of testing observed after BOG in census tracts that received targeted BOG. A total of 4 out of 5 census tracts showed significant increased slope changes in testing trends, meaning that the 2-week post-BOG COVID-19 daily test count slope improved significantly from the 2-week pre-BOG slope. Interestingly, the additional analysis of nontargeted BOG COB census tracts was contrary to what we observed in the BOG-targeted tracts. Here, only 20% (2/10) of the census tracts showed a significant increase in sustained testing. This suggests that daily COVID-19 test-seeking in BOG-targeted census tracts saw a sustained improvement (2 weeks after intervention), whereas test-seeking mostly declined in census tracts that did not receive BOG. The perspective of a COB resident documented in an autoethnographic analysis of BOG provides some insight into our interesting findings [6]. The personal method by which targeted BOG census tracts received tailored information potentially reflected a sense of trust among Brownsville residents and made them more receptive to act on the information they were receiving. The long-term benefits of this intervention were observed during the COVID-19 vaccine rollout in early 2021. As BOG delivery shifted later to social media and broadcasting delivery, a city-specific website called BTX Cares was created and served as a trusted source of SARS-CoV2 testing and vaccine information for COB residents [19]. The trust built through the door-to-door delivery of BOG and the use of BTX Cares for COVID-19 information resulted in successful COVID-19 mass vaccination clinic events hosted by the city.

Limitations

There are some limitations to consider in this study. Although we did account for census tract population size, the short time series evaluated prevented us from establishing or adjusting for temporal or seasonal confounders that might arise in time series analysis. The lack of a control group for comparison is an issue to be considered in this case report. We addressed this limitation by providing a comparison group—those census tracts in the COB that did not receive targeted BOG outreach [20]. It is also possible that selecting census tracts with higher rates of infection also drove testing to some extent, but since the infection levels were not dramatically different between tracts in this small city, this effect is likely to have been limited. Our findings provide grounds for further research in the delivery of translational science through targeted public health.

Conclusions

The impact on LHDs of COVID-19 in 2020 was extraordinary in its scale, gravity, and range of challenges it presented. Many years of limited public health funding meant that many counties and cities were underresourced, undertrained, and therefore ill-prepared, for the crisis presented by the pandemic. Addressing immediate needs requires collaboration and new technology. Overall, this program was based on the cooperation of the community with local authorities and with the academic center and ultimately resulted in a trusted channel of communication between city residents and public health professionals that persisted during the COVID-19 vaccine rollout. Combining academia and public health institutions was one way to address the many issues. The actual process was in fact inexpensive and relatively simple in overall execution, even though analytic methods were relatively new and sophisticated. This experience was based on a long-term relationship dating back to the H1N1 influenza outbreak, when similarly, a lack of local resources and data were considerable barriers to effective interventions [1]. What we present here is a case for precision public health that uses new technologies to improve local public health efforts by generating tailored and spatially targeted interventions. Our experiences and findings advocate not only for strong agency-academic collaborations but also for improved, granular population surveillance data sources on a national scale that can be leveraged to target interventions and deliver the correct intervention to the high-risk population in a timely manner [21,22].

Acknowledgments

We would like to acknowledge the efforts of the City of Brownsville public health staff that made this spatially targeted community intervention possible by delivering this intervention to their community. We would also like to thank the endless support from city officials in all our research endeavors, in particular Art Rodriguez, Michelle Jones, and Alvaro Silva from the City of Brownsville.

Data Availability

The data sets generated and analyzed during this study are not publicly available due to data user agreements between the City of Brownsville and UTHealth Houston School of Public Health, Brownsville, but are available from the corresponding author on reasonable request.

Authors' Contributions

IDLC conceived and designed the analysis. AR, MJ, and ML contributed to data acquisition. IDLC and KZ contributed to data curation and processing. IDLC and CXB conducted the data analysis. IDLC, CXB, and ML contributed to the interpretation of the results. IDLC and SPFH drafted the initial manuscript. CXB, SPFH, ML, MJ, JBM, and IDLC contributed critical revisions through the development of this manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Myopia is a serious public health issue. High school–aged adolescents in Beijing have an alarming prevalence of myopia. Therefore, determining myopia protective factors is essential. Green space has a certain association with myopia protective factors that can protect against myopia.

Objective: This study aims to examine the effects of green space around schools on individual myopia risk in high school–aged adolescents and the school-level myopia prevalence.

Methods: Green space was measured using the normalized difference vegetation index (NDVI). A total of 13,380 samples of 51 high schools were selected from a 2021 Beijing Municipal Health Commission survey. Adolescent myopia was defined as a spherical equivalent of ≤–1.00 diopters in the worse eye. Generalized linear mixed models with a binomial error structure were used to analyze the effects of the NDVI on personal myopia risk and adjust them by other factors, such as demographics, exposure time, and outdoor exercise. The effects of the NDVI on school-level myopia prevalence with adjusted demographics and the relative position factors of trees were analyzed through quasibinomial regression.

Results: The overall prevalence of myopia was 80.61% (10,785/13,380, 95% CI 79.93%-81.27%). Although with a 0.1 increase in the 500 and 1000 m buffer NDVIs adjusted by demographic and other factors, the high school–aged personal myopia risk significantly dropped by 16% (odds ratio [OR] 0.84, 95% CI 0.73-0.97) and 12% (OR 0.88, 95% CI 0.79-0.99), respectively. However, only the adjusted 500 m buffer NDVI (by demographics and the position of trees) with a 0.1 increase significantly reduced the school-level myopia prevalence by 15% (OR 0.85, 95% CI 0.74-0.98). Subgroup analysis showed that the adjusted effects of the 500 m buffer NDVI are significant in schoolgirls (OR 0.82, 95% CI 0.72-0.93), juniors (OR 0.82, 95% CI 0.72-0.94), the Han nationality (OR 0.84, 95% CI 0.72-0.97), 1-year exposure (OR 0.84, 95% CI 0.71-0.99) and 3-year exposure (OR 0.78, 95% CI 0.65-0.94).

Conclusions: The greenness of a 500 m buffer around schools is associated with a lower personal myopia risk among adolescents and a lower prevalence of myopia in schools. With regard to prevention and control activities, green space within a 500 m buffer around schools is suggested as an independent protective factor for adolescent myopia.

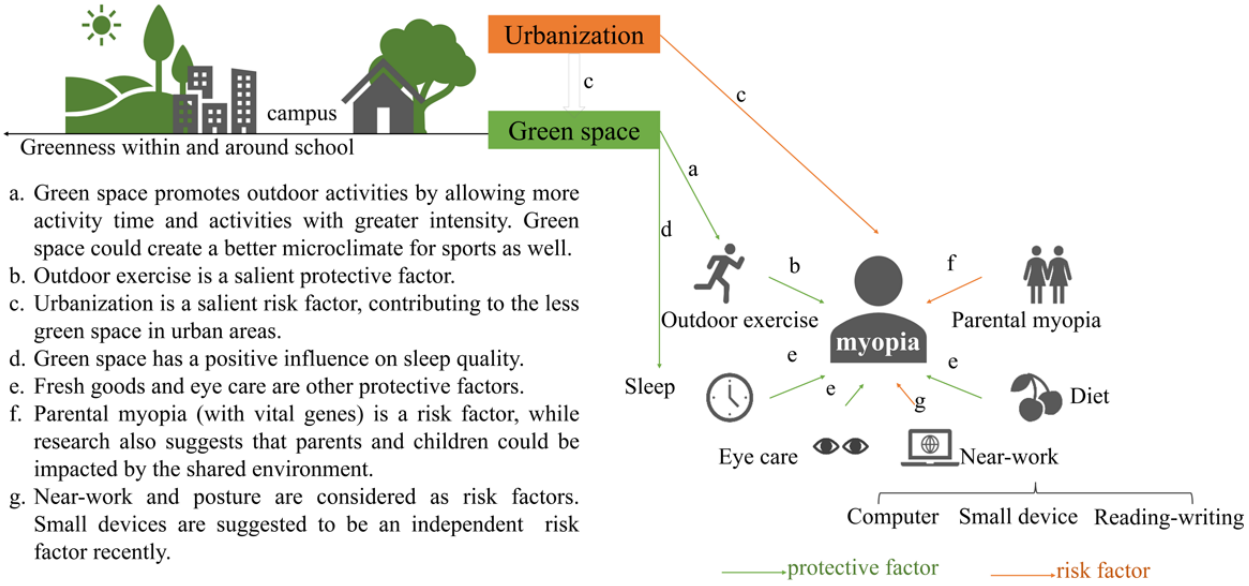
KEYWORDS

high school–aged adolescent; personal myopia risk; school-level myopia prevalence; green space; adjusted effects

Introduction

Myopia, the most common refractive error leading to short-sightedness or nearsightedness [1,2], affects daily life and increases the risk of blindness [3,4]. This serious public health issue is likely to affect approximately half of the world's population by 2050 [5]. Therefore, knowledge of the factors affecting myopia is essential. The genetic and nongenetic factors underlying myopia have been examined [6,7], and nongenetic factors (multiple types) may be more important [8,9]. Research has revealed that urbanization [10,11], outdoor exercise [12-14], parental myopia [15,16], near-work (sustaining a close gaze for reading and writing, using computers, or using small electronic devices) time, body posture [17,18], sleep [19,20], eye care, and diet [21] all impact myopia. These influences vary with demographics [9,22,23] and geographical location [1]. Green space is associated with these factors (Figure 1). Urbanization is considered a risk factor for myopia, possibly due to less green space in urban areas than in suburban or rural areas. Outdoor exercise is a protective factor. More green space promotes more outdoor exercise [24,25] and may reduce near-work time [14]. Moreover, people with higher levels of green space have a lower prevalence of insufficient sleep [26,27]. Hence, greenness may contribute to protection against myopia.

Figure 1. Based on previous studies, greenness may play a role in vision protection against myopia. The green and orange arrow lines indicate protective and risk factors according to previous studies, respectively. Points b, c, e, f, and g represent the influencing factors on myopia, while points a and d explain the associations between green space and influencing factors.



a. Green space promotes outdoor activities by allowing more activity time and activities with greater intensity. Green space could create a better microclimate for sports as well.
b. Outdoor exercise is a salient protective factor.
c. Urbanization is a salient risk factor, contributing to the less green space in urban areas.
d. Green space has a positive influence on sleep quality.
e. Fresh goods and eye care are other protective factors.
f. Parental myopia (with vital genes) is a risk factor, while research also suggests that parents and children could be impacted by the shared environment.
g. Near-work and posture are considered as risk factors. Small devices are suggested to be an independent risk factor recently.

The school is the principal space for school-aged children and adolescents. Previous studies have shown that the greenness level of a campus and the surrounding environment significantly impact students' physical and mental health [28-30]. Recently, researchers have investigated the relationship between school green space and students' myopia [31-33]. Studies focusing on the outdoor surrounding greenness within or around school boundaries have found a negative association between green space exposure and myopia among the school-aged population [34]. However, the evidence for this effect on junior and senior high school students is weak (eg, insufficient study quantity, lacking consideration of trees' distribution in green space). Therefore, there are still gaps in the controlling strategies for high school–aged students' myopia with regard to green space as a protective factor, and more research is warranted.

Our study focused on high school–aged adolescents in Beijing, a population with an alarming prevalence of myopia (once reaching 98.27% in a cross-sectional investigation of senior grade 3 students) [35-37]. We hypothesized that the greenness within or around the school can protect against myopia in the junior and senior high school–aged population. We aimed to determine (1) whether greenness significantly varies between myopia and nonmyopia groups, (2) how greenness acts on individual myopia risk and school myopia prevalence after adjusting for other known influential factors, and (3) whether the greenness protective effect is similar among demographic subgroups. A clarification of these points could elucidate how green space affects myopia in the high school–aged population and potentially contribute to targeted myopia prevention and intervention measures.

Methods

Study Population

The study sample was taken from the monitoring project for common diseases (eg, myopia, obesity) in students and health influence factors conducted by the Beijing Municipal Health Commission in 2021. Various schools involved in this monitoring project were randomly selected from all districts of Beijing. Our study only focused on high school adolescents (junior and senior high schools). We obtained myopia and questionnaire data from 51 high schools and 13,380 students.

Among the 51 schools, 28 (55%) schools were junior high schools, 20 (39%) were senior high schools, and 3 (6%) contained both junior and senior students. Since these 3 school campuses were shared by junior and senior students, there were 48 school plots in total (Figure S1 in Multimedia Appendix 1).

Ethical Considerations

The study was approved by the Ethical Committee of the Peking University Third Hospital (IRB00006761-M2021281) and conducted according to the guidelines of the Declaration of Helsinki.

Myopia Determination

The students included in this study underwent an ophthalmological examination at the school infirmary. The examinations were conducted in accordance with the standards of myopia screening for children and adolescents issued by the Beijing Center for Disease Prevention and Control. The examinations included far-vision examination and refractive examination and were performed by an ophthalmologist having a Chinese national medical practitioner certificate in ophthalmology. Refraction was detected using a desktop noncycloplegic autorefractometer, and all refractometers were accredited to the ISO 10342:2010 standard for ophthalmic instruments and eye refractometers. Adolescent myopia was defined as a spherical equivalent of ≤–1.00 diopters in the worse eye. The worse eye was defined as the eye with the greatest absolute value of the spherical equivalent of the refractive error.

School Green Space

We used the normalized difference vegetation index (NDVI) to measure the schools' green space. The NDVI value ranges from –1 to 1; the higher the NDVI, the higher the level of school green space. GF-2 satellite imagery (multispectral with 3.2 m resolution) was used in our study to calculate the NDVI values. In total, 25 single GF-2 cloud-free images (entirely covering 48 school plots and within 2 years around the myopia data collection time) were selected (data searched from the China Center for Resources Satellite Data and Application [38]). Through radiometric calibration, atmospheric correction and orthorectified (PRC parameters), these images were used to determine the NDVI by brand calculation, according to the following formula: NDVI = (NIR –RED)/(NIR + RED), where RED is the red band and NIR is the near-infrared band. Next, we extracted each plot's average NDVI of buffers (ie, 500 and 1000 m) around the school (Figure S1 in Multimedia Appendix 1). In addition, we analyzed the positions of trees relative to school (teaching) buildings by distinguishing the distribution of trees separated from the buildings with a small space from that with a large space.

Individual Factors

Demographic data were obtained, including birth data (used to convert the sample's age by the current month and year plus the birth month and year), gender (male and female categories), grade (representing exposure time to the school environment: senior/junior grade 1, indicating 1 year of exposure time; senior/junior grades 2 and 3, representing 2 and 3 years of exposure time, respectively), nationality (Han nationality and other categories), place of origin (urban, ie, 6 core urban districts: Dongchen, Xicheng, Haidian, Shijingshan, Fengtai, and Chaoyang [39]; suburban, ie, other 10 districts). In addition, students' heights and weights were collected to calculate their BMI according to the "Screening for Overweight and Obesity Among School-Age Children and Adolescents" protocol (WS/*t* 586—2018).

Information about students' outdoor exercise, including outdoor time on general days (Q1), outdoor time during holidays (Q2), preference for outdoor places at school (Q3), outdoor exercise intensity (Q4), and the number of physical education (PE) classes (Q5); near-work and body gestures, including posture-related distance from the table (Q6) and distance from the screen (Q7), adjusted chair height (Q8), parental control (Q9), and use of electronic devices (Q10); eye care, including the number of daily eye exercises at school (Q11) and the eye rest interval (Q12); dietary and sleep factors, describing sugar (Q13), fresh fruit (Q14), and fresh vegetables (Q15) consumed in the past 7 days; and the average daily sleeping hours (Q16) were acquired from the questionnaire (for details of questions Q1-Q16, see Multimedia Appendix 2).

Statistical Analysis

We analyzed differences between myopia and nonmyopia groups at the single-factor level. Categorical variables (ie, gender, nationality, place of origin, exposure time, position of trees, outdoor exercise factors [Q1-Q3], near-work and body gesture factors [Q6-Q10], eye-care factors [Q11-Q12], and dietary factors [Q13-Q15]) were analyzed using chi-square tests to determine statistical significance, with a 2-sided P value of <.05 as the threshold. Numeric variables (ie, NDVI values, outdoor exercise and sleep factors (Q4, Q5, Q16), age, and BMI) were analyzed using the median Wilcoxon test (P<.05 was considered significant).

Generalized linear mixed models with a binomial error structure were used to test the effects of the NDVI on personal myopia risk. The NDVI and all adjusted factors (ie, demographic factors, outdoor exercise, near-work and body gestures, eye care, diet, sleep, exposure time, and the position of trees) were considered fixed effects. To control for the influence of school variation on adolescents at the personal level, we set "school" as a random factor. Moreover, to assess the influence of different NDVI ranges and their adjusted effects, we developed 6 models. Models 1a, 2a, and 3a represented the regressions of the NDVI (within the school, 500 m buffer around the school, 1000 m buffer around the school, respectively) to myopia. Based on this, adjusted factors were added to Models 1b (ie, Model 1a with the addition of adjusted factors), 2b (ie, Model 2a with the addition of adjusted factors), and 3b (ie, Model 3a with the addition of adjusted factors). For the random and fixed effects for the adjusted NDVI of Models 1b, 2b, and 3b, see Figures S1 and S2 in Multimedia Appendix 3. We used the tolerance and variance inflation factor (VIF) to test collinearity among variables, with tolerance>0.1 and VIF<5 considered as no collinearity. We used the Durbin-Watson (DW) value to test the independence of residuals (with a DW value not close to 0 or 4 meaning that the variables were independent). To analyze the distinct performance of these effects in subgroups, we performed the same generalized linear mixed models under different subgroups divided by school type, gender, nationality, place of origin, and grade (converted to exposure time).

When considering the effects of the NDVI on myopia prevalence at the school level, we first calculated each school's myopia prevalence (myopia students/total students in that school). Second, 6 generalized linear models with a quasibinomial error structure (the quasibinomial was used to replace the binomial for existing overdispersion) were developed in the same way as the regressions earlier. Models 4a, 5a, and 6a only considered the NDVI of 3 buffer scales separately, and Models 4b, 5b, and 6b were the quasibinomial regressions (weighted with the number of students in each school) of the NDVI (within the school, 500 m buffer around the school, 1000 m buffer around the school, respectively) to the school-level myopia prevalence with adjusted factors (ie, the school's average age, gender [proportion of female students], place of origin [urban or suburban], BMI, and position of trees).

Data analyses and visualization were performed using R version 4.1.3 (R Core Team), mainly using the sjplot [40], lme4 [41], and ggplot2 [42] packages.

Results

Myopia Prevalence

The 13,380 students included in this study were aged 11.9-20.9 years (mean 14.86, SD 1.71), and among them, 6803 (50.84%) were male and 6577 (49.16%) female. There were 7850 (58.67%) junior high school-aged students (n=2663, 33.92%, grade 1, n=2610, 33.25%, grade 2, and n=2577, 32.83%, grade 3) and 5530 (41.33%) seniors (n=1908, 34.50%, grade 1, n=1841, 33.29%, grade 2, and n=1781, 32.21%, grade 3). Of the 13,380 adolescents, 5245 (39.20%) were from urban areas and 8135 (60.80%) from suburban areas. In addition, 12,004 (89.72%) of these students were of Han nationality, and 1376 (10.28%) were of other nationalities. According to grade, the exposure times in school were divided into 1, 2, and 3 years, accounting for 4571 (34.16%), 4451 (33.27%), and 4358 (32.57%) of the students, respectively.

The overall myopia prevalence of the high school–aged students was 80.61% (10,785/13,380, 95% CI 79.93%-81.27%). The prevalence of myopia in seniors (4754/5530, 85.97%, 95% CI 84.03%-86.86%) was higher than that in juniors (6031/7850, 76.83%, 95% CI 75.88%-77.75%); see Table 1. With the exception of nationality (*P*=.63) and BMI (*P*=.47), the prevalence of myopia varied significantly with age, gender, and place of origin (*P*<.001); see Table 1. Adolescents with myopia were more likely to be (1) older (median age 14.78 years, IQR 13.75-16.46) compared to those without myopia (median age 14.05 years, IQR 13.01-15.60), (2) schoolgirls (myopia prevalence 5548/6577, 84.4%, 95% CI 83.45%-85.21%) compared to schoolboys (myopia prevalence 5237/6803, 77%, 95% CI 75.96%-77.96%), and (3) urban students (myopia prevalence 4406/5245, 84%, 95% CI 82.98%-84.97%) compared to suburban students (myopia prevalence 6379/8135, 78.4%, 95% CI 77.5%-79.29%).

Table 1. Description of myopia and nonmyopia groups.

Characteristics	Total (N=13,380)	Myopia group (n=10,785, 80.61%)	Nonmyopia group (n=2595, 19.39%)	*P* value[a]
Age (years), median (IQR)	14.63 (13.42-16.31)	14.78 (13.75-16.46)	14.05 (13.01-15.60)	<.001

Exposure time (years), n (%)				<.001
1	4571 (34.16)	3507 (32.52)	1064 (41.00)	N/A
2	4451 (33.27)	3581 (33.20)	870 (33.53)	N/A
3	4358 (32.57)	3697 (34.28)	661 (25.47)	N/A
Position of trees, n (%)				<.001
From buildings with a small space	4857 (36.30)	4018 (37.26)	839 (32.33)	N/A
From buildings with a large space	8523 (63.70)	6767 (62.74)	1756 (67.67)	N/A

[a] Age and the BMI were reported with *P* values in the Wilcoxon test. Other variables were reported with *P* values in the chi-square test.

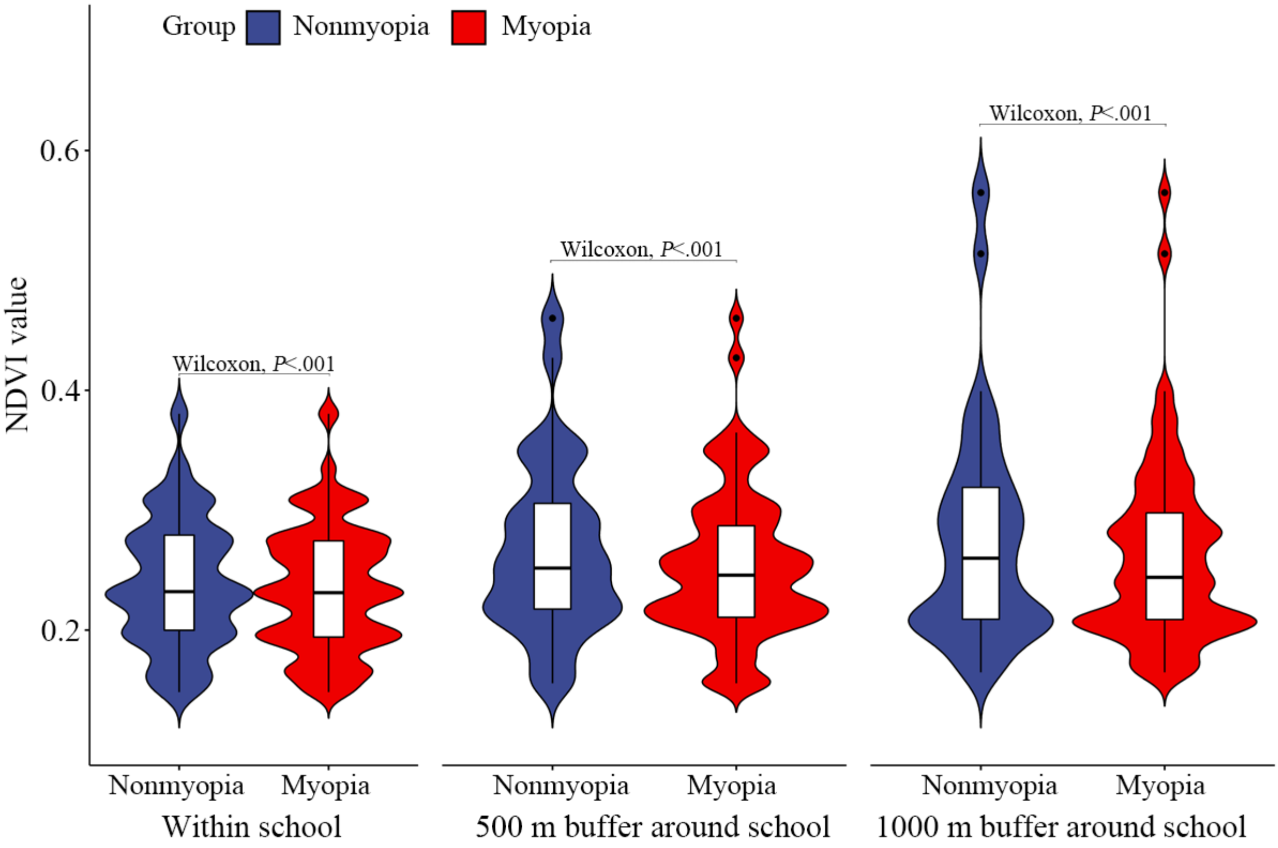
[b] N/A: not applicable.

Factors Influencing the Prevalence of Myopia

We extracted the NDVI within each school boundary and of the 500 and 1000 m buffers (Figure S2 in Multimedia Appendix 1). Significant differences were found in school greenness between the myopia group and the nonmyopia group (*P*<.001); see Figure 2. In the myopia group, the NDVI (1) within the school (median 0.231, IQR 0.194-0.274), (2) within the 500 m buffer (median 0.279, IQR 0.247-0.318), and (3) within the 1000 m buffer (median 0.281, IQR 0.248-0.331) was lower compared to the nonmyopia group (median 0.232, IQR 0.2-0.279; median 0.285, IQR 0.253-0.335; and median 0.296, IQR 0.249-0.351, respectively).

Furthermore, trees located too close to teaching buildings were significantly associated with a higher myopia prevalence (4018/4857, 82.73%, 95% CI 81.64%-83.77%) than trees at a distance with enough space from the buildings (6767/8523, 79.4%, 95% CI 78.53%-80.25%); see Table 1. Moreover, there were significant differences concerning other factors between students with and without myopia (*P*<.001). Students without myopia were likely associated with a higher outdoor level (Q2-Q5), less near-work time with appropriate body posture (Q6-Q8, Q10), better eye care (Q11-Q12), sufficient sleep time (Q16), and high fresh-good intake (Q14); see Multimedia Appendix 2.

Figure 2. Differences in the NDVI between the myopia and nonmyopia groups. The probability density with the minimum, maximum, median, and quartiles are shown in this figure. The red color represents the myopia group, and the blue color represents the nonmyopia group. “Wilcoxon, *P*<.001” means a significant difference in the median by the Wilcoxon test. NDVI: normalized difference vegetation index.



Effects of Influencing Factors on Adolescent Myopia Risk

According to the fixed effects of generalized linear mixed effect models (Table 2), the NDVI of buffers around the school significantly influenced the risk of adolescent myopia without any adjusted factors. With a 0.1 increase in the NDVI of a 500 m buffer (odds ratio [OR] 0.74, 95% CI 0.61-0.89, Model 2a) and a 1000 m buffer (OR 0.79, 95% CI 0.68-0.92, Model 3a) surrounding the school, the adolescent myopia prevalence decreased by 26% and 21%, respectively. However, the decrease in myopia prevalence caused by the 500 m (OR 0.84, 95% CI 0.73-0.97, Model 2b) or the 1000 m (OR 0.88, 95% CI 0.79-0.99, Model 3b) buffer NDVI dropped by 16% and 12%, respectively, due to the adjustment. In addition, neither the NDVI (OR 0.84, 95% CI 0.66-1.06, Model 1a) nor the adjusted NDVI (OR 0.88, 95% CI 0.75-1.04, Model 1b) within the school showed a significant association with the adolescent myopia risk.

Considering all adjusted factors (Table S1 in Multimedia Appendix 4), similar effects of age, gender, exposure time, place of origin, outdoor time during holidays (Q2), preference for outdoor place (Q3), posture-related distance from the table while doing near-work (Q6), and eye-rest interval (Q12) were found to be significantly associated with myopia when adjusting the 500 and 1000 m buffer NDVI. Of these factors, age (OR 1.13, 95% CI 1.06-1.2, Models 2b and 3b) and female gender (OR 1.52, 95% CI 1.38-1.66, Models 2b and 3b) had positive associations with myopia. A close range for reading (Q6; OR 1.22, 95% CI 1.03-1.44, Models 2b and 3b) and an eye-rest interval of 30-60 minutes compared to 15 minutes or less (Q12; OR 1.21, 95% CI 1.05-1.39, Models 2b and 3b) were risk factors for myopia. The outdoor time on holidays was negatively associated with the personal risk of myopia, and persisting in maintaining the outdoor time on holidays reduced the personal risk of myopia by 33% (OR 0.67, 95% CI 0.55-0.82, Models 2b and 3b) compared to hardly doing so. Spending break time outdoors decreased the personal risk of myopia by 10% (OR 0.90, 95% CI 0.8-0.99, Models 2b and 3b) compared to spending break time in the teaching building. In addition, suburbanization was found to lower the personal risk of myopia by approximately 20% when adjusted for NDVI effects (OR 0.81, 95% CI 0.68-0.96 for Model 2b and OR 0.8, 95% CI 0.67-0.95 for Model 3b). However, a 3-year exposure time caused a higher myopia risk than a 1-year exposure time when considering the 500 or the 1000 m buffer NDVI (OR 1.38, 95% CI 1.18-1.63, Model 2b and 3b), but no such significant difference was seen between the 2- and 1-year exposures (OR 1.12, 95% CI 0.99-1.26 for Model 2b and OR 1.12, 95% CI 0.99-1.27 for Model 3b).

Table 2. Summary of the NDVI[a] effect at the personal level and the school level.

	Crude[b]		Adjusted[c]	
	OR[d] (95% CI)[e]	*P* value	OR (95% CI)[e]	*P* value
Personal myopia risk				
Within the school	0.84 (0.66-1.06)	.14	0.88 (0.75-1.04)	.15
500 m buffer around the school	0.74 (0.61-0.89)	.001	0.84 (0.73-0.97)	.02
1000 m buffer around the school	0.79 (0.68-0.92)	.002	0.88 (0.79-0.99)	.04
School myopia prevalence				
Within the school	0.85 (0.67-1.06)	.16	0.94 (0.79-1.11)	.44
500 m buffer around the school	0.73 (0.61-0.87)	<.001	0.85 (0.74-0.98)	.02
1000 m buffer around the school	0.79 (0.69-0.92)	.001	0.89 (0.80-1.01)	.05

[a] NDVI: normalized difference vegetation index.

[b] Odds ratios (ORs) of the NDVI (within the school, 500 m buffer around the school, 1000 m buffer around the school) regressed to the personal myopia risk or the school-level myopia prevalence without multivariable adjustment.

[c] Adjusted ORs with multivariable adjustment.

[d] OR: odds ratio.

[e] OR (95% CI) of the NDVI within the school and of the 500 or 1000 m buffers around the school indicated a 0.1 change in value.

Furthermore, the 500 and 1000 m buffer NDVIs performed differently in various subgroups (Figure 3). The 500 m or 1000 m buffer NDVI significantly influenced juniors (OR 0.82, 95% CI 0.72-0.94 for the 500 m buffer and OR 0.87, 95% CI 0.77-0.97 for the 1000 m buffer), schoolgirls (OR 0.82, 95% CI 0.72-0.93 for the 500 m buffer and OR 0.85, 95% CI 0.76-0.94 for the 1000 m buffer), and the the Han nationality (OR 0.84, 95% CI 0.72-0.97 for the 500 m buffer and OR 0.88, 95% CI 0.78-0.99 for the 1000 m buffer). However, only the 500 m buffer NDVI had a significant association with the suburban group (OR 0.81, 95% CI 0.7-0.94). Moreover, considering the exposure time, the NDVI of buffers around the school (OR 0.78, 95% CI 0.65-0.94 for the 500 m buffer and OR 0.81, 95% CI 0.70-0.94 for the 1000 m buffer) significantly influenced the 3-year exposure group, while only the NDVI of the 500 m buffer around the school (OR 0.84, 95% CI 0.71-0.99) significantly affect the 1-year exposure group.

Figure 3. Effects of the NDVI among subgroups. The effect of the NDVI of buffers around the school were adjusted by demographic factors, outdoor exercise, near-work time, body gestures, eye care, diet, sleep factors, and the position of trees. However, this figure only shows the adjusted effects of the 500 and 1000 m buffer NDVIs surrounding the school. The lines describe the 95% CI range and the points show the OR values, while the yellow color represents the NDVI of the 500 m buffer around the school and the deep-purple color represents the NDVI of the 1000 m buffer around the school. NDVI: normalized difference vegetation index; OR: odds ratio.

Subgroup	OR (95% CI)	*P* value
School type		
Junior		
500 m buffer	0.82 (0.72 to 0.94)	.01
1000 m buffer	0.87 (0.77 to 0.97)	.01
Senior

Influence of the NDVI on School-Level Myopia Prevalence

The school-level myopia prevalence was not significantly affected by the NDVI within the school (OR 0.85, 95% CI 0.67-1.06, Model 4a); see Table 2, while it was distinctly influenced by the 500 and 1000 m buffer NDVIs without any adjusted factors (Table 2). With a 0.1 increase in the 500 and 1000 m buffer NDVIs, the prevalence of myopia at the school level dropped by 27% (OR 0.73, 95% CI 0.61-0.87, Model 5a) and 21% (OR 0.79, 95% CI 0.69-0.92, Model 6a), respectively. However, after adjusting for age, gender, the BMI, place of origin, and the relative position of trees (Table S2 in Multimedia Appendix 4), only the effects of the 500 m buffer NDVI were still influential (Table 2), with its 0.1 increase significantly reducing the school-level myopia prevalence by 15% (OR 0.85, 95% CI 0.74-0.98, Model 5b). Furthermore, in this situation, the suburban (OR 0.82, 95% CI 0.65-1.02) area no longer showed a significant adjusting effect, while age still had a positive association with the school-level myopia prevalence (OR 1.22, 95% CI 1.13-1.33); see Table S2 in Multimedia Appendix 4.

Discussion

Principal Findings

This research shows the alarming overall prevalence of myopia in senior and junior high school students in Beijing of 80.61%(10,785/13,380, 95% CI 79.93%-81.27%). However, the protective effects of the 500 m buffer NDVI were found on both the adolescent myopia risk (OR 0.84, 95% CI 0.73-0.97) and the school-level myopia prevalence (OR 0.85, 95% CI 0.74-0.98), and it was significantly associated with schoolgirls (OR 0.82, 95% CI 0.71-0.93), juniors (OR 0.82, 95% CI 0.72-0.94), the Han nationality (OR 0.84, 95% CI 0.72-0.97), 1-year exposure (OR 0.84, 95% CI 0.71-0.99), and 3-year exposure (OR 0.78, 95% CI 0.65-0.94) myopia risk.

The prevalence of myopia in Beijing is reported to exceed the average level of other Chinese mainland regions [43,44]. However, in the past decades, a series of actions have been taken by the government to prevent myopia among school-aged children and adolescents [45]. Some studies have noted that the myopia prevalence in junior high school students and senior students dropped from 2018 to 2020 according to cohort investigations. Correspondingly, the green space area ratios of Beijing from 2018 to 2020 were 48.44, 48.46, and 48.96, respectively (Beijing Municipal Forestry and Parks Bureau [46]). Despite the lack of direct evidence to determine the associations between the decrease in the prevalence of myopia and the yearly increasing green space ratio, the benefits of a greener city for children’s and adolescents’ vision development might be meaningful because this type of relationship has been demonstrated at the national or regional level by meta-analysis [47].

Our research found important associations between the green space surrounding schools and students’ myopia, in line with our hypothesis. Thus, more attention should be paid to myopia among students in schools with less greenness around the campus environment. The importance of green space within the 500 m buffer around schools for adolescents’ myopia was emphasized in our study. Similarly, the greenness of the 500 m buffer surrounding the school has been underlined for students’ social and health benefits in other studies [48,49]. We considered that students probably tended to live close to their school to minimize time costs or benefit from opportunities offered by the school (school catchment areas probably encompass the properties nearby) [50]. Thus, the 500 m buffer might also cover the students’ outside-school environments. This situation might provide day-long exposure to greener space and reduce the risk of myopia. Moreover, a greener environment could encourage more outside activities after school, encouraging students to enhance social connections with neighbors of the same age instead of playing alone on electronic devices [51]. In addition, with more green space outside schools, students may have greener routes between school and home, and walking home along an avenue with a tree canopy could be highly inspirational [52]. Indeed, “commuting greenness” has been shown to help reduce the need for spectacles [34]. Furthermore, the marked variation in the prevalence of myopia between suburban and urban schools did not occur when the effects of the NDVI of buffers were considered. It is suggested that the greenness level around schools rather than the urbanization of the location could better determine the school prevalence of myopia. The effects of green space around schools, especially the 500 m buffer, need to be further stressed.

In addition, the effect of green space within the 500 m buffer on myopia prevalence varied in different demographic subgroups. Schoolgirls had a higher myopia prevalence and were slightly more sensitive to the 500 m buffer NDVI than schoolboys. This result showed marginalization, which is usually reported in gender variation; that is, females are marginalized with poor health outcomes but gain more than males from green space exposure [53,54]. However, some studies note that nonenvironmental factors affect myopia in schoolgirls and that gender differences are the effect of puberty hormones, which influence schoolgirls’ eye development progress and increase the tendency to develop myopia [55]. Moreover, the NDVI of the 500 m buffer around the school showed significant effects on reducing personal myopia risk both in 1- and 3-year-exposure-time subgroups, but a 3-year exposure time caused a higher myopia risk than a 1-year exposure time. Although we lack evidence about the effects of exposure time combined with the effects of green space on myopia, it could suggest that students are more likely to benefit from a school environment with adequate green surroundings. In addition, the benefit level could rapidly rise initially when they first enter, and then drop to a certain and steady level afterward. The hypothesis about this trend is also mentioned in other studies for the effects of green space on other health outcomes [56].

Our study also showed important results for other influencing factors that were similar to previous studies. Time spent outdoors has been shown to protect against myopia [14,57], and previous studies have revealed the driving mechanisms. It appears that light quality is a crucial factor in avoiding myopia development, and people with myopia have significantly lower daily light exposure [58,59]. Because the intensity of artificial light in indoor environments is much lower than that in outdoor environments [60], the shade from trees placed close to teaching buildings might make the inner classroom darker, with poor distribution of light, which may aggravate students’ refractive error problems. However, some scholars believe that prolonged exposure to a middle-level-light environment could achieve the same protection against myopia as exposure to a strong-light environment [61]. It is conceivable that the total light exposure accumulated via outdoor activities in green space with medium light intensity could effectively prevent and control myopia development, while providing a visually comfortable environment that is not harmful to the skin [62]. In addition, unlike daytime outdoor light exposure, some researchers suggest that excessive artificial light at night (ALAN) exposure results in myopia [63]. Green space has been identified as having a negative correlation with ALAN [64] and may be a potential protective factor for myopia that mitigates harmful night-light doses for children and adolescents. Furthermore, previous studies have investigated seasonal variation and myopia development [65] and have found that myopia progression is slower in the summer than in the winter. They explain this by the association between outdoor light exposure and myopia. However, these studies may have partly neglected the role of seasonal plant landscape changes with more greenery and its function in promoting more physical activity in the summer than in the winter [66]. Thus, outdoor activities in greener spaces might benefit eye development and protect against ametropia.

Importantly, this study highlighted the same beneficial factors related to good eye care, such as reduction in near-work time and better body posture, as other researchers [1]. These should be key points for myopia prevention and control in Beijing. Furthermore, some studies have summarized the control activities that should be included in government policies, school-based prevention, health sector screening and treatment, and family support for prevention [45]. In view of our findings, since adolescents lack outdoor time [67], we recommend that adequate outdoor time in green space for adolescents should be ensured by policy makers, educators, and parents. In addition, the greenness around schools (particularly within the 500 m buffer) should be improved by tree planting and canopy provision, and the government should support these measures. A higher level of greenness for schools is required because campus green space provides further health benefits (eg, improving mental well-being [28,29,68], reducing heat-related illness [69]) beyond myopia reduction. However, the vegetation distribution should be carefully considered. Creating a vision-friendly campus could include a tree cover around the playground or along inner paths, while leaving appropriate spaces between trees and building edges.

Limitations

However, some limitations exist. First, we used cross-sectional myopia data from 2021 as many online classes were conducted during home quarantine due to the COVID-19 pandemic in 2020, which caused long periods of near-work on electronic devices and less outdoor activity time, as well as an increased prevalence of myopia [70-75]. Thus, the myopia prevalence might be overvalued with fewer environmental influences. Second, we lacked information about the green space exposure level of the samples' previous schools (ie, the NDVI and the exposure duration of their previous schools). Therefore, the exposure time in our study might be estimated inaccurately. In addition, we did not include the myopia duration due to the lack of access to students' previous myopia data. Third, noncycloplegic refractometry may overestimate the prevalence of myopia in teenagers with active accommodation [76]. Fourth, we did not consider other types of green space exposure, such as the accessibility and visibility of greenness.

The NDVI (2D perspective) does not precisely represent human vision greenness (3D perspective) [48], although it is an effective indicator to measure the green space level and can explain its effects on general health outcomes. Since a lack of green view is significantly related to eye fatigue, a greenness vision indicator should be considered. Future studies should address these points.

Conclusion

To the best of our knowledge, this is 1 of the few studies to clarify the effects of school green space with buffers and other relevant factors on junior and senior high school students' myopia prevalence. We emphasize that green space around schools is an independent protective factor for adolescents' myopia, and we suggest the importance of the appropriate distribution of within-campus trees for myopia prevention.

Acknowledgments

We thank anonymous reviewers for comments and suggestions that greatly improved the manuscript. We thank all the on-site investigators of the Beijing Municipal Health Commission for the data collection.

This study was funded by the National Natural Science Foundation of China (82004210), the National Key R&D Program of China (2018YFC1704400), the European Union's Horizon 2020 research and innovation program (grant agreement 821242), and the Central Nonprofit Research Institutions of the Chinese Academy of Forestry (CAFYBB2020ZB008). No payment was received by any of the coauthors for the preparation of this paper.

Authors' Contributions

Conceptualization was performed by CW and XG; data curation by CZ and LT; funding acquisition by CW and LT; investigation by XG and HX; methodology by CZ and LT; project administration by CW and XG; validation by LT; visualization and writing—original draft by CZ; and writing—review and editing by ZQ and LT. Abstract

Background: Particulate matter (PM) is detrimental to the respiratory and circulatory systems. However, no study has evaluated the lag effects of weekly exposure to fine PM during the period from preconception to delivery on the risk of hypertensive disorders of pregnancy (HDPs).

Objective: We set out to investigate the lag effect windows of PM on the risk of HDPs on a weekly scale.

Methods: Data from women with de novo HDPs and normotensive pregnant women who were part of the Peking University Retrospective Birth Cohort, based on the hospital information system of Tongzhou district, were obtained for this study. Meteorological data and data on exposure to fine PM were predicted by satellite remote sensing data based on maternal residential address. The de novo HDP group consisted of pregnant women who were diagnosed with gestational hypertension or preeclampsia. Fine PM was defined as $PM_{2.5}$ and PM_1. The gestational stage of participants was from preconception (starting 12 weeks before gestation) to delivery (before the 42nd gestational week). A distributed-lag nonlinear model (DLNM) was nested in a Cox regression model to evaluate the lag effects of weekly PM exposure on de novo HDP hazard by controlling the nonlinear relationship of exposure–reaction. Stratified analyses by employment status (employed or unemployed), education level (higher or lower), and parity (primiparity or multiparity) were performed.

Results: A total of 22,570 pregnant women (mean age 29.1 years) for whom data were available between 2013 and 2017 were included in this study. The prevalence of de novo HDPs was 6.7% (1520/22,570). Our findings showed that PM_1 and $PM_{2.5}$ were significantly associated with an elevated hazard of HDPs. Exposure to PM_1 during the 5th week before gestation to the 6th gestational week increased the hazard of HDPs. A significant lag effect of $PM_{2.5}$ was observed from the 1st week before gestation to the 6th gestational week. The strongest lag effects of PM_1 and $PM_{2.5}$ on de novo HDPs were observed at week 2 and week 6 (hazard ratio [HR] 1.024, 95% CI 1.007-1.042; HR 1.007, 95% CI 1.000-1.015, respectively, per 10 μg/m^3 increase). The stratified analyses indicated that pregnant women who were employed, had low education, and were primiparous were more vulnerable to PM exposure for de novo HDPs.

Conclusions: Exposure to PM_1 and $PM_{2.5}$ was associated with the risk of de novo HDPs. There were significant lag windows between the preconception period and the first trimester. Women who were employed, had low education, and were primiparous were more vulnerable to the effects of PM exposure; more attention should be paid to these groups for early prevention of de novo HDPs.

KEYWORDS

air pollution; PM2.5; PM1; hypertensive disorders of pregnancy; preconceptional period; lag effect; pregnancy; hypertension; hypertensive disorders; risk; pollutants; exposure; maternal health; perinatal health; pollution

Introduction

A risk of multiple adverse health outcomes is attributable to increased exposure to the ambient particulate matter (PM). Fine PM is defined as ambient particles with an aerodynamic diameter ≤2.5 µm or ≤1 µm, that is, $PM_{2.5}$ and PM_1, respectively. PM is derived from a wide range of sources, such as forest fires, coal combustion, industrial processes, and traffic emissions [1]. It is composed of various toxic pollutants, including organic carbon, alkanes, metals, sulfates, and nitrates [2,3]. When people inhale the air, fine PM can easily translocate the abovementioned toxic pollutants across biological membranes from the pulmonary alveoli to the blood circulation, further resulting in systemic and tissue injury due to its physical characteristics of tiny size and large surface area [4]. According to the World Health Organization (WHO) air quality guidelines, about 92% of people in the world are exposed to excessive fine PM. Not long ago, the WHO updated the limit on exposure to fine PM, decreasing it from 10 $\mu g/m^3$ to 5 $\mu g/m^3$, based on research findings from the past 15 years. PM exposure is regarded as a risk factor for cardiovascular diseases and adverse perinatal outcomes [5,6]. An accumulating number of studies have used in vitro and in vivo experiments to show that fine PM can induce cardiovascular toxicity [7]. A recent global disease-burden study also indicated that fine PM was associated with risks of low birth weight, preterm birth, and neonatal and infant mortality, particularly in low- and middle-income countries [8].

Emerging evidence indicates a link between PM exposure and hypertensive disorders of pregnancy (HDPs), which are among the leading risk factors for maternal and fetal morbidity and mortality. Gestational hypertension (GH) and preeclampsia (PE) belong to the de novo type of HDP, which accounts for over 85% of HDP diagnoses [9]. HDPs can not only become complicated with proteinuria, edema, seizure, and liver and kidney injury, but also result in a series of adverse pregnancy outcomes, such as intrauterine growth restriction, preterm birth, stillbirth placental abruption, and postpartum hemorrhage [10,11]. In addition, HDPs have grown to become the second leading cause of maternal death in China. Therefore, HDPs are a significant public health problem in China in terms of maternal health [12]. While the etiology of HDPs is still elusive, in recent years an increasing number of researchers have focused on the effects of the environment on cardiovascular health. They have hypothesized that fine PM could result in HDPs via vascular constriction, inflammation, and oxidative stress. However, findings for an association between fine PM and HDPs are inconsistent. A recent Chinese study showed that fine PM exposure during the first trimester was associated with the risk of HDPs [13]. On the other hand, an American study indicated that fine PM exposure increased the development of HDPs during the second trimester rather than the first trimester [14]. This inconsistency may originate from differing study populations and exposure concentrations. Moreover, it has become imperative to draw attention to fine PM exposure before pregnancy. Based on the Developmental Origins of Health and Disease paradigm, the window of sensitivity to fine PM exposure could begin as far back as the preconception period [15]. There is an increasing consensus that preconception exposure to environmental contaminants can affect well-being in pregnancy. Several studies have indicated that air pollution exposure during the preconception period is associated with a risk of termination of pregnancy [16] and gestational diabetes mellitus [17]. The majority of previous studies only focused on the association between air pollution and maternal health in either specific trimesters or the total pregnancy [18,19]. The dynamic association between fine PM exposure and HDPs at different gestational weeks remains to be investigated in Chinese populations. To our knowledge, no study has assessed the association between weekly fine PM exposure, starting during the preconception period, and HDPs, especially de novo HDPs. If an association is shown, preconception precautions for fine PM exposure will become essential practice for lowering the risk of HDPs.

In this retrospective birth cohort study, we collected ambient data on PM exposure and applied a distributed-lag nonlinear model (DLNM) to examine the association between weekly PM exposure during the period from preconception to delivery and de novo HDPs. Additionally, we evaluated sensitivity lag windows for fine PM for HDPs across different sociodemographic strata.

Methods

Study Population

The study participants were pregnant women who were part of the Peking University Retrospective Birth Cohort for whom data were available in the hospital information system of Tongzhou for the period between January 2013 and December 2017. All the participants received antenatal examinations and gave birth at the Tongzhou Maternal and Child Health Care

Hospital, which is the maternal health center for Tongzhou district, Beijing. The sociodemographic and health details of the participants were recorded at the antenatal examinations, including maternal age (<35 years vs ≥35 years), employment status (employed vs unemployed), parity (nulliparous vs multiparous), prepregnancy weight, height, maternal education level (high school or below, junior college, university or above), maternal ethnicity (Han vs non-Han), first day of last menstrual period, and delivery date. Prepregnancy BMI was calculated by dividing weight (in kilograms) by height (in meters squared) and categorized according to the WHO standards for Asian women: underweight (BMI <18.5 kg/m^2), normal weight (BMI 18.5-23 kg/m^2), overweight (BMI 23-27.5 kg/m^2), or obese (BMI >27.5 kg/m^2) [20]. The study data were extracted from the electronic medical records of Tongzhou Maternal and Child Health Care Hospital and were routinely reviewed by in-house professional data engineers every week.

The inclusion criteria of this study were (1) a single gestation, (2) an available residential address, (3) no history of previous HDPs, and (4) a delivery date before the 42nd gestational week. A total of 43,894 pregnant women met the inclusion criteria. We excluded 21,324 pregnant women who met the following exclusion criteria: (1) preexisting conditions, including metabolic syndrome; hemolysis, elevated liver enzymes, slow platelets; or hypertension before the HDP diagnosis; (2) missing data for delivery date; (3) an age at delivery less than 18 years; and (4) missing values for maternal age, ethnicity, education level, employment status, or prepregnancy BMI. Finally, 22,570 women were included in this study. The flowchart in Multimedia Appendix 1 shows the details of participant selection.

Outcome Measurements

The de novo HDP group was defined as patients who experienced GH or PE during the current pregnancy. The normotensive group was defined as those free of any diagnosis of GH or PE and without a history of hypertensive disorders. Information on the history of hypertensive disorders was obtained from initial antenatal examination records. GH or PE diagnoses were made by obstetricians in accord with the Chinese Clinical Practice Guidelines, which are consistent with the guidelines of developed countries [21]. International Classification of Diseases–10 (ICD-10) codes were used to define GH and PE (the ICD codes for GH and PE are described in our previous study [22]). Medical records containing information related to GH and PE were extracted for double confirmation of the diagnosis and to obtain the week of disease diagnosis.

Assessment of Ambient PM Exposure, Temperature, and Relative Humidity

The pregnant women's residential addresses were collected at the initial antenatal examination. Each residential address was transformed into longitude and latitude values to determine the concentration of $PM_{2.5}$ or PM_1 in the center of the nearest 1 km × 1 km area on a grid. Daily PM concentrations were calculated at a spatial resolution of 1 km × 1 km in Beijing during the study period using satellite remote sensing, meteorology, and land-use information. Details of the calculations and validation of PM daily concentration measurements have been reported previously [23]. Data for daily temperature and relative humidity during the study period were obtained from the National Oceanic and Atmospheric Administration [24]. Average daily values for PM, temperature, and relative humidity from preconception (12 before gestation) to delivery (42 gestational weeks) were used to assess atmospheric exposure in our analysis.

Ethical Considerations

The study was approved by the Institutional Review Board of Peking University Health Science Center (IRB00001052-21023). All the study participants provided written consent. The study data were anonymized to protect the privacy of the study participants.

Statistical Analyses

The Student *t* test (2-tailed) and chi-square test were applied to assess differences in the distribution of characteristics between the subjects with HDPs and those who were normotensive. The relationships among $PM_{2.5}$, PM_1, temperature and relative humidity were assessed with the Pearson correlation test.

We followed the weekly exposure to PM_1 and $PM_{2.5}$ from the 12th week before gestation to the 42nd gestational week [25]. Cox proportional hazard models with a DLNM were used to estimate the association between the weekly $PM_{2.5}$ and PM_1 exposures and the hazard of de novo HDPs. The basis of the Cox proportional hazard model is the proportional hazards assumption, which means that all the study participants had the same hazard function. Our study complied with this assumption, which means that the ratio of the hazards for any 2 individuals was constant over time [26]. A DLNM was adopted to assess the effects of weekly PM exposures on hazards for HDPs by the "cross basic" function (cb) by constructing a 2D cross matrix that included exposure doses and time to control for the lag effect of PM exposure and the nonlinear relationship of exposure–reaction. A natural spline with 3 degrees of freedom was used to further accommodate the nonlinear effects of PM exposure, temperature, and relative humidity. The maximum number of lag weeks was set at 54 (from the 12th week before gestation to the 42nd gestational week). The lag effect of PM exposure was evaluated by the model as follows: $\ln(h(t,X)/h0(t)) = \beta1*Zt + \beta2*ns(temperature,3) + \beta3*ns(relative\ humidity,3) + \beta4*covariables$. "$\ln(h(t,X)/h0(t))$" indicates the hazard of de novo HDPs at the specific lag week (t), and the filed event is de novo HDP, noted as X. Zt represented the cross matrix of PM at specific lag weeks. β2 and β3 are the regression coefficients for temperature and relative humidity with 3 degrees of freedom in the natural spline function. β4 is the coefficient for the covariables, including maternal age, employment status, prepregnancy BMI, maternal education level, parity, maternal ethnicity, and conceptional year.

We also performed several sensitivity analyses to test the consistency of the main results. First, we further used natural splines with 4 and 5 degrees of freedom in the cross matrix to assess the hazards of de novo HDPs. Second, considering the clinical differences between GH and PE, we repeated our analyses excluding GH patients to explore the independent association between PM and PE. Meanwhile, stratified analyses were conducted across strata for differences in employment status, parity, and maternal education level.

All statistical analyses were performed with R (version 4.0.0; R Foundation for Statistical Computing). A 2-sided *P* value <.05 was considered a significant difference.

Results

Characteristics of the Participants

There were 1520 participants with de novo HDPs and 21,050 normotensive participants in this study. Table 1 shows the characteristics of the participants. The mean maternal age of the pregnancies was 29.1 (SD 4.1) years. There were 3802/22,570 (16.8%) unemployed women, and 21,222/22,570 (94%) women of Chinese Han ethnicity. A higher percentage of de novo HDPs was observed in the follow sociodemographic strata: low education level, primiparity, and prepregnancy overweight or obesity.

Table 1. Characteristics of mothers in the birth cohorts.

Characteristics	Total (n=22,570)	Normotensive (n=21,050)	Hypertensive disorders of pregnancy (n=1520)	*P* value

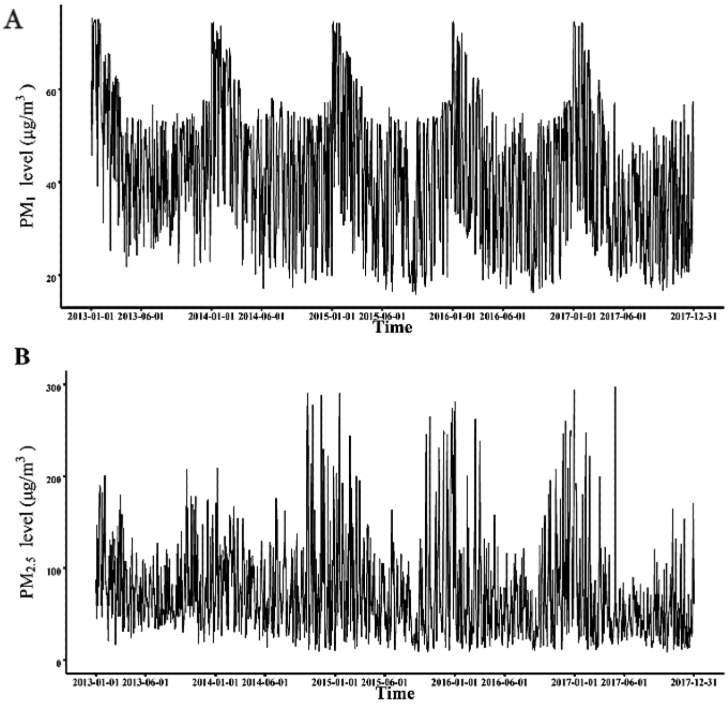
Characteristics of PM Exposure

The distribution of $PM_{2.5}$, PM_1, temperature, and relative humidity is summarized in Multimedia Appendix 2. The average concentration of $PM_{2.5}$ was 74.2 (SD 53.2) μg/m^3, ranging from 8.5 to 398 μg/m^3. The concentration of PM_1 ranged from 16.0 to 75.1 μg/m^3. Mean temperature and relative humidity were 13.5 °C (SD 11.0 °C) and 54.7% (SD 18.2%). Figure 1 presents the daily fluctuation in $PM_{2.5}$ and PM_1 concentration from January 2013 to December 2017, revealing seasonal fluctuations in $PM_{2.5}$ and PM_1 exposure. Meanwhile, $PM_{2.5}$ and PM_1 were strongly correlated (*r*=0.80). The Pearson correlations among $PM_{2.5}$, PM_1, temperature, and relative humidity are depicted in Multimedia Appendix 3.

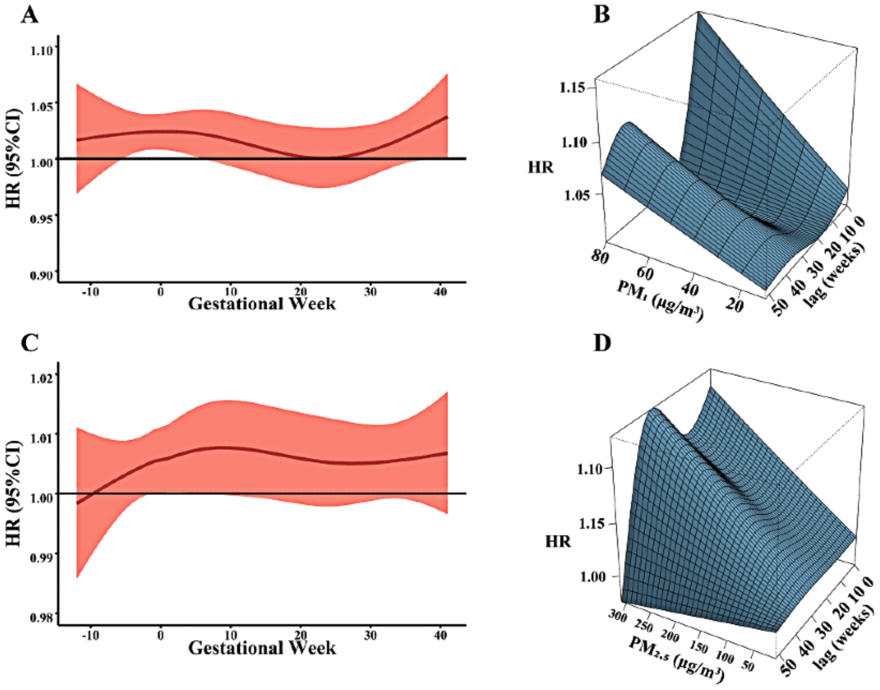
Figure 1. The level of particulate concentration by week. A and B show the daily level of PM_1 and $PM_{2.5}$, respectively, from 2013 to 2017. PM: particulate matter.



Association of Weekly Exposure to PM With HDPs

Figure 2 shows that a 10 $\mu g/m^3$ increase in PM_1 and $PM_{2.5}$ was associated with de novo HDPs in 2D and 3D plots. The hazard of de novo HDPs was associated with PM_1 exposure from the 5th week before gestation to the 6th gestational week, and the strongest effect of PM_1 exposure was observed in the 2nd gestational week (HR 1.024, 95% CI 1.007-1.042; Figure 2A). Figure 2B depicts the effects of PM_1 exposure on de novo HDPs with different exposure levels and different lag weeks, with a significant single peak by lag week from preconception to the first trimester (from lag 36 weeks to lag 47 weeks). For $PM_{2.5}$, the significant lag window was from the 1st week before gestation to the 6th gestational week and the maximum lag effect of $PM_{2.5}$ was found in the 6th gestational week (HR 1.007, 95% CI 1.000-1.015, Figure 2C). Similarly, we also observed a significant single peak from lag 36 weeks to lag 43 weeks when we assessed the association between $PM_{2.5}$ exposure and de novo HDPs for different exposure doses and lag weeks (Figure 2D).

Figure 2. The lag effect of PM on hypertensive disorders of pregnancy in 2D and 3D plots. A and B show the association between PM_1 and de novo hypertensive disorders of pregnancy in 2D and 3D plots, respectively. C and D show the association between $PM_{2.5}$ and de novo hypertensive disorders of pregnancy in 2D and 3D plots, respectively. HR: hazard ratio; PM: particulate matter.



Sensitivity Analyses

We conducted two sensitivity analyses to assess the consistency of the sensitivity windows for PM_1 and $PM_{2.5}$ for de novo HDP hazard. First, using natural splines with 4 and 5 degrees of freedom for the lag constraint, we observed similar results, that is, the significant lag windows for PM_1 and $PM_{2.5}$ spanned the preconception period and the first trimester (Multimedia Appendix 4). Furthermore, we excluded patients with GH to explore the independent association between PM and PE. Multimedia Appendix 5 shows a result consistent with our primary analyses, that is, that the lag windows for PM_1 and $PM_{2.5}$ spanned the preconception period and the first trimester.

Stratified Analyses

In the stratified analyses, we estimated the effects of PM on de novo HDPs across differences in employment status, parity, and maternal education level. In terms of PM_1, a significant sensitivity window for de novo HDPs was observed for employed, primiparous, and low educational status women (Figure 3). Similar findings are shown in Figure 4: women who were employed, primiparous, or had a low education level were more sensitive to $PM_{2.5}$ exposure across the preconception period and the first trimester.

Figure 3. The stratified associations between $PM_{2.5}$ and de novo hypertensive disorders of pregnancy for different maternal characteristics. A and B show the association in unemployed and employed women, respectively. C and D show the association in multiparous and primiparous women, respectively. E and F show the association in women with higher and lower education status, respectively. HR: hazard ratio; PM: particulate matter.

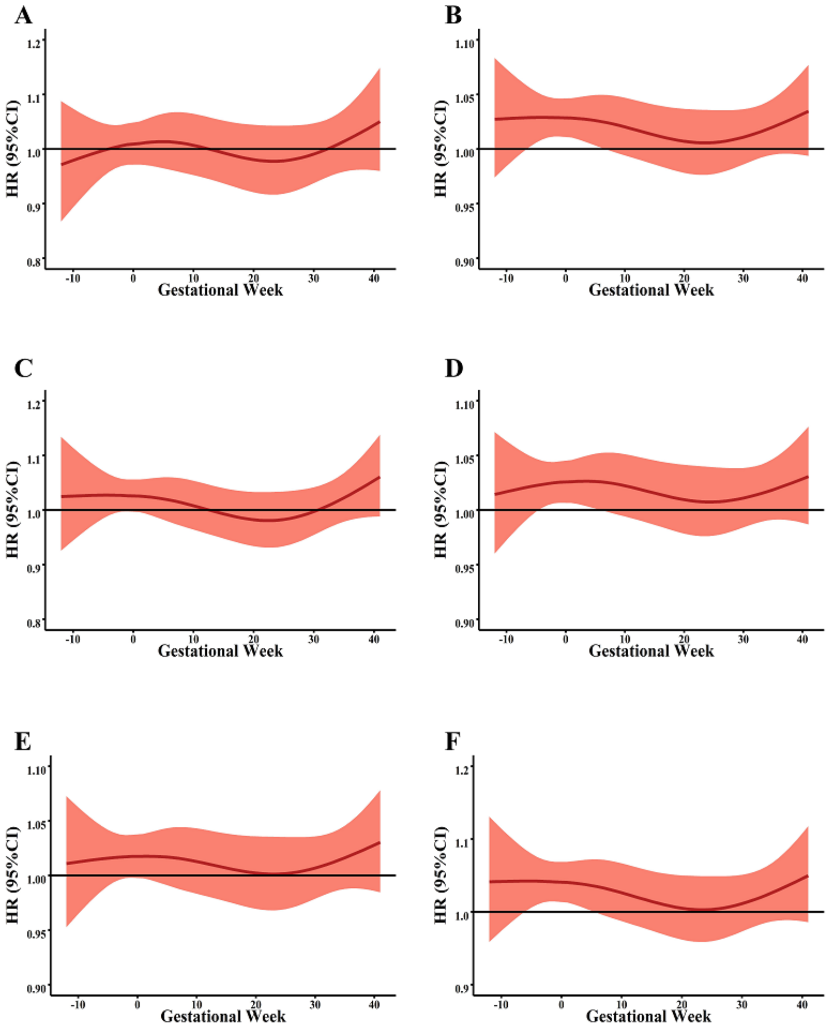


Figure 4. The stratified associations between PM_1 exposure and de novo hypertensive disorders of pregnancy for different maternal characteristics. A and B show the association in unemployed and employed women, respectively. C and D show the association in multiparous and primiparous women, respectively. E and F show the association in women with higher and lower education status, respectively. HR: hazard ratio; PM: particulate matter.

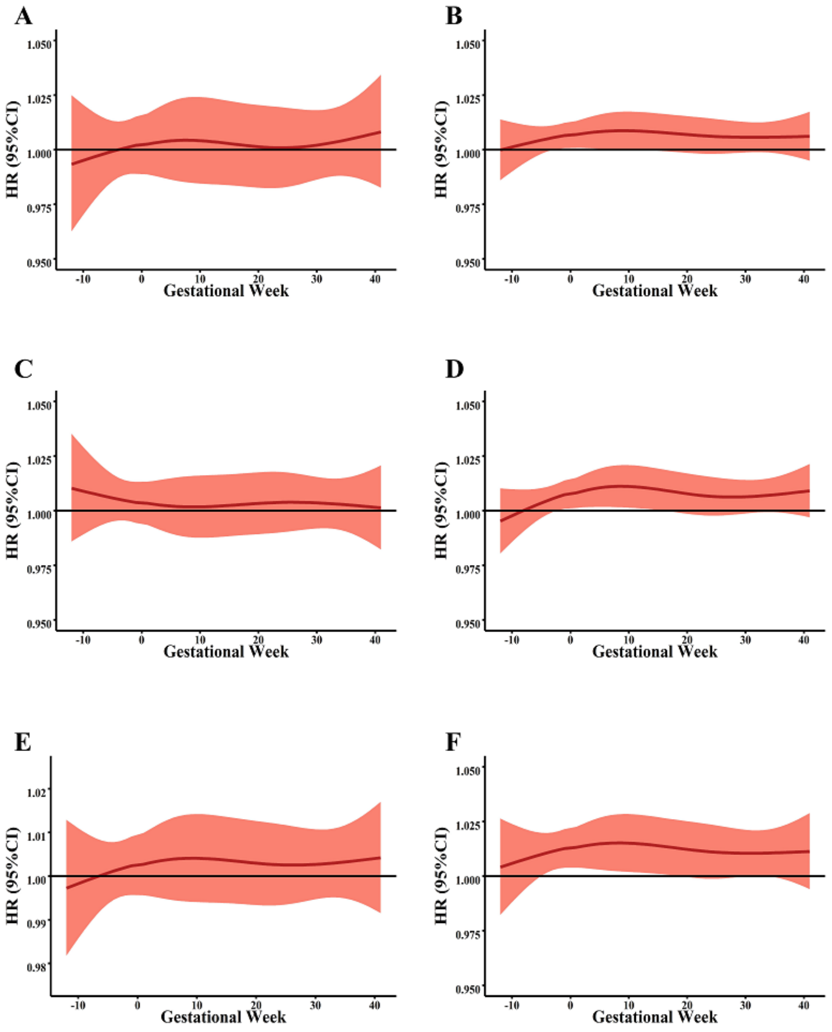

Discussion

Principal Results

This study found that the significant lag windows for PM_1 and $PM_{2.5}$ were from the 5th week before gestation to the 6th gestational week and the 1st week before gestation to the 6th gestational week, respectively, in terms of the de novo HDP hazard. The findings remained robust in sensitivity analyses, which reexamined the associations using different degrees of freedom and after excluding patients with GH. Stratified analyses indicated that pregnant women who were employed, primiparous, or had a lower education level were more sensitive to PM_1 and $PM_{2.5}$ exposure in the prepregnancy period and the first trimester.

In recent years, numerous studies have evaluated the association between air pollution and cardiovascular health during pregnancy. However, there has been no study to assess the adverse effect of preconception air pollution on gestational health in terms of de novo HDPs. We adopted a time-serial study design to explore the weekly effects of PM_1 and $PM_{2.5}$ from the preconception period to delivery. To our knowledge, this is the first study to focus on the detrimental association between PM during both the preconception and gestational periods and de novo HDPs. During the study period, the average exposure to $PM_{2.5}$ was 74.2 $\mu g/m^3$, which is more than 2-fold higher than the recommended maximum level of 35 $\mu g/m^3$ set by the National Ambient Air Quality Standards organization [27]. Moreover, exposure to PM showed seasonal fluctuations, peaking in winter and spring. Considering that our participants were mainly northern Chinese living in Beijing, the capital of China, the high concentration of PM can be attributed to central heating and a dense population.

In this study, the prevalence of de novo HDPs was 6.7% (1520/22,570). However, a lower prevalence (5%) of HDPs was reported in a recent study conducted in Shanghai [13]. In comparison with the Shanghai study, the pregnant subjects in our study were exposed to a higher concentration of PM pollution. Since both Beijing and Shanghai have populations of over 24 million and similar demographic compositions, the prevalence of HDPs is unlikely to have been influenced by differences in industrialization or urbanization between these two megacities. The difference in HDP prevalence might be partially explained by the higher PM exposure in the north due to the climate difference and use of central heating.

In our time-serial study, we observed that the women were sensitive to PM_1 and $PM_{2.5}$ during the preconception period and the first trimester. Our PM exposure measurements were at the week scale, which is more precise than previous studies that have used the trimester scale. Previous studies have made inconsistent findings on the association between fine PM and HDPs. Among 4 US studies, one in California [28] and one in Florida [14] observed that $PM_{2.5}$ exposure was associated with HDPs during pregnancy. However, studies conducted in Rhode Island [29] and New York [30] failed to observe significant associations. There are some potential explanations for these inconsistent results. First, the latitudinal difference may have influenced the temperature and humidity in the different regions. A recent national cohort study indicated that temperature was positively associated with the risk of HDPs during pregnancy [31]. Second, exposure measurement bias may have resulted in a false-negative association. Third, ethnicity differences can affect the association between PM and HDPs. A national cross-sectional study from 2007 to 2018 showed that there was a racial difference in the prevalence of HDPs in the United States [32]. Our study participants mainly lived in Beijing, and 94% were members of the Chinese Han population. Meanwhile, we described our method for high-precision air pollution measurement in a previous study [23]. Our results are consistent with those of the Shanghai study, which had a similar ethnicity and urbanization profile. Thus, climate, measurement, and ethnicity differences were well controlled in our study.

Furthermore, we used a DLNM model, which allowed an examination of the lag effect of PM on HDPs at the week scale, rather than the previously used trimester scale, to improve the precision of the search for the most sensitive gestational week. We also considered potential bias in the model parameters by testing the consistency of our results with different degrees of freedom. Based on the robust results from our sensitivity analyses, we consider that bias from model parameters was not likely. Additionally, our second sensitivity analysis excluding the patients with GE further showed that exposure to fine PM during the preconception period and first trimester was independently associated with the risk of PE. PE is one of the leading causes of adverse pregnancy outcomes, accounting for 10% to 15% of maternal deaths and 15% to 20% of preterm births [33,34]. Early identification of PE risk in clinical practice remains a difficult problem [35]. Our environmental evidence for an association between fine PM exposure and PE might indicate the need for preconception PE prevention to consider environmental hazards.

Considering the strong link with maternal characteristics and gestational blood pressure [36], we further investigated the effects of PM_1 and $PM_{2.5}$ on HDPs across different maternal characteristics, including employment status, parity, and education level. Among employed women, exposure to PM was significantly associated with the risk of HDPs. PM exposure also elevated the risk of HDPs in women who were primiparous and had a low education level, which indicates that women with these maternal characteristics have a higher risk of HDPs with exposure to PM.

Strengths and Limitations

There are several strengths of this study. First, to our knowledge, this was the first to adopt the Cox proportion model with a DLNM to estimate the week-scale sensitivity window to PM for HDPs in a Chinese population. HDPs are a major cause of adverse maternal and prenatal outcomes [37]. However, the identification of risk factors for HDPs has been limited due to complex confounders. Previous studies primarily explored the association between PM and HDPs in a specific trimester [38,39]. Our study analyzed the specific gestational weeks and improved the precision of the sensitivity window. Second, this was the first study to cover the effect of air pollution, starting from the preconception period, on de novo HDPs. Our findings reconfirmed the necessity of focusing on air pollution before pregnancy in terms of de novo HDPs. Third, the large sample size of this study made it possible to determine the effects of PM on subtypes of HDP in stratified analyses.

Some limitations must be noted. First, all the participants were residents of Beijing. The lag windows for PM_1 and $PM_{2.5}$ should be tested in different regions to increase generalizability. Second, PM is a mixture of types of air pollution. The effects of specific PM components should be further explored in future studies.

Conclusions

Exposure to PM_1 and $PM_{2.5}$ was associated with the risk of de novo HDPs. The significant lag windows for PM exposure were between the preconception period and the first trimester. Women who were employed, had a lower education level, or were primiparous were more vulnerable to the effects of PM exposure on the risk of HDPs; more attention should be paid to these groups for the early prevention of de novo HDPs.

Acknowledgments

We sincerely thank the research group of the Peking University Retrospective Birth Cohort, in Tongzhou, for their help with the hospital information system. We appreciate the health professionals at Tongzhou Maternal and Child Health Care Hospital of Beijing for the data collection and management. This study was sponsored by the Beijing Natural Science Foundation (7212144) and National Natural Science Foundation of China (92046019 and 82204055).

Abstract

Background: It is well-known that secondhand smoke exposure in childhood or adolescence is positively associated with morbidity and mortality. However, less is known about the current status of and most recent trends in secondhand smoke exposure among adolescents in China.

Objective: We aimed to assess recent changes in the prevalence of secondhand smoke exposure among adolescents in China using nationally representative data.

Methods: We used data from 2 repeated national cross-sectional surveys conducted in 2013-2014 and 2019. A total of 155,117 students (median age 13.5 years) in 2013-2014 and 147,270 students (median age 13.1 years) in 2019 were included in this study. Sociodemographic factors and secondhand smoke exposure information were collected via a standardized questionnaire. Exposure was defined as secondhand smoke exposure ≥1 day during the past 7 days at home or in public places. Other frequencies of secondhand smoke exposure (ie, ≥3 days, ≥5 days, and every day) during the past 7 days were also assessed. The weighted prevalence of secondhand smoke exposure was calculated according to the complex sample design for surveys.

Results: The prevalence of secondhand smoke exposure in any place (home or public places ≥1 day during the past 7 days) decreased from 2013-2014 (72.9%, 95% CI 71.5%-74.3%) to 2019 (63.2%, 95% CI 62%-64.5%), as did exposure at home (2013-2014: 44.4%, 95% CI 43.1%-45.7%; 2019: 34.1%, 95% CI 33.1%-35.2%) and in public places (2013-2014: 68.3%, 95% CI 66.9%-69.6%; 2019: 57.3%, 95% CI 56%-58.6%). The prevalence of secondhand smoke exposure decreased with increased gross domestic product per capita in each of the 2 survey years irrespective of exposure frequency or location. The prevalence of exposure at other frequencies (ie, ≥3 days, ≥5 days, or every day during the past 7 days) also decreased in any place, at home, and in public places. Secondhand smoke exposure was associated with higher school grade level (ninth vs seventh grade: odds ratio [OR] 1.76, 95% CI 1.68-1.84), gender (boys vs girls: OR 1.18, 95% CI 1.15-1.22), urban status (urban vs rural: OR 1.10, 95% CI 1.01-1.19), and cigarette smoking (yes vs no: OR 6.67, 95% CI 5.83-7.62).

Conclusions: Although the prevalence of secondhand smoke exposure among Chinese adolescents declined from 2013-2014 to 2019, it remains unacceptably high. More effective strategies and stronger action are needed in China to further, and dramatically, curb secondhand smoke exposure among adolescents.

KEYWORDS

secondhand smoke exposure; trends; adolescents; China; secondhand smoke; youth

Introduction

Background

Tobacco products, especially combustible ones, are harmful not only to users' health but also the health of nonsmokers who are exposed to secondhand smoke [1]. The World Health Organization (WHO) reports that exposure to secondhand smoke leads to 1.2 million deaths annually [2]. There is no safe or risk-free level of secondhand smoke exposure for children and adolescents [3], and more than 65,000 children die each year from diseases related to secondhand smoke exposure [2]. Secondhand smoke exposure occurs in various environments (at home or in any public place) and causes short-term damage in childhood (eg, slowed lung growth, worsened asthma, respiratory infections, and sudden infant death syndrome) [1], a long-term burden of cardiovascular disease [4], and mortality in adulthood [5].

China has the largest number of tobacco consumers in the world. Although the prevalence of current tobacco smoking decreased from 1990 to 2019 (males: –18.2%; females: –20.9%) among individuals aged 15 years or older in China, the prevalence of current tobacco smoking remained high in 2019 (males: 49.7%; females: 3.54%) [6]. Secondhand smoke exposure remains a serious public health concern in China despite evidence that has suggested the prevalence of secondhand smoke exposure in the workplace declined from 55.2% in 2010 to 45.3% in 2015 among Chinese nonsmokers aged 16 to 60 years [7]. In addition, national data from 2013 to 2016 showed that 41.7% (95% CI 40.9%-42.3%) of Chinese youth aged 6 to 17 years were exposed to secondhand smoke at home ≥1 day during the past 7 days [8]. This prevalence of secondhand smoke exposure among Chinese adolescents was higher than the global average level (72.9% vs 62.9%, respectively) [9].

Although considerable work on tobacco control has been undertaken in China in recent years, including the protection of teenagers from secondhand smoke exposure [10,11], there are no contemporary data on the prevalence of secondhand smoke exposure among adolescents in this country. Moreover, most previous studies only reported the prevalence of secondhand smoke exposure at home and public places in general [9,12,13]; no studies were able to precisely categorize the types of public places where exposure occurs. Such data are needed to monitor and guide effective interventions to protect adolescents from secondhand smoke exposure.

Objectives

Using repeated nationally representative data, we aimed to assess trends in the prevalence of secondhand smoke exposure between 2013-2014 and 2019 according to different locations (at home, in closed public places, in open public places, and on public transportation).

Methods

Study Participants

We used repeated cross-sectional data on secondhand smoke exposure collected from the Global Youth Tobacco Survey (GYTS)-China, which was a part of the GYTS conducted in China from October 1, 2013, to April 1, 2014, and the China National Youth Tobacco Survey (NYTS), conducted from May 1, 2019, to December 31, 2019. Each of these 2 national surveys was a national, representative, school-based, cross-sectional survey administered to middle school students. Both surveys used similar sampling, questionnaires, and survey methodologies and covered 31 provinces, autonomous regions, and municipalities (hereafter referred to as “provinces”) in China. Both surveys used the same 3-stage stratified cluster random sampling strategy. In the first stage, surveillance points were randomly selected from each province, stratified by urban-rural area by probability proportional to size sampling proportional to population size, to be nationally representative, with a total of 336 surveillance points in 2013-2014 and 347 surveillance points in 2019. In the second stage, 3 middle schools were randomly selected at each surveillance point. In the third stage, 1 class was randomly selected from each grade of the selected school. All students in the selected class were eligible to participate. The median age of the study population was 13.5 years in 2013-2014 and 13.1 years in 2019.

Definition of Secondhand Smoke Exposure

Exposure to secondhand smoke at home was assessed with the question “During the past 7 days, on how many days have people smoked in your presence, in your home?”; exposure in closed public places was assessed with the question “During the past 7 days, on how many days have people smoked in your presence in closed public places other than in your home (such as school buildings, conference halls, gymnasiums, bars, shops, restaurants, shopping malls, movie theaters, etc.)?”; exposure in open public places was assessed with the question “During the past 7 days, on how many days have people smoked in your presence in open public places (such as playgrounds, sidewalks, entrances to buildings, parks, bus stops, parks, etc.)?”; exposure on public transportation was assessed with the question “During the past 7 days, on how many days have people smoked in your presence in any public transportation vehicles (such as trains, buses, or taxicabs, etc.)?" In addition to reporting on secondhand smoke exposure in the individual public places mentioned above, we also unified heterogeneous information by combining exposure that was reported in closed public places, in open public places, and on public transportation together as one variable: "public places." Moreover, we also combined exposure at home and public places as "any place." Exposure to secondhand smoke at any location (ie, at home, in closed public places, in open public places, on public transportation, in any public place, or in any place) was defined as exposure to secondhand smoke on ≥1 day during the past 7 days. We also assessed different frequencies (≥3 days, ≥5 days, and every day during the past 7 days) of secondhand smoke exposure based on the students' responses. To ensure each participant understood that the question was asked about secondhand smoke from others, rather than from themselves, each question was explained by the trained investigators beforehand.

Cigarette smoking was defined as smoking on ≥1 day during the past 30 days with the question "During the past 30 days, on how many days did you smoke cigarettes?" [14]. Exposure to secondhand smoke in schools was assessed with the question "During the past 30 days, did you see anyone smoke inside the school building or outside on school property?" Attitude on the hazards of secondhand smoke exposure was assessed with the question "Do you think the smoke from other people's cigarettes smoking is harmful to you?" with the corresponding answers "Definitely not, probably not, probably yes, and definitely yes." Participants were classified into groups based on whether the gross domestic product (GDP) per capita of their province was low, middle, or high. For 2013-2014 (when the exchange rate was US $1=RMB 6.08), the GDP categories were RMB <35,000, RMB 35,000 to 50,000, and RMB >50,000, respectively. For 2019 (when the exchange rate was US $1=RMB 6.98), the categories were RMB <50,000, RMB 50,000 to 70,000, and RMB >70,000, respectively. Further details of the GDP per capita in 2013 and 2019 in China are available online [15,16].

Ethical Considerations

Both surveys (2013-2014 and 2019) were approved by the National Health Commission, and the proposal and protocols were reviewed by the Institutional Review Board of the Chinese Center for Disease Control and Prevention (202008). All participating students gave oral informed consent. Our study did not contain any identifiable information from individual participants.

Statistical Analysis

The national, regional, and subgroup (by sex, residence, GDP per capita category, and cigarette smoking status) prevalence with the 95% CI of secondhand smoke exposure in 2013-2014 and 2019 among adolescents was calculated with consideration of sampling weights, strata, and primary sampling units from each survey. The absolute change rate with 95% CI in the prevalence of secondhand smoke exposure was calculated as the prevalence in 2013-2014 subtracted from the prevalence in 2019. The chi-square trend test was used to compare differences in prevalence by school grade, sex, residence, region, GDP per capita category, and cigarette smoking status between 2013-2014 and 2019. Multivariable logistic regression models were used to assess the association between secondhand smoke exposure and its potential influencing factors (school grade, sex, residence, region, GDP per capita category, and cigarette smoking status). All analyses were conducted using SAS (SAS Institute). Two-sided P values <.05 were considered statistically significant.

Results

Participant Characteristics

Table 1 presents the demographic data from the 2 national surveys conducted in 2013-2014 and 2019. In 2019, the proportions of adolescents who were in a higher school grade (ninth grade), resided in a rural region, and were current cigarette users were somewhat lower than in 2013-2014. Data from 155,117 adolescents (boys: n=82,057, 52.9%) in the 2013-2014 survey and 147,270 adolescents (boys: n=78,789, 53.5%) in the 2019 survey were included in this study.

Trends in Prevalence of Secondhand Smoke Exposure

The overall prevalence of secondhand smoke exposure in any place (on ≥1 day during the past 7 days) decreased from 2013-2014 (72.9%, 95% CI 71.5%-74.3%) to 2019 (63.2%, 95% CI 62%-64.5%), while the prevalence of secondhand smoke exposure at home decreased from 44.4% (95% CI 43.1%-45.7%) in 2013-2014 to 34.1% (95% CI 33.1%-35.2%) in 2019, as did secondhand smoke exposure in public places (2013-2014: 68.3%, 95% CI 66.9%-69.6%; 2019: 57.3%, 95% CI 56%-58.6%), as shown in Tables 2, 3, and 4. The prevalence was high in any place, in public places, and at home across all 31 provinces, with the prevalence of secondhand smoke exposure in public places higher compared to exposure at home in each province in both 2013-2014 and 2019 (Figure 1 and Multimedia Appendix 1, Tables S1-S4). The prevalence exceeded 60% in 2019 in 25 of 31 provinces. The 5 provinces where the prevalence was much higher than other provinces were Yunnan (75.1%, 95% CI 66.2%-84%), Hunan (73.6%, 95% CI 68.9%-78.3%), Beijing (73.2%, 95% CI 69.5%-76.9%), Shanghai (72.5%, 95% CI 62.5%-82.5%), and Gansu (70.2%, 95% CI 62.5%-78%). The prevalence of secondhand smoke exposure also decreased according to different exposure frequencies and locations. For example, there was a downward trend in daily exposure in any place (from 31%, 95% CI 29.9%-32.1% in 2013-2014 to 24.7%, 95% CI 23.8%-25.7% in 2019), at home (from 14.2%, 95% CI 13.6%-14.8% in 2013-2014 to 12.4%, 95% CI 11.8%-13% in 2019), and in public places (from 25.1%, 95% CI 24.2%-26% in 2013-2014 to 18.7%, 95% CI 17.8%-19.5% in 2019), as shown in Tables 2, 3, and 4 and Multimedia Appendix 1, Table S5.

The prevalence of secondhand smoke exposure increased as school grade increased regardless of exposure frequency (≥1 day, ≥3 days, ≥5 days, or 7 days during the past 7 days), location (any place, home, or public place), and survey year (2013-2014 or 2019). The prevalence of secondhand smoke exposure decreased as GDP per capita category increased irrespective of exposure frequency, location, or survey year (Tables 2, 3, and 4 and Multimedia Appendix 1, Table S5). The prevalence of exposure was higher among boys (vs girls), current cigarette smokers (vs nonsmokers), and adolescents who lived in an urban region (vs rural region, except for secondhand smoke exposure at home). A higher prevalence of secondhand smoke exposure was observed in the northwest, south, and southwest regions, with lower exposure in the east and northeast regions (Tables 2, 3, and 4). A downward trend in the prevalence of secondhand smoke exposure in any type of public place (closed public places, open public places, and public transportation) and in schools on ≥1 day during the past 7 days was also observed (Multimedia Appendix 1, Tables S6-S7 and Figure S1).

Table 2. Trends in the prevalence of secondhand smoke exposure in any place (on ≥1 day during the past 7 days) by age, sex, residence, region, gross domestic product per capita category, and status of cigarette smoking among Chinese adolescents from 2013-2014 to 2019.

	Prevalence in 2013-2014, %	95% CI	Prevalence in 2019, %	95% CI	Absolute change in prevalence, %	95% CI

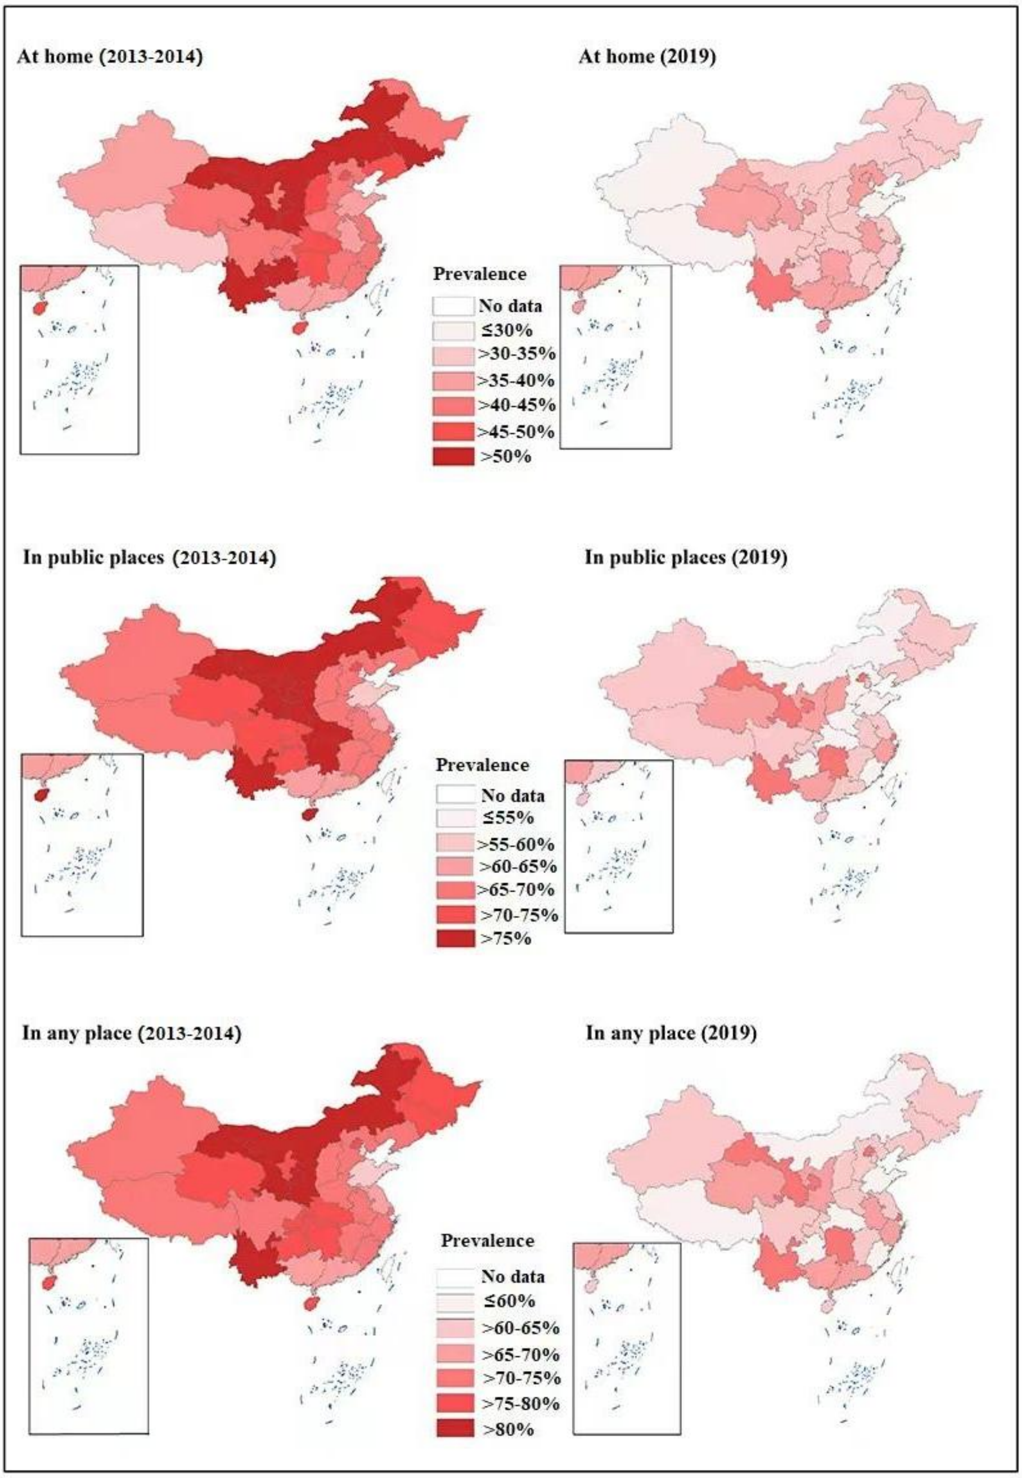
Figure 1. Trends in the geographical distribution of secondhand smoke exposure (on ≥1 day during the past 7 days) at home, in public places, and in any place among Chinese adolescents from 2013-2014 to 2019.



Association Between Secondhand Smoke Exposure and Potential Factors

In the multivariable logistic regression analysis, adolescents were more likely to be exposed to secondhand smoke in the combined data set (2013-2014 and 2019) if they were in a higher school grade (ninth vs seventh grade: odds ratio [OR] 1.76, 95% CI 1.68-1.84), were boys (boys vs girls: OR 1.18, 95% CI 1.15-1.22), lived in an urban setting (urban vs rural: OR 1.10, 95% CI 1.01-1.19), and were a current cigarette smoker (smoker vs nonsmoker: OR 6.67, 95% CI 5.83-7.62). These results were largely independent of survey year (2013-2014 or 2019; Table 5).

Table 5. Multivariable odds ratios and 95% CIs for factors associated with secondhand smoke exposure (on ≥1 day during the past 7 days) among Chinese adolescents. All variables listed in the table were introduced into logistic regression models.

Trends in Attitude Toward Secondhand Smoke Exposure

We observed no change in the proportion of adolescents who thought secondhand smoke exposure was harmful to them between the surveys (2013-2014: 73.9%, 95% CI 73.3%-74.5%; 2019: 73.7%, 95% CI 72.7%-74.8%). This observation was consistent across subgroups by grade, residence, region, and GDP per capita category. However, we noted fewer girls and cigarette smokers and more boys, proportionally, considered smoking to be harmful in 2019 compared to 2013-2014 (Multimedia Appendix 1, Table S8).

Discussion

Principal Findings

A decrease in the prevalence of secondhand smoke exposure occurred from 2013-2014 to 2019 among middle school–aged students in China. This decline was observed irrespective of sex, residence, region, provincial economic level, and location of exposure (in any place, at home, and in public places). However, the prevalence remained high in 2019 (63.2% in any place, 34.1% at home, and 57.3% in public places), highlighting the need for more effective strategies to control tobacco use and further curtail secondhand smoke exposure in China.

To the best of our knowledge, this is the first study to assess in detail the latest information on the prevalence of secondhand smoke exposure and trends in this exposure among adolescents in China using nationally representative data. Overall, in 2019 the prevalence (on ≥1 day during the past 7 days) was 34.1% (95% CI 33.1%-35.2%) at home, which is higher than in the United States (25.3%, 95% CI 23.4%-27.3%), while the prevalence of exposure was similar on public transportation between the 2 countries (China: 23.4%, 95% CI 22.3%-24.4%; United States: 23.3%, 95% CI 21.4%-25.4%) [17]. The prevalence of exposure to secondhand smoke was 57.3% (95% CI 56%-58.6%) in public places and 63.2% (95% CI 62%-64.5%) in any place in 2019, which was higher than in many other countries [9,18,19]. In addition, nearly a quarter (24.7%, 95% CI 23.8%-25.7%) of adolescents were exposed to secondhand smoke in any place daily, one-tenth (12.4%, 95% CI 11.8%-13%) at home and one-fifth (18.7%, 95% CI 17.8%-19.5%) in public places. Data from the 2010-2018 GYTS among 711,366 adolescents aged 12 to 16 years in 142 countries showed that the global prevalence of secondhand smoke exposure (on ≥1 day) was 33.1% (95% CI 32.1%-34.1%) at home, 57.6% (95% CI 56.4%-58.8%) in public places, and 62.9% (95% CI 61.7%-64.1%) in any place; the daily exposure prevalence was 12.3% (95% CI 11.7%-13%) at home, 23.5% (95% CI 22.5%-24.5%) in public places, and 32.5% (95% CI 31.5%-33.6%) in any place [9]. While these data highlight the fact that secondhand smoke exposure remains a serious public health issue worldwide, our data, using the same instruments of exposure measurement, show that exposure in China is comparatively much higher.

One advantage of our data over previous studies is that our exposure assessment was able to further categorize the types of public places where exposure occurred. It is obvious that the health risk should be higher for exposure in enclosed public places than open public places. Our findings showed that the prevalence in enclosed public places (45.8%) was similar to that in open public places (48.6%) in 2019, although the prevalence was lower on public transportation (23.4%). Another important finding is that in 2019 nearly 50% of adolescents were exposed to secondhand smoke in schools, suggesting that many school staff are cigarette smokers who not only set a bad example for students, but also expose students to their secondhand smoke. These data reinforce the fact that secondhand smoke exposure among adolescents remains a serious public health issue, especially in public places, and identifies key exposure sites outside of the home that could be targeted for intervention.

We observed that the prevalence of secondhand smoke exposure increased as school grade increased, which can be explained as older adolescents from higher grades being more accepting of tobacco use among their peers and being more likely to smoke themselves; both factors increase the probability of secondhand smoke exposure [14,20]. We also found that the prevalence of exposure decreased when moving from low to high provincial GDP per capita categories, as others have shown [21,22]. This might be partly explained by lower awareness of the harm of secondhand smoke exposure among adolescents in lower GDP per capita regions than higher GDP per capita regions. Moreover, many economically developed municipalities, such as Beijing and Shanghai, have implemented stricter smoke-free policies than other municipalities or provinces. Notably, however, there was little difference observed in the prevalence of secondhand smoke exposure among adolescents across the 7 geographical regions. These findings further emphasize the fact that secondhand smoke exposure among adolescents remains a serious concern across mainland China. We found that almost all adolescent cigarette smokers (89.9%) were exposed to secondhand smoke (≥1 day during the past 7 days), although exposure was also high in adolescents who did not smoke cigarettes (55.9%). These data are consistent with those from other studies showing a positive relationship between secondhand smoke exposure and cigarette smoking [20,23]. This finding further suggests that preventing smoking among adolescents would help lower the prevalence of secondhand smoke exposure among this population.

Of note, the prevalence of secondhand smoke exposure among adolescents decreased by approximately 10% from 2013-2014 to 2019 regardless of location (in any place, at home, and in public places). In 2005, China ratified the WHO Framework Convention on Tobacco Control (FCTC), which came into force on January 9, 2006 [24]. Since then, a series of tobacco control measures have been drafted in China. In 2007, the Inter-Ministry Coordination and Steering Committee for Implementation of WHO FCTC was established under the State Council [25]. In 2009, the Ministry of Finance and State Taxation Administration decided to adjust the taxation of tobacco products. In 2000 (when the exchange rate was US $1=RMB 8.28), the tax rate was 45% for tobacco products priced RMB ≥50/carton and 30% for products priced RMB <50/carton; in 2009 (when the exchange rate was US $1=RMB 6.81), the rates were 56% for products priced RMB ≥70/carton and 36% for products priced RMB <70/carton) [26]. To protect youth from secondhand smoke exposure, the General Office of the Ministry of Education further strengthened tobacco control in schools (ie, strengthening tobacco control propaganda and education, ensuring that teachers set a good example for students, and establishing a perfect system for tobacco control) in 2010 [27]. Based on the actions above, China has made some progress in tobacco control. It was reported that the prevalence of secondhand smoke exposure among mainly adult people aged ≥15 years declined from 55.2% (95% CI 50.4%-59.9%) in 2010 to 45.3% (95% CI 41.4%-49.2%) in 2015 [7]. Despite these efforts, tobacco control is only slowly improving in China. We found that the prevalence of secondhand smoke exposure at home and in public places is still unacceptably high. To investigate whether a hygiene intervention for Chinese smokers in households with young children would lead to a reduction of secondhand smoke exposure among children, 180 families were randomly divided into an intervention group (n=98 families) and a control group (n=82 families). The results suggested that a smoking hygiene intervention might be an effective measure in reducing the prevalence of secondhand smoke exposure among children [28]. Smoke-free car laws have also been tested as rational and effective measures in reducing secondhand smoke exposure among youth [29,30]. Furthermore, we found that nearly three-fourths of adolescents are aware of the harms to them of secondhand smoke. Feng et al [31] reported that 68.5% of adult nonsmokers and 60.6% of adult smokers believed that secondhand smoke exposure could cause lung cancer. This provides a solid foundation for national smoke-free legislation. These findings call for stronger action to promote the process of achieving a smoke-free world.

Limitations

Although our study has several strengths (2 surveys were conducted in a nationally representative sample of Chinese adolescents and followed strict quality assurance and control procedures to ensure the validity and reliability of the data; to our knowledge, this study reports the most recent prevalence and trend estimates of secondhand smoke exposure among adolescents in mainland China), several limitations should be noted. First, the prevalence of secondhand smoke exposure was estimated by self-report, which is subject to recall bias. However, the questions used to collect the exposure data have been tested with good reliability and adequate validity [32,33]. Further studies using objective biomarkers of secondhand smoke exposure (eg, plasma, saliva, or urinary cotinine or other nicotine biomarkers) could improve the reliability of our results. Second, each of the 2 surveys was a school-based survey, and our estimates of prevalence are conservative given that risk behaviors among those who leave school may be higher than among those who remain in school [34]. Third, only middle school students were included in our analyses; thus, our findings could not be directly generalized to youth in other age groups. Fourth, our study did not provide enough information on secondhand smoke exposure (eg, exposure to different types of tobacco and exposure duration per day). Fifth, data from Taiwan, Hong Kong, and Macao were missing, thus limiting the generalizability of our findings to adolescents throughout China. Sixth, a causal association should not necessarily be inferred, because this study had a cross-sectional design. Seventh, many other factors influencing secondhand smoke exposure, such as social, economic, and individual factors, were not considered in this study.

Conclusions

Although the prevalence of secondhand smoke exposure among Chinese adolescents has declined from 2013-2014 to 2019, exposure remains unacceptably high. These findings suggest more effective strategies and stronger action, especially in public places, but also at home, are needed in China to further curtail secondhand smoke exposure among adolescents.

Abstract

Background: In the past few decades, liver disease has gradually become one of the major causes of death and illness worldwide. Hepatitis is one of the most common liver diseases in China. There have been intermittent and epidemic outbreaks of hepatitis worldwide, with a tendency toward cyclical recurrences. This periodicity poses challenges to epidemic prevention and control.

Objective: In this study, we aimed to investigate the relationship between the periodic characteristics of the hepatitis epidemic and local meteorological elements in Guangdong, China, which is a representative province with the largest population and gross domestic product in China.

Methods: Time series data sets from January 2013 to December 2020 for 4 notifiable infectious diseases caused by hepatitis viruses (ie, hepatitis A, B, C, and E viruses) and monthly data of meteorological elements (ie, temperature, precipitation, and humidity) were used in this study. Power spectrum analysis was conducted on time series data, and correlation and regression analyses were performed to assess the relationship between the epidemics and meteorological elements.

Results: The 4 hepatitis epidemics showed clear periodic phenomena in the 8-year data set in connection with meteorological elements. Based on the correlation analysis, temperature demonstrated the strongest correlation with hepatitis A, B, and C epidemics, while humidity was most significantly associated with the hepatitis E epidemic. Regression analysis revealed a positive and significant coefficient between temperature and hepatitis A, B, and C epidemics in Guangdong, while humidity had a strong and significant association with the hepatitis E epidemic, and its relationship with temperature was relatively weak.

Conclusions: These findings provide a better understanding of the mechanisms underlying different hepatitis epidemics and their connection to meteorological factors. This understanding can help guide local governments in predicting and preparing for future epidemics based on weather patterns and potentially aid in the development of effective prevention measures and policies.

Introduction

Hepatitis, which describes an inflammation of the liver, is one of the most common diseases in the world. Hepatitis can be caused by a variety of factors. However, viruses are the most prevalent cause. Hepatitis A [1-4], B [5-9], C [10-14], and E [1,15-18] are the 4 most common types of hepatitis in China, and they are caused by the hepatitis A [19,20], B [21], C [22,23], and E viruses (HAV, HBV, HCV, and HEV), respectively. The hepatitis viruses can survive for a long time in a variety of harsh environments and have a strong resistance to external factors [24]. Hepatitis A and E are transmitted through the digestive tract via fecal-oral transmission and contaminated food or water [25,26]. Hepatitis B and C are spread through the blood or bodily fluids of an infected person, mother-to-child transmission, and sexual transmission [8,27-29]. In 2020, the number of confirmed cases of hepatitis A, B, C, and E in Guangdong Province was 1594, 18,4524, 28,068, and 2070, respectively. This represents an increase of 1.10 times, 1.15 times, 1.23 times, and a decrease of 0.75 times, respectively, compared to statistics from 2013. Hepatitis A, B, and C showed an upward trend, whereas hepatitis E showed a downward trend.

Viruses can be transmitted in 2 ways: horizontal and vertical transmission. Horizontal transmission involves the transmission of a virus from one person to another within the same generation, while vertical transmission refers to the transmission of viruses from mother to child. Hepatitis infections often show an age-dependent property, with more severe symptoms observed in adults [19]. People exposed to HBV through horizontal transmission often develop self-limited acute infections, while people who contract the virus from their mothers through vertical transmission tend to become chronic HBV carriers [21]. This difference in infection severity may be due to the difference in immune response between adults and young children [21]. The infection of hepatitis also showed genotype-dependent properties. For example, in HEV, there are 4 genotypes (HEV 1-4) [30]. The prevalence of HEV1 and HEV2 in developing regions have led to large-scale outbreaks. If infection occurs during pregnancy, it leads to severe hepatitis. In contrast, HEV3 and HEV4 are mainly observed in developed regions and are common in both humans and animals, with pigs as the main host [15].

Recrudescence at a fixed frequency is a common feature of infectious diseases throughout the world [31-34]. Previous research has shown that hepatitis epidemics in China exhibit oscillatory properties at a national level [35,36]. Natural forces (eg, temperature [37] and natural disasters [38]) might drive this oscillatory infection. Several examples have shown that epidemics, such as measles [39], pertussis [40-44], influenza [45], and rabies [46-48], can have oscillations. However, whether the oscillatory phenomena of hepatitis epidemics were influenced by environmental factors remains unclear.

In light of the above, in this study, we aimed to explore the oscillatory properties of the hepatitis epidemic in Guangdong (20°13'-25°31' N and 109°39'-117°19' E) as well as the potential natural contributors to the oscillatory outbreaks. We obtained data for the period from January 2013 to December 2020 on 4 notifiable infectious diseases caused by hepatitis viruses (including HAV, HBV, HCV, and HEV) in Guangdong and the meteorological elements (eg, temperature, precipitation, and humidity) in the same time frame. Power spectrum analysis was conducted on these data to capture the oscillatory strength of the outbreaks. We then explored the relationship between meteorological elements and oscillatory properties based on the regression and correlation analyses.

Methods

Data and Sources

Time series data on available monthly reported and confirmed cases of 4 hepatitis diseases (A, B, C, and E) were obtained for Guangdong province in China's mainland, from January 2013 to December 2020, from the Health Commission of Guangdong. The data set is available to the public around the world and is reported monthly. Monthly reported data of meteorological elements (eg, temperature, precipitation, and humidity) of Guangdong province from January 2013 to December 2020 were obtained from the China Statistical Yearbook 2014-2021. The meteorological factors included in this study are continuous values and vary with time, which would directly reflect the actual natural conditions each month. This data set is also available to the public around the world and is reported annually.

Ethical Considerations

For this study, the data we used are open to the public. Our study did not involve any interventions in human participants. This study was approved by the ethics committee of Beijing Sport University, China (2022142H).

Power Spectrum Analysis

We used spectrum analysis to quantify fluctuations and the recurrence of epidemics. Similar methods have been used in classic and modern studies in the field of public health [35,36,49], medicine [50-53], and biological research [54,55]. The power spectral density for each infectious disease was computed via the multitaper method using the Chronux toolbox [56], an open-source data analysis toolbox [57]. The definition of the peak in the power spectrum is the ratio of the power in a specific frequency (eg, once or twice a year) and the power in the surrounding frequencies (0.75-1.25 and 1.75-2.25). In this study, a ratio larger than 3 was considered an obvious oscillatory peak.

Tuning Curves for Monthly Infected Cases

The tuning curve of monthly infected cases depicts the basic character of disease outbreaks, providing a direct view of the situation each month based on the historical data. We took the monthly average number of infected cases of each hepatitis epidemic and computed them into a tuning curve (equation 1). Each type of hepatitis epidemic in this study has a tuning curve, and the periodic pattern within a year would be obvious based on it.

In this equation, N represents the number of the year.

Tuning Curves for Meteorological Factors

The tuning curve of meteorological factors (eg, temperature, precipitation, and humidity) depicts the basic character of natural conditions, providing a direct view of the situation each month based on historical data. We computed the monthly average of meteorological factors into a tuning curve (equation 2). Each meteorological factor in this study has a tuning curve, and the periodic pattern within a year is obvious based on it.

In this equation, N represents the number of the year.

Regression Analysis

The regression model was shown as equation 3.

In this equation, β represents the regression coefficients of the model, and *y(t)* represents the number of cases with hepatitis infection. The regression analysis was conducted using the regress function in MATLAB (2020a) [58].

Correlation Analysis

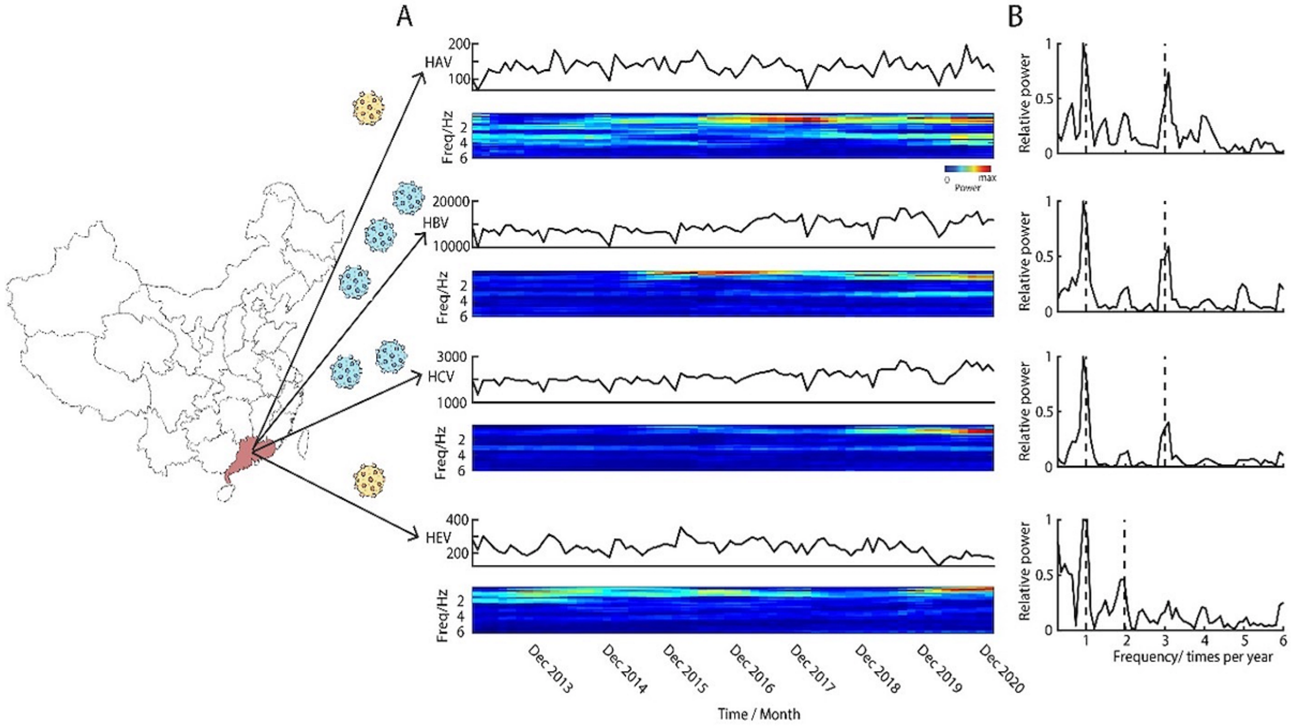
We used the Pearson correlation to measure the relationship between infected cases and meteorological elements. The correlation analysis was conducted using the corr function in MATLAB (2020a).

Results

Periodic Phenomena of Hepatitis Epidemics in Guangdong, China

This study analyzed the monthly data of confirmed cases of 4 hepatitis diseases in Guangdong from January 2013 to December 2020 (Figure 1). Time series data of the 4 hepatitis epidemics (A, B, C, and E) in Guangdong is shown in Figure 1A. It is clear that all hepatitis epidemics in Guangdong have obvious oscillatory patterns based on their power spectrum (Figure 1B), which shows different peaks (eg, peaking once, twice, or 3 times a year). However, for the oscillatory patterns, the hepatitis E epidemic (the fourth row in Figure 1B) differs from the other 3 hepatitis epidemics (first 3 rows in Figure 1B). Hepatitis A, B, and C epidemics show 2 main peaks (occurring once and 3 times per year) in the power spectrums, whereas the hepatitis E epidemic, in addition to the cycle of outbreaks once a year, will have another cycle of outbreaks twice a year.

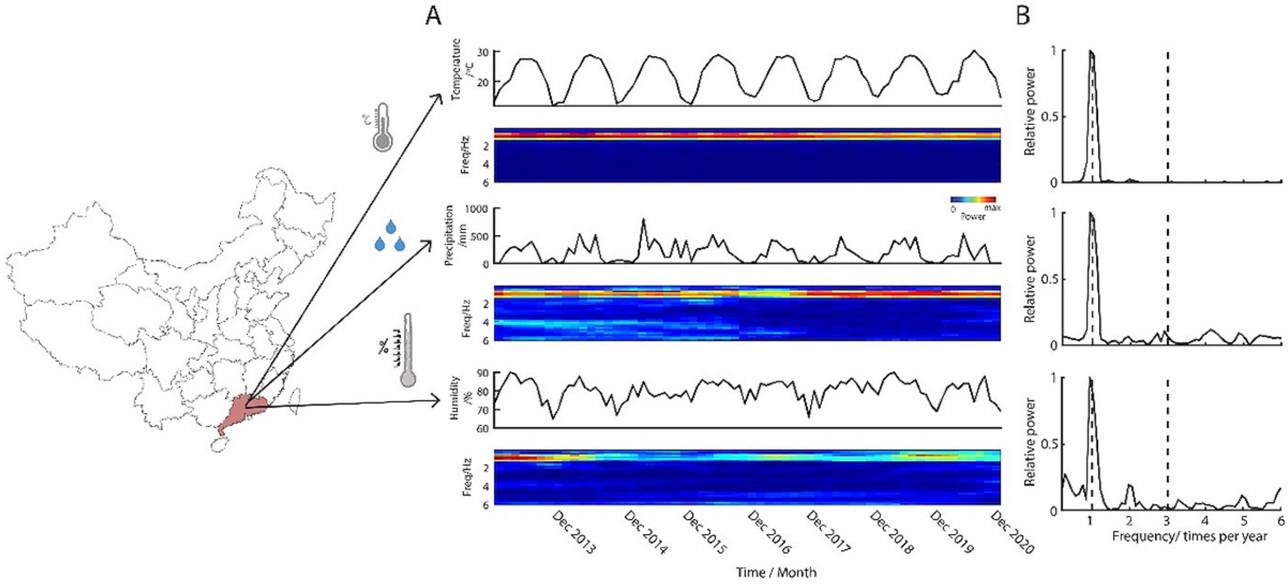
Figure 1. Periodic phenomena of hepatitis epidemics with power spectrum. Left map shows the geological location of Guangdong. (A) shows the monthly incidences of hepatitis A, B, C, and E viruses (HAV, HBV, HCV, and HEV) and its spectrogram from January 2013 to December 2020 in Guangdong. (B) The power spectrum of time series data shown in panel A. The y-axis is the relative power, which is defined as power(f)/max(power(f)).



Periodic Phenomena of Meteorological Elements in Guangdong, China

Meteorological elements might be a potential contributor to the periodic phenomenon of the epidemic; therefore, we also conducted the power spectrum analysis of the time series data of temperature, precipitation, and humidity in Guangdong province (Figure 2A and Figure 2B). All 3 meteorological elements in Guangdong exhibit evident oscillatory patterns throughout time, indicating that the epidemics and meteorological elements may be correlated.

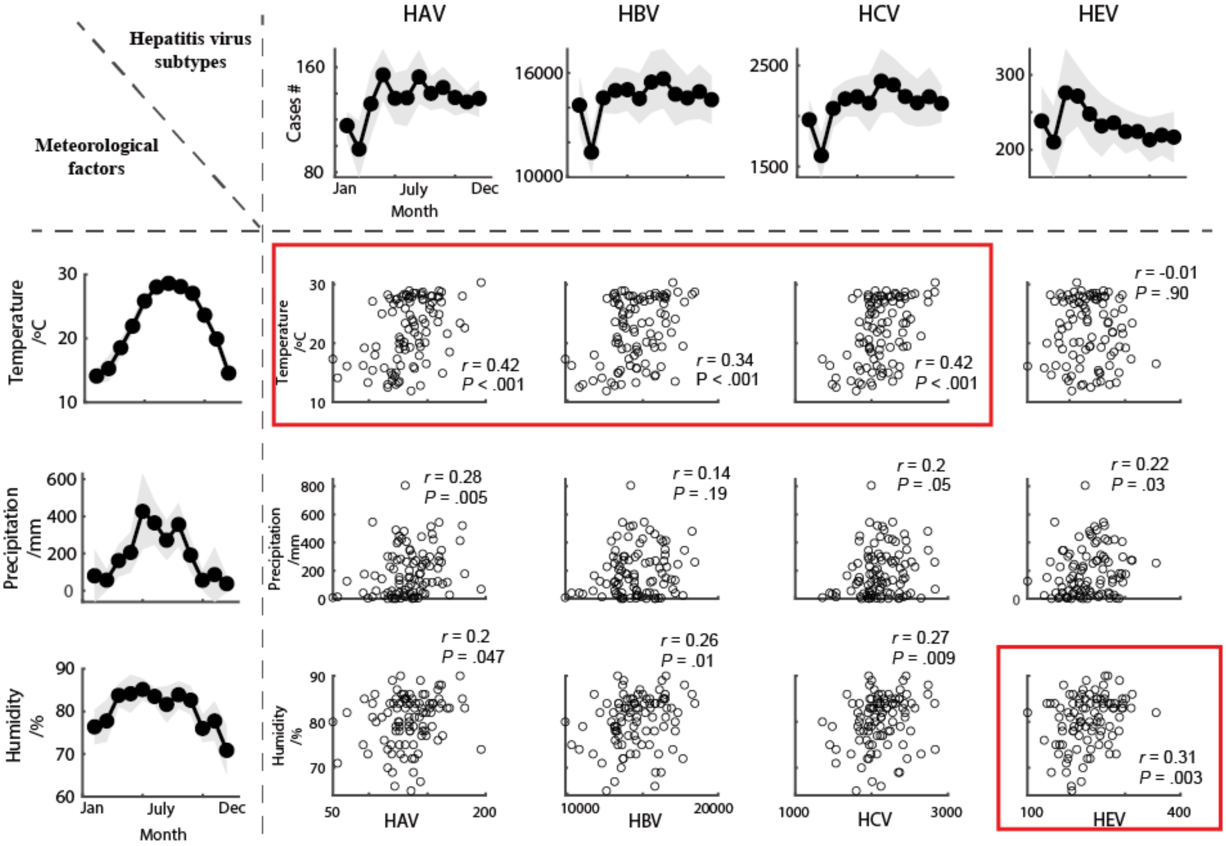
Figure 2. Meteorological elements of hepatitis epidemics with power spectrum. Left map shows the geological location of Guangdong. (A) The monthly time series meteorological elements (temperature, precipitation, and humidity) and its spectrogram from January 2013 to December 2020 in Guangdong. (B) The power spectrum of time series data shown in panel A. The y-axis is the relative power, which is defined as power(f)/max(power(f)).



Relationship Between the Periodic Characteristics of Hepatitis Infection and Meteorological Elements in Guangdong, China

From the observation of the average infected cases of the hepatitis epidemic (first row in Figure 3) and the average meteorological elements (first column in Figure 3), hepatitis infections may be influenced by several natural factors. We then investigated the relationship between hepatitis epidemics and meteorological elements in Guangdong in detail based on multiple analysis approaches.

Figure 3. Relationship between infected cases of hepatitis epidemic and meteorological elements. Top row: the tunning curves for the number of infected cases of 4 hepatitis epidemics over a year, with the grey area denoting the standard error of mean. Left column: the tunning curves for an index of natural factors for each month of each year. Rows 2-4 show scatter plots between the number of cases of each hepatitis type and temperature, precipitation, and humidity, respectively. Each column represents a different type of hepatitis. The red square in each plot indicates conditions that showed significant results in both correlation and regression analyses. HAV: hepatitis A virus; HBV: hepatitis B virus; HCV: hepatitis C virus; HEV: hepatitis E virus.



From the correlation analysis, we discovered a substantial positive association between temperature and the incidence of HAV (*P*<.001), HBV (*P*<.001), and HCV (*P*<.001), showing that the warmer the temperature, the more infected patients there are. Precipitation was positively correlated with HAV (*P*=.005) and HEV (*P*=.03), indicating that the more rainfall there is, the higher the incidence of HAV and HEV. Humidity was positively correlated with HAV (*P*=.047), HBV (*P*=.01), HCV (*P*=.009), and HEV (*P*=.003), showing that the more humid the environment is, the greater the prevalence of hepatitis A, B, C, and E (Figure 3). No additional significant findings were identified. The correlation analysis revealed that temperature had the most significant correlation with HAV, HBV, and HCV, while humidity had the most significant correlation with HEV (depicted by the red square in Figure 3). Since humidity is often affected by precipitation, to further validate their relationship and exclude the influence of other factors (eg, precipitation), we built 2 regression models to investigate how meteorological factors predict the number of hepatitis infections, with and without precipitation as a variable.

From the regression analysis between the number of hepatitis infections and meteorological factors (Table 1), we first checked collinearity by variance inflation factor.

All the variance inflation factors are in the range from 1.5 to 2 (ie, 1.64, 1.93, and 1.78). The correlation coefficients among the 3 meteorological factors (ie, temperature, precipitation, and humidity) were lower than 0.8 (temperature and precipitation: 0.59; temperature and humidity: 0.54; and precipitation and humidity: 0.63, respectively), which would not be affected by collinearity. In the first regression model, using 3 meteorological factors to predict the number of hepatitis infections, the coefficients of temperature in the prediction of hepatitis A, B, and C were significantly positive (hepatitis A: *F*=6.995; *P*<.001, hepatitis B: *F*=5.428; *P*=.001, and hepatitis C: *F*=8.66; *P*<.001) but not significant for the coefficients of precipitation and humidity, suggesting that temperature can positively predict the incidence of hepatitis A, B, and C and is the main contributor to these 3 epidemics. In terms of the hepatitis E epidemic (*F*=4.74; *P*=.004), we found a significant positive coefficient for humidity (*P*=.004) and a weak but significant negative coefficient for temperature (*P*=.03), indicating that a more humid and less warm environment can predict higher incidences of hepatitis E. The second regression model that excluded precipitation as a predictor showed a result that was consistent with the model with 3 predictors, except that the significance level was more robust for humidity to predict HEV infections (Table 2).

In sum, we found that warmer temperatures can predict a higher prevalence of hepatitis A, B, and C in Guangdong. Meanwhile, higher humidity and lower temperature can both predict a higher prevalence of hepatitis E.

Discussion

Principal Findings

In this study, we found that hepatitis epidemics (A, B, C, and E) have different oscillatory properties, and hepatitis A, B, and C in Guangdong have a stronger association with temperature, while hepatitis E showed a stronger association with humidity. Different types of hepatitis will have different periodic characteristics and different associations with different natural environments, which is crucial for epidemic prevention and management. Understanding the temporal characteristics of infectious diseases is essential for effective epidemic prevention, as it may inform the development and implementation of appropriate policies and strategies.

Comparison With Prior Work

To our knowledge, this is the first study to investigate the periodic characteristics of the hepatitis epidemics and their relationship with natural factors, which fills a gap in this field. Previous works have mainly focused on descriptive statistics, detailing the number of infections without describing the precise time characteristics [1,3,18], such as oscillations. Some studies showed that hepatitis epidemics have strong oscillations at a national level [36], but they have not been refined to a more detailed geographical scale (eg, at province levels).

Another issue is the influence of meteorological factors on hepatitis epidemics. HAV and HEV are 2 distinct viruses. Although HAV and HEV share similarities in their fecal-oral transmission route [25,26], our results demonstrate that hepatitis A and E epidemics have different relationships with meteorological factors (hepatitis A epidemic being associated with temperature and hepatitis E epidemic being associated with humidity). This result indicates that even though the 2 viruses share similar transmission modes, the relationship with natural indicators is not necessarily the same, which further indicates that they have unique transmission mechanisms that are not shared, such as host ranges and genotypes.

First, the host range of HAV is limited to humans and several nonhuman primates [59]. There is a tendency for people to engage in more social activities during warmer weather, which increases the likelihood of HAV transmission. In contrast, HEV infects a variety of animal species, including deer, rabbits, and mollusks, but it primarily infects pigs [15,30,60]. Higher humidity is harmful to the health of pigs [61], which will increase contact between pigs and people employed in occupations related to pigs, leading to an increase in HEV infections among the animals and humans who come into contact with an infected animal. Additionally, runoff from outdoor pig farms can contaminate surface water as well as crops that receive this surface water [60]. Higher humidity can increase the risk of HEV contamination of surface water from outdoor pig farms and other sources, and heavy rainfall can lead to the spread of contaminated water to crops and other areas, potentially increasing the incidence of HEV infections. For these reasons, it might be of general value to further investigate water contamination during periods of high rainfall to better understand this phenomenon. Nonetheless, it remains important to implement measures to prevent contamination of water sources and monitor water quality, especially in areas with high levels of outdoor pig farming or other potential sources of contamination.

Second, there are 4 main genotypes of HEV. Genotypes 1 and 2 cause outbreaks or epidemics in humans [62], while genotypes 3 and 4 primarily infect various mammalian species, such as pigs and sheep, but can also infect humans and lead to sporadic cases of hepatitis E. Climate change can affect the environment [63], potentially impacting the quality of water and food sources. For example, the outbreak of HEV genotype 4 infection is more likely to be caused by contaminated tap water rather than contaminated food and contaminated water network on days with heavy rainfall [64]. However, this is not the case for HAV.

Further research is needed to confirm these hypotheses using detailed biological experiments. Previous studies on how temperature affects viral transmission have been equivocal. For example, norovirus prevalence was associated with low water temperatures [65,66], but enterovirus 71 [67] infections began to rise at temperatures above 13°C and declined at temperatures higher than approximately 26°C, exhibiting a V-shaped relationship with the temperature. This phenomenon indicates that transmission patterns are likely influenced by a combination of biological, environmental, and behavioral factors.

Limitations

One limitation of our study is the limited data. Despite being a representative province, our study only includes a single province in China. In the future, we will further obtain more data and apply similar methods to assess infectious diseases in more regions with varying climates. Even though we have made explorations, several factors remain unclear and cannot be addressed at present. For example, hepatitis A and E have similar propagation principles, but their oscillatory strength is very different in Guangdong Province. In the future, higher-dimensional data will be required to provide more clarity. Another potential limitation is that we did not explore the interaction of the variables and the potential nonlinear relationships in the regression model, which should be considered in other studies in the future, where necessary.

Conclusions

Our study makes a link between climate change and the recurrence of infectious disease epidemics, enabling us to predict the magnitude of the epidemics based on various weather conditions. It is essential for local meteorological and medical departments to collaborate closely to prepare for the prevention and control of various epidemics. Additionally, the general public should be informed about the impact of different weather conditions on the spread of disease so that they can take appropriate measures to reduce the spread of viruses.

Abstract

Background: Associations between short-term exposure to ambient particulate matter (PM) air pollutants and mortality or hospital admissions have been well-documented in previous studies. Less is known about the associations of hourly exposure to PM air pollutants with ambulance emergency calls (AECs) for all causes and specific causes by conducting a case-crossover study. In addition, different patterns of AECs may be attributed to different seasons and daytime or nighttime periods.

Objective: In this study, we quantified the risk of all-cause and cause-specific AECs associated with hourly PM air pollutants between January 1, 2013, and December 31, 2019, in Shenzhen, China. We also examined whether the observed associations of PM air pollutants with AECs for all causes differed across strata defined by sex, age, season, and the time of day.

Methods: We used ambulance emergency dispatch data and environmental data between January 1, 2013, and December 31, 2019, from the Shenzhen Ambulance Emergency Centre and the National Environmental Monitor Station to conduct a time-stratified case-crossover study to estimate the associations of air pollutants (ie, PM with an aerodynamic diameter less than 2.5 µm [$PM_{2.5}$] or 10 µm [PM_{10}]) with all-cause and cause-specific AECs. We generated a well-established, distributed lag nonlinear model for nonlinear concentration response and nonlinear lag-response functions. We used conditional logistic regression to estimate odds ratios with 95% CIs, adjusted for public holidays, season, the time of day, the day of the week, hourly temperature, and hourly humidity, to examine the association of all-cause and cause-specific AECs with hourly air pollutant concentrations.

Results: A total of 3,022,164 patients were identified during the study period in Shenzhen. Each IQR increase in $PM_{2.5}$ (24.0 µg/m^3) and PM_{10} (34.0 µg/m^3) concentrations over 24 hours was associated with an increased risk of AECs ($PM_{2.5}$: all-cause, 1.8%, 95% CI 0.8%-2.4%; PM_{10}: all-cause, 2.0%, 95% CI 1.1%-2.9%). We observed a stronger association of all-cause AECs with $PM_{2.5}$ and PM_{10} in the daytime than in the nighttime ($PM_{2.5}$: daytime, 1.7%, 95% CI 0.5%-3.0%; nighttime, 1.4%, 95% CI 0.3%-2.6%; PM_{10}: daytime, 2.1%, 95% CI 0.9%-3.4%; nighttime, 1.7%, 95% CI 0.6%-2.8%) and in the older group than in the younger group ($PM_{2.5}$: 18-64 years, 1.4%, 95% CI 0.6%-2.1%; ≥65 years, 1.6%, 95% CI 0.6%-2.6%; PM_{10}: 18-64 years, 1.8%, 95% CI 0.9%-2.6%; ≥65 years, 2.0%, 95% CI 1.1%-3.0%).

Conclusions: The risk of all-cause AECs increased consistently with increasing concentrations of PM air pollutants, showing a nearly linear relationship with no apparent thresholds. PM air pollution increase was associated with a higher risk of all-cause AECs and cardiovascular diseases–, respiratory diseases–, and reproductive illnesses–related AECs. The results of this study may be valuable to air pollution attributable to the distribution of emergency resources and consistent air pollution control.

particulate matter air pollution; ambulance emergency calls; AECs; environmental epidemiology; public health; air pollution; environmental data; patient data

Introduction

It is well-known that exposure to ambient particulate matter (PM) causes huge public health burdens due to substantial excess morbidity and mortality [1]. Over the past decade, a growing number of epidemiological studies have examined associations between short-term exposure to air pollutants and the incidence of cardiovascular disease (ie, acute coronary syndrome and myocardial infarction) [2-9]. China's government has established several policies to control air pollution with great effort, and the severity of air pollution has been eliminated to some extent. However, with continued urbanization and climate change, air pollution still requires focused efforts [10,11]. Therefore, the burden of disease associated with air pollutants is substantial and should be the focus of further research.

Although previous studies have documented the effects of short-term daily air pollution exposure on cardiovascular diseases, less is known about the effects of hourly air pollution exposure using a case-crossover study design. Moreover, most comprehensive studies on air pollutants' health effects have focused on cardiovascular or respiratory diseases–related mortality or hospital admissions, with limited evidence on assessing all-cause health impacts on ambulance emergency calls (AECs). Di et al [12] conducted a study that included 22,433,862 case-days and 76,143,209 control-days and found that each short-term increase of 10 $\mu g/m^3$ was statistically significantly associated with a relative increase of 1.05% (95% CI 0.95%-1.15%) in the daily mortality rate from 2000 to 2012. Ito et al [13] conducted a time-series study that observed a positive association between PM with an aerodynamic diameter less than 2.5 µm [$PM_{2.5}$], daily deaths, and emergency hospitalizations for cardiovascular diseases in New York City. AECs may serve as a more sensitive indicator of the health effects of air pollutants and a more appropriate signal for syndromic surveillance [14,15]. In addition, different patterns of AECs may be attributed to different seasons and daytime or nighttime periods. Identifying these potential patterns can be useful in helping people avoid exposure, but more evidence is needed. Although a few previous studies investigated hourly PM air pollutants' association with disease onset, limitations such as a small sample size with a short period, the lack of all-cause disease as a variable, and only focusing on $PM_{2.5}$ should not be ignored. For example, one Canadian study that only included 500,302 individuals found that exposure to elevated hourly $PM_{2.5}$ during wildfire seasons was associated with increased odds of dispatches related to respiratory and cardiovascular conditions over 5 years [16]. Therefore, it is imperative to conduct a time-stratified case-crossover study that includes a relatively large sample size with a long study period to investigate the associations of PM air pollutants with all-cause and cause-specific AECs. In this study, we quantified the risk of all-cause and cause-specific AECs associated with hourly air pollutants (ie, $PM_{2.5}$ and PM with an aerodynamic diameter less than 10 µm [PM_{10}]) between January 1, 2013, and December 31, 2019, in Shenzhen, China. We also examined whether the observed associations of PM air pollutants with AECs for all causes differed across strata defined by sex, age, season, and the time of day.

Methods

Study Population

Shenzhen is a major city located in the Pearl River Delta region of China, adjacent to Hong Kong. As one of the country's 4 province-level municipalities, Shenzhen has a population of 17.68 million and a gross domestic product per capita of CNY ¥173,700 (US $24,446) as of 2021. The Shenzhen Center for Prehospital Care developed the 120 Emergency Medical Services system in 1994, which includes 73 emergency networks and 103 emergency stations. In 2022, the center received 2,278,232 all-cause emergency calls, an increase of 41.96% from the previous year, and had 295,295 emergency dispatches, an increase of 14.23% from the previous year. Shenzhen has a subtropical monsoon climate that is typical of southern areas of China. We recruited individuals aged >18 years who called the emergency ambulance to reach the hospital, and those with time records linked to transfer were eligible to be included during the period from 2013 to 2019. We used ambulance emergency dispatch data and environmental data between January 1, 2013, and December 31, 2019, from the Shenzhen Ambulance Emergency Centre and the National Environmental Monitor Station, which included patients' self-reported medical claims, the time of AECs, prehospital diagnosis, demographic characteristics, and hourly air pollutant concentrations. Each call in the emergency data set was linked to a patient care report that was completed by the attending paramedics.

Study Design

We used a time-stratified case-crossover study design to estimate the associations of PM pollutants (ie, $PM_{2.5}$ and PM_{10}) with all-cause and cause-specific AECs. Each patient was exposed to PM pollutants before the hour in which the AEC occurred, compared to control periods of the same individual when the AEC did not occur [17,18]. This study design allows for the elimination of potential confounding from all known and unknown time-invariant factors (ie, age, sex, ethnicity, behavioral factors, and socioeconomic status) and covariant factors that vary slowly, such as seasonality [19]. We determined that each case index hour was the hour in which the AEC occurred (ie, case period), and we used 3 or 4 control index hours to match this hour by the same hour of the day, day of the week, month, and year with the case index hour to control for long-term time trends [12]. For example, if the first AEC occurred at 6 AM on Monday, May 20, 2013, we would define 6 AM on Monday, May 20, 2013, as the case index hour and 6 AM on all other Mondays in May 2013 (May 6, 13, and 27) as the control index hours.

Environmental Data Ascertainment

We obtained hourly concentrations of air pollutants (ie, $PM_{2.5}$ and PM_{10}) from the National Environmental Monitor Station during the study period. The station provides real-time data on criteria air pollutants across all nationally controlled monitoring stations operated by the China National Environmental Monitoring Centre with strict standard data quality control procedures. To facilitate communication, we first defined each IQR increase as the difference between the 25th and 75th percentile of air pollutant concentrations [20]. We also defined the extreme concentration (ie, $PM_{2.5}$ and PM_{10}) as the maximum concentration equal to the 97.5th percentile of concentrations over the study period. We calculated a population-weighted average of each IQR concentration increase and the maximum hourly concentration for each hour [21].

AECs Ascertainment

We combined patients' self-reported medical claims and prehospital diagnosis as the final diagnosis. Our primary outcome was all-cause AECs, which we further classified into 3 cause-specific categories: AECs related to cardiovascular diseases, respiratory diseases, and reproductive illnesses. For instance, we classified hypertension, acute ischemic stroke, myocardial infarction, ischemic heart disease, acute coronary syndrome, and unstable angina as cardiovascular diseases–related AECs, whereas calls due to lung diseases, bronchitis, respiratory difficulties, and asthma were categorized as respiratory diseases–related AECs. Similarly, calls related to pregnancy, abortion, or other reproductive disorders were classified as reproductive illnesses–related AECs. Additionally, we created a separate category for AECs due to injury, poisoning, mental health disorders, endocrine disorders, and digestive disorders. We were careful to exclude any vague claims such as dizziness, abdominal pain, discomfort, unconsciousness, headache, and allergy while generating disease stratification. We excluded patients who had both missing self-reported claims and missing prehospital diagnoses. We extracted the relevant demographic information (ie, age, sex, and year) and admission date for each diagnosis. We calculated cause-specific AECs by 24 hours and all-cause AECs by age to reflect the hourly distribution of AECs.

Statistical Analysis

We generated a well-established, distributed lag nonlinear model for nonlinear concentration-response and nonlinear lag-response functions [16]. We modeled the concentration-response function using a natural cubic B-spline with 1 or 2 knots to account for potential nonlinear relationships. We also modeled the lag-response function using a linear function with 1 or 2 knots placed on the log scale of lags up to 48 hours. We used conditional logistic regression to estimate odds ratios (ORs) with 95% CIs, examining the association of all-cause and cause-specific AECs with hourly air pollution concentration. The following covariates were adjusted in our main models: natural spline functions with 3 degrees of freedom for temperature and humidity, public holidays, and the day of the week. We converted ORs with 95% CIs to percentage changes in the risk of all-cause and cause-specific AECs associated with each IQR increase in air pollutant concentrations [20,22,23]. The following equations were used:

$$\text{Percentage change IQR} = (e^{\beta \times \text{IQR}} - 1) \times 100\% \quad \textbf{(1)}$$

$$\text{Lower 95\% CI} = (e^{[\beta - 1.96 \times \text{SE}] \times \text{IQR}} - 1) \times 100\% \quad \textbf{(2)}$$

$$\text{Upper 95\% CI} = (e^{[\beta + 1.96 \times \text{SE}] \times \text{IQR}} - 1) \times 100\% \quad \textbf{(3)}$$

where β is the regression coefficient.

We conducted several stratified analyses by age (18-64 vs ≥65 years), sex (male vs female), season (warm vs cool), and the time of day (daytime vs nighttime) to examine potential effect modifications. The warm season ranged from March to October and the cool season ranged from November to February in Shenzhen. Nighttime is defined as being from 8:00 PM to 7:00 AM in the next day, and daytime is defined as being from 8:00 AM to 7:00 PM within one day [20]. Missing rates of PM air pollutants were less than 0.51%, and we filled in missing data by using the next or previous entry.

We conducted a number of sensitivity analyses to assess the robustness of our results. First, we examined the correlations between several air pollutants to estimate the multicollinearity. Second, we repeated the main analyses based on exposure to the extreme concentration, rather than using only each IQR increase, to observe the robustness of the exposure metric. Third, we used variable key modeling parameters, including modelling the concentration-response functions using a natural B-spline with 3 internal knots for all-cause AECs and 2 or 3 knots for cause-specific AECs and the lag-response function using a natural cubic B-spline with 4 knots for all-cause AECs and 2 or 3 knots for cause-specific AECs placed on the log scale of lags up to 48 hours.

All analyses were performed in R (version 4.2.1; R Foundation for Statistical Computing). The *survival* package was used for conditional logistic regression, and the *dlnm* package was used for the distributed lag nonlinear model.

Ethics Approval

Ethics approval and consent to participate in this project was approved by the Peking University Health Science Center Institutional Review Board (PUIRB-YS2023123). Informed consent was obtained from all participants prior to questionnaire administration.

Results

A total of 3,022,164 patients were identified during the study period in Shenzhen: 64.3% (n=1,942,832) were male, 81.5% (n=2,462,968) were aged 20-64 years, 21.1% (n=636,288) made AECs due to cardiovascular diseases, and 51.4% (n=1,553,480) called the ambulance in the daytime (Table 1). The average hourly concentrations of $PM_{2.5}$ (32.2 $\mu g/m^3$) and PM_{10} (49.6 $\mu g/m^3$) before the index hour were well above the recently updated World Health Organization Global Air Quality Guidelines 2021 [24] (annual average: $PM_{2.5}$, 5.0 $\mu g/m^3$; PM_{10}, 10.0 $\mu g/m^3$; Table S1 in Multimedia Appendix 1). AECs due to cardiovascular diseases rode 2 crests at 9:00 AM and 8:00 PM over 24 hours, the fluctuations of AECs due to respiratory diseases were relatively gentle, and AECs due to reproductive illnesses peaked at 3:00 AM and 11:00 PM (Figure 1). We found significant differences in all-cause and cause-specific AECs between daytime and nighttime, stratified by age (Table 2). For example, the proportion of all-cause AECs was 34.5% (n=128,928) in the ≥65 years group and 49% (n=90,792; <20 years) and 54.1% (n=1,333,684; 20-64 years) in the younger groups at nighttime. We found that all-cause AECs reached their zeniths at 7:00 AM and 9:00 AM in the ≥65 years group, and the 20-64 years group reached their peaks at 6:00 AM and 10:00 PM over 24 hours (Figure S1 in Multimedia Appendix 1).

Table 1. Baseline characteristics of populations in Shenzhen from 2013 to 2019.

Baseline characteristics	Patient (N=3,022,164), n (%)
Age (years)	
<20	185,152 (6.1)
20-64	2,462,968 (81.5)
≥65	373,884 (12.4)
Sex	
Male	1,942,832 (64.3)
Female	1,079,256 (35.7)
Cases by year

[a] Daytime is from 8:00 AM to 7:00 PM within one day; nighttime is from 8:00 PM to 7:00 AM in the next day.

[b] Not applicable.

There were moderate to high correlations among air pollutants (Table S2 in Multimedia Appendix 1). $PM_{2.5}$ was positively correlated with PM_{10}, nitrogen dioxide, ozone, and sulfur dioxide (Spearman *r*=0.93, 0.61, 0.56, and 0.62, respectively), and PM_{10} was positively correlated with $PM_{2.5}$, nitrogen dioxide, ozone, and sulfur dioxide (Spearman *r*=0.93, 0.64, 0.52, and 0.66, respectively).

We found associations of exposure to $PM_{2.5}$ and PM_{10} with a higher incidence of all-cause AECs in the concurrent hour. After that, the associations gradually eliminated and became not statistically significant after approximately 15 to 48 hours (Table 3), so we decided to use the duration of 0 to 24 hours to derive the risk estimates (Figures 2 and 3). Each IQR increase in the concentrations of $PM_{2.5}$ (24.0 μg/m^3) and PM_{10} (34.0 μg/m^3) in 24 hours was associated with a higher risk of AECs ($PM_{2.5}$: all-cause, 1.8%, 95% CI 0.8%-2.4%; cardiovascular diseases, 1.9%, 95% CI 0.2%-3.1%; respiratory diseases, 2.5%, 95%CI –0.9% to 6.1%; reproductive illnesses, 1.9%, 95% CI 1.0%-4.8%; PM_{10}: all-cause, 2.0%, 95% CI 1.1%-2.9%; cardiovascular diseases, 2.0%, 95% CI 0.6%-3.4%; respiratory illnesses, 2.9%, 95% CI –0.6% to 6.6%; reproductive illnesses, 2.1%, 95% CI 0.8%-5.1%; Table 3 and Figures 2 and 3).

Figures 4 and 5 show the concentration-response curves of all-cause and cause-specific AECs for $PM_{2.5}$ and PM_{10}. The risk of all-cause AECs increased consistently with increasing concentrations of PM air pollutants, showing a nearly linear relationship with no apparent thresholds. In general, the risk of all-cause and cause-specific AECs increased dramatically with the accumulated concentration of $PM_{2.5}$ and PM_{10}. The magnitude of the associations varied slightly for the cardiovascular diseases–related AECs, whereas the association had a difference in respiratory diseases– and reproductive illness–related AECs.

In stratified analyses, we observed a stronger association of all-cause AECs with $PM_{2.5}$ and PM_{10} in the daytime than in the nighttime ($PM_{2.5}$: daytime, 1.7%, 95% CI 0.5%-3.0%; nighttime, 1.4%, 95% CI 0.3%-2.6%; PM_{10}: daytime, 2.1%, 95% CI 0.9%-3.4%; nighttime, 1.7%, 95% CI 0.6%-2.8%) and in the older group than the younger group ($PM_{2.5}$: 18-64 years, 1.4%, 95% CI 0.6%-2.1%; ≥65 years, 1.6%, 95% CI 0.6%-2.6%; PM_{10}: 18-64 years, 1.8%, 95% CI 0.9%-2.6%; ≥65 years, 2.0%, 95% CI 1.1%-3.0%; Table 4). For subtypes of AECs, we found stronger associations of respiratory diseases– and reproductive illnesses–related AECs with $PM_{2.5}$ and PM_{10} in the daytime than in the nighttime and weaker associations of cardiovascular diseases–related AECs with $PM_{2.5}$ and PM_{10} in the daytime than in the nighttime (Table 4). Cardiovascular diseases–related

AECs with $PM_{2.5}$ and PM_{10} had stronger association in the older group than in the younger group (Table 4).

A series of sensitivity analyses showed that the results were consistent with each IQR increase when the extreme concentration was considered as the exposure metric (Tables S3 and S4 and Figures S2-S7 in Multimedia Appendix 1). The results were consistent when we adopted an alternative number of knots or degrees of freedom for the distribution of air pollution concentration.

Table 3. Risk of ambulance emergency calls (AECs) associated with each IQR[a] increase in PM2.5[b] and PM10[c] concentration over different lags in Shenzhen from 2013 to 2019. The models were adjusted for public holidays, days of the week, hourly temperature, and hourly humidity.

AECs	0-12 hours, percentage change (95% CI)		0-24 hours, percentage change (95% CI)		0-36 hours, percentage change (95% CI)		0-48 hours, percentage change (95% CI)

[a] IQR: IQR of $PM_{2.5}$ was defined as the 25th to 75th percentile (24.0 μg/m^3); IQR of PM_{10} was defined as the 25th to 75th percentile (34.0 μg/m^3).

[b] $PM_{2.5}$: particulate matter less than 2.5 μm in diameter.

[c] PM_{10}: particulate matter less than 10 μm in diameter.

Figure 2. Lag structures for the associations of all-cause ambulance emergency calls with each IQR increase in $PM_{2.5}$ and PM_{10} concentration over lags of up to 24 hours in Shenzhen from 2013 to 2019. The overall lag structure curves are calculated using a linear with 2 knots placed on the log scale of lags to model the lag-response association. The solid black lines are the average percentage change in the risk of all-cause ambulance emergency calls with each IQR increase in $PM_{2.5}$ and PM_{10} concentration (24.0 μg/m^3 and 34.0 μg/m^3, respectively), and the dotted lines are the 95% CIs. $PM_{2.5}$ and PM_{10}: particulate matter less than 2.5 and 10 μm in diameter, respectively.

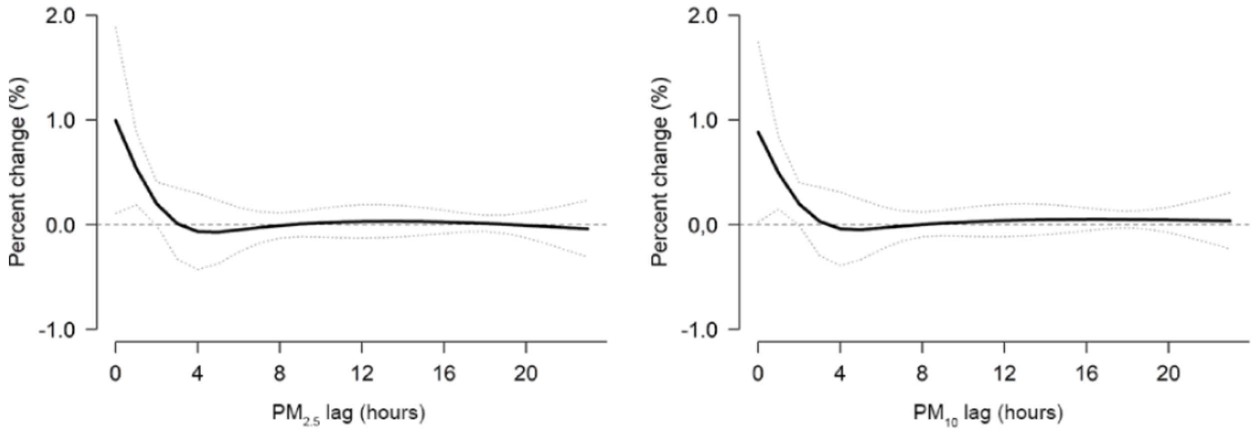

Figure 3. Lag structures for the associations of ambulance emergency calls due to cardiovascular, respiratory, and reproductive diseases with each IQR increase in $PM_{2.5}$ and PM_{10} concentration over lags of up to 24 hours in Shenzhen from 2013 to 2019. A and D represent cardiovascular diseases, B and E represent respiratory diseases, and C and F represent reproductive illnesses. The overall lag structure curves are calculated using a linear with 1 or 2 knots placed on the log scale of lags to model the lag-response association. The black solid lines are the average percentage change in the risk of ambulance emergency calls due to cardiovascular, respiratory, and reproductive diseases with each IQR increase in $PM_{2.5}$ and PM_{10} concentration (24.0 μg/m^3 and 34.0 μg/m^3, respectively), and the dotted lines are the 95% CIs. $PM_{2.5}$ and PM_{10}: particulate matter less than 2.5 and 10 μm in diameter, respectively.

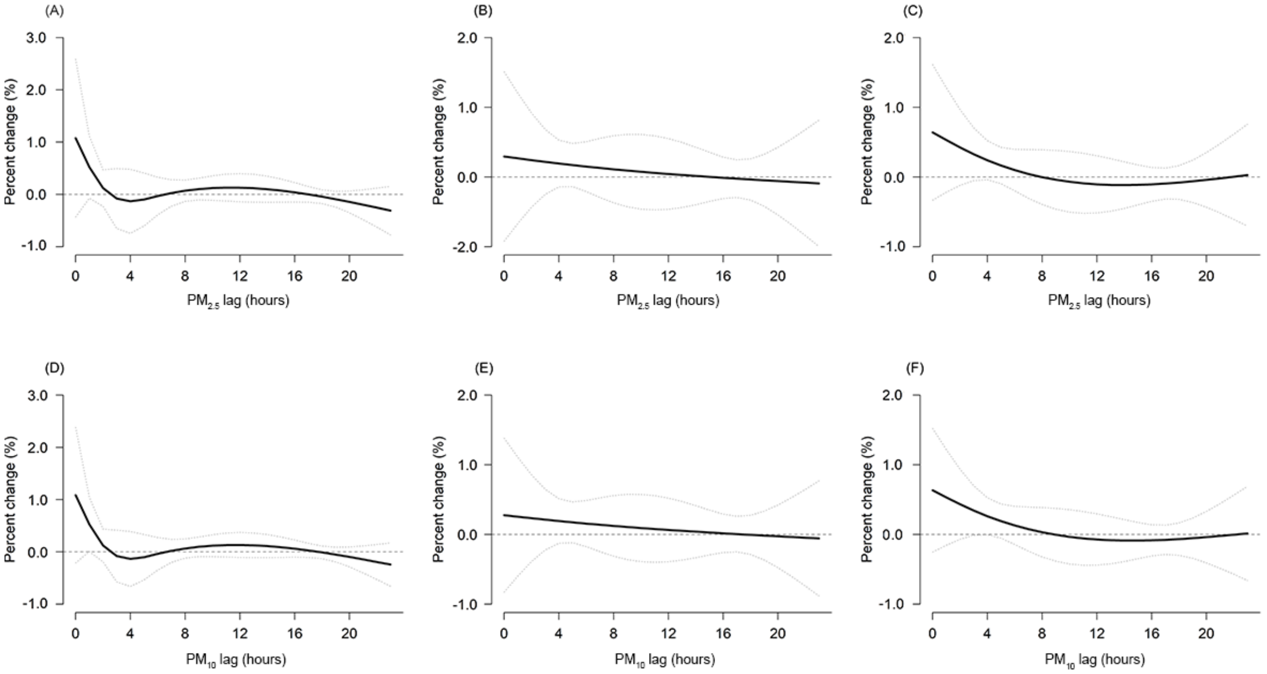

Figure 4. Cumulative concentration-response curves for the association of all-cause ambulance emergency calls with $PM_{2.5}$ and PM_{10} over lags of up to 24 hours in Shenzhen from 2013 to 2019. The cumulative exposure-response curves are calculated using a natural B-spline with 2 knots to model the exposure-response association. The black solid lines are the average percentage change in the risk of all-cause ambulance emergency calls, and the dotted lines are the 95% CIs. $PM_{2.5}$ and PM_{10}: particulate matter less than 2.5 and 10 μm in diameter, respectively.

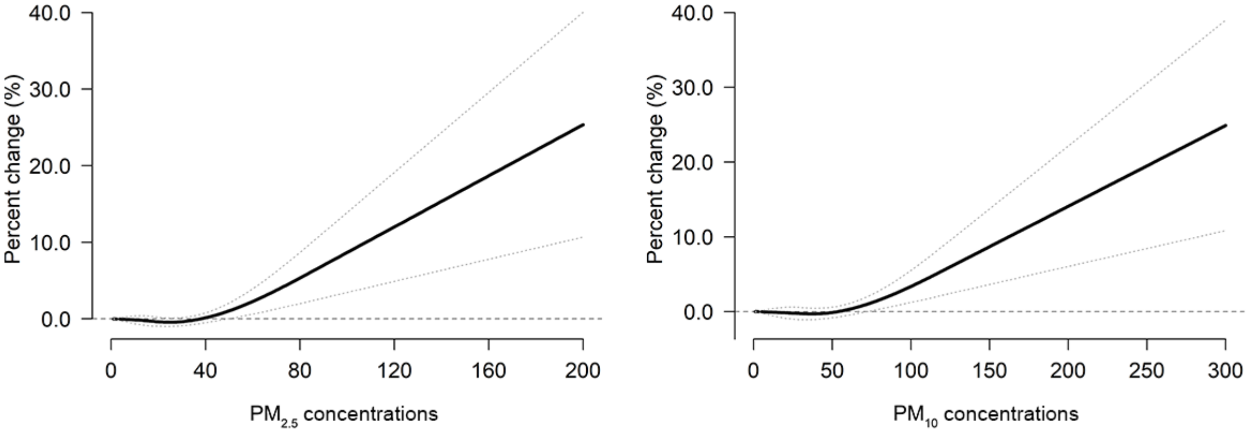

Figure 5. Cumulative concentration-response curves for the associations of ambulance emergency calls due to cardiovascular, respiratory, and reproductive diseases with $PM_{2.5}$ and PM_{10} over lags of up to 24 hours in Shenzhen from 2013 to 2019. A and D represent cardiovascular diseases, B and E represent respiratory diseases, and C and F represent reproductive illnesses. The cumulative exposure-response curves are calculated using a natural B-spline with 1 or 2 knots to model the exposure-response association. The black solid lines are the average percentage change in the risk of ambulance emergency calls due to cardiovascular, respiratory, and reproductive diseases with PM2.5 and PM_{10}, and the dotted lines are the 95% CIs. $PM_{2.5}$ and PM_{10}: particulate matter less than 2.5 and 10 µm in diameter, respectively.

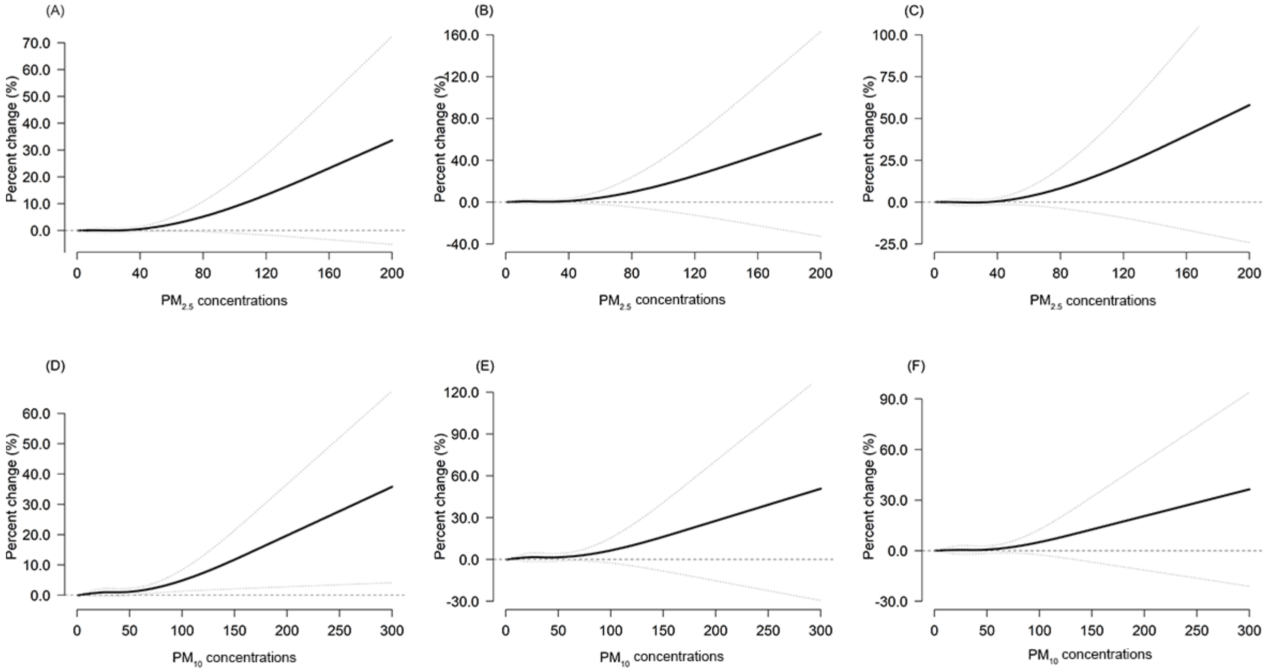

Table 4. Risk of ambulance emergency calls associated with each IQR[a] increase in PM2.5[b] and PM10[c] concentrations over lags of 0-24 hours, stratified by sex, age, season, and the time of day, in Shenzhen from 2013 to 2019. The models were adjusted public holidays, days of the week, hourly temperature, and hourly humidity.

[a] IQR: IQR of $PM_{2.5}$ was defined as the 25th to 75th percentile (24.0 μg/m^3); IQR of PM_{10} was defined as the 25th to 75th percentile (34.0 μg/m^3).

[b] $PM_{2.5}$: particulate matter less than 2.5 μm in diameter.

[c] PM_{10}: particulate matter less than 10 μm in diameter.

[d] Season: warm season is from 1st April 1 to October 31 of each year; cool season is from November 1 to 31 March 31 of each year.

[e] Time of the day: daytime is from 8:00 AM to 7:00 PM within one day; nighttime is from 8:00 PM to 7:00 AM in the next day.

Discussion

Principal Findings

We observed the associations of transient exposure to air pollutants with an increased risk of all-cause AECs, without any discernible threshold effects. The associations were stronger for $PM_{2.5}$ than for PM_{10}. In addition, the risks were apparent and statistically significant within 0-4 hours after exposure to the air pollutants. The excess relative risks showed substantial differences between the time-of-day strata.

Our findings were consistent with a robust body of previous studies demonstrating the positive associations of hourly air pollutants with all-cause and cause-specific AECs [15,16,23,25-30]. However, much of the existing evidence has focused on assessing the associations between cardiovascular diseases–related hospital admissions and exposures at the daily timescale through time-series analyses [31,32]. We have filled these knowledge gaps and generalized these results to the emergency medical service setting, as this study demonstrated that AECs may serve as a sensitive and timely marker of the adverse health effects of air pollution.

Given the use of different exposure metrics, time periods, study designs, and analytical strategies, our results cannot be compared directly across studies. For example, an analysis of Shenzhen AECs between January 18, 2013, and December 31, 2016, found that each 10 μg/m^3 increase in $PM_{2.5}$ and PM_{10} was associated with a 1.44% (95% CI, 0.70-2.19%) and 0.95% (95% CI, 0.39-1.51%) increase in hourly AECs over 5 hours, respectively [23]. In another study in Shenzhen [25], the authors observed positive associations of exposure to $PM_{2.5}$ with an increased risk of emergency department visits across different lag days using daily excessive concentration hours and the daily mean metric. In contrast, relatively weak effects were found for hourly peak $PM_{2.5}$. Rao et al [33] conducted a case-crossover study by using British Columbia Emergency Health Service data from 2010 to 2015 in Canada and showed a positive association between cardiovascular disease–related AECs and $PM_{2.5}$ exposure (OR 1.007, 95% CI 0.997-1.031), and there was a slight increase in the odds of respiratory disease–related AECs at 1.005 (95% CI 0.998, 1.013) over 48 hours. Another study conducted by Ai et al [15] between 2014 and 2016 found that each 10 μg/m^3 increase in $PM_{2.5}$ and $PM1_0$ was associated with a 0.19% (95% CI 0.03-0.35%) and 0.13% (95% CI, 0.02-0.24%) increase of all-cause AECs, respectively, whereas no significant effects of $PM_{2.5}$ and PM_{10} on cardiovascular morbidity were found.

We observed significant effects during the first 24 hours after exposure to the PM pollutants. Several human and animal studies have shown that acute exposure to PM may enhance thrombogenicity through various pathways, including platelet activation, oxidative stress, and the interplay between interleukin-6 and tissue factors [30,34,35]. A few studies have also identified the possible pathways, including endothelial dysfunction, inflammation, dyslipidemia, and autonomic and vascular dysfunction [33,36].

The stratified analyses showed stronger associations of air pollutants with cardiovascular diseases–related AECs in the nighttime than in the daytime, which is in line with existing evidence [22,37]. This may be due to low atmospheric pressure that always occurs during the night (from 1:00 AM to 5:00 AM). Moreover, we found several significant season differences in associations of PM air pollutants with respiratory diseases–related AECs, which could be explained by the virus or allergen being more active in the warm season. Our analysis observed stronger associations of all-cause AECs in the daytime, this could be explained by people often spending more time outdoors during the day and that the associations were estimated based on fixed-site monitors [20]. In addition, there were no associations of air pollutants with AECs stratified by sex in our study. These results were in line with previous literature [7,17], indicating that all patients, regardless of sex, seem to be at higher AEC risks after transient exposure to air pollution.

This study has several limitations. First, we used the individual weighted average of hourly air pollution concentrations as a proxy for personal exposure. Although there is some degree of exposure misclassification that may lead to the underestimation of associations, this limitation may not be avoidable in most time-series studies [22,38-40]. Second, we used prehospital diagnosis rather than medical diagnosis with specific International Classification of Disease codes because data on the final clinical diagnosis were not available. However, we defined our subtypes of AECs using the Medical Priority Dispatch System [16,41], which should not substantially bias our results. Third, we did not have detailed information on the locations of environmental monitoring stations and the proximity of roads, making it challenging to explore the possible effect modification of the associations. Fourth, we were unable to match the monitor station measurements to the closest patient because we were unable to acquire patients' location information. Therefore, we used the average city-level PM concentration as the exposure for patients in this study. Although the impact of this limitation is likely minimal, we plan to gather and analyze this association in future studies [20].

This study has some strengths. First, the Shenzhen Ambulance Emergency Centre provided high-quality data covering most hospitals in Shenzhen. The large sample size and individual-level data allowed us to conduct comprehensive statistical analyses to maximize the validity of the study results. Second, the time-stratified case-crossover study design facilitated causal inference of the study results by adjusting for time-invariant confounding [18,40]. Third, we collected hourly data on air pollutants when all-cause or cause-specific AECs occurred, which characterized the subdaily time effects of exposure to AECs.

Air pollution–related AECs are considered as a public health problem. This study provides the distributions of all-cause and cause-specific AECs over 24 hours and the associations of each IQR increase with AEC risks. The adverse health effects of air pollution are preventable through a combination of reducing exposure, reducing susceptibility, and improving adaptive capacity. In the context of public health preparedness for air pollution, local government response systems should typically provide air pollution–related information to the public, develop strategies to reduce air pollution–related risks, and allocate emergency ambulance resources equitably. It is also important for hospitals and emergency centers to adapt their procedures to meet the increased demands associated with air pollution. For example, local health systems need not only to allocate more resources (ie, health care providers and medical facilities) to general emergency care but also to increase the capacity of health care providers to provide specialized emergency care (ie, cardiovascular and respiratory diseases) at night because of the stronger associations of PM air pollutants found during nighttime hours.

Conclusion

PM air pollutants were associated with a higher relative risk of all-cause AECs and cardiovascular diseases–, respiratory diseases–, and reproductive illnesses–related AECs. The risk of all-cause AECs increased consistently with increasing concentrations of PM air pollutants, showing a nearly linear relationship with no apparent thresholds. The results of this study may be valuable to air pollution attributable to the distribution of emergency resources and consistent air pollution control.

Abstract

Background: Drowning is a serious public health problem worldwide. Previous epidemiological studies on the association between meteorological factors and drowning mainly focused on individual weather factors, and the combined effect of mixed exposure to multiple meteorological factors on drowning is unclear.

Objective: We aimed to investigate the combined effects of multiple meteorological factors on unintentional drowning mortality in China and to identify the important meteorological factors contributing to drowning mortality.

Methods: Unintentional drowning death data (based on International Classification of Diseases, 10th Edition, codes W65-74) from January 1, 2013, to December 31, 2018, were collected from the Disease Surveillance Points System for Guangdong, Hunan, Zhejiang, Yunnan, and Jilin Provinces, China. Daily meteorological data, including daily mean temperature, relative humidity, sunlight duration, and rainfall in the same period were obtained from the Chinese Academy of Meteorological Science Data Center. We constructed a time-stratified case-crossover design and applied a generalized additive model to examine the effect of individual weather factors on drowning mortality, and then used quantile g-computation to estimate the joint effect of the mixed exposure to meteorological factors.

Results: A total of 46,179 drowning deaths were reported in the 5 provinces in China from 2013 to 2018. In an effect analysis of individual exposure, we observed a positive effect for sunlight duration, a negative effect for relative humidity, and U-shaped associations for temperature and rainfall with drowning mortality. In a joint effect analysis of the above 4 meteorological factors, a 2.99% (95% CI 0.26%-5.80%) increase in drowning mortality was observed per quartile rise in exposure mixture. For the total population, sunlight duration was the most important weather factor for drowning mortality, with a 93.1% positive contribution to the overall effects, while rainfall was mainly a negative factor for drowning deaths (90.5%) and temperature and relative humidity contributed 6.9% and –9.5% to the overall effects, respectively.

Conclusions: This study found that mixed exposure to temperature, relative humidity, sunlight duration, and rainfall was positively associated with drowning mortality and that sunlight duration, rather than temperature, may be the most important meteorological factor for drowning mortality. These findings imply that it is necessary to incorporate sunshine hours and temperature into early warning systems for drowning prevention in the future.

Introduction

Drowning is the process of experiencing respiratory impairment from submersion or immersion in liquid [1]; it is a serious public health problem worldwide. The World Health Organization (WHO) reported that an estimated 236,000 people died from drowning in 2019. Globally, drowning is the third leading cause of death by unintentional injury, accounting for 7% of all injury-related deaths [2]. Despite the downward trend in drowning mortality rates [3], there are still considerable disparities across countries. Developed countries tend to have lower drowning mortality; for example, in the United States, the drowning mortality rate was 1.23 per 100,000 from 2010 to 2019 [4]. However, developing regions, like Southeast Asia, are the regions with the highest drowning mortality rates in the world. In the last decades, China has made great progress in drowning prevention and control, and the drowning mortality rate has decreased from 15.09 per 100,000 in 1990 to 3.97 per 100,000 in 2019 [5]; however, this is still a high drowning burden compared with most other countries.

Prior studies on drowning mainly focused on epidemiological characteristics or risk factor analysis [6-8], clinical first aid [9,10], and intervention policy assessment [11,12]. Few studies have investigated the association of meteorological factors with drowning. Among these few studies, several reports indicate that there is a clear seasonal distribution of drowning deaths, with the highest drowning mortality in the summer [13]. The summer heat itself may not increase the risk of drowning, but it may lead to changes in behavior that increase susceptibility to drowning, such as increased water-related activities, increased alcohol consumption, or decreased use of personal flotation devices [14]. In terms of humidity, several studies report that high relative humidity (RH) at high temperatures significantly increases body temperature and increases the chance that people engage in water-related activities such as swimming [15], which in turn leads to an increased risk of drowning. Flooding due to extremely heavy rainfall is also an important cause of drowning mortality. For example, in July 2021, a flood occurred in Henan Province, China, due to persistent extremely heavy rainfall, and this incident resulted in hundreds of drowning deaths [16]. Even though there is no research on the association between duration of sunlight (DS) and drowning, there is research illustrating the importance of daylight hours for those who plan to enjoy swimming in a lake or outdoor pool, thereby potentially increasing the chance of drowning [17]. These studies focused on the effects of single weather factors on drowning. However, in the real world, people are exposed to multiple weather factors simultaneously, not only one at a time. Regrettably, no prior studies have examined the combined effects of exposure to multiple meteorological factors on drowning.

Indeed, it is a challenge to quantify the combined effects of multiple meteorological exposure factors on drowning using traditional statistical models. In order to reduce collinearity in the model, previous multivariate regression models, such as linear regression, generalized linear regression, and generalized additive models (GAMs) have usually explored the association between a single or limited environmental factors and health outcomes. However, this approach could not accurately reveal the true impact of multiple environmental exposures [18]. In recent years, several advanced statistical methods, such as quantile g-computation, have been developed to examine the joint health effects of exposure mixture [19], which provides an opportunity for combined-effect analysis of exposure mixture in environmental epidemiology. Quantile g-computation not only allows for nonlinear correlation analysis, but also calculates the positive and negative weights contributed by each exposure.

This study aimed to investigate the combined effects of multiple meteorological factors, including mean temperature (MT), RH, DS, and rainfall, on drowning mortality based on a data set from 5 provinces in China using a quantile g-computation model [19] and to further quantify the relative importance of each meteorological factor. Our findings may provide scientific information for developing an early warning system for drowning based on multiple meteorological factors to prevent drowning in the context of global warming.

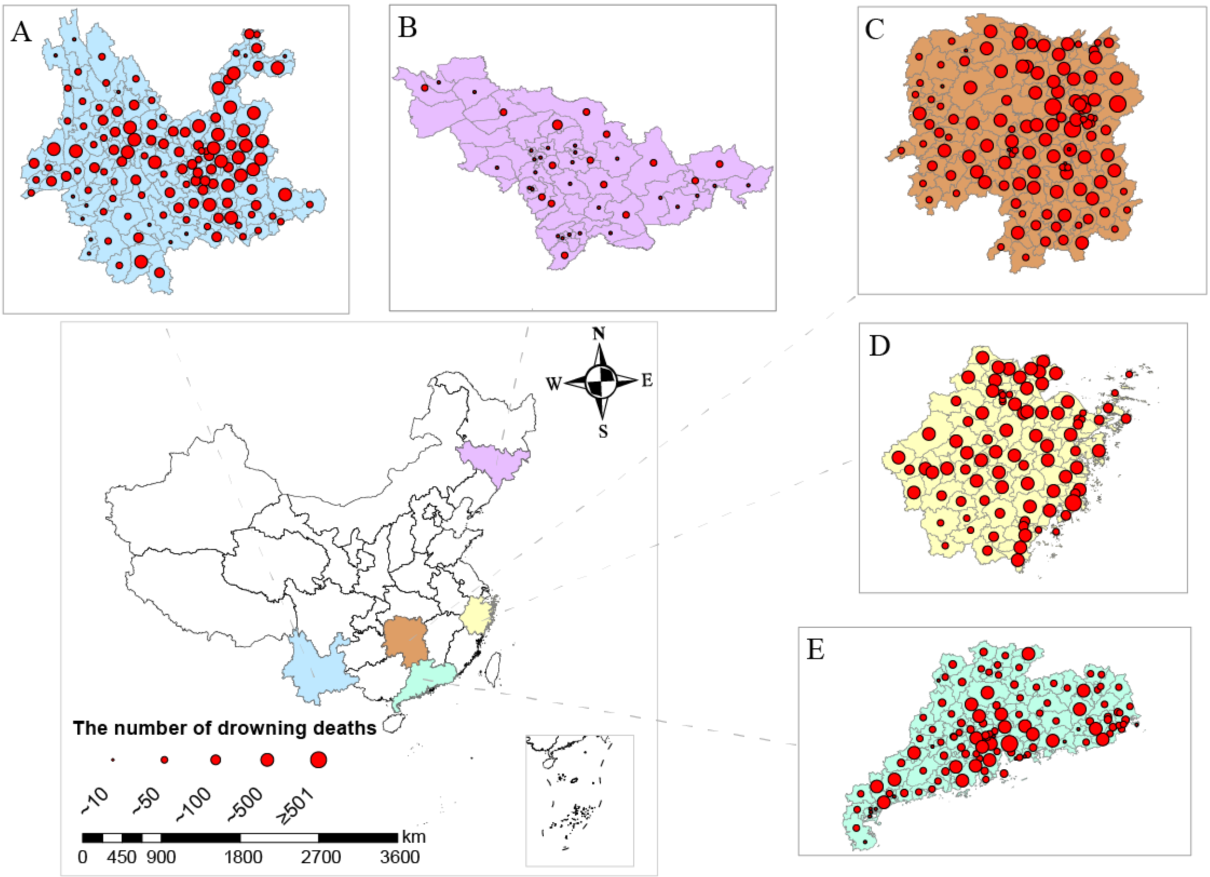
Methods

Data Collection

In this study, the study sites in China were Guangdong Province in south China, Hunan Province in the middle part of the Yangtze River, Zhejiang Province on the southeast coast of China, Yunnan Province in southwest China, and Jilin Province in northeast China. Guangdong and Hunan are both regions with rich sunlight, heat, and water resources. Zhejiang Province is rich in marine resources. Both Jilin and Yunnan provinces have many rivers and lakes.

Drowning mortality data from January 1, 2013, to December 31, 2018, in these 5 Chinese provinces were collected from the Provincial Disease Surveillance Points System. The information on each death included the date of death, cause of death, address, gender, age, education level, and cause of death code. In the International Classification of Diseases, 10th Edition (ICD-10), the codes W65 to 74 are unintentional drowning deaths, excluding drownings due to cataclysms or transportation accidents. The spatial distribution of drowning deaths in the 5 provinces is shown in Figure 1.

Figure 1. Spatial distribution of drowning deaths at the district and county level in 5 provinces. (A) Yunnan Province; (B) Jilin Province; (C) Hunan Province; (D) Zhejiang Province; (E) Guangdong Province.



Daily meteorological data, including daily MT, RH, DS, and rainfall from 2013 to 2018 were collected from the China Meteorological Science Data Center, which collects data from 698 meteorological surveillance points across the country [20]. In order to obtain accurate daily MT and RH at a county level, we used Australian National University Splines (ANUSPLIN) thin plate smoothing [21] to interpolate station meteorological data to form raster data for daily MT and RH with a resolution of 0.01° × 0.01°. In the spatial interpolation model, we introduced latitude, longitude, and altitude as independent variables. The interpolation was validated using the 10-fold crossover method with good prediction accuracy, as previously described [22]. Daily mean DS and rainfall amount were calculated by averaging the values of all stations in each city because these 2 weather factors returned inaccurate data from interpolation in our preliminary analysis.

Air pollution might be a confounding factor, so we also collected data on fine particulate matter (PM2.5) as a representative of air pollutants to control for possible confounding effects. Daily air pollution data (ie, PM2.5) were derived from the National Urban Air Quality Real-Time Release Platform [23]. Because the air pollution surveillance points did not completely cover our study provinces, the land use regression method, based on the random forest model, was used to predict ambient air pollutants; the model showed good prediction capability [24].

Ethics Approval

Ethical approval was obtained from the Medical Research Ethics Committee of Guangdong Provincial Center for Disease Control and Prevention (2019025), and all procedures followed the ethical standards specified by the institution.

Statistical Analysis

This study used a case-crossover design based on temporal stratification, which was further adapted from the case-crossover design of Levy et al [25]. The basic principle is to stratify time so that each case with an outcome is treated as a case group, while exposures in the same year, month, and day of the week are treated as controls, meaning that each case has 3 to 4 controls, thereby effectively controlling for confounding factors, including long-term trends, gender, and age, and effectively avoiding control selection bias in the original case-crossover design and enabling unbiased estimates to be obtained. This research design has been widely used to investigate the effects of short-term environmental exposure on population health, especially in the field of health-effect assessment of meteorological factors [26] and air pollution [27].

Descriptive analyses were represented by numbers, means, maximum values, minimum values, and medians (quartiles), respectively. Spearman correlation was used to examine the correlations between meteorological factors and PM2.5.

Few previous studies have reported the effects of wind speed and air pressure on drowning. Moreover, after preliminary analysis, we observed that wind speed and air pressure had little effect on drowning mortality (Multimedia Appendix 1). Therefore, these 2 weather factors were not included in the joint-effect analysis. In our study, we first conducted individual meteorological factor analysis using a GAM [28] after adjusting for confounding factors (ie, PM2.5) to assess the individual effect of each meteorological factor (MT, RH, DS, and rainfall) on drowning mortality. The GAM equation is as follows:

$$\mathrm{Logit(case)=s(Variable,df)+s(PM_{2.5},df)+}\alpha,$$

where *Logit()* is the connection function, *case* indicates the case type with 1 for cases and 0 for controls; *Variable* represents the meteorological factors to be analyzed, that is, MT, RH, DS and rainfall; *PM2.5* is the concentration of PM2.5; *s()* is the nonparametric smoothing function, which is used to fit the nonlinear relationship between meteorological factors (ie, PM2.5 and drowning, respectively), with 3 degrees of freedom selected by generalized cross-validation [29]; and α denotes the intercept term.

Second, in order to further estimate the joint effect of multiple meteorological factor exposure on drowning mortality, we used a quantile g-computation model [30]. Quantile g-computation is a new approach to estimate the joint effects of exposure mixture [19]. It has been used to evaluate the change in health outcome for each quantile of mixed exposure to multiple environmental factors [31-33], and it does not require the same effect directions between exposure variables and outcome [18]. In this study, the model was implemented through categorizing MT, RH, DS, and rainfall in quartiles, , coded as 0, 1, 2, and 3. The mixture is first fitted nonlinearly to drowning and then linearized according to the results. The quantile g-computation model equation is as follows (confounders *Z* could also be included):

where (the change in drowning for a 1-unit change in all exposures) and each meteorological factor is given a negative or positive weight. The quantile g-computation estimator of the exposure response, ψ, is the sum of the regression coefficients across the included exposures. If all β_j are in the same direction, then the weight for each component (indexed by *k*) is defined as , which is the proportion of the effect due to that component and sums to 1.0. If factors have different directions of effect, then the weights are interpreted as the proportion of the positive or negative partial effect, and the positive and negative weights together sum to 2.0 [32]. After obtaining regression coefficients for 71 cities, values from different cities were combined using meta-analysis to obtain the exposure-response relationship between exposure mixture and drowning risk. The results of the nonlinear fit were expressed as exposure response curves.

The linearized results were expressed in terms of excess risk (ER) with the 95% CI. The formula for ER is as follows:

$$\mathrm{ER} = [\exp(\beta) - 1] \times 100\%$$

where β is the effect of exposure mixture in meta-analysis.

Moreover, we used the quantile g-computation model to conduct subgroup analysis by sex (male, female), age group (<25 years, 25-64 years, ≥65 years) and season (the cold season, from October to March, and the warm season, from April to September). The following formula was used for the between-group variability test:

where b_1 and b_2 are the effect estimates of the 2 groups, respectively, and SE_1 and SE_2 are the SEs of the estimated effects of the 2 groups, respectively [34].

Sensitivity analysis was performed by changing the parameters of the model as well as by adjusting the confounding factors in order to verify the stability and reliability of the model. In the GAM, we conducted a sensitivity analysis by changing the degrees of freedom (*df*=2,4,5) for MT, RH, DS, and rainfall. In the quantile g-computation model, model 1 removed the confounding factor PM2.5 for sensitivity analysis. Model 2, model 3, and model 4 used 2-day, 3-day, and 4-day moving averages for MT, RH, and PM2.5 for sensitivity analysis.

All tests were conducted 2-sided, and effects with $P<.05$ were considered statistically significant. All analyses were conducted with R (version 4.1.0; R Foundation for Statistical Computing) and the *mgcv*, *qgcomp*, *mvmeta*, and *metafor* R packages.

Results

Descriptive Analysis

There were 46,179 drowning deaths in the 5 Chinese provinces from 2013 to 2018, with an average of 21 and a maximum of 68 drowning deaths per day. Each city had an average of 1 drowning death per day, with a maximum of 10 deaths (Table 1). A total of 17,408 people died from drowning during the summer seasons. The number of drowning deaths was the highest in Hunan Province and the lowest in Jilin Province. The number of drowning deaths was much higher for males (n=29,805, 64.5%) than females (n=16,374, 35.5%). The daily MT, RH, rainfall and PM2.5 during the study period were 20.4 °C, 76.7%, 4.5 mm, and 37.6 μg/m^3, respectively (Table 2).

Table 1. Descriptive statistics of meteorological factors and daily drowning deaths by season, province, sex, and age group from 2013 to 2018.

Characteristics	Drowning deaths overall (n=46,179), n (%)	Drowning deaths per day, n					
		Mean (total=21.1)	Minimum (total=3)	P_{25}[a] (total=14)	P_{50}[b] (total=19)	P_{75}[c] (total=26)	Maximum (total=68)

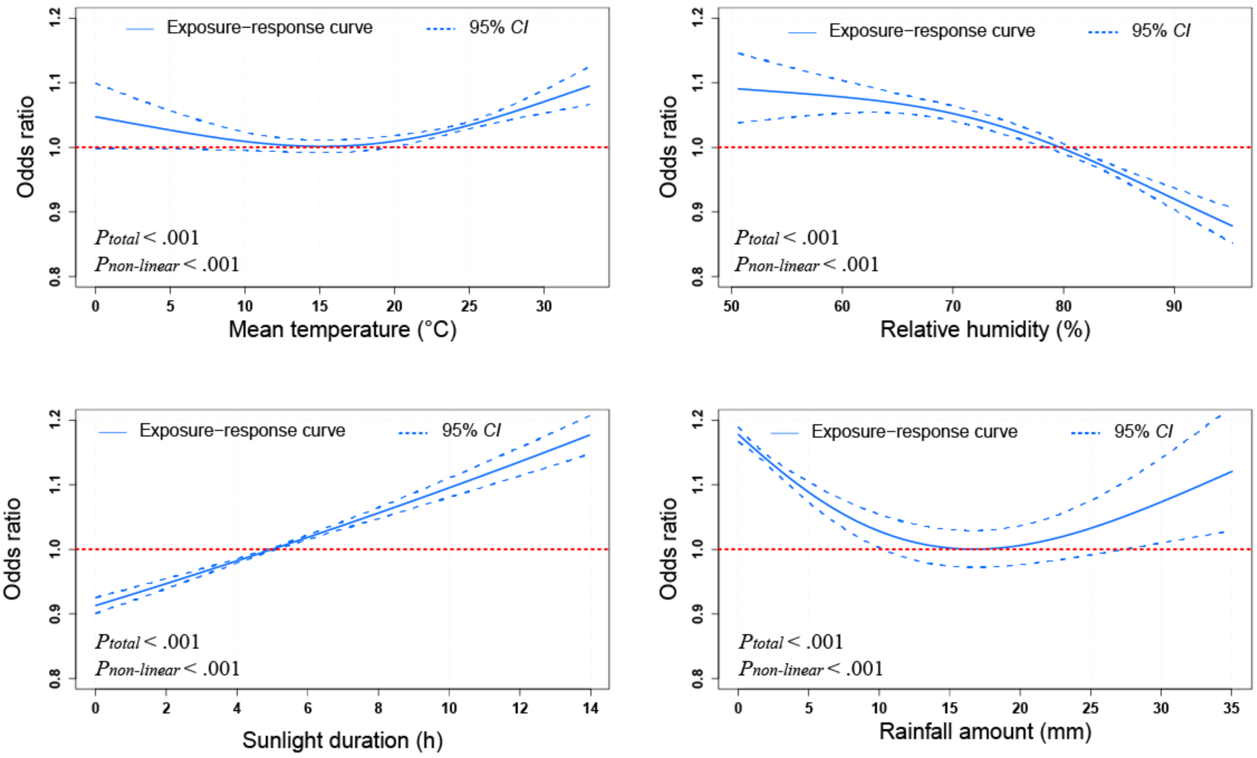
Individual Effect of Meteorological Factors on Drowning Mortality

Among the 4 meteorological factors, the strongest correlation was observed between RH and DS (r=–0.61; *P*<.05; Multimedia Appendix 2). As shown in Figure 2, in an individual-effect analysis, there were U-shaped relationships between MT, rainfall and drowning mortality, with the lowest risk at 15.4 °C for MT and 16.6 mm for rainfall, respectively. RH was negatively associated with drowning mortality, while DS was positively associated with drowning mortality.

In the sensitivity analysis of the GAM, the relationship curves for MT, RH, DS, and rainfall with drowning deaths changed little after changing the degrees of freedom in the spline function. (Multimedia Appendix 3)

Figure 2. The associations of daily mean temperature, relative humidity, sunlight duration, and rainfall with drowning mortality in generalized additive models. Solid lines represent the exposure-response curve; dotted lines represent the 95% CI.



Combined Effect of Multiple Meteorological Factors on Drowning Mortality

In the exposure mixture analysis using quantile g-computation, mixed exposure to the 4 meteorological factors was approximately linearly associated with the risk of drowning. The risk tended to increase with each percentile (Figure 3). Meanwhile, we conducted an effect modification analysis of city-level characteristics and found that the risk of drowning caused by meteorological exposure mixture was higher in cities with higher population density, while urban gross domestic product, latitude, longitude, and altitude were found to have only weak modification effects (Multimedia Appendix 4).

After linearization, we observed a 2.99% (95% CI 0.26%-5.80%) drowning mortality increase per quartile rise in the 4 meteorological factors (Figure 4). Subgroup analyses showed that the effect for males was higher than for females with a statistically significant difference (Z=2.21; P=.03). The risk of drowning was heterogeneous across age groups in combined effects. Although those aged 25 to 64 years had the highest risk (ER 4.56%, 95% CI 0.07%-9.25% per quartile rise in the 4 meteorological factors), the difference among all age groups was not statistically significant. The drowning risk attributed to mixed exposure to the 4 weather factors in the warm season seemed higher than in the cold season, but the difference was also not statistically significant (Z=1.61; P=.11).

Figure 5 further shows the relative contribution of each meteorological factor to the combined effect. Sunlight duration had a positive weight with a much higher proportion among all subgroups: 93.1%, 94.1%, 100%, 88.9%, 83.1%, and 83.9% for the total population, males, females, and people aged 0 to 24 years, 25 to 64 years, and ≥65 years, respectively. RH negatively contributed to the combined effect in the total population (9.5%), females (26%), males (9.9%), and young people aged 0 to 24 years (43.2%) and positively contributed in people aged 25 to 64 years (12.4%) and ≥65 years (16.1%). Temperature contributed positively in the total population (6.9%), males (5.9%), the population aged 0 to 24 years (11.1%), and the population aged 25 to 64 years (4.5%), while it made a negative contribution in females (17.8%) and people aged ≥65 years (37.2%). Rainfall always contributed negatively to drowning mortality among all populations (90.5%, 90.2%, 56.2%, 56.8%, 100%, and 62.8% for the total population, males, females, people aged 0 to 24 years, 25 to 64 years, and ≥65 years, respectively; Figure 5).

In a quantile g-computation model sensitivity analysis, the results were basically stable whether adjusting or not adjusting for PM2.5 in the model. The excess risk of drowning increased when moving averages of each weather factor were used in the model (Multimedia Appendix 5).

Figure 3. Exposure-response relationships between meteorological exposure mixture and drowning risk in 71 cities from a quantile g-computation analysis. The line is the exposure response curve, and the blue shaded area is the 95% CI at each percentile.

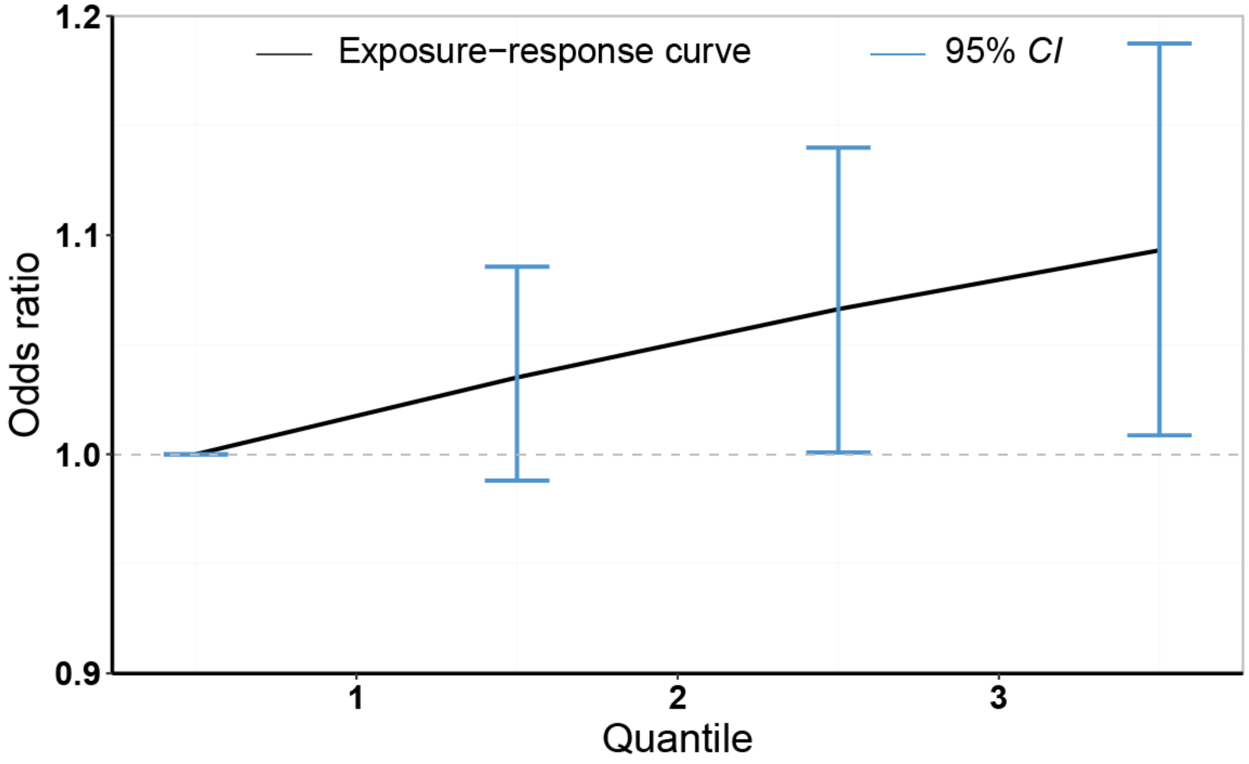


Figure 4. Excess risk (as a percentage) of drowning mortality per quartile increase in mixed daily mean temperature, relative humidity, sunlight duration, and rainfall in 71 cities.

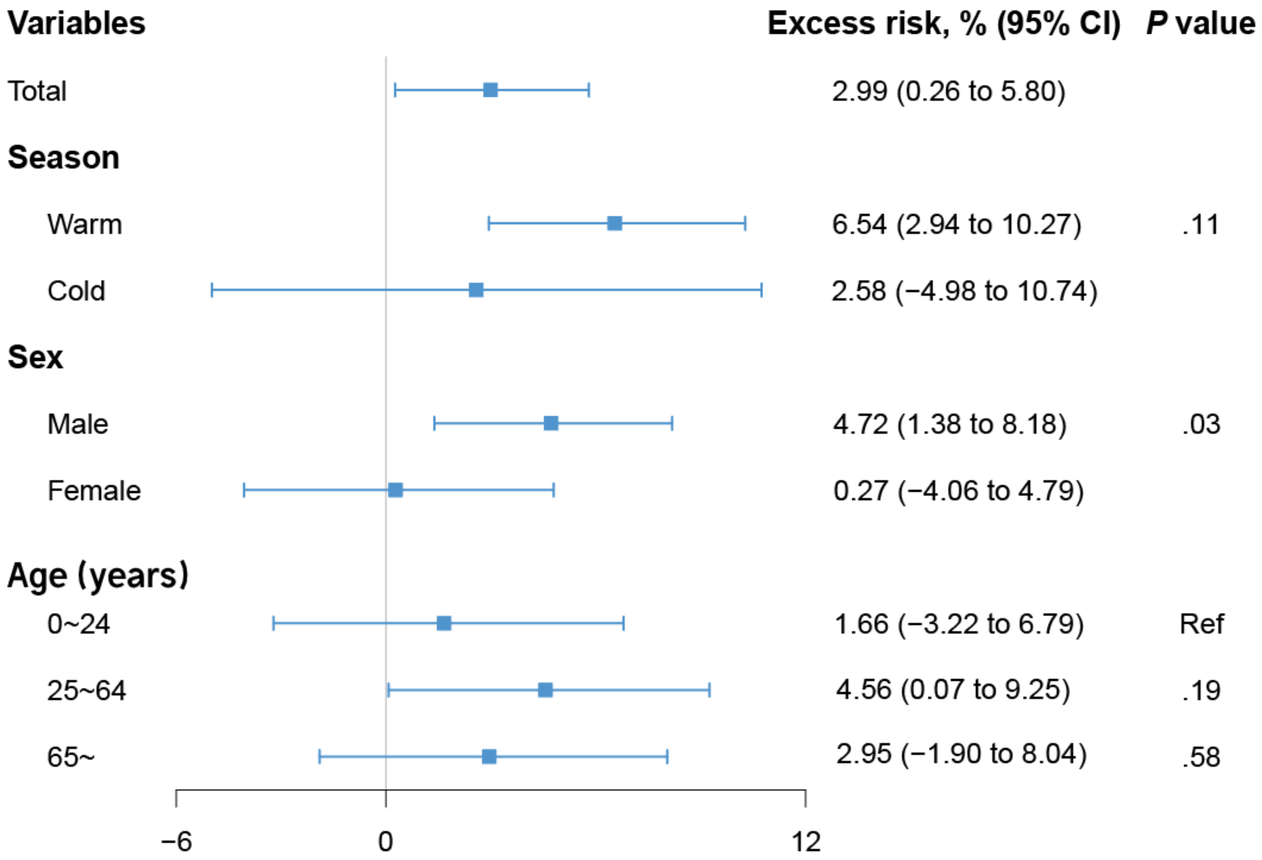

Figure 5. Weights representing the proportion of the positive or negative partial effect of each meteorological factor in quantile g-computation model by sex and age group.

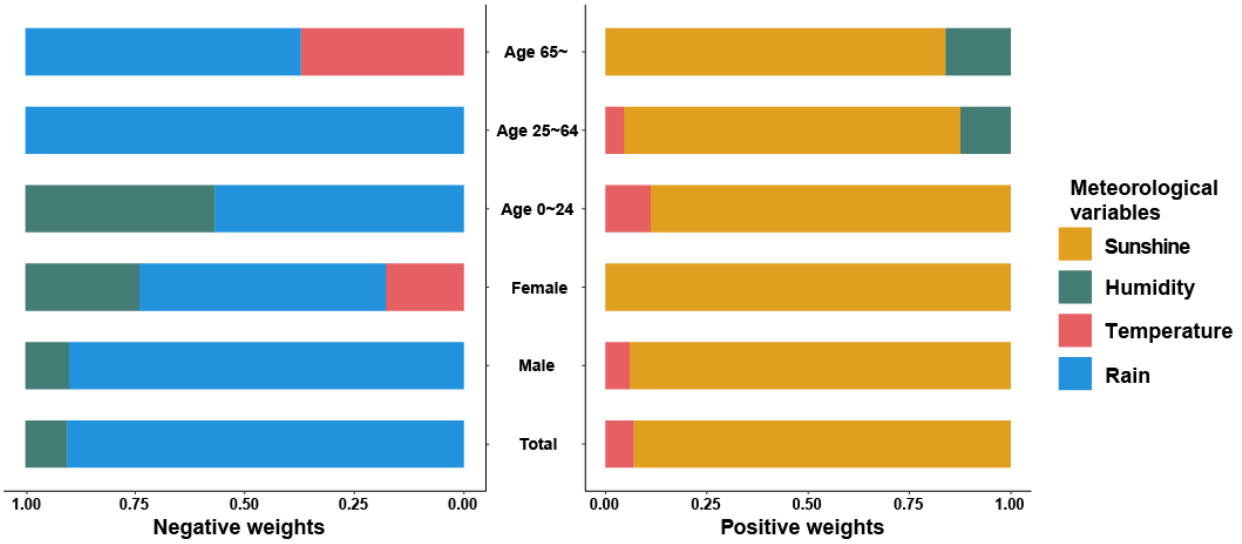

Discussion

Principal Findings

In this study, we examined the combined effect of daily MT, RH, DS, and rainfall on drowning mortality in China. We found that for every quartile increase in meteorological factors, the risk of drowning death in the population increased by 2.99%. We also observed that the 4 meteorological factors had a positively combined effect on drowning mortality in all subgroups except those aged 0 to 24 years; adults aged 25 to 64 years may be more susceptible to mixed exposure to the 4 meteorological factors. Moreover, we showed that DS, rather than MT, was the most important meteorological factor contributing to drowning mortality. These findings have important public health implications for developing an early warning system to reduce drowning mortality in the context of global warming.

Results Interpretation and Implications

An increasing number of epidemiological studies have examined the relationship between exposure to single meteorological factors and the risk of drowning. Consistent with our findings, a study conducted by Chauvin et al [35] reported an increase in the risk of drowning death as ambient temperature rose. When the human body is exposed to high temperatures, the blood vessels in the skin dilate rapidly and sweating increases to accelerate the discharge of excess heat; when entering the water, heavy sweating could lead to electrolyte deficiencies, and swimming in water at this time may lead to dangerous reactions, such as convulsions [36]. Therefore, high temperatures increase the risk of drowning. Additionally, alcohol consumption at high temperatures is an important risk factor for drowning [37,38], as this could affect physiological reactions and behavioral patterns, thereby increasing the risk of drowning. A prior study reported that alcohol consumption was positively correlated with MT [39]. Individuals that consume alcohol have an increased risk of drowning due to greater skin blood flow and sweating. Also, alcohol can cross the human cerebrovascular barrier directly and affect mental and cognitive performance, and the heat sensation associated with alcohol consumption may increase exposure to water [40]. For instance, an Australian study reported that there was a higher tendency to see people consuming alcohol alongside rivers on hot days [41].

To date, we have not found any study on the association of RH with drowning mortality. Among prior studies, RH is often treated as a confounding variable in the model fitting [42,43]. In our study, we observed that RH was negatively associated with the risk of drowning in an individual analysis of meteorological factors and negatively contributed to drowning mortality in most subgroups in a combined-effect analysis. The underlying mechanism of this finding is unclear and requires further in-depth studies in the future.

In terms of DS, existing studies mainly focus on sunlight exposure and skin cancer or suicide [44-46]. The combined effect analysis in our study shows that DS was the most important weather factor in increasing drowning mortality in all subgroups. Possible explanations for this are that (1) longer daylight hours may be associated with higher temperatures, thereby increasing opportunities for water activities, and (2) light has the neurobiological effect of interacting with the brain serotonin system and may influence serotonin-related behavior [46]. Finally, when daylight hours are short, people are less likely to be active outside and are likely to reduce their contact with bodies of water, which in turn may lead to a decreased incidence of drowning.

We further observed that rainfall was a negative factor for unintentional drowning risk in the combined-effect analysis. Previous studies have shown a negative correlation between rainfall and physical activity and a positive association with sedentary time during weekdays [47]. Therefore, rainfall might make it more difficult for people to work outdoors, which in turn may reduce the chance of contact with bodies of water. In contrast, Murray and Carter [48] showed that high rainfall (180.55 mm to 202.25 mm) was associated with increased drowning deaths in Fiji. The rainfall amount in this study was less than 35 mm, which is more likely to reduce people’s willingness to go outside; thus, we observed a reduced risk of drowning. In addition, the deaths in this study did not include flood-related drownings or disaster drownings.

In the stratified analysis, we further observed that males exhibited higher risk than females when exposed to meteorological mixed factors, which is consistent with previous studies. For example, the risk of drowning death is 1.67 times higher in men than women on hot days [14]. Compared to females, males are more likely to work in hot outdoor environments, resulting in potentially greater access to bodies of water and higher risk of drowning. We also observed that for people aged 0 to 24 years, there was no statistically significant association between mixed exposure to the 4 meteorological factors and drowning. This is contrary to previous studies. For instance, a study in Shanghai reported that drowning deaths among children aged 0 to 14 years mainly occurred in the hot season, while other age groups showed less seasonality in drowning [49]. Possible reasons for this are that the young population is more likely to be influenced by individual personality traits (eg, an active and strong spirit for exploring outside) and behavioral patterns and less influenced by external weather factors and the environment; on the other hand, children also end up in bodies of water due to unintentional falls and fights. Meteorological exposure mixture had the greatest effect on people aged 25 to 64 years; one possible explanation for this finding was that adults were more likely to consume alcohol in hot weather, and drinking alcohol increases exposure to water [50]. Moreover, this age group is the main workforce, with a high chance of occupational exposure to bodies of water, which may increase drowning deaths [51].

Several previous studies have estimated the risk of drowning associated with exposure to a single meteorological factor. However, people are exposed to a variety of meteorological factors simultaneously, so it is important to use an exposure mixture approach to measure the combined effects of weather factors on human health. In this study, we estimated the combined effects of 4 weather factors using a quantile g-computation model. This model helps design potential public health interventions for specific sources of exposure [19].

Multiple sectors in the government, such as education departments, health departments, and meteorological departments, should collaborate to develop an early warning system taking into account DS as a potentially critical weather factor to reduce the risk of drowning in the high-risk season. In addition, in areas with a high risk of drowning, governments should provide adequate and safe swimming places to reduce the possibility of people going into dangerous waters for recreation.

Limitations

This study has several limitations that must be noted. First, due to the lack of individual exposure data, we used meteorological data obtained by spatial interpolation as a proxy in each city, and there may be some exposure misclassification bias. Second, although this study is based on 5 provinces, which are to some extent nationally representative, extrapolation of the results needs to be done with caution. Third, drowning is influenced by family factors and socioeconomic factors, which were not included in this study. Finally, we only included unintentional drowning (ICD-10 codes W65-74) in this study, which excludes drowning due to cataclysm (ICD-10 codes X34-X39) and transportation accidents (ICD-10 codes V01-V99). This may not adequately reflect the true number of drowning deaths [52].

Conclusion

This study shows that mixed exposure to the 4 weather factors was positively associated with drowning mortality, which was primarily driven by DS and MT. This finding implies that it is necessary to incorporate sunshine hours and temperature into early warning systems for drowning in the future.

Abstract

Background: Indoor air pollution has been reported to have adverse effects on the eye; however, the health effects of exposure to cooking with solid fuels on visual impairment remain unclear in China.

Objective: We aimed to examine the association between cooking with solid fuels and visual impairment, including distance visual impairment (DVI) and near visual impairment (NVI).

Methods: Data were obtained from the China Health and Retirement Longitudinal Study, a nationwide survey of adults aged over 45 years who were enrolled in 2011 (Wave 1) and followed up in Wave 2 (2013), Wave 3 (2015), and Wave 4 (2018). We used Cox proportional hazards models to determine the association between solid fuels use and visual impairment. Additionally, the impact of switching cooking fuel types on vision function were examined through wave-specific data analysis (Wave 1 and Wave 4). Interaction and subgroup analyses were performed to explore the potential effect modifiers. Data were collected using the stratified multistage random sampling method and further analyzed using SPSS 27.0 and R 4.2.1 statistical software packages.

Results: A total of 9559 middle-aged and older Chinese adults without visual impairment at baseline were included in the study, with 51.2% (n=4914) of the participants reporting that they cooked with solid fuels. During the follow-up period, 2644 (27.5%) and 3130 (32.6%) participants developed DVI and NVI, respectively. Compared with the clean fuel users, participants who cooked with solid fuels had a higher risk of DVI (hazards ratio [HR] 1.38, 95% CI 1.28-1.50) and NVI (HR 1.18, 95% CI 1.10-1.27). In addition, switching the cooking fuel type from clean to solid fuels was associated with an elevated risk of DVI (HR 1.51, 95% CI 1.15-1.98) and NVI (HR 1.39, 95% CI 1.06-1.82) compared to persistently using clean fuels during the follow-up period, although no protective effect of switching from solid to clean fuels on NVI was found (P=.52). In subgroup analysis, we found that cooking with solid fuels increased the risk of DVI in participants younger than 65 years (HR 1.41, 95% CI 1.28-1.55), men (HR 1.45, 95% CI 1.28-1.65), urban residents (HR 1.41, 95% CI 1.08-1.75), and smokers (HR 1.43, 95% CI 1.25-1.64). By contrast, negative effects of cooking with solid fuels on NVI were found in nonsmokers (HR 1.21, 95% CI 1.11-1.33) and urban residents (HR 1.20, 95% CI 1.10-1.37).

Conclusions: Cooking with solid fuels was associated with an increased risk of visual impairment among middle-aged and older Chinese adults. These findings indicate that promoting the utilization of clean fuels is conducive to reducing the burden of visual impairment for the public.

KEYWORDS

indoor air pollution; solid fuel; visual impairment; cohort study; Chinese

Introduction

Incomplete and inefficient combustion of solid fuels (including biomass and coal) is the primary cause of indoor air pollution, affecting approximately half the global population [1]. Prolonged exposure to indoor air pollution has many negative impacts on individuals' health, such as causing respiratory disease, cancer, and eye problems, and is the foremost cause of premature death in developing countries [2]. Among the many human organs that could be affected by indoor air pollution, the eyes are directly exposed to the emissions from solid fuel combustion, including high levels of fine particulate matter ($PM_{2.5}$) and carbon monoxide. These emissions would stimulate the production of reactive oxygen species, which can seriously impair the viability of eye cells and accelerate oxidation of the lens [3]. Moreover, the hazardous materials resulting from solid fuel combustion can also affect the body's cardiovascular circulation system, leading to increased intraocular pressure through the aqueous humor.

Eye problems such as tearing, redness, itching, and stinging are widely reported to be linked to indoor air pollution [3,4]. A recent large cohort study provided evidence that prolonged exposure to indoor air pollution, which was mainly attributed to cooking with solid fuels, would increase the risk of major eye diseases (eg, conjunctiva disorders, cataracts) [5]. Moreover, long-term exposure to eye problems and eye diseases could result in severe visual impairment and even blindness [6-8]. Based on these findings [3-8], it is hypothesized that indoor air pollution exposure may be an environmental risk factor associated with visual impairment.

An estimated 2.2 billion people globally have visual impairments, with nearly half of these cases being preventable or untreated [9]. Untreated vision loss could have significant and lasting effects on a person's ability to perform daily activities and access public services [10]. In China, the most populous country in the word, 30%-50% of adults over the age of 80 years and 7%-20% of adults over the age of 50 years were estimated to have visual impairments [11], ranking second in years lived with disability among all health impairments. As the population is aging rapidly, the burden of visual impairment is predicted to continue to rise [10,12].

Given the widespread use of solid fuels in China [13], evidence on the association of solid fuel use and visual impairment is urgently needed for policy makers to take effective actions to relieve the burden of visual impairment by promoting cleaner household energy.

To fill the above knowledge gap on the link between solid fuel use and visual impairment among Chinese adults, we performed this study to assess the longitudinal association between self-reported cooking with solid fuels and visual impairment in a nationally representative sample obtained from the China Health and Retirement Longitudinal Study (CHARLS). This prospective cohort study assessed the impact of indoor air pollution on visual impairment among middle-aged and older Chinese adults from 2011 to 2018 for the first time and also examined the effects of switching cooking fuel types on vision function over time.

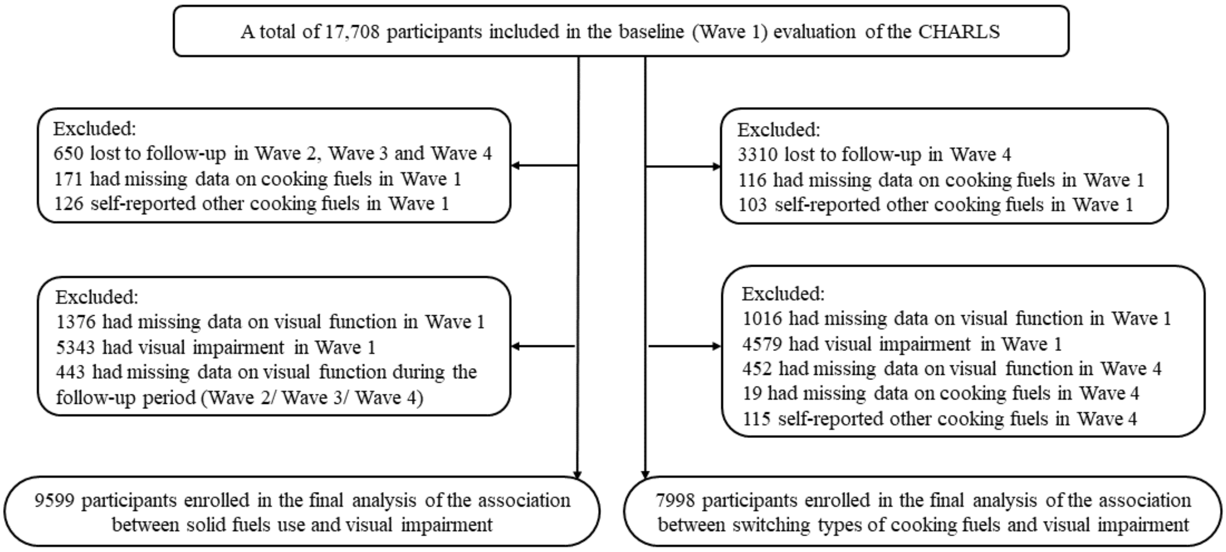
Methods

Study Population

This nationwide population-based cohort study utilized data from the CHARLS, which was implemented by the National School of Development of Peking University. An unbiased and representative sample was obtained by proportional and multistage stratified sampling [14]. In the first stage, all counties in China were stratified by region. Regions were divided by urban districts or rural counties and per capita statistics on gross domestic product. Using the probability-proportional-to-size sampling technique, 150 county-level units were randomly chosen from the sampling frame. In the second stage, three primary sampling units (PSUs) were selected in each county based on a probability proportional to the population size. In the third stage, a random sample of 24 households was selected among all the households mapped in each selected PSU. Finally, for each selected household, one resident aged ≥45 years and their spouse were randomly selected as the participants in the survey. Briefly, the CHARLS survey included Chinese residents from 450 communities covering 150 county-level units in 28 provinces. From May 2011 to March 2012, a total of 17,708 residents with a response rate above 80% participated in the baseline survey (Wave 1). CHARLS respondents are followed every 2 years through a face-to-face computer-assisted personal interview to obtain individual information on sociodemographic characteristics, lifestyle behaviors, indoor air pollution, health status, and other factors of interest. Interviewers helped respondents who had sight problems by reading the questions in the standardized questionnaire during the interview process. To date, follow-up survey data are available for Wave 2 (2013), Wave 3 (2015-2016), and Wave 4 (2018) of CHARLS.

We used the data from all four waves to examine the relationship between solid fuel use and visual impairment; a total of 9559 individuals were selected based on the following exclusion criteria: (1) 650 lost to follow-up in Wave 2, Wave 3, and Wave 4; (2) 171 had missing data on cooking fuels in Wave 1; (3) 126 self-reported other cooking fuels in Wave 1; (4) 1376 had missing data on visual function in Wave 1; (5) 5343 had visual impairment in Wave 1; and (6) 443 had missing data on visual function during the follow-up period (Wave 2/Wave 3/Wave 4) (Figure 1).

Figure 1. Flowchart of the selection process of participants. CHARLS: China Health and Retirement Longitudinal Study.



In addition, we used the wave-specific data of Wave 1 and Wave 4 to examine the association between switching the fuel type and visual impairment; 7998 individuals were selected based on the following exclusion criteria: (1) 3310 lost to follow-up in Wave 4; (2) 116 had missing data on cooking fuels in Wave 1; (3) 103 self-reported other cooking fuels in Wave 1; (4) 1016 had missing data on visual function in Wave 1; (5) 4579 had visual impairment in Wave 1; (6) 452 had missing data on visual function in Wave 4; (7) 19 had missing data on cooking fuels in Wave 4; and (8) 115 self-reported other cooking fuels in Wave 4.

Vision Assessment

Individuals' distance vision was assessed by self-reported visual status when recognizing friends across the street (while wearing corrective lenses or glasses, if applicable) and personal near vision was assessed by self-reported visual status when reading regular newspapers (while wearing glasses or corrective lenses, if applicable). Possible responses to these questions were "poor," "fair," "good," "very good,", and "excellent." Those reporting "poor" for near and distance vision were defined as having near visual impairment (NVI) and distance visual impairment (DVI), respectively. Those reporting "excellent," "very good," "good," or "fair" were defined as having no visual impairment (reference group). Visual impairment assessment and categorization were performed in accordance with previous studies [15-17].

Assessment of Cooking With Solid Fuels

The question "What are your main sources of cooking fuels?" was used to assess indoor cooking fuel types. At baseline, reporting "coal," "crop residue," and "wood" was defined as cooking with solid fuels. The main types of solid fuels were classified into coal and biomass ("crop residue" and "wood"). Reporting "liquefied petroleum," "natural gas," "electricity," and "marsh gas" was defined as cooking with clean fuels. We compared data from respondents who reported cooking with clean fuels to those of the solid fuel users. In addition, we collected information on self-reported cooking fuel types in Wave 4, which had an additional choice of "do not cook" compared to the answers regarding the baseline question. We categorized "do not cook" as clean fuel, and assessed the association of switching cooking fuel types with visual impairment. Therefore, participants could be classified as switching from solid fuels to clean fuels or from clean fuels to solid fuels.

Covariates

Baseline demographics (including age, gender, marital status, education level, residence) and health-related status (including smoking status, alcohol drinking, sleep duration, BMI, and chronic diseases) were included as covariates in our analyses. We classified cohabitation and marriage as married. Education level was divided into illiteracy (0 years) and others (≥1 year). Residence was divided into rural and urban areas [18]. BMI was calculated as weight divided by the square of height (kg/m^2) [19]. Alcohol drinking was classified into drinker and nondrinker. Smoking status was classified into smoker and nonsmoker. Dyslipidemia, chronic lung disease, hypertension, heart disease, diabetes, and cancer were identified by self-reported physician diagnoses.

Statistical Analysis

The baseline characteristics are described according the type of cooking fuels. Continuous variables were summarized as mean (SD) and were compared with independent *t* tests. Categorical variables were summarized as frequencies (percentages) and were compared with the χ^2 test. A Cox proportional hazard model was performed to assess the effects of solid fuel use on visual impairment. We also compared data of participants who switched from clean fuels to solid fuels or from solid fuels to clean fuels with those who persistently used clean or solid fuels through wave-specific analysis. The proportional hazard assumption was examined using the Schoenfeld residual test. Model 1 was an unadjusted model. Model 2 was adjusted for age, gender, BMI, marital status, education level, residence, alcohol drinking, smoking status, and sleep duration. Model 3 was further adjusted for hypertension, dyslipidemia, diabetes, cancer, chronic lung disease, and heart disease based on Model 2. The percentage of missing covariates was less than 5% for all covariates, which conformed to an arbitrary missingness pattern. We used multiple imputation to account for these missing values. The Markov chain Monte Carlo method was used to analyze the complete data set and interpolate each missing value five times to obtain five complete data sets. Statistical analysis was then performed on each filled data set separately and the combined results of the five analyses were used to select the data set with the largest relative efficiency value. Additionally, we performed subgroup analyses and interactions analysis stratified by age, sex, residence area, and smoking status to assess potential effect modifications. The sensitivity analysis was conducted by excluding participants who reported not cooking in Wave 4 to ensure that our findings were robust. Cox proportional hazards model results are presented as hazard ratios with 95% CIs. Statistical analyses were performed using SPSS 27.0 and R 4.2.1 software. Two-tailed *P* values less than .05 were considered statistically significant.

Ethical Considerations

The CHARLS was approved by the Research Ethics Committee of Peking University (IRB00001052-11015). This survey was anonymous and the answers are protected by privacy law. Written informed consent clarifying the study purposes was obtained from each participant before completing the interview.

Results

Characteristics of the Study Participants

A total of 9559 participants without visual impairment at baseline were included. The average age of included participants was 57.7 (SD 9.5) years and 50.3% of them were women. Overall, 51.2% (n=4914) of the participants primarily cooked with solid fuels (Table 1), and 15.3% (n=1469), 13.6% (n=1309), 18.4% (n=1770), 1.4% (n=137), 10.8% (n=1035), and 40.5% (n=3879) of the participants reported cooking with liquefied petroleum, natural gas, electricity, marsh gas, coal, and crop residue/wood burning at baseline, respectively. However, only 32.1% of the participants reported cooking with solid fuels in Wave 4, including 5.6% cooking with coal and 26.5% cooking with crop residue/wood burning (see Multimedia Appendix 1). In general, participants who reported cooking with solid fuels at baseline were more likely to be current smokers and reported less sleep time, lower educational levels, and lower BMI compared with clean fuel users. Significantly more participants living in rural areas and those suffering from chronic lung diseases used solid fuels (both *P*<.001). Additionally, significantly more individuals with hypertension, diabetes, and dyslipidemia used clean fuels for cooking rather than solid fuels (*P*=.04, *P*<.001, and *P*<.001, respectively).

Association Between Cooking With Solid Fuels and Visual Impairment

During the follow-up period, 2644 (27.5%) and 3130 (32.6%) of the 9599 total participants reported DVI and NVI, respectively (Table 2). The effects of cooking with solid fuels on visual impairment are presented in Table 2. In the crude model, using solid fuels for cooking elevated the risk of DVI and NVI. The findings from Model 1 and Model 2 were consistent with those of the crude model. After adjusting for extensive confounders (Model 3), we found that participants who cooked with solid fuels had a significantly increased risk of DVI and NVI. In addition, compared with the clean fuel users, the participants who cooked with coal had a significantly increased risk of DVI and NVI. Moreover, cooking with biomass significantly increased the risk of DVI and NVI (see Multimedia Appendix 2).

Through the wave-specific data, we found that participants who switched their cooking type from clean to solid fuels had a 51% elevated risk of DVI and a 39% elevated risk of NVI compared with the persistent clean fuel users. However, there was no evidence of an impact of switching from solid to clean fuels on NVI (*P*=.52). After excluding participants who reported not cooking in Wave 4, our findings remained robust (see Multimedia Appendix 3).

Subgroup Analyses on the Association Between Cooking With Solid Fuels and Visual Impairment

We performed analyses of interactions and subgroups on the relationship between using solid fuels for cooking and visual impairment in Model 3 (Table 3). We found that cooking with solid fuels had an increased risk of DVI among participants younger than 65 years, men, urban residents, and smokers. However, cooking with solid fuels resulted in a higher risk of NVI for nonsmokers and urban residents.

Table 3. Subgroup analysis of the association between solid fuel use and visual impairment among middle-aged and older Chinese adults.

Discussion

Summary of Findings

This study demonstrated that cooking with solid fuels increased the risks of visual impairment, with an adverse effect of solid fuel use found for both DVI and NVI, especially for participants living in urban areas. Moreover, switching from clean to solid fuels was demonstrated to increase the risk of DVI and NVI compared to the persistent use of clean fuel. These main findings are consistent with evidence from previous studies conducted in countries neighboring China. In India, the older population, who are highly reliant on using unclean cooking fuel, had a higher prevalence of visual impairment [20]. In Nepal, the incidence of cataracts was two-fold higher in women using biomass for cooking compared to that of women using clean fuel [21]. This study thus adds to the accumulating evidence of adverse vision health consequences potentially arising from the use of unclean cooking fuels in low- and middle-income countries [22].

The essential mechanisms of the impacts of solid fuel utilization on visual impairment are undefined [23]. One possible reason is that burning solid fuels produces high levels of gaseous pollutants that increase the risk of eye diseases and may lead to vision impairment. On the one hand, $PM_{2.5}$ is the primary pollutant in solid fuel smog, which represents a mixture of thousands of harmful chemicals such as heavy metals and polycyclic aromatic hydrocarbons [24]. A previous study showed that for each 1 $\mu g/m^3$ rise in ambient $PM_{2.5}$ exposure, the risk of glaucoma increased by 6% [25]. Free radicals accelerate the oxidation of the lens when the eye organ is directly exposed to the fumes of solid fuel, which results in an increased risk of cataracts [26] as the leading cause of vision impairment or loss worldwide [27,28]. On the other hand, incomplete combustion of solid fuel produces carbon monoxide, which is harmful to the eyes due to hypoxia [29]. Another possibility is that indoor air pollutants resulting from solid fuel combustion can affect the body's cardiovascular system and the effect on the aqueous humor can lead to increased intraocular pressure. Moreover, when burning solid fuels, the anterior eyes are more susceptible to damage from sparks, wood dust, or sharp wood and the consequent ocular trauma would increase the risk of vision impairment [30,31]. Heat exposure associated with burning solid fuels may be another potential risk factor for eye diseases [32,33], which would contribute to the development of age-related cataracts and the early onset of presbyopia if the transient temperature elevation in the lens recurs over many years. In addition, previous studies have linked long-term solid fuel use to diabetes [34], depression [35], and cognitive impairment [36], which were reported as potential risk factors affecting vision health.

Previous studies observed that women were more likely to develop eye diseases linked to solid fuel use [37-39], suggesting that as women traditionally played a vital role in cooking, they had observably higher indoor air pollution exposure. However, our study showed that men cooking with solid fuels appeared to be at a higher risk of DVI than women. This result is consistent with the cross-sectional study from India, which failed to find that the visual impairment risk associated with use of unclean cooking fuels was higher for women and in households without a separate kitchen or ventilation [20]. One possible reason for this inconsistency might be differences in the study populations. In our study, most of the individuals were retirees aged over 60 years, who tend to spend most of their time at home, which would increase the frequency of couples cooking together. This situation thereby increases the exposure to indoor air pollution caused by the use of solid fuels for men. Moreover, there is no doubt that the smoking rate is much higher among men than among women and there may be an interaction between vision impairment and solid fuel use due to the apparent gender difference in smoking habits.

More harmful impacts of cooking with solid fuels on NVI were noted among urban residents. Rural areas are usually less economically developed and have a lower population density than urban areas. Higher industrialization in urban areas may increase the risk of visual impairment since rapid industrialization would result in worse indoor air pollution and associated health outcomes [40]. Additionally, the higher population density in urban areas leads to a lower living space per capita, which may elevate the indoor pollutant concentration [41]. Despite some households having installed ventilation devices to prevent severe indoor air pollution, the level of air pollutants in domestic kitchens using solid fuels remains high [42]. In addition, switching cooking fuels from solid to clean fuels failed to decrease the risks of cataracts and conjunctiva disorders compared to the persistent use of solid fuels [5]. Taking this into consideration, it is necessary to call on the general public to use clean energy to reduce indoor air pollution and promote healthy vision, especially in rural areas.

Simultaneously, an interesting result emerging from our study was that switching from clean fuels to solid fuels could increase the risk of visual impairment compared with the continued use of clean fuels. The switch of cooking fuels from clean fuels to biomass fuels might be related to the migration from urban to rural areas among older people in China, which has been a prevalent trend in recent years [43,44]. Older adults generally prefer solid fuels more than younger adults and they are consequently more prone to the adverse effects of indoor air pollution. A cohort study with a 3-year follow-up period found that cooking with biomass fuels was associated with a higher risk of visual impairment among older Chinese adults with a mean baseline age of 82.56 years [43]. The persistent formation of lens fibers and the relative thickening of the lens cortex are important features during the aging process, resulting in changes in the refractive index of the lens [45]. This would in turn result in a higher risk of visual impairment when older adults change their cooking fuels from clean to solid fuels as their eyes may not be able to adapt to the sudden deterioration of air quality caused by solid fuels. Therefore, public health policies and investments that support cleaner household energy can effectively reduce the key sources of ambient air pollution, especially by avoiding the persistent use of solid fuels or switching from clean fuels to solid fuels, to further relieve the burden on visual impairment.

Limitations

This study has several limitations. First, with the rapid development of modernization, urbanization, and industrialization in China over the past three decades, more and more rural residents have gradually begun to use clean energy. Some of the participants in this study may have switched from solid to clean fuels prior to the baseline assessment, which would lead to an underestimate of the impact of solid fuels on visual function. Second, individual visual acuity and the exposure level to household pollutants cannot be accurately estimated due to data unavailability; thus, further research should use an objective assessment to verify the data and adjust for lead-time bias [46]. Third, there remain some potential confounders that we were unable to measure that could also have an impact, including occupational dust [31], heat exposure [33], or sunlight [47].

Conclusion

Overall, our study demonstrated that using solid fuels for cooking was significantly associated with elevated risks of visual impairment among Chinese adults aged over 45 years, especially among participants living in urban areas. Furthermore, switching the cooking fuel type from clean to solid fuels may also significantly increase the risk of visual impairment. Therefore, this study highlights the value of promoting the availability of household clean fuels and encouraging the consistent use of clean fuels to decrease the burden of visual impairment.

Acknowledgments

We thank the China Health and Retirement Longitudinal Study research team for providing the data as well as all of the study participants for their contribution. This study was funded by the Fundamental Research Funds for the Central Universities, Huazhong University of Science and Technology (2020WKZDJC015).

Abstract

Background: There is limited evidence regarding the adverse impact of particulate matters (PMs) on multiple body systems from both epidemiological and mechanistic studies. The association between size-fractionated PMs and mortality risk, as well as the burden of a whole spectrum of causes of death, remains poorly characterized.

Objective: We aimed to examine the wide range of susceptible diseases affected by different sizes of PMs. We also assessed the association between PMs with an aerodynamic diameter less than 1 μm (PM_1), 2.5 μm ($PM_{2.5}$), and 10 μm (PM_{10}) and deaths from 36 causes in Guangzhou, China.

Methods: Daily data were obtained on cause-specific mortality, PMs, and meteorology from 2014 to 2016. A time-stratified case-crossover approach was applied to estimate the risk and burden of cause-specific mortality attributable to PMs after adjusting for potential confounding variables, such as long-term trend and seasonality, relative humidity, temperature, air pressure, and public holidays. Stratification analyses were further conducted to explore the potential modification effects of season and demographic characteristics (eg, gender and age). We also assessed the reduction in mortality achieved by meeting the new air quality guidelines set by the World Health Organization (WHO).

Results: Positive and monotonic associations were generally observed between PMs and mortality. For every 10 $\mu g/m^3$ increase in 4-day moving average concentrations of PM_1, $PM_{2.5}$, and PM_{10}, the risk of all-cause mortality increased by 2.00% (95% CI 1.08%-2.92%), 1.54% (95% CI 0.93%-2.16%), and 1.38% (95% CI 0.95%-1.82%), respectively. Significant effects of size-fractionated PMs were observed for deaths attributed to nonaccidental causes, cardiovascular disease, respiratory disease, neoplasms, chronic rheumatic heart diseases, hypertensive diseases, cerebrovascular diseases, stroke, influenza, and pneumonia. If daily concentrations of PM_1, $PM_{2.5}$, and PM_{10} reached the WHO target levels of 10, 15, and 45 $\mu g/m^3$, 7921 (95% empirical CI [eCI] 4454-11,206), 8303 (95% eCI 5063-11,248), and 8326 (95% eCI 5980-10690) deaths could be prevented, respectively. The effect estimates of PMs were relatively higher during hot months, among female individuals, and among those aged 85 years and older, although the differences between subgroups were not statistically significant.

Conclusions: We observed positive and monotonical exposure-response curves between PMs and deaths from several diseases. The effect of PM_1 was stronger on mortality than that of $PM_{2.5}$ and PM_{10}. A substantial number of premature deaths could be preventable by adhering to the WHO's new guidelines for PMs. Our findings highlight the importance of a size-based strategy in controlling PMs and managing their health impact.

KEYWORDS

size-fractionated particulate matter; cause-specific mortality; cardiovascular disease; respiratory disease; neoplasm; attributable burden

Introduction

With the rapid socioeconomic development and fast urbanization, air pollution—particularly the particulate matters (PMs)—has become the biggest environmental challenge to human health globally [1]. According to the recent assessment of the global burden of disease, PMs accounted for over 4.1 million deaths [2]. As the largest developing country, China faces a disproportionately high health burden due to PM pollution [3]. The improvement of air pollution control policies warrants an in-depth knowledge and quantification of the health impact of PMs.

PMs consist of discrete particles that vary in size, which is an important characteristic influencing their hazardous effects. PMs with aerodynamic diameters less than 1 μm (PM_1), 2.5 μm ($PM_{2.5}$), and 10 μm (PM_{10}) have been studied extensively due to their ability to enter and deposit in the respiratory tract. Previous epidemiological investigations have identified the harmful impact of PM_{10} and $PM_{2.5}$ on human health [4,5]. In recent years, PM_1 has also raised increasing concerns due to emerging evidence indicating higher health risks associated with PMs of smaller sizes [6-9].

Prior studies mainly focused on the impact of size-fractionated PMs on mortality from common chronic diseases (ie, circulatory and respiratory diseases) [1,3,4,6]. Although less explored, PMs have been linked to an increased risk of developing and dying from diabetes and pancreatic cancer [5,10]. The risk of dying from external causes, including intentional self-harm, was also associated with increased levels of PMs [11]. There is limited evidence to suggest that PMs might also affect other systems, such as digestive, nervous, and genitourinary systems [12,13]. Mechanistic studies have revealed that environmental exposures can cause oxidative stress and inflammation, genomic and epigenetic alterations, mitochondrial dysfunction, endocrine disruption, altered intercellular communication, altered microbiome communities, and impaired nervous system function [14]. We, therefore, hypothesize that size-fractionated PMs can increase the risk of death from diseases involving multiple human body systems, and this excess risk might vary depending on the size of PMs.

We performed a comprehensive evaluation of the relationship between size-fractionated PMs and cause-specific mortality using granular data collected from Guangzhou, a city in China highly polluted by PMs, with PM_1 and $PM_{2.5}$ concentrations reaching as high as 122 $μg/m^3$ and 150 $μg/m^3$ during our study period. Our aim was to examine the wide range of susceptible diseases affected by different sizes of PMs. Specifically, we examined deaths from 10 broad categories of causes (ie, all cause, nonaccidental, cardiovascular, respiratory, digestive, genitourinary, nervous system, endocrine system, external causes, and neoplasms), along with their 26 subcategories. These categories were assumed to be affected by PMs based on existing evidence, as mentioned earlier.

Methods

Health Data

Daily mortality data and weekly counts of influenza-like illness (ILI) for the years 2014-2016 were collected from the Guangzhou Center for Disease Control and Prevention. The causes of death were coded according to the International Classification of Diseases, Tenth Revision. All-cause and nonaccidental mortality were defined using the codes A00-Z99 and A00-R99 (from the International Classification of Diseases, Tenth Revision), respectively. We also extracted data regarding deaths due to cardiovascular (I00-I99), respiratory (J00-J99), digestive (K00-K93), and genitourinary diseases (N00-N99), together with diseases of the nervous system (G00-G99) and endocrine system (D50-D89 and E00-E90). Data on deaths from external causes (V01-Y89) and neoplasms (C00-D48) were also collected. In addition, 26 subcategories within the previously mentioned 10 broad disease categories were also considered (Table S1 in Multimedia Appendix 1). In addition, daily counts of deaths were further categorized by age group (≤64, 65-74, 75-84, and ≥85 years) and gender.

Environmental Data

Daily concentrations of PM_1 during the 2014-2016 period were collected from the monitoring stations of the Chinese Atmosphere Watch Network in Guangzhou [15,16]. Data for $PM_{2.5}$ and PM_{10} were obtained from Guangzhou Bureau of Environmental Protection, together with data for other air pollutants, including ozone, sulfur dioxide, nitrogen dioxide, and carbon monoxide. We averaged the daily concentrations for each pollutant from 11 fixed-site monitoring stations in Guangzhou (Figure S1 in Multimedia Appendix 1). China Meteorological Data Service Center provided the daily meteorological data in Guangzhou, containing daily relative humidity (%); minimum, mean, and maximum temperatures (^oC); and air pressure (hPa).

Ethical Considerations

This study involved only a secondary analysis of daily aggregated and deidentified data, and it is classified as exempt from institutional review board approval according to the Chinese legal documents on ethics review issued by the National Health Commission of the People’s Republic of China (document number: 4; 2023) [17].

Statistical Analyses

We conducted a time-stratified case-crossover method to evaluate the impact of PMs (PM_1, $PM_{2.5}$, and PM_{10}) on mortality [11,18]. The following quasi-Poisson function accounting for overdispersion was used to assess the relationship between size-fractionated PMs and cause-specific mortality:

where Y_t is the observed number of daily deaths on day t; α is the model intercept; $Strata_t$ denotes the time stratum variable used to control for seasonality and long-term trend; NS represents the natural cubic spline function, with 3 dfs for relative humidity (RH_t) and air pressure (PRE_t) and 6 dfs for mean temperature ($TEMP_t$); λ , γ, and η are the vectors of coefficients. β denotes the changes in mortality risk per every 10 μg/m^3 increase in the concentrations of PM pollutants [3,5,6]. Given that influenza could potentially confound the association between air pollution and health [19], the daily average of ILI_t occurrence was also included in the model. Relative risk [$RR=exp(\beta)$] was estimated from the model and the impact of PMs was expressed as the percentage change [$(RR\text{-}1) \times 100\%$] in the daily number of mortality associated with a 10 μg/m^3 increment in PMs.

Furthermore, a smoothing spline function with 3 dfs was used to evaluate the exposure-response relationship between PMs (PM_1, $PM_{2.5}$, and PM_{10}) and mortality risk. We also conducted a sensitivity analysis by changing the dfs (5-9) to test the robustness of the association. To investigate the lag patterns of PMs, we fitted the models using different single lags. Moving average approach was further applied to capture the cumulative lag effects of PMs.

To estimate the excess mortality burden caused by size-fractionated PMs with daily concentrations higher than the recommended target, we considered 5 target levels of $PM_{2.5}$ and PM_{10} as per the World Health Organization’s (WHO) new air quality guidelines. The air quality guideline level and 4 interim targets for $PM_{2.5}$ are 15, 25, 37.5, 50, and 75 μg/m^3, respectively, while for $PM_{10,}$ they are 45, 50, 75, 100, and 150 μg/m^3, respectively [20]. There are no officially announced target levels for PM_1 yet; however, given the high correlation between PM_1 and $PM_{2.5}$ and the fact that they are both secondary pollutants emitted from some common sources [21], we assumed the percentiles of the PM_1 target levels to be the same as those of the $PM_{2.5}$ target levels. We were able to identify the PM_1 target levels (10, 20, 30, 40, and 55 μg/m^3) by locating these percentiles within the PM_1 distribution (Table S2 in Multimedia Appendix 1). The death burden due to PMs was calculated by combining the relative risk of PMs associated with their daily concentrations and the corresponding observed daily number of deaths. The total number of deaths attributable to each specific PM target was computed by summing the excess deaths when daily PM concentrations exceeded that target. The empirical CI (eCI) for the attributable deaths was estimated using Monte Carlo simulation with 1000 replications [5,22].

Stratification analyses were conducted to explore the potential modification effects of season (cold period: November-April; warm period: May-October) and demographical characteristics (gender and age) on the relationship between PMs and mortality. The z statistic was performed to test the statistical difference between the 2 relative risks obtained from the subgroup analyses [23,24].

Sensitivity Analyses

The robustness of our main findings was examined by several analytical strategies. First, we changed the dfs for daily meteorological variables from 3 to 6. Second, we changed the dfs for the time variable from 3 to 9 per year. Finally, to test the confounding influence of other air pollutants, we performed the two-pollutant models by separately introducing a pair of air pollutants that are not highly correlated, thus avoiding collinearity (Spearman correlation coefficient <0.7) [3,25]. All the data analyses were conducted using the R software (version 4.0.1; R Core Team), and a 2-sided P value less than .05 was considered statistically significant.

Results

Summary of Descriptive Statistics

In total, there were 146,459 all-cause deaths from 2014 to 2016 in Guangzhou. The number of deaths was 138,396 for nonaccidental causes, including 56,587 circulatory deaths, 21,395 respiratory deaths, 4587 deaths from digestive diseases, 1303 from nervous system diseases, 1930 from genitourinary diseases, 8052 from external causes, 5469 from endocrine diseases, and 41,709 from neoplasms. The average concentrations of daily PM_1, $PM_{2.5}$, and PM_{10} were 28 (SD 13) μg/m^3, 38 (SD 21) μg/m^3, and 56 (SD 28) μg/m^3, respectively (Table 1 and Table S1 In Multimedia Appendix 1). The correlation coefficients between PM_1, $PM_{2.5}$, PM_{10}, and other air pollutants were less than 0.7, except for nitrogen dioxide. Temperature and relative humidity were negatively correlated with PMs, while air pressure was positively correlated with PMs (Table S3 in Multimedia Appendix 1).

Table 1. Summary statistics of environment and mortality data from 2014 to 2016 in Guangzhou, China.

Variables	Mean (SD)	Minimum, n	Percentile[a]					Maximum, n
			P5	P25	P50	P75	P95

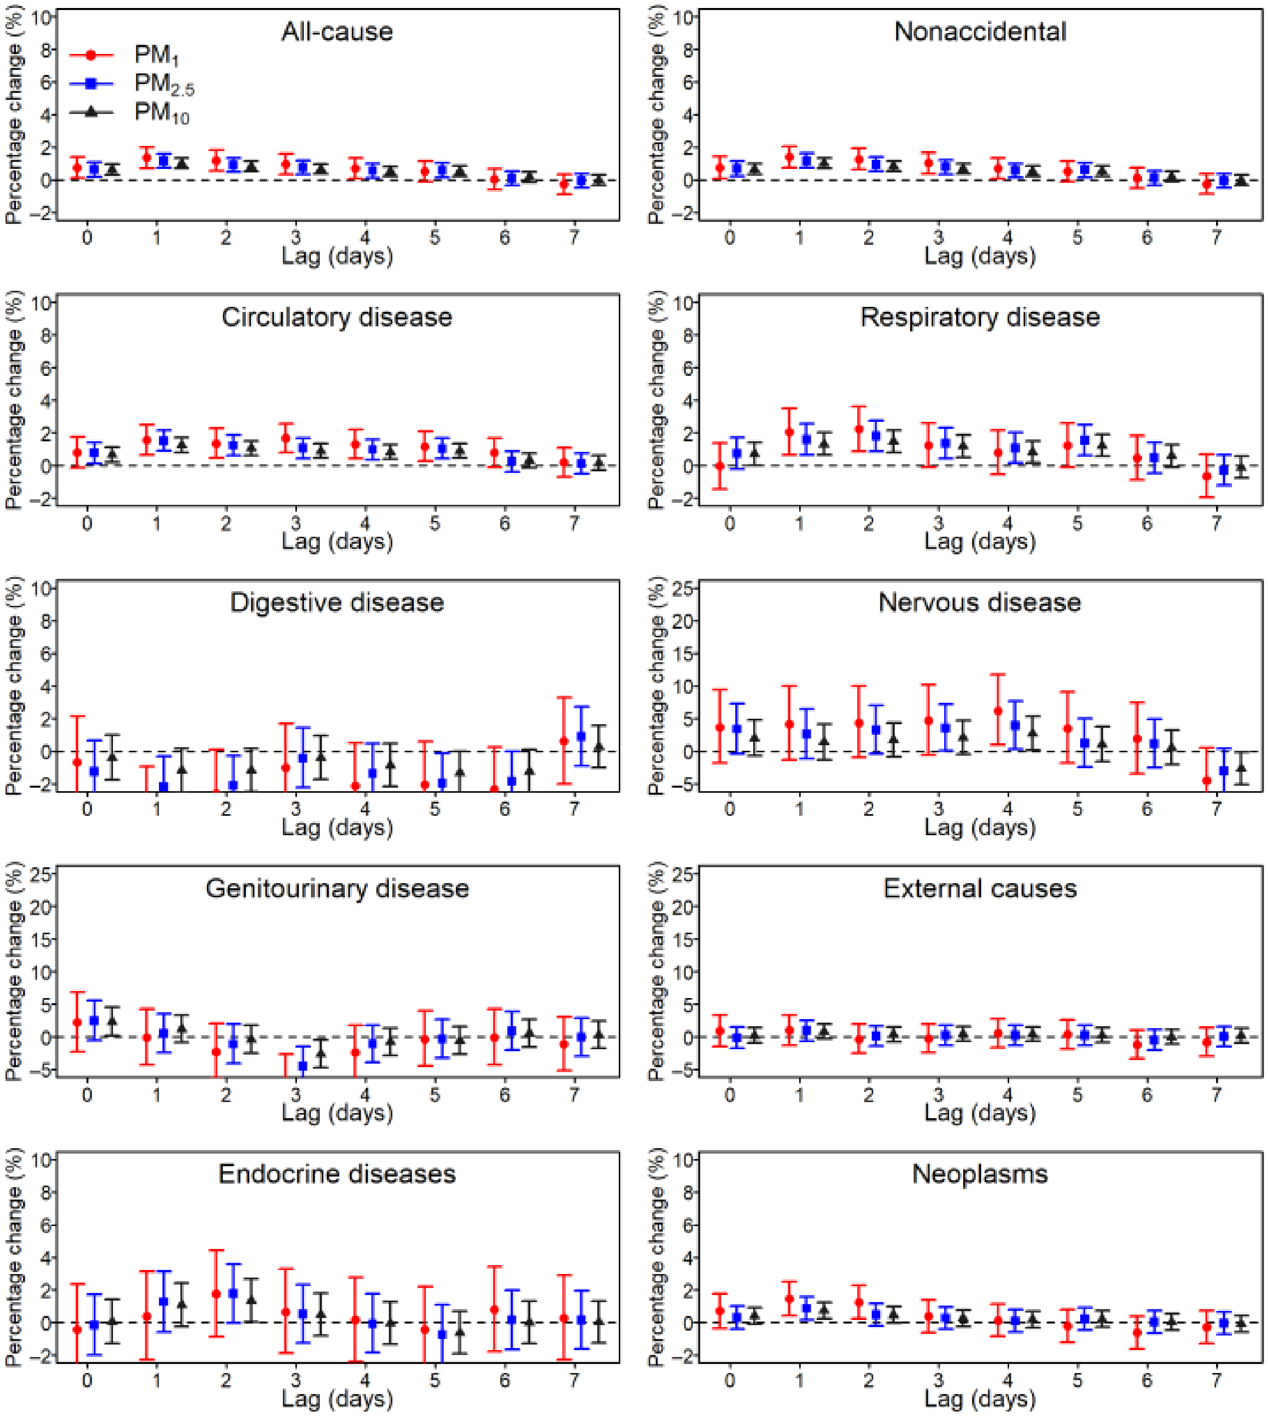
[a] P5, P25, P50, P75, and P95 denote the 5th, 25th, 50th, 75th, and 95th percentiles.

[b] PM_1: particulate matters with an aerodynamic diameter less than 1 µm.

Lag Pattern Effects of PMs on Mortality

The lag pattern effects of PM_1, $PM_{2.5}$, and PM_{10} on mortality risk manifested similar patterns, with estimates peaking at lag 1 or lag 2 for all-cause and nonaccidental mortality as well as for deaths from circulatory diseases, respiratory diseases, and neoplasms. The effects generally lasted for 4 days (Figure 1); however, the effects were statistically nonsignificant at different lag days for other diseases.

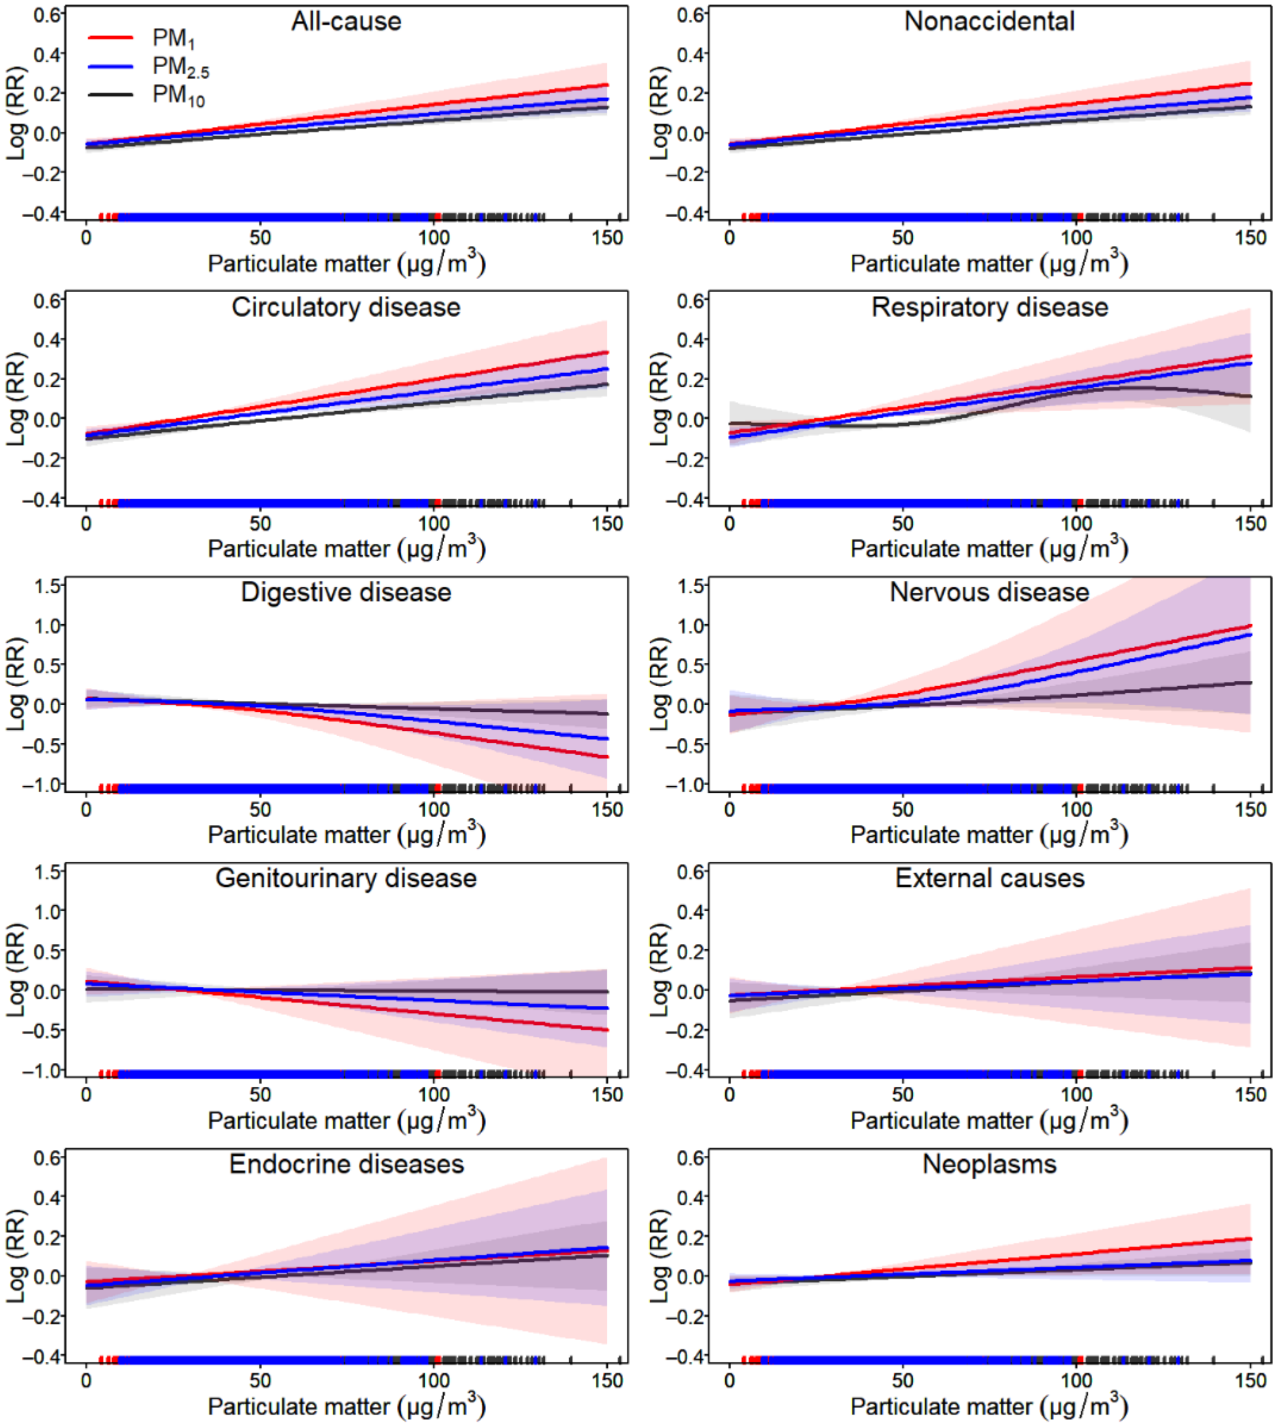
Figure 1. The percentage change (%) of cause-specific mortality associated with a 10 μg/m3 increase in size-fractionated particulate matters (PMs) on lag days 0-10. The vertical red, blue, and black lines denote the effect estimates of PM_1, $PM_{2.5}$, and PM_{10}, respectively, on mortality across lag days.



Dose-Response Relationships Between Size-Fractionated PMs and Mortality

The association between size-fractionated PMs and mortality at lag days 0-3 were generally positive and monotonically increasing (Figure 2). Similar associations were obtained when using 5-9 dfs for the spline function (Figures S2-S4 in Multimedia Appendix 1).

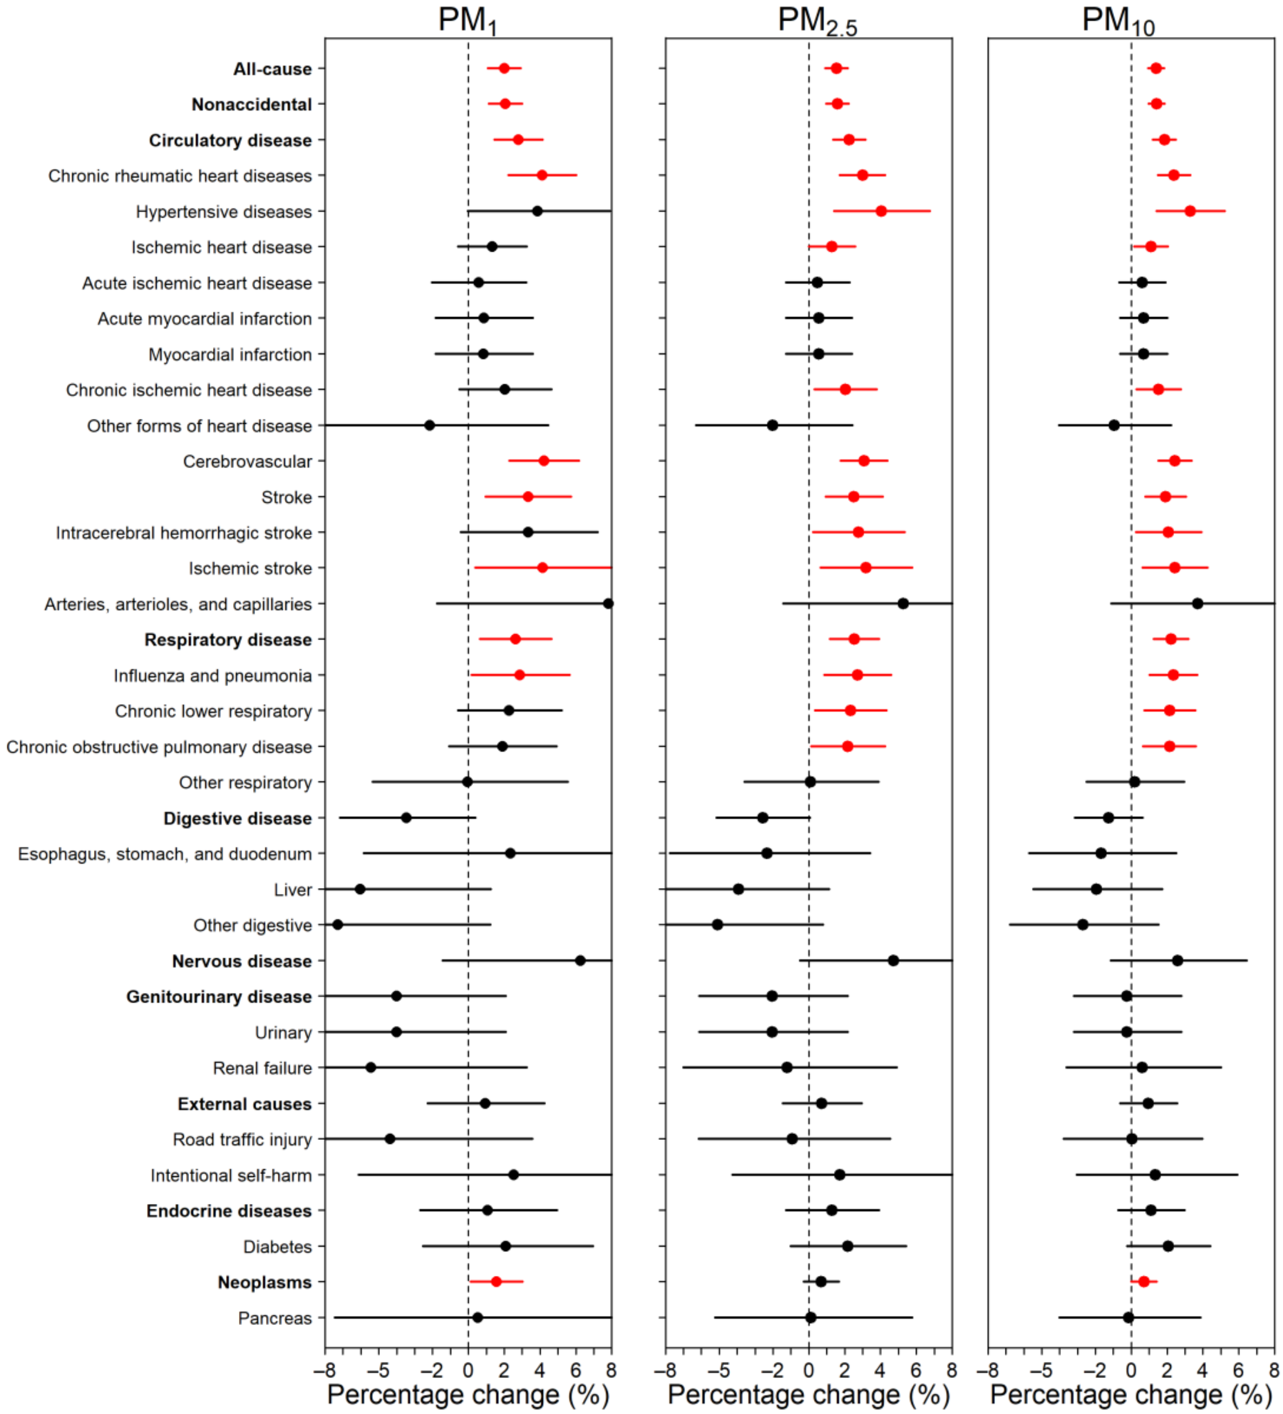
Figure 2. The concentration-response curves of size-fractionated particulate matters (PMs) and cause-specific mortality on lag days 0-3, using a 3-df smoothness for particulate matters. Red, blue, and black lines denote the PM_1-mortality, $PM_{2.5}$-mortality, and PM_{10}-mortality associations, respectively; the shaded areas represent the 95% CIs. RR: relative risk.



Diseases Sensitive to Size-Fractionated PMs

For every 10 μg/m^3 increment in 4-day average concentrations of PM_1, $PM_{2.5}$, and PM_{10}, the risk of all-cause mortality increased by 2.00% (95% CI 1.08%-2.92%), 1.54% (95% CI 0.93%-2.16%), and 1.38% (95% CI 0.95%-1.82%), respectively. The increments in nonaccidental mortality were similar across the 3 PMs (2.06%, 1.59%, and 1.41%). The largest effect estimates were observed for cardiovascular diseases (2.78%, 2.25%, and 1.85%) and respiratory diseases (2.61%, 2.53%, and 2.21%). The association between size-fractionated PMs and deaths from neoplasms were marginally significant, with effect estimates of 1.55% (95% CI 0.11%-3.01%), 0.69% (95% CI –0.28% to 1.67%), and 0.71% (95% CI 0.01%-1.40%; Figure 3 and Table S4 in Multimedia Appendix 1). The effect estimates of all size-fractionated PMs were statistically nonsignificant for deaths from nervous system diseases, digestive system diseases, genitourinary diseases, external causes, and endocrine diseases. For specific subcategories, significant effect estimates of PMs were detected among deaths due to chronic rheumatic heart diseases, hypertensive and cerebrovascular diseases, stroke (notably ischemic stroke), influenza, and pneumonia.

Figure 3. Percentage change (%) of cause-specific mortality per 10 μg/m3 increase in PM_1, $PM_{2.5}$, and PM_{10} on lag days 0-3. For each cause, point estimates (dots) and 95% CIs (horizontal lines) are shown. Red lines indicate statistically significant estimates. PM: particulate matter.



PMs' Effects on Mortality by Season and Individual Characteristics

In the subgroup analyses by season, age, and gender, we found a slightly greater impact of PM_1 on mortality in hot months compared to cold ones. The mortality risk of PM_1 was higher among older people, particularly for those aged ≥85 years. The effect estimates of PM_1 were slightly stronger in female individuals compared to their male counterparts for overall and nonaccidental mortality and deaths from neoplasms. However, the opposite trend was observed for cardiovascular diseases and respiratory diseases (Table 2). A similar trend by seasons and individual characteristics was observed for $PM_{2.5}$ and PM_{10} (Tables S5 and S6 in Multimedia Appendix 1). However, the differences in mortality risks of PM between subgroups (ie, season, age, and gender) were not statistically significant ($P>.05$).

Table 2. Percentage change in mortality per 10 μg/m3 increase in PM_1 on lag days 0-3, stratified by season, age group, and gender.

Variables	Causes of death (%, 95% CI)				
	All cause	Nonaccidental	Cardiovascular	Respiratory	Neoplasms
Total	2.00 (1.08 to 2.92)	2.06 (1.13 to 3.00)	2.78 (1.46 to 4.13)	2.61 (0.63 to 4.63)	1.55 (0.11 to 3.01)
Season					
Cold	1.66 (0.64 to 2.69)	1.74 (0.70 to 2.79)	2.14 (0.69 to 3.63)	2.56 (0.36 to 4.81)	1.29 (–0.35 to 2.96)
Hot	3.11 (1.31 to 4.94)	3.13 (1.29 to 5.00)	5.18 (2.44 to 8.00)	2.79 (–1.20 to 6.95)	2.27 (–0.38 to 5.00)
Age (years)					
0-64	1.22 (–0.24 to 2.70)	1.49 (–0.07 to 3.07)	2.21 (–0.83 to 5.34)	2.70 (–3.94 to 9.79)	0.61 (–1.46 to 2.72)
65-74	1.50 (–0.32 to 3.35)	1.47 (–0.39 to 3.36)	1.74 (–1.21 to 4.78)	–0.87 (–6.20 to 4.75)	2.55 (–0.30 to 5.48)
75-84	2.17 (0.73 to 3.63)	2.21 (0.75 to 3.69)	2.85 (0.84 to 4.90)	2.91 (–0.15 to 6.07)	1.04 (–1.58 to 3.74)
≥85	2.83 (1.22 to 4.47)	2.77 (1.14 to 4.42)	3.45 (1.23 to 5.72)	3.28 (0.33 to 6.31)	4.87 (0.17 to 9.78)
Gender					
Male	1.88 (0.81 to 2.97)	1.96 (0.86 to 3.08)	3.49 (1.81 to 5.20)	2.96 (0.41 to 5.57)	1.05 (–0.71 to 2.83)
Female	2.16 (0.90 to 3.44)	2.20 (0.92 to 3.50)	2.07 (0.26 to 3.90)	2.15 (–0.73 to 5.11)	2.43 (0.04 to 4.89)

As presented in Table 3, the excess all-cause deaths advanced by PM_1 were 7921 (95% eCI 4454-11,206), 6790 (95% eCI 3704-9611), 4899 (95% eCI 2696-6971), 3053 (95% eCI 1790-4393), and 1278 (95% eCI 711-1831), respectively, when the daily concentrations exceeded the target levels of 10, 20, 30, 40, and 55 μg/m^3. For $PM_{2.5}$, the excess death burden was 8303 (95% eCI 5063-11,248), 7194 (95% eCI 4183-9833), 5504 (95% eCI 3245-7620), 3717 (95% eCI 2242-5171), and 1352 (95% eCI 840-1861), with daily concentrations exceeding the WHO targets (15, 25, 37.5, 50, and 75 μg/m^3), respectively (Table S7 in Multimedia Appendix 1). For PM_{10}, 8326 (95% eCI 5980-10,690), 7565 (95% eCI 5130-9602), 4487 (95% eCI 3068-5843), 1991 (95% eCI 1360-2582), and 299 (95% eCI 209-384) deaths were caused, with daily concentrations exceeding the WHO targets (45, 50, 75, 100, and 150 μg/m^3), respectively (Table S8 in Multimedia Appendix 1). Therefore, 5.4%, 5.7%, and 5.7% of all deaths in Guangzhou were preventable by reaching the lowest target levels of PM_1, $PM_{2.5}$, and PM_{10}, respectively.

Table 3. The number of deaths from cause-specific disease (95% empirical CI) advanced by particulate matters (PM) with an aerodynamic diameter less than 1 µm (PM_1) with the concentrations exceeding the target levels from 2014 to 2016.

Cause of death	PM_1 targets (µg/m^3)				
	10	20	30	40	55
All cause	7921 (4454 to 11,206)	6790 (3704 to 9611)	4899 (2696 to 6971)	3053 (1790 to 4393)	1278 (711 to 1831)

Cause of death	PM_1 targets (μg/m^3)				
	10	20	30	40	55
Pancreas	17 (–275 to 254)	14 (–289 to 212)	10 (–186 to 153)	6 (–102 to 87)	2 (–37 to 31)

Sensitivity Analyses

In the sensitivity analyses, when we used 3-6 dfs for relative humidity, mean temperature, and air pressure and spline function with 5-9 dfs per year for calendar days, the effect sizes remained stable. In the two-pollutant models, after separately including ozone, sulfur dioxide, and carbon monoxide in the main model, the effect estimations of PMs on mortality remained similar and statistically significant (Figures S5-S7 in Multimedia Appendix 1).

Discussion

Principal Findings

To the best of our knowledge, this is the first investigation to assess the associations between size-fractionated PM exposure and deaths from a wide range of causes within the same population. In comparison to PM_{10} and $PM_{2.5}$, we observed a stronger association between PM_1 and mortality risk from cardiorespiratory diseases and neoplasms. Among more specific diseases, significant effect estimates of PM_1 were found among deaths due to hypertensive diseases, chronic rheumatic heart diseases, stroke (notably ischemic stroke), influenza, and pneumonia. Over 5% of all deaths were caused by PMs, with the daily concentrations exceeding the target levels in the WHO's air quality guidelines.

Comparison With Prior Work

Consistent with previous research [8,26-28], we found that the health risk increased with the shrinkage in PM size, with PM_1 ranking the highest in effect estimates. For instance, Zhang et al [8] revealed that for every 10 μg/m^3 increment in PM_1, $PM_{2.5}$, and PM_{10}, the hospital admissions due to cardiovascular diseases increased by 6.7%, 4.5%, and 3.4%, respectively. This gradient in health risk might be mainly attributed to the different particle sizes of PMs, which affect their deposition and absorption in the lungs [7,29]. As the particle size decreases, the surface area increases, leading to a greater catalytic effect on the generation of active oxygen. Smaller molecular size is also conducive to cell absorption, which may further cause the production of high reactive oxygen species, DNA damage, and an increase in interleukin 8 [30]. It is important to note that the relationships between size-fractionated PMs and cause-specific mortality were mostly monotonical in our study, suggesting no safe threshold for these PM pollutants and that any efforts to reduce the PM levels could achieve appreciable health benefits.

A large number of diseases were susceptible to size-fractionated PMs in our study, most of them originating from cardiorespiratory systems. Previous studies mainly focused on the broad categories of diseases and found similar results—the mortality risk was highest for circulatory and respiratory diseases in general [9]. For the subcategories of causes of deaths, significant impact was detected among deaths due to hypertensive diseases, chronic rheumatic heart diseases, stroke (notably ischemic stroke), influenza, and pneumonia for all size-fractionated PMs. This highlights the importance of prioritizing resource allocations during exposure periods and raising awareness of self-protection among patients with these diseases.

It is interesting to note the positive association between PMs and cancer mortality. Attribution bias might partially explain this finding, that is, the incorrect recording of cause of death as cancer, rather than recording the actual causes, if there is a diagnosis of cancer in a person's medical history. In other words, the risk of dying from comorbidities (eg, cardiorespiratory diseases and infection) in patients with cancer increases during highly polluted days, but the cause of death may be falsely assigned to cancer. This bias is almost inevitable, even in developed countries, where death registration data are fairly good [31]. Meanwhile, we cannot exclude the possibility that there is a true relationship between short-term exposure to PMs and cancer mortality. Indeed, there are studies showing the acute impact of PMs on cancer hospitalization and mortality [32,33]. However, we acknowledge that the underlying mechanism remains poorly characterized. Although it is unknown whether this elevated risk of death among patients with cancer is due to competing mortality or cancer-specific mortality, the message is clear—patients with cancer could be vulnerable when exposed to air pollution, and significant efforts are needed to raise awareness among these populations and provide the much-needed protective measures.

Furthermore, the association of size-fractionated PMs with mortality varied by season, age group, and gender. The mortality risks of PMs were stronger during warm seasons, which is in line with previous findings [6,9]. The sources of PMs varied at different temperature levels, and PM_1 may be present in more toxic forms in warmer seasons, potentially transmiting faster and staying longer in the air [34]. During warm seasons, people are prone to open windows and go outdoors more frequently [35], and the absorption of air pollutants may also be enhanced through the temperature regulation system (eg, by increasing sweating, minute ventilation, and cardiac output) [34]. People aged 85 years and older were the most vulnerable to PMs. With the rapid aging in Guangzhou, the death burden is set to increase if stricter controls on air pollution are unavailable in the coming years. The gender effect varies by different health outcomes. For instance, Hu et al [6] (2018) and Yin et al [9] (2020) found that the effect of PM_1 on all-cause mortality among female individuals was larger than that in their male counterparts. Yin et al [27] (2020) reported a stronger impact of PM_1 on male individuals for circulatory diseases. The varying impact of PMs between genders may be partly explained by the biological differences between male and female individuals, such as different gas-blood barrier permeability, particle deposition efficiency, and hormonal status [27]. Another reason may be due to between-gender demographic and behavioral differences, including occupational type, smoking, and lifestyle, which may modify the PM-mortality relationship [6].

Limitations

Some limitations of this study need to be noted. First, there might be diagnostic errors, and therefore, misclassification in the specific causes of death. However, the influence is likely to be small in our study because several quality control measures are available in the Guangzhou death registration system to ensure the accuracy of death classifications [36]. Second, we estimated the death burden of size-fractionated PMs by using several recommended target levels as the reference. However, since no safe threshold was detected for all PMs, our calculations are largely conservative in terms of the health benefits that can be achieved by reducing PMs levels. Finally, as an ecological study, we were unable to explore the individual-level PM-mortality association or control for potential covariates at an individual level, such as smoking habits and occupational exposures. Therefore, the causal relationship cannot be tested in our study. Our study was mainly intended to generate hypotheses on their association, and further research is warranted to test and validate these findings.

Conclusions

Our study indicates that smaller particles are more hazardous to human health. Among specific diseases, significant effect estimates of PM_1 were found for deaths due to hypertensive diseases, chronic rheumatic heart diseases, stroke, influenza, and pneumonia. Our findings highlight the importance of size-based strategies in the control of PMs and management of their health impact.

Acknowledgments

This study was supported by the National Natural Science Foundation of China (grants 82003552 and 82204131), Guangdong Basic and Applied Basic Research Foundation (grant 2021A1515110625), and Guangzhou Science and Technology Planning Project (grants 202201011243 and 202201011617).

Abstract

Background: Soil-transmitted helminths (STHs) are widely distributed throughout the world. Various factors, including the environment, socioeconomic characteristics, and access to water and sanitation, play an important role in the spread and persistence of these parasites within communities. They, in turn, affect the growth and development of members of the community, especially children. Studies in the northern provinces of Argentina have shown variable prevalence of STHs, but the factors associated with their presence have not been completely elucidated.

Objective: This cross-sectional study aimed to identify the socioeconomic and environmental factors related to STH infection in indigenous villages located in Puerto Iguazú (Misiones), Argentina.

Methods: Between 2018 and 2019, stool samples were collected from individuals ≥1 year residing in 3 villages: Mini-Marangatú, Yriapú, and Fortín Mbororé. Standard parasitological methods were used to determine STH prevalence. Standardized questionnaires were used to assess participants' habits, customs, and household characteristics, and environmental data were obtained through satellite imagery. Multilinear regression with Akaike information criterion stepwise variables was used to explore relevant associations.

Results: A total of 342 individuals from the 3 villages participated in this study. The prevalence of STHs varied across villages: 89.6% (43/48), in Mini-Marangatú, 80.8% (101/125) in Yriapú, and 68.5% (115/169) in Fortín Mbororé. Notably, there was a significant difference in hookworm infection among the villages (*P*=.02). The analysis highlighted the significant influence of specific environmental factors on STH presence and spatial distribution, particularly in relation to hookworm infection. Vegetation patterns represented by the Vegetation Heterogeneity Index, created ad hoc for this study, emerged as a critical factor, with 2 significant predictors related to it (*P*=.002 and *P*=.004) alongside impervious surface density with a significant predictor (*P*<.001). The multilinear regression model yielded a high *F* test score (F_{108}=4.75, *P*<.001), indicating a strong fit (R^2=0.5465). Furthermore, socioeconomic factors, including walking barefoot in houses with dirt floors and overcrowding, were significantly correlated with hookworm infection intensity (*P*<.001 and *P*=.001, respectively). We also used the multilinear regression model to calculate hookworm infection intensity (F_{110}=21.15, *P*<.001; R^2=0.4971).

Conclusions: Our study underscores the complexity of STH transmission, as villages with similar living conditions and environmental characteristics displayed varied STH prevalence and spatial distribution. Specific environmental factors, such as vegetation pattern and impervious surface density, played major roles in STH presence, demonstrating the crucial relationship between environmental factors and hookworm infection distribution. Moreover, our findings emphasize the significant influence of socioeconomic factors on hookworm infection intensity. By gaining insights into this complex interplay, our research contributes to a better understanding of STH transmission characteristics, thereby informing targeted public health interventions for effective control.

KEYWORDS

soil-transmitted helminths; hookworm; prevalence; intensity: distribution: Iguazú; Argentina

Introduction

Soil-transmitted helminth (STH) infections are the most prevalent among the neglected tropical diseases (NTDs) worldwide, affecting over 1.5 billion people as of 2023 [1]. These diverse diseases have an enormous impact on individuals, families, and communities in low- and middle-income countries, and they constitute a serious obstacle to socioeconomic development and quality of life, leading to loss of productivity and exacerbating poverty [2]. NTDs are mainly prevalent in tropical and subtropical areas, where they mostly affect impoverished communities and disproportionately affect women and children [2,3]. STHs are intestinal parasites (IPs), with the most common species affecting humans being *Ascaris lumbricoides*, *Trichuris trichiura*, and the hookworms *Necator americanus* and *Ancylostoma duodenale* [4]. Although *Strongyloides stercoralis* is a common STH in Latin America and the Caribbean, it is not included in this group due to its complex life cycle and specific characteristics for diagnosis, quantification, and treatment [5,6].

Previous studies have shown the involvement of different factors in the transmission of STHs, including socioeconomic factors, such as the Human Development Index; nutritional and immunological factors; and environmental factors, such as the Normalized Difference Vegetation Index (NDVI) and the Enhanced Vegetation Index (EVI) [7-9]. All these factors exert an economic impact on the population and thus also play a role in the perpetuation of poverty [10,11].

Argentina has a heterogeneous prevalence of STHs (between 0% and 88.9%) throughout the country, and the northeast and northwest provinces of Misiones, Chaco, or Salta are identified as endemic [12-16], with varying rates of infection depending on socioeconomic status, sanitary and environmental conditions, and access to water [16-19]. Despite its high prevalence of STHs, Argentina does not currently have a deworming program as approved by the World Health Assembly (WHA) through resolution WHA54.19 [20].

The Misiones province is composed of 10,218 indigenous people from the Mbyá-Guaraní ethnic group distributed among 116 communities that live mostly in rural areas [21,22] under precarious and poor sanitary conditions, with high rates of malnutrition among children [17]. IPs are highly endemic in this area, especially among indigenous communities [23], with varying prevalence rates depending on age, hygiene habits, access to water and basic sanitation, and nutritional conditions, among others [16,17,24]. These factors can cause or aggravate malnutrition, leading to anemia and growth delays in children [18,25].

Geographic information system (GIS), remote sensing (RS), and digital elevation model (DEM) technologies provide information to identify and analyze determinants of disease distribution, thereby facilitating the development of risk prediction models in relation to environmental variables. This, in turn, aids the design of strategies to identify and prevent these infections. In this study, we collected parasitological and socioeconomic data from different Mbyá-Guaraní villages of Puerto Iguazú, Misiones, Argentina, as well as environmental variables, to determine the main factors associated with STH infection in this region.

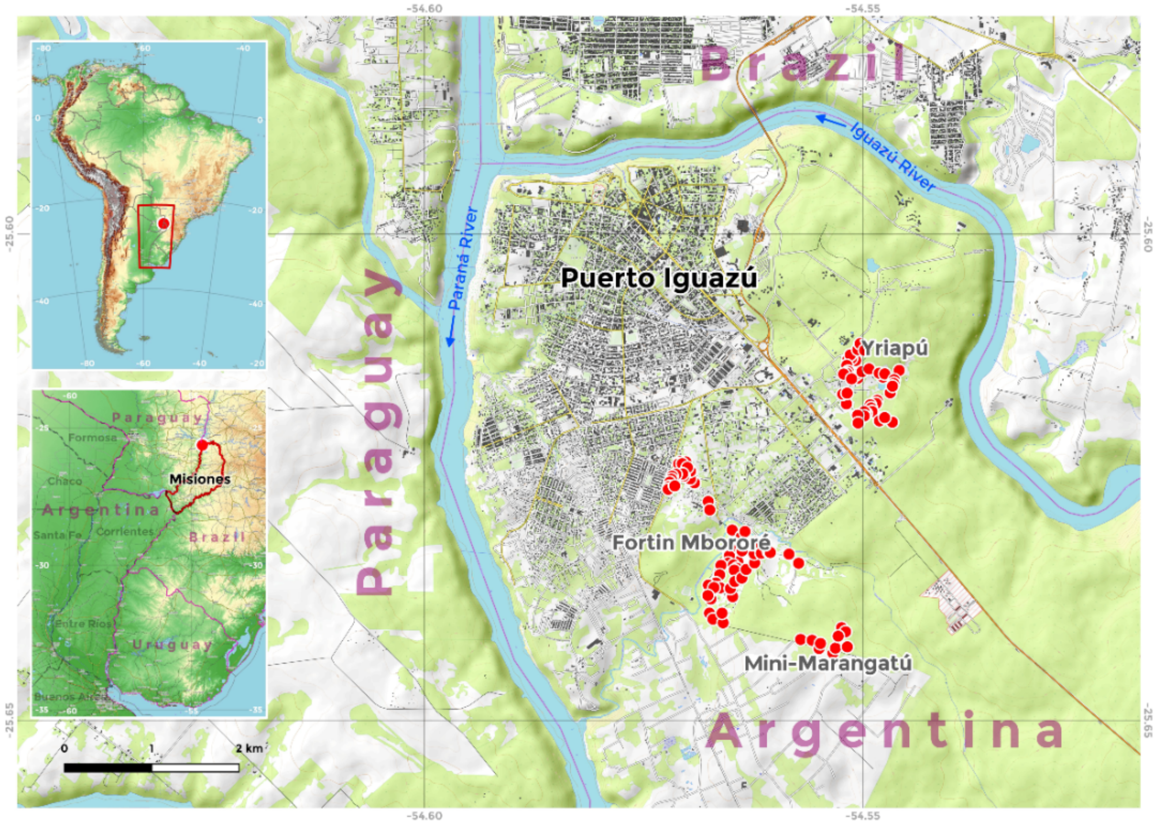
Methods

Study Area

Puerto Iguazu is a city located in the province of Misiones in northeastern Argentina. It is naturally divided by the Paraná and Iguazú Rivers, which act as the physical borders between Argentina, Brazil, and Paraguay. According to the most recent national census data, the city has over 42,800 inhabitants [26].

This study was carried out in the rural area of Puerto Iguazú, around the city´s periphery, where Mbyá Guaraní indigenous communities have settled into 3 villages: Fortín Mbororé, Mini-Marangatú, and Yriapú. Previous studies in this area have shown a high prevalence of IPs, specifically STHs [12,16,27]. Moreover, these villages are adequately sized to enable the enrollment of enough participants to explore the relationship between STH infection and its determinants, with 200 families in Fortín Mbororé, 35 in Mini-Marangatú, and 100 in Yriapú (Figure 1).

Figure 1. Map of the study area. Points represent each of the georeferenced households from the 3 villages included in the study, Fortín Mbororé, Mini-Marangatú, and Yriapú, which are adjacent to Puerto Iguazú, Misiones, Argentina. Map created using QGIS with overlay imagery from OpenTopoMap (CC-BY-SA) via the QuickMapServices plugin (version 0.19.29). Copyright belongs to OpenStreetMap contributors [28]. Map data are from August 27, 2021.



The family subsistence economy of the communities that participated in this study is from guided tours organized to visit the village, handcrafts, and social plans [12]. These communities share similar water and sanitation conditions and are homogeneous in their economic status, with low monthly incomes. Living conditions are characterized by a lack of water and sanitation [19]. Houses are scattered, surrounded by vegetation, and made of adobe bricks with unimproved roofs and dirt floors.

Study Design

Stool samples were collected from participants from all 3 villages. The households were visited, georeferenced, and characterized using a questionnaire. Stool containers were provided, along with verbal instructions on how to collect the samples, and retrieved on the following day. The fresh samples were transported without a fixative in a refrigerated icebox and kept at 4 °C in the lab until analysis within 24 hours of collection. The inclusion criteria were based on age (participants had to be at least 1 year of age) and willingness to participate, evidenced through the informed consent process. Individuals who lived or worked for long periods of time outside the study area and those with conditions that impaired an understanding of the consent process were excluded from the study. Considering that the area is in the tropical forest biome, which involves deforestation of tropical and subtropical forests for agriculture, the extension of grasslands may affect the viability of STH eggs and larvae. Nevertheless, several publications have suggested that the forest mass is in the process of forest transition, where the recovery of natural systems such as forests is taking place [29].

Ethics Approval

The institutional review board of the Ministry of Health of the Province of Misiones approved this study protocol and consent forms (171403/2018). Written consent was obtained from all the parents/guardians for children under 16 years of age. All individuals aged 16 years and older are considered adults in Argentina; therefore, written consent was obtained from them directly.

Parasitological Analysis

The collected stool samples were analyzed using the Ritchie concentration technique, Baermann concentration, and Kato-Katz technique to measure the infection intensity of STH, as previously described [12]. The parasitological parameters used were the prevalence of IPs and the intensity of STH infections in eggs per gram of feces.

Living Conditions and Environmental Characterization

Habits, customs, and household characteristics were analyzed at the household level using GIS. The variables, which were collected using a standardized questionnaire, are summarized in Table 1.

Table 1. Variables analyzed at individual, household, and village levels.

Variables	Description	Results
Education	Education level of household inhabitants	From none to university level
Income	Source of income	Formal employment, public sector, tourism, animal farming, crafts, and social plans, among others
Animal farming	Presence of pets or animal farming	Dogs, cats, chickens, pigs, ducks, and other
Health coverage	Type of health insurance	Public system, private health insurance, and prepaid health insurance, among others
Household characteristics		
Roof	Type of material	Wood, branches, adobe, and metal sheets
Wall	Type of material	Wood, cement, dirt, bricks, and adobe
Floor	Type of material	Wood, dirt floor, cement, and smoothed floor
Electricity	Source of electricity	None, public network, generator, and other
Water source	For human consumption, cooking, or washing	Borehole, tap water, well, and other
Water treatment	Any type of treatment	Boiling, chemical treatment, and other
Excreta disposal	Excretal disposal	Open defecation or latrine
Cooking	Source of heat for cooking	Gas stove or oven, electric stove, wood stove, and other
Garbage disposal	Type of disposal	Municipal system, burning, burying, and other
Behavioral aspects		
Barefoot	Use of footwear	Yes or no
Hand washing	Practice of handwashing before eating and after defecation	Yes or no

Environmental and geographical data were collected using RS together with DEM. From the RS, the Soil-Adjusted Vegetation Index (SAVI), Vegetation Heterogeneity Index (VHI), Enhanced Normalized Difference Impervious Surfaces Index (ENDISI), and Bare Soil Index (BSI) were obtained. From the DEM, the Topographic Position Index (TPI) and Topographic Wetness Index (TWI) were calculated. The characteristics and sources of these indices are detailed in Table 2 and Multimedia Appendix 1.

Table 2. Environmental and geographical indices used to determine their association with the presence of soil-transmitted helminths (STH) in villages from Puerto Iguazú, Misiones, Argentina.

Index	Source	Characteristics
Topographic Position Index [30]	30-m resolution DEM[a] from the IGN[b] [31]	• This index measures the altitude of a point with respect to its surrounding area. • Positive values indicate that the central point is located higher than its average surroundings (such as ridges and hilltops), negative values indicate a position lower than the average (valley and sinkholes), and a near-zero value indicates a flat or continuous slope. • The index used is a multiscale mean of 100-, 200- and 500-meter radii.
Topographic Wetness Index [32]	30-m resolution DEM from IGN [31]	• It identifies potential points of water accumulation (humidity) based on topographic elements. • This index is used as a proxy for the measurement of soil humidity.
Soil-Adjusted Vegetation Index [33]	2019 mean annual surface reflectance from Sentinel 2 imagery [34], retrieved and processed with GEE[c] [35]	• This is a modification of the Normal Density Vegetation Index, which corrects for the brightness of the soil when vegetation is scarce. • It is used to estimate the quantity, quality, and development of vegetation through RSd.
Vegetation Heterogeneity Index	2019 mean annual surface reflectance from Sentinel 2 imagery [34], retrieved and processed with GEE [35]	• The index is used to identify areas of more or less vegetation with respect to their surroundings (80 m radius). • The SD of these values was also mapped to show the heterogeneity of the vegetation in the study area. Low values indicate a subtle variation, while high levels show abrupt changes in the vegetation around each household.
Enhanced Normalized Difference Impervious Surfaces Index [36]	2019 mean annual surface reflectance from Sentinel 2 imagery [34], retrieved and processed with GEE [35]	• It detects impervious surfaces (buildings, asphalted roads, etc). • A threshold of 0.15 was applied to set a value of 1 for impervious areas and 0 for other surfaces. • This binary map was used to get a map with the imperviousness index within a radius of 500 m for each household, with continuous values from 0 to 1.
Bare Soil Index [37]	2019 mean annual surface reflectance from Sentinel 2 imagery [34], retrieved and processed with GEE [35]	• This index combines blue, red, and infrared bands to capture variations in the soil. • Short infrared and red bands are used to quantify the mineral composition of the soil, while blue bands and infrared bands are used for vegetation cover. • Values range between −1 and 1, with higher values indicating bare soil.

Statistical Analyses

Data were analyzed using Stata 12 software (StataCorp) and RStudio (R Foundation for Statistical Computing). Measures were evaluated using proportion with 95% CIs and means with SDs. The chi-square test was used to compare significant associations between different variables. The age variable was categorized into 5 groups: group 1 (0-5 years), group 2 (6-10 years), group 3 (11-20 years), group 4 (21-40 years), and group 5 (>40 years).

To determine the spatial distribution of STH infection in the study area, an algorithm based on the kernel density estimation (KDE) [38-40] technique was used to identify areas where infection was more prevalent than expected, assuming a homogenous distribution (null hypothesis), by calculating the difference from it using the SD as the unit of measurement. Therefore, positive or negative values indicated higher or lower values of infection than expected under the null hypothesis. With the main results and this same method (a quartic kernel shape and bandwidth of 200 m), the distribution of other variables was calculated: intensity of hookworm infection, households with dirt floors where inhabitants walked barefoot, and households with overcrowding. Variables that showed a significant correlation with the presence and intensity of hookworm infection were then used in a multiple linear regression analysis [41]. Predictors of infection were selected using a stepwise method that selected the best predictors using the Akaike information criterion. Values were considered significant at *P*<.05, with a 95% CI. The full statistical report is available in Multimedia Appendix 2.

Results

Study Population

A total of 342 individuals from the 3 villages participated in this study and provided stool samples: 169 (49.4%) individuals from Fortin Mbororé, 125 (44.5%) from Yriapú, and 48 (14%) from Mini-Marangatú. The population distribution in the 3 communities was 53.8% (91/168) men and 46.2% (78/169) women in Fortin Mbororé, 56.8% (71/125) men and 43.2% (54/125) women in Yriapú, and 50% (24/48) for both sexes in Mini-Marangatú. The mean age of participants was 21 (SD 17.9) years in Fortin Mbororé, 10.4 (SD 11.43) years in Yriapú, and 15 (SD 12.21) years in Mini-Marangatú.

Prevalence of IPs

The overall prevalence of IPs in the 3 villages was 95.8% (46/48) in Mini-Marangatú, 95.2% (119/125) in Yriapú, and 91.1% (154/169) in Fortín Mbororé. Protozoan infection ranged from 87.5% (42/48) in Mini-Marangatú to 81.6% (102/125) in Yriapú, while helminth infections were highest in Mini-Marangatú (44/448, 91.7%), followed by Yriapú (104/125, 83.2%) and lower in Fortin Mbororé (126/169, 74.6%) (Table 3). The STH prevalence was 68.1% (115/169) in Fortín Mbororé, 80.8% (101/125) in Yriapú, and 89.6% (43/48) in Mini-Marangatú. Infection caused by *T. trichiura* was only detected in Mini-Marangatú village, with only 1 (2.1%) case, and no *A. lumbricoides* infections were detected in this village. The most prevalent STH was hookworm, reaching statistically different infection rates ($\chi^2_2=7.6$, $P=.02$) between the 3 villages: Mini-Marangatú (42/48, 87.5%), Yriapú (92/125, 73.6%), and Fortín Mbororé (114/169, 67.5%). The descriptive characteristics of STH infections in the 3 villages are provided in Table 3.

Table 3. Descriptive characteristics and prevalence of intestinal parasites in individuals from Fortin Mbororé, Yriapú, and Mini-Marangatú.

Characteristics	Fortin Mbororé	Yriapú	Mini-Marangatú
Age (years), mean (SD)	21 (17.9)	10.4 (11.43)	15 (12.21)

[a] —: not available.

Hookworm infection was higher in the age groups ranging from 0 to 5 years and from 6 to 10 years in Yriapú and lower in Fortin Mbororé, especially in the western area located near the urban area of Puerto Iguazú. Moreover, statistical differences between age groups were observed within Fortin Mbororé ($\chi^2_4=27.9$, $P<.001$) and Mini-Marangatú ($\chi^2_4=17.5$, $P=.002$). Mixed infections with different STH species were also observed (Tables 4 and 5), together with the intensity of infection. *Trichuris trichiura* and *A. lumbricoides* were present mainly as light-intensity infections. On the other hand, heavy-intensity hookworm infections were detected in all 3 villages. The highest rate of individuals with heavy infections (22/42, 52.4%) were found in Mini-Marangatú, but no statistical differences were observed between the types of intensity.

Table 4. Intensity of soil-transmitted helminth (STH) infections in individuals from Fortin Mbororé, Yriapú, and Mini-Marangatú.

Infections	Fortin Mbororé, n (%)			Yriapú, n (%)			Mini-Marangatú, n (%)		
	Light	Moderate	Heavy	Light	Moderate	Heavy	Light	Moderate	Heavy
Hookworm	67 (58.8)	12 (10.5)	35 (30.7)	61 (66.3)	11 (12)	20 (21.7)	15 (35.7)	5 (11.9)	22 (52.4)

Living Conditions

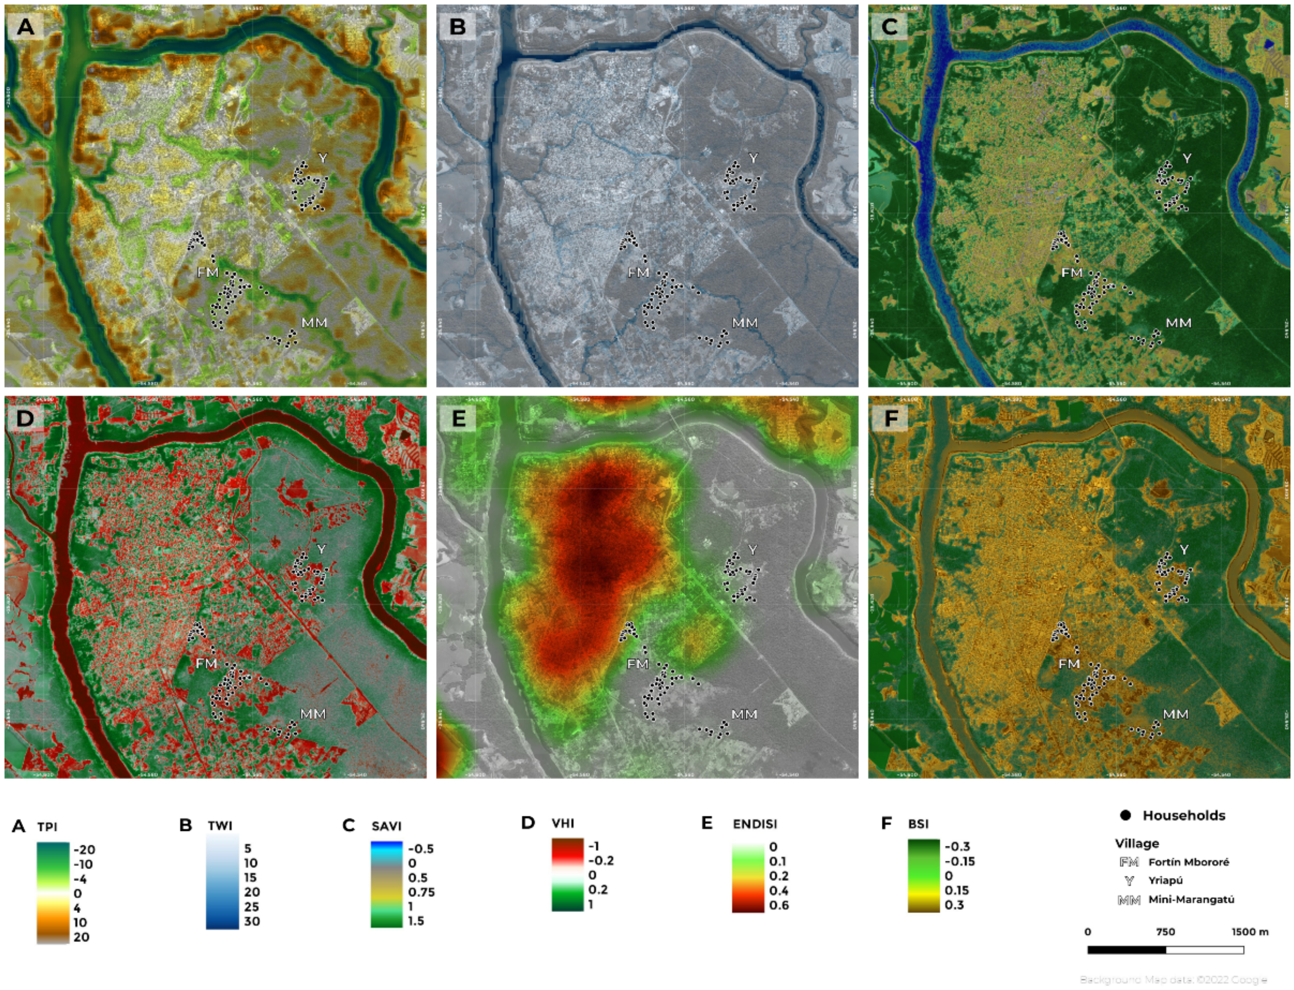
Living conditions between the villages were usually similar. The average number of inhabitants per household was 5.3 for Fortin Mbororé, 5.1 for Yriapú, and 5.8 for Mini-Marangatú. Most households had a single room for sleeping; therefore, overcrowding was common. Generally, houses were made of wooden walls and dirt floors—90% (43/48) in Mini-Marangatú and 50% (61/121) in Yriapú. In the case of Fortin Mbororé, this figure was reduced to 35% (58/166) since 40% (66/166) of the households had cement floors. Practically the entire population, both children and adults from all 3 villages, walked barefoot. Although 22.9% (38/166) of households practiced open defecation, most had a latrine that consisted of a simple ground excavation. With respect to the source of drinking water, all the families in Mini-Marangatú obtained their water from boreholes, along with 75% (92/121) in Yriapú and 49% (81/166) in Fortin Mbororé. Family incomes were low and precarious, mostly coming from animal farming, crafts, or social plans. In the newer village of Mini-Marangatú, which branched off from Fortin Mbororé, 60% (99/166) of the families obtained their income from crafts.

Only the type of floor was observed to be associated with hookworm transmission, with a significantly higher prevalence of hookworm found in individuals from Yriapú village living in dirt floor houses (χ^2_3=8.8, P=.03). Lack of sanitation and hygiene, water source, the use of a latrine with simple ground excavation, and source of income were not related to a higher prevalence of hookworms. Walking barefoot and living in overcrowding conditions were significantly related to the intensity of hookworm infection (P<.001 and P=.003, respectively; F_{110}=46.2, P<.001), indicating the significance of the model (R^2=0.46).

Environmental Characterization

Figure 2 shows the distribution of the different environmental indices in the study area. TPI helps discriminate between areas that are depressed and those that have some prominence and thus are less prone to accumulating water, and TWI detects hydrological flow paths and thus proximity to streaming water and other bodies of water. The values of these 2 indices indicate that the study area was irregular with depressed areas and small hills (Figure 2A), with many water courses running through it, including the Mbocay stream (Figure 2B). Yriapú is located at the edge of a slightly depressed area, while Fortin Mbororé is divided into 2 parts by the Mbocay stream. Both sides of the village are on flat ground. Mini-Marangatú is located close to the crest of a small hill.

Figure 2. Distribution of the different indexes used in the study area from Puerto Iguazú, Misiones, Argentina. (A) Topographic Position Index (TPI). (B) Topographic Wetness Index (TWI). (C). Soil-Adjusted Vegetation Index (SAVI). (D) Vegetation Heterogeneity Index (VHI). (E) Enhanced Normalized Difference Impervious Surface Index (ENDISI). (F) Bare Soil Index (BSI). Map created using QGIS with background imagery from Google Maps via the QuickMapServices plugin (version 0.19.29). Copyright 2021 Google. Map data 2021 Google.

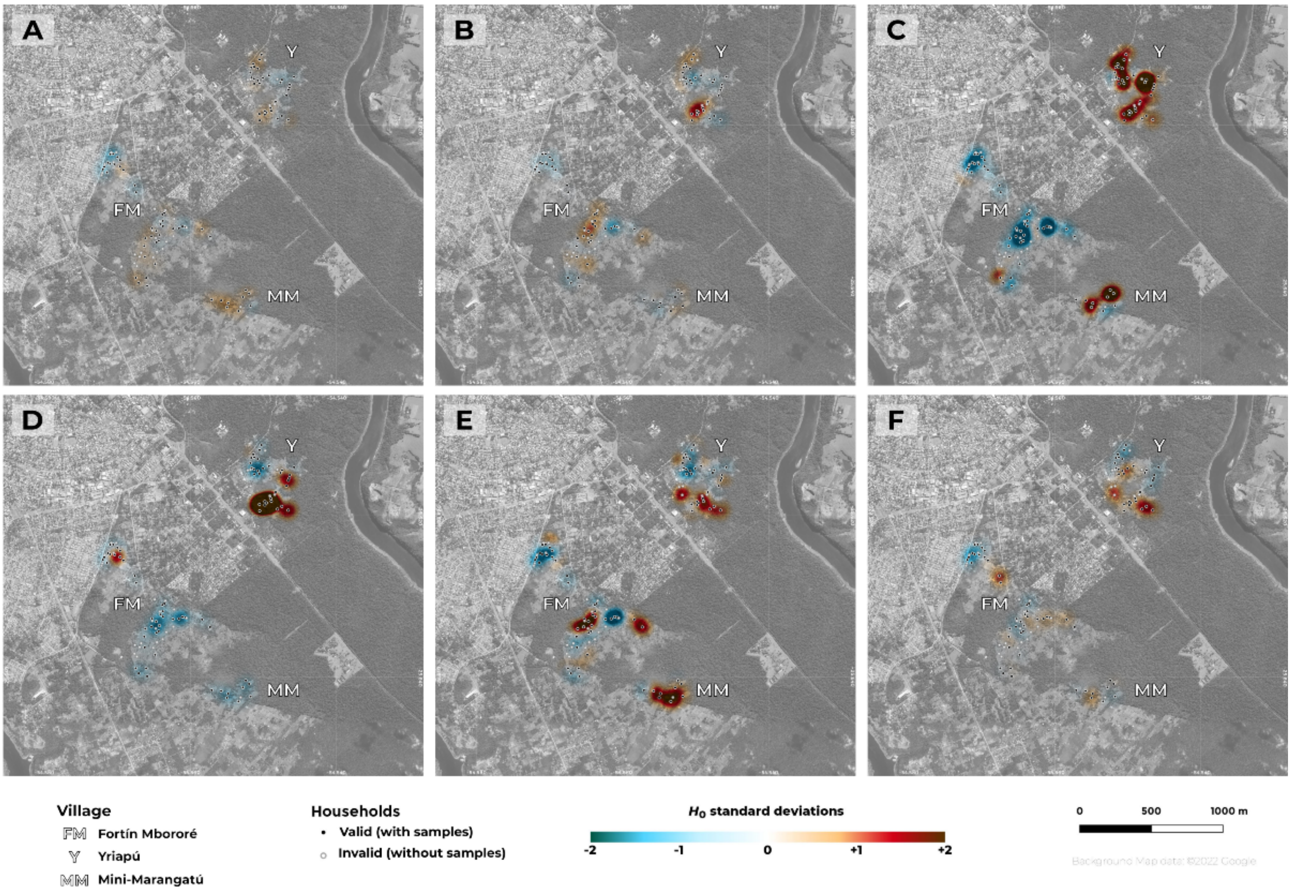


For the presence of vegetation, SAVI and VHI were used, with SAVI measuring vigor and VHI estimating the heterogeneity of the vegetation landscape. As depicted in Figures 2C and D, some differences in the distribution of the SAVI were observed between the villages. Western Fortin Mbororé had lower values than the central area of the village, while both Mini-Marangatú and Yriapú were surrounded by more vigorous vegetation (Figure 2C). Through the VHI, the difference between bare soil and the presence of vegetation was greatest in Mini-Marangatú and very small in Fortin Mbororé. The other 2 indices, ENDISI and BSI, were used to indicate the presence of bare soil (Figure 2E and 2F) but with different focuses: ENDISI on urbanized areas and BSI on natural soil. Again, Fortin Mbororé had a greater presence of bare soil around the houses, especially in the western area where households were located close to the urban city of Puerto Iguazú, whereas both Yriapú and Mini-Marangatú had patches of bare soil and vegetation.

Spatial Distribution of STH

The KDE technique was used to analyze the spatial distribution of STH in the study area and observe differences between the villages. As shown in Figure 3A, the distribution of hookworm-positive individuals was not entirely homogenous, and the differences in the SD were not pronounced and were present throughout the entire study area. There was a slight concentration of cases in Mini-Marangatú, followed by Yriapú. Some differences were observed within Fortin Mbororé, where households closer to the urbanized area of Puerto Iguazú (northwest) had lower values than those farther away (southwest).

Figure 3. Spatial distribution obtained using the kernel density estimation (KDE) technique for (A) hookworm infection, (B) hookworm intensity, (C) Strongyloides stercoralis infection, (D) Ascaris lumbricoides infection, (E) households with dirt floors where inhabitants walk barefoot, and (F) households with overcrowding. Map created using QGIS with background imagery from Google Maps via the QuickMapServices plugin (version 0.19.29). Copyright 2021 Google. Map data 2021 Google.



With respect to the intensity of hookworm infection (Figure 3B), positive cases from Yriapú were mostly of light intensity, while higher-intensity cases were clustered only in the southern area of Yriapú. Although the prevalence of other STH was lower than that of hookworm, the KDE analysis also showed a heterogeneous distribution, with a marked difference in the SD of *S. stercoralis*, showing a high concentration of positive cases in Yriapú and Mini-Marangatú compared to Fortin Mbororé (Figure 3C). *Ascaris lumbricoides* infections were detected mostly in Yriapú village (Figure 3D).

Figure 3E shows the distribution of households with dirt floors and individuals who usually walk barefoot. Given that many houses in Fortin Mbororé had cement floors, the difference in the SD was more evident in Mini-Marangatú and southwestern Fortin Mbororé compared to Yriapú. The distribution of households with overcrowding (Figure 3F) was homogeneous in the study area, although there was a clustering in Yriapú.

The multivariate model used to identify the factors most related to the distribution of hookworm in the study area selected the following predictors: mean VHI, SD of VHI, and ENDISI and households with dirt floors and individuals who walk barefoot. In this model, only the environmental variables were significantly associated (P<.001) with the presence of hookworm infection, which explained 56% (248/342) of the variability observed in the distribution of cases in the study area (F_{108}=34.75, P<.001). The predictors for hookworm intensity selected by the multivariate model were the distribution of dirt floor households with individuals that walked barefoot and households with overcrowding. Both variables showed a significant association (P<.001) with the intensity of hookworm infection and predicted 45% (153/342) of the variability observed in the distribution of the cases.

Discussion

Principal Findings

This study uncovers factors associated with the presence and intensity of STH infection, especially hookworm, in rural areas of Puerto Iguazú. The high prevalence observed coincides with previous studies in other rural areas of the region [5,15,42,43], as well as a higher prevalence in the infant population [3,5]. Hookworm prevalence was above 70% in all villages (114/169 in Fortín Mbororé, 92/125 in Yriapú, and 42/48 in Mini-Marangatú), with the highest prevalence observed in Mini-Marangatú, located in the easternmost area.

In the multivariate analysis for hookworm infection, barefoot walking and overcrowding were implicated in an increase in the intensity of infection, while the type of household floor material was associated with an increase in transmission. These results coincide with those already observed in other studies [12,44,45]. Although other studies indicate that hygienic conditions, water, type of latrine, and level of education are related to a higher hookworm prevalence [16,19,46-48], in this study, these factors did not show statistical significance. These different results may be due to the uniformity of these variables throughout the different villages since most of the households shared the same characteristics. Moreover, although the villages were independent population centers managed by their own community leader or cacique, they were relatively close to each other, thus sharing similar environmental and economic conditions.

Since hygienic conditions have been shown to greatly influence transmission through the fecal-oral route [19], as in the case of *A. lumbricoides*, the proximity to the Mbocay stream in the villages of Fortin Mbororé (eastern zone) and Mini-Marangatú could have generated different *A. lumbricoides* infection rates between the villages. In addition, the high density of construction observed in the western area of Fortin Mbororé, through the ENDISI, may have affected the transmission of this parasite, given that low humidity can hinder egg embryonation [9].

With respect to environmental factors and their predictors, previous studies have highlighted the role of humidity, temperature, and soil type in the transmission of STH [16,45,48,49]. Higher humidity and temperature have been shown to be favorable conditions for the survival of heterogonic stages of *S. stercoralis* [50,51]. A joint analysis of the TPI and TWI allowed us to determine that the village of Yriapú is situated in a depressed area with higher humidity accumulation, which could be a factor behind the high prevalence of *S. stercoralis* observed in this village. Available studies also show the association of humidity and vegetation indices in the prevalence of *S. stercoralis* [52].

To analyze the effect of vegetation on the transmission of STH, the VHI, which was developed specifically for this study, helped identify areas with more or less vegetation with respect to each surrounding household. The algorithm is similar to the TPI; however, instead of elevation, the data source is a vegetational index (in this case, SAVI). High values of this index around households were associated with increased hookworm infection, which indicates the importance not only of the vigorousness of vegetation but also its distribution pattern in the landscape of the study area. High values of this index around the Mini-Marangatú households coincided with the highest prevalence of hookworm in this area. These vegetation and humidity indices, which demonstrate the influence of vegetation on hookworm distribution, coincided with the risk of hookworm infection in areas of VHI values reported in other studies [44,49,53].

Previous studies suggested that infection is more probable in households surrounded by bare soil, among other factors [52,54-56]. Fortin Mbororé has bare soil surrounding its houses, especially in the western area located close to the urbanized area of the city. Although bare soil is an environmental factor that has been shown to be associated with STH infections, this area had lower hookworm infection rates.

The ENDISI aids in detecting impervious surfaces, particularly the amount of water stored. The survival of hookworm larvae depends on the soil's water-retaining properties. When the soil dries out, the water is restricted to the thin film around individual soil particles, and the infective larval stage remains quiescent in the moisture film until it makes contact with its host [57]. The lower hookworm infection rates observed in Fortin Mbororé may be because this area is highly influenced by the ENDISI since urban development and infrastructure density modify soil permeability and moisture. This can have a negative effect on the persistence and survival of this type of parasite, which requires humidity to survive and develop its larval stages [51,58].

In general, villages sharing similar living conditions and environmental characteristics contributed to the high infection rates observed. This study demonstrated that living conditions play a role in the intensity of hookworm infection, and environmental variables are significantly associated with its presence. However, the specific differences observed in certain areas aid in elucidating how human development and social and sanitary conditions may influence lower infection rates among individuals and villages located in endemic areas. Evidence from previous studies and the results obtained herein show that environmental factors such as temperature, vegetation, and humidity play a role in the presence and maintenance of STHs in the soil. Therefore, environmental changes caused by climate change could modify the distribution of these parasites, although deforestation, bare soil, high temperature, and lack of humidity could restrict their presence.

The limitations of this study include the sensitivity of the techniques used to detect STHs since low burdens of infection could be missed. Additionally, in this area, hookworm was the most prevalent STH; therefore, studies conducted in areas with a greater presence of other species of the group would be beneficial. Further studies in more heterogeneous communities with similar environmental characteristics could help aid our understanding of the socioeconomic and building characteristics that determine the presence and intensity of STH infections.

Conclusion

This study, conducted in an endemic area for STHs, especially hookworms, reinforces the importance of the environment in the establishment of this group of parasites, which require passage through the soil for their development. Additionally, we observed that living conditions, like walking barefoot, having dirt floors, or overcrowding, are associated with the intensity of hookworm infection. Given that environmental variables cannot be changed, it is important to work on those aspects that can be modified, such as the characteristics of the house, the availability of water and sanitation, and periodic deworming as suggested by the World Health Organization deworming guidelines [59].

Acknowledgments

We appreciate the participation of the community from Fortín Mbororé, Yriapú, and Mini-Marangatú and permission to work in the village from their leaders (caciques). We would like to thank all our colleagues from Mundo Sano's office in Iguazú for collaborating with us on the study logistics and data collection. Finally, we would like to acknowledge the institutional support from Marcelo Abril (Mundo Sano) and Marcelo Scavuzzo and his team from Instituto de Altos Estudios Espaciales "Mario Gulich," Comisión Nacional de Actividades Espaciales (CONAE).

Data Availability

Data supporting the conclusions of this article are included within the article. The datasets used and/or analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

EC carried out laboratory analyses, analyzed and interpreted the data, and wrote the draft of the manuscript. CG was involved in the acquisition of data and community relations with the cacique. LS developed, analyzed, and interpreted the mathematical models as well as the figures. CMA was involved in the conception and design of the study, analysis, and interpretation, and revising the final draft of the manuscript. MVP was involved in the conception and design of the study, acquisition of data, analysis and interpretation, and revision of the final draft of the manuscript. All authors read and approved the final manuscript.

Abstract

Background: According to previous reports, obesity especially visceral fat has become an important public health problem, causing an estimation of 20.5 disability-adjusted life years per 1000 inhabitants. Those who exercised for 1 or 2 days per week and reached the recommended 150 minutes of moderate physical activity (PA) per week have been defined as "weekend warriors" (WWs). Although the benefits of PA in suppressing obesity have been widely studied, the association of WWs with the Visceral Adiposity Index (VAI) and the difference between WW activity and regular PA are yet to be explored.

Objective: This study aims to explore the association between WW activity and other PA patterns with VAI in US adults.

Methods: The National Health and Nutrition Examination Survey 2007-2016 data set was used, and the analytic sample was limited to adults 20 years and older who had complete information about VAI, PA patterns, and other covariates, including demographic characteristics, behavioral factors, and disease conditions. Participants' characteristics in different PA pattern groups were tested using the Rao and Scott adjusted χ^2 test and ANOVA. Univariate and multivariate stepped linear regression models were then used to explore the association between the PA pattern and VAI. Finally, stratified analyses and interaction effects were conducted to investigate whether the association was stable among subgroups.

Results: The final sample included 9642 adults 20 years or older, which is representative of 158.1 million noninstitutionalized US adults, with 52.15% (n=5169) being male and 70.8% (n=4443) being non-Hispanic White. Gender, age group, race, education level, income level, marital status, smoking status, alcoholism, VAI, cardiovascular disease, and diabetes were all correlated with the PA pattern, but no relationship between hypertension and PA pattern was observed. After adjusting for demographic covariates, smoking status, alcoholism, cardiovascular disease, diabetes, and hypertension, WW and regularly active adults had a β of .307 (95% CI –0.611 to –0.003) and .354 (95% CI –0.467 to –0.241), respectively, for reduced VAI when compared with inactive adults, but no significant effect of lowering VAI (β=–.132, 95% CI –0.282 to 0.018) was observed in insufficiently active adults when compared with inactive adults. Besides, no significant difference was exhibited between WW adults and regularly active adults (β=.047, 95% CI –0.258 to 0.352), suggesting WW adults had the same benefit of decreasing VAI as regularly active adults. Stratified analyses results exhibited that WW activity was related to reduced VAI in female adults aged 20-44 years who were non-Hispanic Black, other, or multiracial; high school or General Educational Development education; and never married, and the association between PA pattern and VAI remained stable in all demographic subgroups.

Conclusions: Compared with inactive adults, WWs could reduce VAI, and there was no significant difference between WWs and regular active adults in decreasing VAI. Our study provides compelling evidence of the beneficial effect of WW activity on visceral obesity.

KEYWORDS

weekend warrior; Visceral Adiposity Index; NHANES; physical activity; obesity

Introduction

Physical activity (PA) has been proven to be beneficial by a number of studies, including for reducing chronic disease risk, improving mental state, and prolonging life [1-3]. The World Health Organization recommended that people aged 18 to 64 years should perform at least 150 minutes of moderate-intensity aerobic exercise per week, 75 minutes of high-intensity aerobic exercise per week, or an equivalent combination [4]. Randomized clinical trials have also shown that short-term periodic intermittent PA could improve cardiopulmonary health and other health outcomes, such as blood lipid levels and obesity [5].

In contrast to those who did 30 minutes of moderate-intensity PA for 5 days per week, those who did all exercise on 1 or 2 days per week were usually defined as “weekend warriors” (WWs) [6,7]. As society has become more fast paced worldwide, participating in sports frequently may be less suitable for a busy lifestyle, which has caused a gradual increase in the proportion of WWs. However, at present, the scientific community still knows little about WWs and whether their exercise schedule is more beneficial than inactivity or if WW activity had the same benefits as regularly active (RA) adults.

According to previous reports, obesity, especially visceral fat, has become an important public health problem, causing an estimation of 20.5 disability-adjusted life years per 1000 inhabitants. The economic impact of care for comorbidities associated with obesity could amount to US $2.158 billion. [8]. Obesity is related with various diseases, including cardiovascular disease (CVD), prodrome diabetes, type 2 diabetes mellitus (T2DM), hypertension, hyperlipidemia, sleep apnea, and some malignant tumors [9]. BMI as a routine weight measurement index has been widely used in scientific research [10,11]. However, BMI focuses on measuring overweight, which is not a reliable index to estimate body fat distribution. In contrast, the Visceral Adiposity Index (VAI) is a simple gender-specific indicator of visceral fat dysfunction, which can estimate body fat distribution. Moreover, VAI could be used as a risk predictor of functional impairment and disease, including for CVD, T2DM, nonalcoholic cirrhosis, or erectile dysfunction [12-18]. According to previous research, it is widely accepted that PA could reduce BMI and prevent obesity [10,19,20]. However, the association of WW activity with VAI and the difference between WW activity and regular PA remain to be explored.

Therefore, we obtained data from the National Health and Nutrition Examination Survey (NHANES) to conduct an analysis concerning WW activity and VAI. Through this research, we would like to make the public aware of the benefits of PA on VAI and make suggestions on how to reduce VAI to further reduce various metabolic disease risks. At the same time, the impact of different modes of PA on VAI is an interesting research direction. We also used large-scale data to analyze the different PA modes and VAI so as to provide guidance on the choice of PA mode.

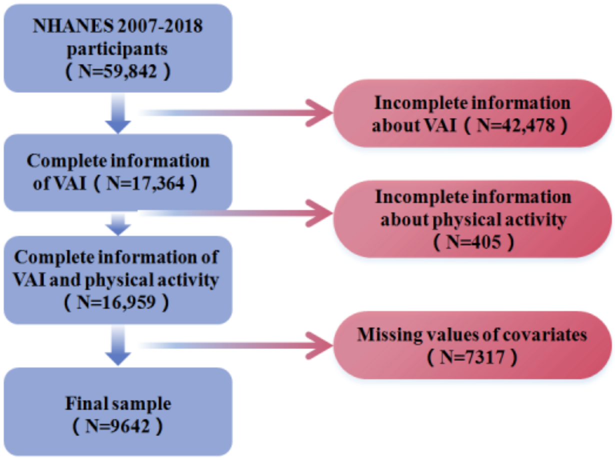
Methods

Study Population

Data was derived from the six continuous NHANES cycles from 2007-2008 to 2017-2018, which is a nationally representative population-based survey for assessing adult and child health and nutritional status in the United States [21]. The examination components consisted of medical, dental, and physiological measurements, and laboratory tests, which were supervised by trained medical personnel. Furthermore, the adoption of various modern equipment and compensation for the participants enabled the NHANES to collect reliable and high-quality data.

The total sample size of adults from the 2007 to 2018 cycle was 9642. Additional details on the study design, sampling, and exclusion criteria are described in Figure 1.

Figure 1. Flowchart of study design. NHANES: National Health and Nutrition Examination Survey; VAI: Visceral Adiposity Index.



Ethics Approval

All participants in NHANES provide informed consent and NHANES is approved by the research ethics review board of the Centers for Disease Control and Prevention [22].

Outcome Ascertainment

The VAI was measured with the following sex-specific formula: VAI = [waist circumference (WC) / 39.68 + (1.88 * BMI)] * (triglycerides / 1.03) * (1.31 / high-density lipoprotein cholesterol [HDL-C]) for males and VAI = [WC / 36.58 + (1.89

* BMI)] * (triglycerides / 0.81) * (1.52 / HDL-C) for females, in which triglycerides and HDL-C were expressed in mmol/L, WC expressed in cm, and BMI expressed in kg/m^2 [23]. The Cobas 6000 Chemistry Analyzer is optimized for workloads using a combination of photometric and ion-selective electrode determinations (c501 module), and electrochemiluminescence technology in the detection of triglyceride concentration [24]. HDL-C was measured with a magnesium/dextran sulfate solution that was first added to the specimen to form water-soluble complexes with non–HDL-C fractions [25].

PA and Other Covariates

PA in this study was assessed with a PA questionnaire in which participants were asked about the frequency and duration of vigorous and moderate sports, fitness, and recreational activities for at least 10 continuous minutes in a typical week. PA was calculated with the combination of frequency (times per week) and duration (duration per time), and total PA was calculated with the formula 2 * vigorous PA + moderate PA, since 1 minute of vigorous-intensity activity was defined as equivalent to 2 minutes of moderate-intensity activity according to PA guidelines [4]. Therefore, PA patterns were categorized into the following: inactive (no vigorous or moderate PA), insufficiently active (<150 minutes per week of total PA), WW (at least 150 minutes per week of total PA in 1 or 2 sessions), and RA (at least 150 minutes per week of total PA in more than 2 sessions).

Based on previous studies, covariates in this study included demographic data such as gender (male, female), age (20-44, 45-64, ≥65 years), race (non-Hispanic White, non-Hispanic Black, Mexican Americans, and other or multiracial races), education level (less than high school graduate, high school degree or equivalent, more than high school degree), income level (measured with as the ratio of family income to poverty [PIR]: low income PIR≤1.3, middle income 1.3<PIR<3.5, or high income PIR≥3.5), marital status (married or living with partner; divorced, separated, or widowed; never married). Behavioral risk factors included smoking status (never smoked, former smoker, current smoker) and alcoholism (yes, no). CVD was defined as a self-reported congestive heart failure, coronary heart disease, angina, myocardial infarction, or stroke diagnosed by a professional doctor. Diabetes was defined as a fasting plasma glucose ≥126 mg/dL, 2-hour plasma glucose ≥200 mg/dL, hemoglobin A_{1c} ≥6.5%, or self-reported diabetes diagnosed by a professional doctor. Hypertension was defined as an average systolic pressure ≥140 mm Hg and diastolic pressure ≥90 mm Hg in 3 tests [26-29].

Statistical Analysis

According to analytic guidelines published by the National Center for Health Statistics, stratum and primary sampling units were taken into account for the complex, multistage, probability sampling design. Since 6 consecutive cycles were derived from NHANES, the 2-year mobile examination center weight divided by 6 was adopted to be representative of the general population.

Initially, participants' characteristics in different groups were tested using the Rao and Scott [30] adjusted χ^2 test and ANOVA. Univariate and multivariate binary stepped logistic regression models were then used to explore the association between PA pattern and depression risk. Model 1 was nonadjusted, while model 2 was adjusted for demographic data. Model 3 was adjusted for demographic data, behavioral factors, and disease condition. Finally, a stratified analyses and interaction effect were conducted to investigate whether the association was stable among subgroups. Statistical analyses were performed using the Stata software (version 16.0, StataCorp LLC). All statistical tests were 2-sided, and significance was considered at α=.05.

Results

Characteristics of Study Participants

As described in Figure 1, 16,059 participants with complete information about VAI and PA pattern were enrolled in the study, and 1542, 2417, 10, 2464, and 884 participants were excluded because of incomplete information about income level, marital status, smoking status, alcoholism, and hypertension, respectively. The final sample included 9642 adults 20 years and older, which is representative for 158.1 million noninstitutionalized US adults, with 52.15% (n=5169) being male and 70.8% (n=4443) being non-Hispanic White.

The characteristics of participants in different PA pattern groups are presented in Table 1. Gender, age group, race, education level, income level, marital status, smoking status, alcoholism, VAI, CVD, and diabetes were all correlated with the PA pattern, but no relationship between hypertension and the PA pattern was observed. To be more specific, WW adults were more likely to be male, be aged 20-44 years, be non-Hispanic White, have some college or above, have a PIR≥3.5, be married or living with a partner, have never smoked, have lower VAI, be nonalcoholic, have CVD, and have diabetes.

Relationship Between PA Pattern and VAI

The results of the binary univariate and multivariate logistic regression models of PA pattern on VAI were presented in Table 2 and Figure 2, and all models revealed a significantly lower VAI among WW and RA adults when compared with inactive adults. After adjusting for demographic covariates, smoking status, alcoholism, CVD, diabetes, and hypertension, WW and RA adults' VAI reduced by 0.307 (95% CI –0.611 to –0.003) and 0.354 (95% CI –0.467 to –0.241), respectively, but no significant effect was observed for VAI reduction (β=–.132, 95% CI –0.282 to 0.018) in insufficiently active adults. Moreover, no significant difference was exhibited between WW adults and RA adults, suggesting WW adults had the same benefit of decreasing VAI as RA adults.

Stratified Analyses According to Demographic Characteristics

To better understand the association between PA pattern and VAI in various subgroups, we conducted stratified analyses according to demographic characteristics. As described in Table 3, the WW activity pattern was related to a reduced VAI in female participants aged 20-44 years who were non-Hispanic Black, other, or multiracial, had a high school degree or General Educational Development, and were never married. The results of the interaction analyses revealed that all *P* values did not reach the significant level, indicating that the association between PA pattern and VAI remained stable in all demographic subgroups.

Discussion

With NHANES, we found that the WW exercise pattern in US adults is helpful to reduce VAI compared with no exercise. In particular, there was no difference between WWs and RA adults, suggesting that WW activity had the same VAI reduction effect as regular activity. Moreover, stratified analysis and interaction analysis confirmed the stability of the results. This might suggest for people who cannot exercise regularly that WW activity could reduce visceral obesity and improve health.

To the best of our knowledge, this is the first analysis to explore the impact of PA patterns, especially of WWs, on VAI. At present, most studies focus on the influence of the sedentary behaviors and leisure time PA (LTPA) ratio on disease or health status [31,32]. Through a cohort study of a nationally representative sample of US cancer survivors, it was found that the combination of sedentary and physical inactivity was associated with the high risk of death [2]. Including the mode of PA adds to the analysis of the LTPA ratio and concerns not only the duration but also the frequency of exercise. Therefore, the NHANES database was used in this study to determine the effects of WW and other PA patterns on visceral fat distribution with VAI.

We took inactivity as the reference. In model 1, no covariates were considered, and insufficiently active, WW, and RA adults had reduced VAI. In model 2, after adjusting for demographic data, the results were similar to the univariate analysis. In model 3, WW and RA adults had reduced VAI after adjusting for demographic data, behavioral factors, and disease conditions, while no significant difference was observed in insufficiently active adults and inactive adults. In detail, RA adults had the largest negative correlation with VAI (β=–.35; *P*<.001), and

WW adults also had an obvious negative correlation (β=–.31; *P*=.047). Eekelen et al [33] found that moderate-to-vigorous PA (MVPA) was associated with less body fat, visceral fat, and liver fat. Mild PA seems to be associated with less body fat but not visceral fat or liver fat. This suggests that exercise would preferentially reduce visceral fat compared to caloric restriction, which might be because visceral fat is more metabolically active and sensitive to lipolytic activation in the adrenal system. Similarly, inactive and insufficiently active adults had elevated VAI when compared with RA adults. Nevertheless, no significant difference was observed in WW and RA adults, indicating the importance of PA duration rather than frequency.

Moreover, the linear regression showed other influencing factors of VAI (see Multimedia Appendix 1 for details). Using no exercise or regular exercise as a reference, age, race, income, marriage, smoking, and diabetes all had an impact on VAI. In the age group, there was no difference in VAI between those aged 20-44 years and those aged 45-64 years, but adults 65 years or older were significantly negatively correlated with VAI, which might be caused by emaciation in older adults. Cameron et al [11] reported the interaction between age and PA. They found that a decrease in BMI and body fat percentage was greater in the older adult group than in the younger group, which was consistent with our results.

Our results showed that non-Hispanic Black participants were more likely to reduce VAI than non-Hispanic White participants. Some studies found that, after correcting for total fat mass, Black women had less visceral adipose tissue than White women, while White people had more visceral adipose tissue than African American people [10]. African American people were more likely to reduce visceral adipose tissue, which supported our results.

There was no difference between middle-income and low-income groups on VAI, while the VAI of the high-income group was significantly lower than that of the low-income group. Ameye and Swinnen [34] reported that obesity varies with income but in a nonlinear way. Overall, obesity in low-income countries increased with greater income but was not related with income in middle-income countries, while it decreases with greater income in high-income countries. Since our data set was from the United States, it was in line with Ameye and Swinnen [34], and it may be related to social stigma around overweight and good medical resources in high-income countries.

Unmarried people were more likely to reduce VAI than married people. According to Lee et al [35], the prevalence of abdominal obesity in married participants was higher than those with other marriage statuses, which was consistent with our results. This marriage-related difference might be due to the fact that marriage increased the frequency of meals and snacks, thus increasing total energy consumption. Compared with married people, unmarried people were more eager to lose weight and maintain weight to make themselves more attractive for future marriage.

Smokers might have higher VAI than nonsmokers. Wehby et al [36] used a sample of 1057 mothers from Norway and found a heterogeneous effect of smoking on BMI. With an increase in smoking, BMI would increase at low/medium BMI levels, while BMI would decrease at high BMI levels. They observed genetic effects on the relationship between smoking and increased BMI, and gene analysis (eg, *CHRNA3*) had consistent evidence that increased BMI was related with smoking, which may explain our results.

Participants who were diabetic could increase VAI more than those without diabetes. According to Haslam's [37] review, experimental results showed that after 6 months of overfeeding, the BMI of young men without a family history of diabetes would increase to 28.0 kg/m^2, and the levels of fasting plasma insulin, glucose, and triglyceride would also increase reversibly, thereby impairing glucose tolerance. About 90% of patients with type 2 diabetes had a BMI greater than 23.0 kg/m^2. Patients who are diabetic might take drugs that cause weight gain, while vulnerable individuals who are already obese may take drugs that cause hypoglycemia.

VAI has been proven by many studies to be a predictor of cardiovascular and metabolic diseases such as hypertension, T2DM, CVD, and nonalcoholic fatty liver disease. Therefore, we planned to conduct a structural equation model in the next study to analyze the mediation effect of VAI: whether the activity pattern might affect VAI and related diseases. This future research direction would improve the relationship between exercise, diet, and visceral obesity, and further specify the analysis of activity and diet patterns.

There were several advantages in this study. First, we adopted a large-scale data set including 9642 participants, thus ensuring representativeness. Second, the topic of activity and obesity was specified in this study, thus the association between visceral obesity and different exercise modes. Finally, this study used a hierarchical linear regression method to analyze the covariates of VAI in detail. However, there were still some limitations. First, this study was based on a cross-sectional investigation, which could not infer the causal relationship between activity patterns and VAI. Second, there are many factors related to VAI, and the variables included in this study are limited. Third, since this study focused on the activity patterns, it did not further explore the relationship between exercise intensity, exercise/sedentary ratio, and VAI, which could be explored in the next study.

In conclusion, although the benefits of physical activities were well known, many people had limited time to engage in activities, and MVPA only accounted for 5% of the total time for daytime activities. Therefore, the role of WW activity is worth researching. According to our results, we found that, compared with no activity, WWs could reduce VAI, and there was no difference between WWs and RA adults, indicating that WW activity is worth promoting for people who cannot exercise regularly. This research also suggested that the duration of PA was more important than the frequency of activity. With this study, we want to make the public aware of the benefits about WW PA and encourage those who are tired from work but want to keep healthy to exercise during the weekend to reduce VAI.

Data Availability

The data sets were derived from NHANES 2007-2008 to 2017-2018 [38], and only publicly available data was used in this study. The data sets generated or analyzed during this study are available from the corresponding author on reasonable request.

Conflicts of Interest

Abstract

Background: Food prepared out of home is typically energy-dense and nutrient-poor. Online food delivery services have become a popular way to purchase such food. The number of accessible food outlets through these services can influence how frequently they are used. Anecdotally, food outlet access through online food delivery services increased in England between 2020 and 2022, in the context of the COVID-19 pandemic. However, the extent to which this access changed is poorly understood.

Objective: We aimed to investigate monthly changes in online access to food prepared out of home in England in the context of the first 2 years of the COVID-19 pandemic compared with November 2019 and the extent to which any changes were associated with deprivation.

Methods: In November 2019 and monthly between June 2020 and March 2022, we used automated data collection to construct a data set containing information about all food outlets in England registered to accept orders through the leading online food delivery service. Across postcode districts, we identified the number and percentage of food outlets registered to accept orders and the number that was accessible. We used generalized estimating equations (adjusted for population density, the number of food outlets in the physical food environment, and rural/urban classification) to investigate the change in outcomes compared with prepandemic levels (November 2019). We stratified analyses by deprivation quintile (Q).

Results: Across England, the summed number of food outlets registered to accept orders online increased from 29,232 in November 2019 to 49,752 in March 2022. Across postcode districts, the median percentage of food outlets registered to accept orders online increased from 14.3 (IQR 3.8-26.0) in November 2019 to 24.0 (IQR 6.2-43.5) in March 2022. The median number of food outlets accessible online decreased from 63.5 (IQR 16.0-156.0) in November 2019 to 57.0 (IQR 11.0-163.0) in March 2022. However, we observed variation by deprivation. In March 2022, the median number of outlets accessible online was 175.0 (IQR 104.0-292.0) in the most deprived areas (Q5) compared with 27.0 (IQR 8.5-60.5) in the least deprived (Q1). In adjusted analyses, we estimated that the number of outlets accessible online in the most deprived areas was 10% higher in March 2022 compared with November 2019 (incidence rate ratios: 1.10, 95% CI 1.07-1.13). In the least deprived areas, we estimated a 19% decrease (incidence rate ratios: 0.81, 95% CI 0.79-0.83).

Conclusions: The number of food outlets accessible online increased only in the most deprived areas in England. Future research might attempt to understand the extent to which changes in online food access were associated with changes in online food delivery service use and the possible implications on diet quality and health.

KEYWORDS

COVID-19; digital food environment; fast foods; online food delivery services; public health

Introduction

Purchasing and consuming food prepared out of home has become increasingly popular in many countries [1]. This food accounted for over 50% of total food expenditure in the United States in 2018 [2], and more than one-quarter of total food and beverage expenditure in the United Kingdom between 2015 and 2017 [3]. Food prepared out of home is often energy-dense [4,5], with the majority of items that are served by large chain restaurants exceeding recommended levels for sodium, fat, saturated fat, or sugars [6]. In turn, more frequent consumption of food prepared out of home has been positively associated with bodyweight [7]. Online food delivery services are now an established way of purchasing such food [8]. It is plausible, therefore, that the use of these services has implications for dietary practices, obesity, and health [9].

When using online food delivery services (such as UberEats), customers receive aggregated information about all food outlets that will deliver to them based on their location. Customers then select a food outlet and place and pay for their order on a single platform. Orders are forwarded to food outlets where meals are prepared before being delivered by couriers working for them or the online food delivery service [9]. As in the physical food environment [10], there is evidence that the number of food outlets accessible to individuals online (ie, the number that will deliver to them) can influence online food delivery service use. Among adults living in the United Kingdom, only those with the highest number of food outlets accessible online (between 182 and 879 outlets) self-reported any online food delivery service use in the previous week [11]. Even before the COVID-19 pandemic, the potential for this food-purchasing practice was not equally distributed across England, where the adjusted mean number of food outlets accessible online in 2019 was over 100 in the most deprived areas, compared with 70 in the least deprived areas [12]. This difference could contribute to known socioeconomic inequalities in diet-related health [13].

Government responses to the COVID-19 pandemic with respect to out of home food retail varied across countries worldwide. The Supplemental Nutrition Assistance Program was extended to include digital food retail in the United States [14], and the rules regarding the delivery of food prepared out of home and alcohol were relaxed in Australia [15]. In the United Kingdom, emergency regulations that allowed bars, cafés, pubs, and restaurants to offer a takeaway food service without specific permission were in place between March 2020 and March 2022 [16-18]. Further details are shown in Table 1.

Table 1. Details of selected emergency regulations introduced, action taken, and broader events in England in relation to the COVID-19 pandemic and food outlets selling food prepared out of home.

Time	Emergency regulations introduced, action taken, and broader events
Before March 2020	• Food outlets in the physical food environment operated with a *primary use* based on their core business operations. The *primary use* of hot food takeaway outlets would be to serve food prepared out of home for off-premises consumption after previously receiving Local Authority[a] planning permission to operate. • Other establishments (bars, cafés, pubs, and restaurants) could offer a hot food takeaway service *in addition* to their primary use but would need Local Authority planning permission to do so. • All food outlets with a customer-facing premises in the physical food environment could feasibly register to accept orders online regardless of their primary use without Local Authority planning permission[b].
March 2020	• Bars, cafés, pubs, and restaurants were forced to close for on-premises food consumption as part of *first* national lockdown[c]. • Emergency regulations allowed bars, cafés, pubs, and restaurants to offer a hot food takeaway service in addition to their primary use introduced.
July 2020	• Bars, cafés, pubs, and restaurants were allowed to reopen for on-premises food consumption but only with table service and with restricted capacity.
August 2020	• The *Eat Out to Help Out* scheme that offered a 50% discount on meals, up to £10 (US $12) per person, every Monday, Tuesday, and Wednesday between August 3 and 31 was introduced for on-premises food consumption.
November 2020	• Bars, cafés, pubs, and restaurants were forced to close for on-premises food consumption as part of *second* national lockdownc. • Emergency regulations introduced in March 2020 were extended until March 2022.
December 2020	• Bars, cafés, pubs, and restaurants were allowed to reopen for on-premises food consumption but only with table service and with restricted capacity.
January 2021	• Bars, cafés, pubs, and restaurants were forced to close for on-premises food consumption as part of *third* national lockdownc.
April 2021	• Bars, cafés, pubs, and restaurants were allowed to reopen for on-premises food consumption but only with table service and with restricted capacity.
July 2021	• Restrictions necessitating table service only and capacity limits for on-premises food consumption inside bars, cafés, pubs, and restaurants ended.
March 2022	• Emergency regulations introduced in March 2020 ended.
After March 2022	• Bars, cafés, pubs, and restaurants *should* revert to their primary use and *should* stop offering a hot food takeaway service if adopted as part of emergency regulations. To continue offering an additional hot food takeaway service, Local Authority planning permission would be required. • All food outlets with customer-facing premises in the physical food environment can feasibly register to accept orders online regardless of their primary use without Local Authority planning permission.

[a] Local Authorities are administrative bodies that operate at a subnational and subregional level.

[b] Registration to accept orders through online food delivery services remained viable regardless of any subsequent action or change.

[c] As part of lockdown orders in England, individuals were instructed to remain *at home*.

With regard to the link between the information outlined in Table 1 and online food delivery services, food sold through these services is typically prepared in the kitchens of food outlets that are customer facing in the physical food environment [9]. The location of these premises is socioeconomically distributed in England, with higher numbers and concentrations in more deprived areas [19]. As such, in more deprived areas, it is possible that a greater number of existing food outlets chose to operate within emergency regulations introduced during the COVID-19 pandemic and registered to accept orders online. In turn, this could influence absolute and relative levels of online food accessibility and aforementioned inequalities.

First, we aimed to investigate changes in levels of online access to food prepared out of home in England during the first 2 years of the COVID-19 pandemic. Second, we aimed to identify the extent to which any changes were associated with area-level deprivation.

Methods

In this study, we built on our previous research that investigated cross-sectional associations between deprivation and online food outlet access in England [12]. Given that we have previously reported our methods in full, in this study we provide an overview.

Study Setting, Period, and Analytic Scale

The setting for our study was England, and the study period was from November 2019 to March 2022, which coincided with the end of emergency regulations introduced during the

COVID-19 pandemic (Table 1). Data were not collected between December 2019 and May 2020, meaning that first available data after November 2019 were from June 2020.

We completed analyses at the postcode district level because this reflects how food outlets registered to accept orders online delineated where they would deliver to in November 2019. Postcode districts are contained in the first half of full postcodes. For example, for the *postcode* CB2 0QQ, the *postcode district* is CB2. Postcode districts have an average size of 33 square miles [20] and a median population of 23,610 (IQR 13,320-34,560) [21].

We used postcode district boundary data from 2012, sourced from the United Kingdom Data Service [22], to map postcode districts in a Geographic Information System (GIS; ArcGIS version 10.7.1; ESRI Inc). We considered 2118 postcode districts eligible for inclusion in our analyses, reflecting those with boundaries entirely within or intersecting the border of England.

Exposure Measure

We modeled our exposure measure (time) based on the frequency of data collection for our outcomes (monthly). We investigated changes in each of our outcomes over time compared with baseline (November 2019).

Outcome Measures

Data Source and Collection

For each outcome, we collected data from an online food delivery service that was considered to be the UK market leader, Just Eat. In 2019, approximately 30,000 food outlets in the United Kingdom were registered to accept orders through this service, and there were approximately 170 million orders placed by customers [23,24]. In pilot analyses conducted in 2020, only a minority of food outlets registered to accept orders through Deliveroo (the next largest online food delivery service platform in the United Kingdom) were not also registered to accept orders through Just Eat [12]. Therefore, we collected data from Just Eat as a representation of online food delivery services. We refer to our data source as “the online food delivery service” hereafter.

In November 2019 and then monthly between June 2020 and March 2022, we used a web-browser extension to identify and collect the postcode of all food outlets in England that were registered to accept orders through the online food delivery service [25].

Number of Food Outlets Registered to Accept Orders Online

To accept orders through the online food delivery service, food outlets must register with them. In doing so, food outlets will have information about their business displayed on the online food delivery service platform irrespective of the location where they would deliver. We used Doogal (a free-to-use web service) to geocode the postcode of each food outlet identified during data collection [26] and excluded those that could not be geocoded (monthly range 0.08%-1.40%). We then mapped the locations of food outlets in our GIS based on supplied coordinates and counted the number located in each postcode district boundary.

Number of Food Outlets Accessible Online

In November 2019, June 2020, and July 2020, food outlets registered to accept orders online published the postcode districts that they would deliver to as their delivery areas. After July 2020, the online food delivery service no longer published this information. Therefore, between August 2020 and March 2022, after we searched the online food delivery service website by a given postcode district, we identified unique food outlets that appeared in our search results. We counted this number to determine those that would be accessible for a given population living in each postcode district (this is the number of food outlets that could be ordered from). Although we used 2 approaches, resultant data used in the outcome construction were the same.

Percentage of Food Outlets Registered to Accept Orders Online

We compared the number of food outlets registered to accept orders online with the number of outlets located in the physical food environment of the same postcode district. In doing so, we estimated the percentage of food outlets registered to accept orders online.

For the denominator (the number of outlets located in the physical food environment of a postcode district), we used the Ordnance Survey Points of Interest (OS POI) data set. These are commercial data containing information about retailers across multiple sectors, collated from more than 170 suppliers [27]. We extracted information for the following food outlet classifications: “Fast food and takeaway outlets” (food outlets selling food for off-premises consumption); “Fast food delivery services” (food outlets selling food for delivery, not explicitly online); “Fish and Chip shops” (food outlets selling a traditional British cuisine, typically for off-premises consumption); “Restaurants” (food outlets selling food for on-premises consumption); “Pubs, Bars, Inns” (establishments that primarily serve alcohol, that can also sell food for on-premises consumption); and “Cafe, Snack Bars & Tea Rooms” (food outlets selling food with no distinguishable consumption location). We selected these classifications based on a priori knowledge that they included food outlets typically registered to accept orders online and to reflect emergency regulations introduced during the COVID-19 pandemic (Table 1). We used coordinates supplied with OS POI data to map the locations of food outlets in our GIS. These coordinates have a stated accuracy of 1 meter [27].

We matched monthly data from the online food delivery service with OS POI data collected quarterly (Multimedia Appendix 1). We did not match individual food outlets listed in each data set, meaning that this outcome is the number of food outlets registered to accept orders online (based on data from the online food delivery service) as a percentage of the number of food outlets in the physical food environment (based on OS POI data set). Although we report a percentage, we acknowledge that in the strictest sense, we did not calculate it as such. We bounded this measure between 0% and 100% because the number of food outlets registered to accept orders online should not exceed the number of food outlets in the physical food environment. When the percentage exceeded 100%, it represented that a retailer not classified as a food outlet in OS POI data (according to our included classifications) was registered to accept orders online. We excluded postcode districts when this occurred (n=3).

Covariates

Food sold through online food delivery services is typically prepared in the kitchens of food outlets located in the physical food environment. Therefore, online food outlet access might be a function of physical food outlet access. We used OS POI data to account for the number of food outlets in the physical food environment when we did not use it as the denominator (ie, for the percentage of food outlets registered to accept orders online).

We used data from the 2019 Index of Multiple Deprivation to measure relative deprivation. This is a compound measure that includes metrics across the following domains: income deprivation, employment deprivation, crime, health deprivation and disability, education, skills and training deprivation, barriers to housing and services, and living environment deprivation [28]. Deprivation values are available for lower super output areas (LSOAs) in England, which are administrative boundaries with a mean residential population of 1500 people [21]. We calculated the mean Index of Multiple Deprivation value of LSOAs within, and intersecting, the boundary of each postcode district. For analyses, we split postcode districts into quintiles (Qs) of deprivation, with Q5 being the most deprived.

We used data from the 2011 rural/urban classification to categorize postcode districts as “rural,” when LSOAs within or intersecting their boundary were most frequently rural (populations <10,000 people within combined settlements, most of whom lived in rural-related areas), or “urban,” when intersecting LSOAs were most frequently urban (populations >10,000 people within combined settlements, most of whom lived in urban-related areas) [29]. We used data from the 2011 UK census [30] to identify the number of individuals who usually lived in a postcode district. Of the 2118 postcode districts, data for rural/urban classification and population density were available for 2097 (99%) and 2088 (95.4%) postcode districts, respectively, and did not change over the study period.

Statistical Analysis

Overview

We used the longitudinal analysis (“xt”) suite of tools in Stata (version 16.1; StataCorp) to complete statistical analysis [31]. We report findings from the start (November 2019) to the end (March 2022) of the study period in the *Results* section. Findings for all time points (November 2019 and then monthly between June 2020 and March 2022) are available in Multimedia Appendix 1.

Descriptive Statistics

For each measure, we calculated the median (IQR) or the mean (SD) and the percentage change from baseline at each time point.

Inferential Statistics

We used generalized estimating equations (GEE) to investigate changes in each outcome over time (the exposure measure).

We completed a complete case analysis, whereby included postcode districts had complete data on all relevant measures. Data for count-based outcomes (the number of food outlets registered to accept orders online and the number of food outlets accessible online) were not normally distributed and were overdispersed. We used negative binomial GEE to account for this. Negative binomial GEE report incidence rate ratios (IRRs) and 95% CIs. In the context of this study, IRRs are the expected change in the outcome value at each time point compared with the baseline value (November 2019). For the percentage of food outlets registered to accept orders online, we rescaled the data to be between 0 and 1 and specified a binomial distribution [32]. Model coefficients for this outcome are the change at each time point compared with baseline values. We first completed unadjusted analyses and then analyses adjusted for covariates. For the number of food outlets registered to accept orders online and the number of food outlets accessible online, we included population density, rural/urban classification, and the number of food outlets in the physical food environment as covariates in our adjusted model. For the percentage of food outlets registered to accept orders online, we only included population density and rural/urban classification as covariates.

We report the findings from our adjusted models in the *Results* section, and our unadjusted models in Multimedia Appendix 1. From our adjusted models, we also estimated the mean count from IRRs and the mean percentage from coefficients and report these in the *Results* section. We report the respective IRRs and coefficients in Multimedia Appendix 1.

Associations With Deprivation

For each outcome, we included an interaction term between time and deprivation in our adjusted GEE and completed a post hoc test for significance (with statistical significance set at $P<.01$ to account for multiple testing). When interaction terms were significant, we completed analyses stratified by deprivation. In November 2019, there were inequalities in access to food outlets selling food prepared out of home online [12]. For each outcome, we calculated a slope index of inequality measure at baseline (November 2019) and at the end of the study period (March 2022) to investigate how inequalities changed over time. This measure of inequality is the difference in the respective outcome between the least and most deprived areas, estimated using linear regression [33,34].

Ethical Considerations

Our study relied on publicly available data. Research ethics committee approval was not required.

Results

Overview

A descriptive summary of online food access in England is shown in Table 2 and Tables S1-S8 in Multimedia Appendix 1.

Table 2. Descriptive summary of online food accessibility at the postcode district level in England, stratified by deprivation quintile[a].

[a] Data are reported as median (IQR); postcode districts are small geographical units used for mail routing in England.

[b] Food outlets in the physical food environment registered to accept orders through the UK market leading online food delivery service.

[c] Baseline=November 2019.

[d] Food outlets registered to accept orders through the UK marketing leading online food delivery service that would deliver to a given postcode district.

[e] Calculated as the number of food outlets registered to accept orders through the UK market leading online food delivery service compared with the number of the physical food environment.

Number of Food Outlets Registered to Accept Orders Online

The summed number of food outlets registered to accept orders online in England increased from 29,232 in November 2019 to 49,752 in March 2022, equating to 70.2% growth (Figure 1).

The median number of food outlets registered to accept orders online per postcode district was 7.0 (IQR 1.0-21.0) in November 2019 and 13.0 (IQR 3.0-34.0) in March 2022. The median percent change from baseline (November 2019) per postcode district was 65.4 (IQR 33.3-100.0) in March 2022. The overall increase in the number of food outlets registered to accept orders was significant at each time point in our adjusted model (Table S10 in Multimedia Appendix 1 provides the IRRs), and there was significant effect modification by deprivation (*P*<.001). Estimated means calculated from IRRs of our adjusted negative binomial GEE are shown in Figure 2. At each level of deprivation, we observed that the estimated number of outlets registered to accept orders online had initially increased from baseline levels (November 2019); this decreased immediately after June 2020 and was then followed by a more consistent upward trend. The estimated number was consistently highest in the most deprived areas (Q5) and lowest in the least deprived (Q1). Absolute growth over time was also highest in the most deprived areas. For these areas, the estimated number was 39.1 outlets at the end of the study period, compared with 24.6 outlets at baseline, whereas for the least deprived areas, this was 6.6 and 3.5 outlets, respectively. The slope index of inequality between the least and most deprived areas was 5.0 (95% CI 4.5-4.5) outlets at baseline, and 7.8 (95% CI 7.0-8.6) outlets in March 2022.

Figure 1. Summed number (count) of food outlets registered to accept orders online in England between November 2019 and March 2022. Shaded bars represent time points reported in the Results section: baseline (November 2019) and end (March 2022). No data were available from December 2019 to May 2020.

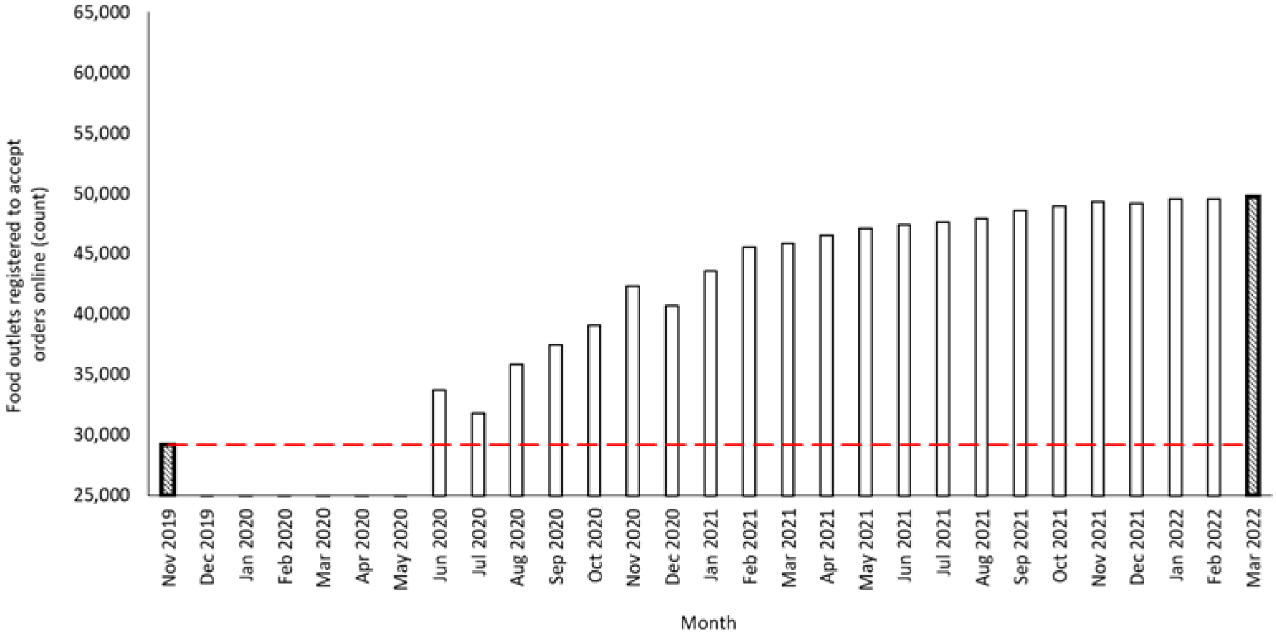

Figure 2. Estimated mean number (count) of food outlets registered to accept orders online in England, stratified by deprivation Q, where Q5 represents the most deprived postcode districts. Estimated number calculated from IRRs of a negative binomial generalized estimated equation adjusted for population density, rural/urban classification, and the number of food outlets in the physical food environment. In all, 2067 postcode districts were included. IRR: incidence rate ratio; Q: quintile.

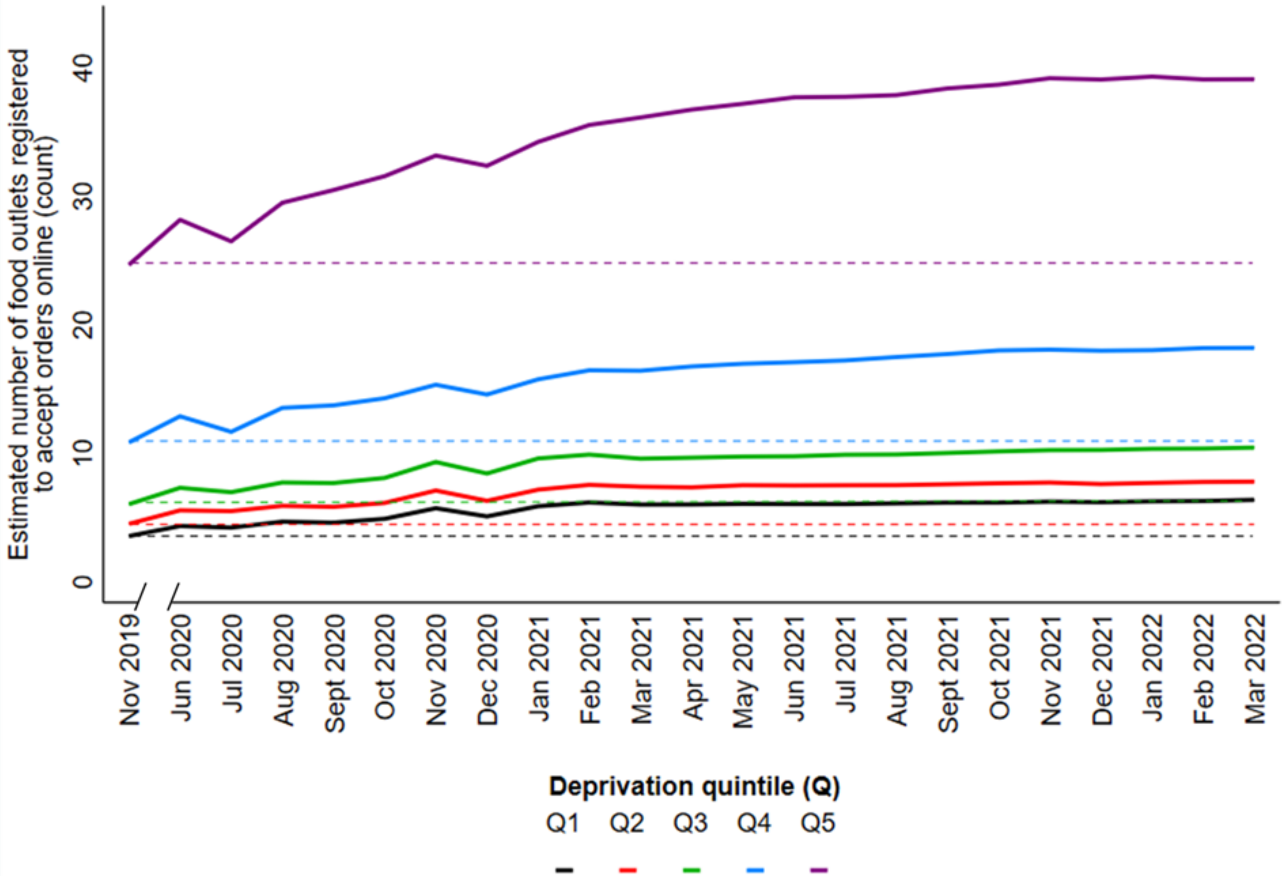
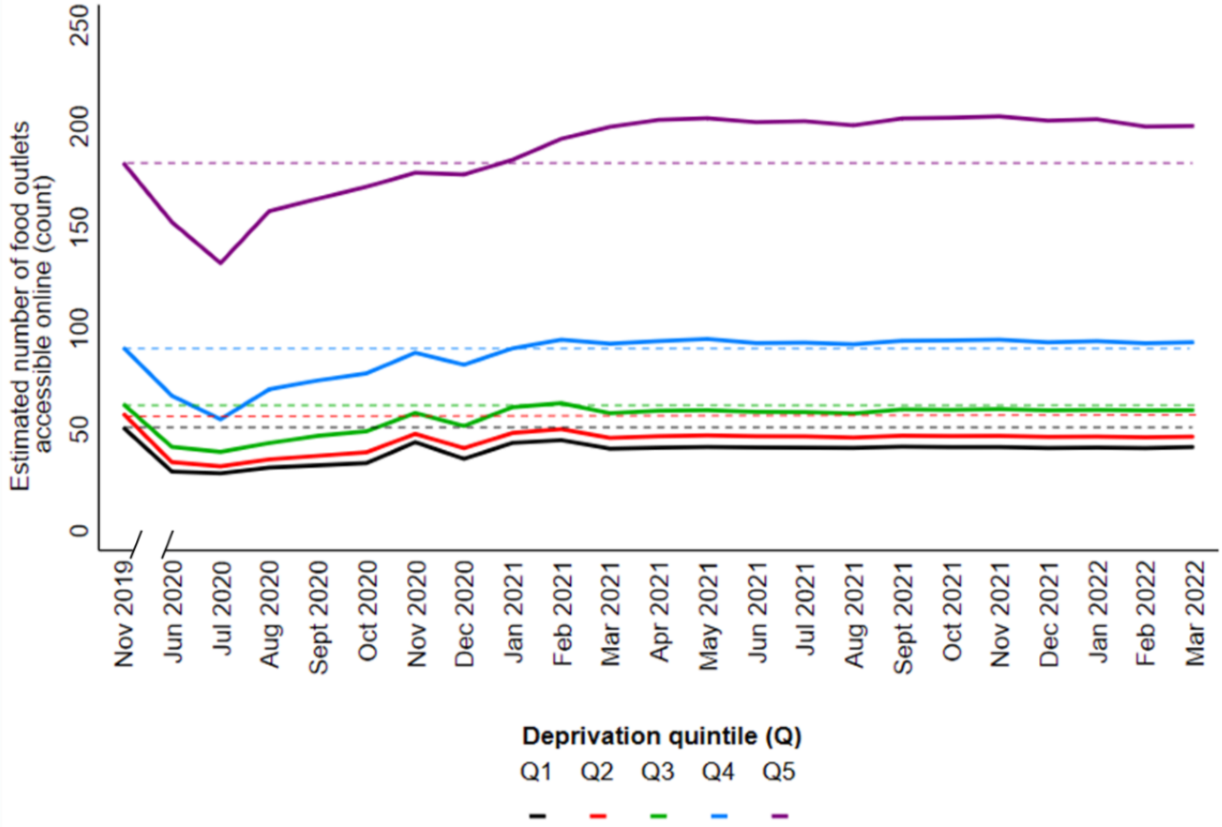


Number of Food Outlets Accessible Online

The median number of food outlets accessible online per postcode district was 63.5 (IQR 16.0-156.0) in November 2019 and 57.0 (IQR 11.0-163.0) in March 2022. The median percent change from baseline per postcode district was 0.0 (IQR −32.0 to 33.3) in March 2022. The overall decrease in the number of food outlets accessible online was significant at each time point in our adjusted model (Table S12 in Multimedia Appendix 1 provides the IRRs), and there was a significant effect modification by deprivation (*P*<.001). Estimated means calculated from the IRRs of our adjusted negative binomial GEE are shown in Figure 3. At each level of deprivation, we observed that the estimated number of food outlets accessible online had decreased from baseline in June 2020. Although this was followed by an upward trajectory, the estimated number remained lower than baseline in less deprived areas (Q1-Q3) but surpassed baseline in those in the 2 upper Qs of deprivation (Q4 and Q5). For the most deprived areas (Q5), the estimated number increased from 181.9 outlets in November 2019 to 200.0 outlets in March 2022, and this contributed to an increasing gap in online food outlet access between the least and most deprived areas. The slope index of inequality between the least and most deprived areas was 32.0 (95% CI 28.1-35.9) outlets at baseline and 37.3 (95% CI 31.8-42.9) outlets in March 2022.

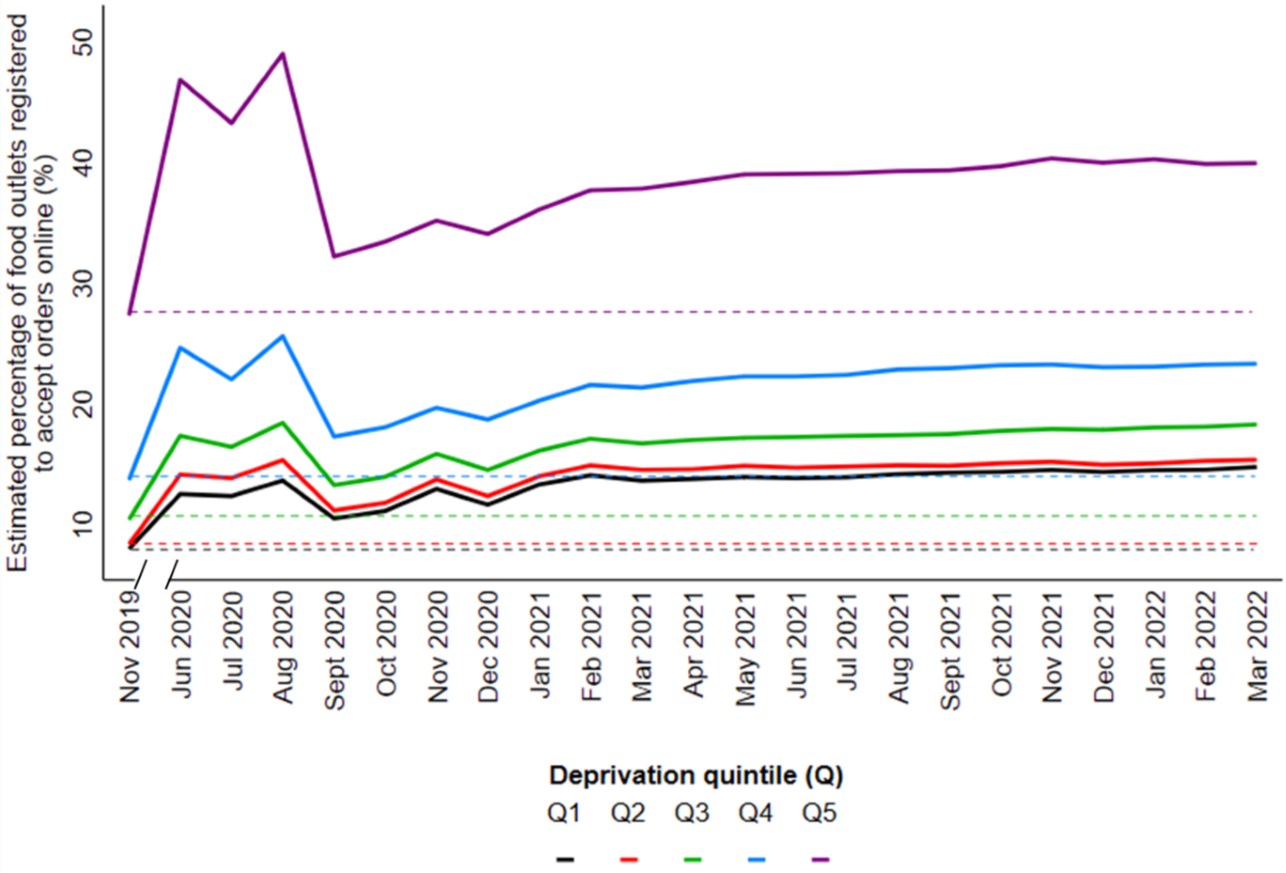
Figure 3. Estimated mean number (count) of food outlets accessible online in England, stratified by deprivation Q, where Q5 represents the most deprived postcode districts. Estimated number calculated from IRRs of a negative binomial generalized estimated equation adjusted for population density, rural/urban classification, and the number of food outlets in the physical food environment. In all, 2067 postcode districts were included. IRR: incidence rate ratio; Q: quintile.



Percentage of Food Outlets Registered to Accept Orders Online

The median number of food outlets registered to accept orders online as a percentage of the number of food outlets in the physical food environment per postcode district was 14.3 (IQR 3.8-26.0) in November 2019 and 24.0 (IQR 6.2-43.5) in March 2022. The median percent change from baseline per postcode district was 55.3 (IQR 23.0-96.1) in March 2022. The overall increase in the percentage of food outlets registered to accept orders online was significant at each time point in our adjusted model (Table S14 in Multimedia Appendix 1 provides the coefficients), and there was a significant effect modification by deprivation (*P*<.001). Estimated means calculated from the coefficients of our adjusted GEE are shown in Figure 4. We observed an initial increase from baseline in June 2020 that was followed by a slight decline, a second increase that equaled or surpassed previous levels, and then another decline before a more stable increase. Although this trend was evident across all levels of deprivation and the estimated percentage was significantly increased at each level of deprivation by the end of the study period, the magnitude varied. Nevertheless, the estimated mean percentage was the highest in the most deprived areas (40.0% in March 2022 compared with 27.4% in November 2019), with these areas also having a higher growth over time in absolute terms, compared with other areas. The slope index of inequality between the least and most deprived areas was 4.5% (95% CI 4.1-4.9) at baseline and 5.9% (95% CI 5.4-6.5) in March 2022.

Figure 4. Estimated mean percentage (%) of food outlets registered to accept orders online in England, stratified by derivation Q, where Q5 represents the most deprived postcode districts. Estimated percentage calculated from coefficients of a generalized estimating equation adjusted for population density and rural/urban classification. In all, 2065 postcode districts were included. Q: quintile.



Discussion

Summary of Findings

To the best of our knowledge, our study was the first to examine changes in levels of online food access across an entire country during the COVID-19 pandemic. We identified an increase in the number of food outlets registered to accept orders online, reaching approximately 50,000 in England by March 2022. There was a parallel increase in the percentage of food outlets in the physical food environment registered to accept orders online. In contrast, the number of food outlets accessible online, that is, those that would deliver to a given population living in a postcode district, was on average lower in March 2022 than before the COVID-19 pandemic. The magnitude of change for all measures of online food access varied by level of deprivation. The most deprived postcode districts consistently had the highest number and percentage of food outlets registered to accept orders online. Importantly, contrary to the trend for England as a whole, only in the most deprived postcode districts was the number of food outlets accessible online higher in March 2022 than at baseline. We did not observe this for postcode districts at any other level of deprivation, with the number *decreasing* in less deprived areas. As a result, there is some evidence that existing socioeconomic inequalities in the opportunity to use online food delivery services to purchase food prepared out of home widened over time.

Comparison With Prior Work

Our finding that an increased number of food outlets had registered to accept orders online in the first 2 years of the COVID-19 pandemic aligns with the reports presented in business and news media from major online food delivery services operating in England [35,36]. Moreover, the decrease in July 2020 accords with contemporaneous reports of food outlet closures and decreased order volume through online food delivery services [37]. For the most part, after July 2020, we observed an increase in the number of food outlets registered to accept orders online. As opportunities for on-premises food consumption were limited by national stay-at-home orders imposed in March 2020, followed by periods of time with restrictions on the capacity for on-premises dining, food outlet owners perhaps made a strategic business decision to register to accept orders online as a way to generate revenue.

For England as a whole, we identified an overall decline in the number of food outlets *accessible* online (ie, the number that will deliver to a given population living in a postcode district) between November 2019 and March 2022. This is in contrast to the increased number of food outlets *registered* to accept orders over the same period (irrespective of whom they would deliver to). The decline we observed was particularly pronounced in the early stages of the COVID-19 pandemic, which might have reflected a period of transition among those that had only recently registered to accept orders online. Food outlets unaccustomed to food delivery plausibly operated with a more limited delivery radius to ensure they could fulfill customer orders. Moreover, at this time, there was broader workforce capacity instability owing to self-isolation rules, unclear restrictions on maximum travel distances legally allowed, and concerns for online food delivery service courier safety [38]. All of which might have contributed to the implementation of limited delivery areas.

Although the initial decline in the number of food outlets accessible online was followed by an increase at all levels of deprivation, it was only among more deprived areas, and particularly the most deprived, that the number eventually surpassed prepandemic levels over the period of our study. The number of food outlets accessible online was already the highest in the most deprived areas in England before the pandemic [12]. However, we found evidence of an increasing divergence between the most and least deprived areas, suggesting that inequality in online food access widened during the period of our study. A perceived lack of demand in less deprived areas might have meant that registered food outlets chose not to include them in their delivery areas. Moreover, the delivery of food sold through online food delivery services is mostly completed by couriers on bicycles. As such, there is a natural limit in the distance that can be traveled while maintaining food quality. In rural, less deprived areas, this challenge might be insurmountable. Regardless, given that the number of food outlets accessible online is positively associated with online food delivery service use [11], it is possible that food-purchasing practices, diet, and health were negatively influenced during the COVID-19 pandemic, especially among populations living in more deprived areas. Although adults living in the United Kingdom self-reported a decrease in their diet quality during the COVID-19 pandemic [39], evidence on changes in the frequency of having food prepared out of home delivered is inconsistent [40]. Further research is required to understand the extent to which the changes in online food outlet access we observed were associated with changes in online food delivery service use during the same period and subsequent implications for diet and health. This future research could incorporate further measures of food access, for example, accounting for the affordability of food sold, which is recognized by online food delivery service customers as being an important consideration preceding use [41]. It is plausible that it is not financially viable for populations living in the most deprived areas to use online food delivery services despite the increase in the number of food outlets accessible, especially owing to the increase in the cost of living in the United Kingdom and elsewhere [42].

The number of food outlets registered to accept orders online as a percentage of the number of food outlets in the physical food environment had increased by the end of the study period. However, this increase was only apparent after a period of instability. Owners of food outlets with customer-facing premises in the physical food environment reported that although being registered to accept orders online was a way for customers to access their food when on-premises food consumption and travel was restricted, simultaneously managing orders placed in-person and online was difficult [38]. If food outlets that did not previously accept orders online only did so out of necessity when on-premises food consumption was restricted, it is plausible that they subsequently deregistered when restrictions ended. This scenario would partly explain the successive increases and decreases that coincided with the start and end of restrictions introduced during the COVID-19 pandemic (Figure 4).

Although the relative change over time with respect to the percentage of food outlets registered to accept orders online was consistent across all levels of deprivation, the absolute change was highest in the most deprived areas, which led to a widening of absolute inequality in online access to food prepared out of home. Food sold through online food delivery services is typically prepared in the kitchen facilities of food outlets located in the physical food environment [9]. Our finding is likely a reflection of the existing urban form in the most deprived areas in England, which is characterized by a high density and concentration of food outlets [43,44]. Although we cannot be certain, if more food outlets were operating within emergency regulations introduced during the COVID-19 pandemic, more outlets may have also registered to accept orders online. Our findings therefore provide evidence to suggest that the introduction of emergency regulations at least partly contributed to widening inequality in this exposure.

There remains considerable scope for the percentage of food outlets in the physical food environment that are registered to accept orders online to increase. This emphasizes the coexisting and overlapping nature of digital and physical food environments, which together provide multiple opportunities to purchase energy-dense, nutrient-poor food [45]. However, there are likely to be natural limits to growth because all food outlets do not necessarily need or want to register to accept orders online. In fact, the relative stability from June 2021 onward suggests that a plateau might have already occurred. An important limitation of this paper is that we do not have additional prepandemic data that would allow us to account for any existing trends in analyses. Nevertheless, our findings and associated data can contribute to future surveillance of longer-term trends.

Possible Implications for Public Health and Policy

Urban planning has been used by over half of local authorities in England to promote the creation of healthier physical food environments, specifically by preventing new takeaway food outlets from opening [46]. To our knowledge, restrictions targeted specifically at online food delivery services are not in place. Although not yet fully clear, similar to the physical food environment, interventions to restrict access to food prepared out of home through these services might be increasingly necessary in the future [47,48]. At this point, public health interventions that do not necessarily attempt to restrict online food access but instead attempt to mitigate the potential public health burden posed by online food delivery service use possibly represent the most appropriate route to regulation. For example, changing the nutritional composition of food sold inside outlets would be expected to have a crossover effect and also change food sold online. Additionally, in England, in 2022, mandatory calorie labeling of non–prepacked food and soft drinks was introduced for retailers that operate with more than 250 employees, which meant that this information had to be displayed both inside food outlets and on the platforms of online food delivery services [49,50]. The introduction of this regulation recognizes the role of the digital food environment in the purchase of food prepared out of home. Research in the future could seek to further understand if and how regulations in the physical food environment can be extended to the digital food environment.

Furthermore, there has been evolution in the preparation location for the food sold through online food delivery services. This is best demonstrated by the development of facilities known as dark kitchens [51]. These facilities allow food businesses to register to accept orders through online food delivery services and prepare meals for delivery without the financial costs of having a customer-facing premises. To date, there is only limited evidence on the dark kitchen business model, which may not be generalizable beyond the data collection context of a single London borough [52]. Nevertheless, the development of these facilities plausibly influenced our findings related to the percentage of food outlets registered to accept orders online. Future research might seek to understand the public health implications of the dark kitchen business model, including how it uniquely contributes to the number of food outlets accessible online.

Methodological Considerations and Limitations

Our data collection spanned 2 years and allowed us to closely monitor trends in important metrics of online food outlet access. In doing so, we present new baseline levels for future assessment. Nevertheless, our study is not without limitations. Our analysis was observational, and we cannot definitively conclude that the changes we observed were due to the COVID-19 pandemic. We also do not have sufficient prepandemic data that would allow underlying or existing trends to be accounted for in analyses. This is particularly the case for changes between November 2019 and June 2020 when we had no data, and we could not determine whether changes coincided with the COVID-19 pandemic.

We completed data collection at a single time point on a monthly basis. If food outlets were only registered to accept orders or accessible in the intervening period, they might not have been returned in our searches. However, the changes in the number of food outlets accessible online that we observed, especially the initial decrease in June 2020, is similar to reports of food outlet closures and decreased order volume at this time [37].

We did not track individual food outlets over the study period. Instead, we studied the total number of food outlets registered to accept orders at any given time point. This means that we are unable to comment on the number that were newly registered during the COVID-19 pandemic. It would be interesting for future work to investigate the extent to which food outlets that registered only during this period remained registered.

Our findings demonstrate *potential* online food outlet access. For this to be realized, any given individual must be an online food delivery service customer. As such, our findings do not necessarily translate into realized individual-level online food outlet access [53].

We used postcode districts as our unit of analysis and acknowledge the possibility that our findings are subject to the modifiable areal unit problem. Although the spatial unit that we adopted for analyses has the potential to introduce bias [54], our approach was data driven to allow consistency with our previous research [12]. Relatedly, using postcode districts as our unit of analysis also meant that we were limited to using boundary data from 2012. These data were not temporally aligned with further covariate data that were the most recently published or collected.

Conclusions

We investigated changes in multiple measures of food access through online food delivery services during the first 2 years of the COVID-19 pandemic. We identified that the number of food outlets in England that were registered to accept orders online increased. In parallel, the number of food outlets registered to accept orders online as a percentage of the number of food outlets in the physical food environment increased. Although the number of food outlets that could be accessed decreased for the whole of England, trends differed by the level of deprivation. The number of outlets decreased compared with prepandemic levels in the least deprived areas and increased to surpass prepandemic levels *only* in the most deprived.

Overall, then, we identified considerable changes in measures of online food accessibility during a period when on-premises food consumption was often restricted. Our data from March 2022 represent a new baseline to which future changes in measures of online food accessibility can be investigated. Future research might attempt to understand the extent to which the changes we identified were associated with the changes in online food delivery service use and, in turn, the implications for diet quality and health.

Acknowledgments

MK was funded by the National Institute for Health and Care Research (NIHR) School for Public Health Research (SPHR; grant number PD_SPH_2015). This work was supported by the Medical Research Council (grant number MC_UU_00006_7). The views expressed are those of the authors and not necessarily those of any of the above named funders. Abstract

Background: Despite the release of updated metrics for Life’s Essential 8 (LE8), key indicators for assessing cardiovascular health (CVH) status, there is currently no report on their distribution among Chinese children.

Objective: This study aimed to assess the nationwide distribution of CVH in Chinese school-aged children using LE8 scores and analyze temporal changes in these scores over time.

Methods: Participants aged 7 to 19 years from 11 waves (between 1989 and 2018) of the China Health and Nutrition Survey were included in this study. LE8 components were grouped into 2 domains of health behaviors (diet, physical activity, nicotine exposure, sleep) and health factors (BMI, blood lipids, blood glucose, blood pressure). Scores of overall CVH and each LE8 metric were calculated individually. Temporal changes were assessed with joint point regression models by rural and urban living residence. The causal relationships between health behaviors and health factors that changed the most over time were built with cross-lagged panel models.

Results: A total of 21,921 participants, 52.6% (n=11,537) of whom were male, who had data for at least 4 CVH components were included in the analysis. The mean age was 13 (SD 3.6) years. The overall CVH score remained stable in most regions, with the lowest found in Shandong from East China, which had a mean between 67 (SD 10.9) and 67.2 (SD 12.4). In contrast, the highest score was found in Guizhou from Southwest China, with a mean between 71.4 (SD 10.8) and 74.3 (SD 10.3). In rural areas, the diet score decreased significantly from 1997 onward with a speed of 0.18 (95% CI: 0.15-0.21; *P*<.001) per year, and the BMI score decreased significantly from 2005 onward with a speed of 0.56 (95% CI 0.44-0.68; *P*<.001) per year. In urban areas, the diet score decreased from 1994 onward with a speed of 0.03 (95% CI: 0.001-0.07; *P*=.04) per year, and the BMI score decreased from 2002 onward with a speed of 0.63 (95% CI 0.47-0.79; *P*<.001) per year. The sleep score dropped constantly in both urban and rural areas, with a speed of 0.69 (95% CI 0.58-0.80; *P*<.001) and 0.69 (95% CI: 0.52-0.86; *P*<.001) per year, respectively. A decline in the diet score led to a decline in the BMI score with a coefficient of 0.190 (95% CI 0.030-0.351; *P*=.02), while a decline in the BMI score led to a decline in sleep health with a coefficient of 0.089 (95% CI 0.010-0.168; *P*=.03).

Conclusions: Chinese school-aged children and adolescents were generally of moderate CVH status, but mutual influences existed between CVH metrics. Dietary interventions should be prioritized for promoting overall CVH in the future.

KEYWORDS

cardiovascular health; school-aged children; temporal change; China Health and Nutrition Survey

Introduction

Cardiovascular disease (CVD) is the leading cause of death and disability in the world, in large part because of risk factors modifiable by changes in behavior [1,2]. Individuals with an unfavorable cardiovascular health (CVH) status during childhood are more likely to develop subclinical atherosclerosis and subsequent CVD later in life [3]. Controlling and reducing CVD-related mortality and morbidity are not only one of the key indicators of the United Nations' Sustainable Development Goals [2] but also one of the top priorities of the 2030 Healthy China Plan [4].

Although the overall CVD mortality has stalled in recent years, especially in middle- and low-income countries [5], efficient prevention strategies could further effectively reduce age-adjusted death rates due to CVD [6,7]. This points to the importance of recognizing, evaluating, and maintaining overall CVH.

The newly released Life's Essential 8 (LE8), key measures for improving heart health released by the American Heart Association, provide a comprehensive tool to evaluate overall CVH status and specific metrics of CVH behaviors or factors. Compared with the previous version, Life's Simple 7 [8], the new version provides not only classifications of CVH status but also continuous scores that are helpful for both cross-sectional and longitudinal analyses on differences and trends in CVH status distribution. The revised version incorporates newly identified risk factors, such as sleep health, alongside metrics that have demonstrated stronger associations with long-term CVD, such as the replacement of total cholesterol with non–high-density lipoprotein (HDL) cholesterol [9,10].

The newly released metrics have garnered significant attention in the field of CVH research. However, prior studies have not addressed either the national distribution of CVH status among Chinese school-aged children or the temporal changes in CVH metrics over time. Accordingly, in this study, we collected data pertaining to children and adolescents aged 7 to 19 years from waves spanning 1989 to 2018 in the China Health and Nutrition Survey (CHNS). We aimed to analyze temporal trends and geographical variations in CVH in Chinese school-aged children. Additionally, we aimed to investigate whether changes in health behaviors over the past 3 decades have had an impact on health factors.

Methods

Study Participants

The study data were obtained from 11 waves of the CHNS, an open prospective cohort study carried out by the University of North Carolina at Chapel Hill in partnership with the National Institute for Nutrition and Health of the Chinese Center for Disease Control and Prevention [11]. The baseline survey was conducted in 1989 and followed up in 1991, 1993, 1997, 2000, 2004, 2006, 2009, 2011, 2015, and 2018, respectively.

This project covered 15 provinces (autonomous regions and municipalities) including Heilongjiang, Liaoning (did not participate in 1997), Jiangsu, Shandong, Henan, Hubei, Hunan, Guangxi, Guizhou, Beijing, Shanghai, Chongqing, Shaanxi, Zhejiang, and Yunnan. Notably, Heilongjiang only participated from 1997 onward; Beijing, Chongqing, and Shanghai participated from 2011 onward; and Zhejiang, Yunnan, and Shaanxi participated from 2015 onward. A multistage, stratified, clustered random method was used for sampling. Based on the national administrative regions, a weighted sampling scheme was used to randomly select 2 cities and 4 counties from each province. Next, 2 urban and 2 suburban neighborhoods were randomly selected in each city, and 1 township and 3 villages were randomly selected in each county. Urban neighborhoods in the cities and townships in the counties were grouped into urban areas, and suburban neighborhoods in the cities and villages in the counties were grouped into rural areas. More design details are described elsewhere [11,12].

Study Measurements

Dietary Survey

A 3-day consecutive 24-hour-dietary recall method was employed to gather information on the consumption of all foods and drinks. Due to notable variations in the Chinese diet between weekdays and weekends, we recorded the consumption for 2 workdays and 1 weekend day. After training, investigators conducted face-to-face interviews, asking participants about their food and beverage intake over the past 24 hours for 3 consecutive days. Simultaneously, a household weighing method was used to document the consumption of cooking oil and condiments over the corresponding 3 days. The allocation of cooking oil and condiment consumption to individuals was based on how often they cooked at home, meal proportions, and the ratio of individual energy intake to household energy intake. To minimize the recall bias, respondents were asked to write down what they ate and drank every day.

Food items were categorized according to the categories outlined in the China Food Composition Tables. In this study, the term "milk" referred to the equivalent of liquid milk, encompassing various dairy and dairy products converted based on the protein content of every 100 grams of the edible portion. The category "beans" included soybeans, other legumes, and their products. The intakes of soybean flour and soybean milk were converted into the equivalent of soybeans, considering the protein content of every 100 grams of the edible portion. Salt intake consisted of sodium chloride (NaCl) from cooking salt, paste, and sauce.

Anthropometric Measurements

The participants' height, weight, systolic blood pressure (SBP), and diastolic blood pressure (DBP) were measured by trained investigators. Height was recorded to the nearest 0.1 centimeters.

Weight was recorded to the nearest 0.1 kilograms. BMI was calculated as weight (kg)/height^2 (m^2).

Blood Sample Collection

In the years 2009, 2015, and 2018, the CHNS project collected fasting venous blood samples from participants aged 7 years and above. The fasting plasma glucose (FPG) concentration was measured using the GOD-PAP (glucose oxidase-phenol-4-aminoantipyrineenzymatic) method (Randox Laboratories Ltd). Glycated hemoglobin (HbA1c) levels were measured using a high-performance liquid chromatography system (model HLC-723 G7; Tosoh Corp). Participants' diagnosis of diabetes mellitus was confirmed based on doctor diagnoses, as reported by participants themselves or by their parents in cases where adolescents could not answer. Total cholesterol and HDL cholesterol were measured using the CHOD-PAP (cholesterol oxidase: P-aminophenazone) method (Kyowa Medex Co Ltd). Non-HDL cholesterol was calculated as the difference between total cholesterol and HDL cholesterol.

Nicotine Exposure

Nicotine exposure was assessed through active smoking and secondhand smoke exposure. Active smoking was categorized into three groups: (1) individuals who had never smoked, (2) those who had smoked at any point or had quit smoking for more than 30 days, and (3) those who were currently smoking or had quit smoking within the last 30 days. Secondhand smoke exposure was defined as living with people who smoke.

Physical Activity

Physical activity data, comprehensively collected in this project since 2000, were obtained through questionnaires. Physical activity encompassed occupational, domestic, travel, and leisure activities.

Sleep Duration Data

Sleep duration data, including both night sleep time and daytime sleep time, were collected from questionnaires as part of the study.

Quantification of CVH Components

The methods for measuring, evaluating, and quantifying the 8 CVH components are displayed in Tables S1 and S2 of Multimedia Appendix 1. These methods closely aligned with the original LE8 metrics tailored for children and adolescents under the age of 19 years. The 8 components comprised of 4 health behaviors (diet, physical activity, nicotine exposure, and sleep health) and 4 health factors (BMI, non-HDL cholesterol, FPG, and blood pressure), as defined by the LE8 reference. Furthermore, sleep health was evaluated in accordance with the Healthy China Initiative (2019-2030), which recommends a sleep duration of 10 hours for primary school students, 9 hours for secondary school students, and 8 hours for high school students. Age and sex-specific BMI percentiles were generated based on growth references from the World Health Organization [13]. SBP and DBP were transformed into age, sex, and height–specific percentiles, and evaluated based on the American Academy of Pediatrics' Clinical Practice Guideline for Screening and Management of High Blood Pressure in Children and Adolescents, released in 2017 [14].

Statistical Analyses

Each of the LE8 components was scored on a scale ranging from 0 to 100, with the total CVH score calculated as the average of the 8 component scores. Overall CVH scores between 80 and 100 were categorized as high CVH, scores between 50 and 79 were categorized as moderate CVH, and scores between 0 and 49 were classified as low CVH. The mean and SD were calculated for continuous variables, and numbers and percentages were calculated for categorical variables. The median and IQR were reported for non-HDL cholesterol. Geographical regions were categorized as North China, Northeast China, East China, Central China, Southwest China, and Northwest China according to codes for the administrative divisions of the People's Republic of China (GB/*t* 2260), as outlined in Table S3 of Multimedia Appendix 1. Joint point regression models were used to analyze the differences in CVH scores over time, considering rural or urban living residence. Adjustments were made for the children's age and sex as appropriate. Since scores for both health behaviors and health factors decreased sharply after 2004, cross-lagged panel models were applied to explore causal relationships between changes in health behaviors and health factors. Model fit was evaluated based on the Comparative Fit Index and Tucker-Lewis Index scores greater than 0.95, with a root mean squared error of approximation less than 0.05 being indicative of good fit [15]. All statistical analyses were performed using Stata software (version 14.0; StataCorp). The associations were considered significant at 2-sided $P<.05$.

Ethics Approval

This study was approved by the institutional review board of the University of North Carolina at Chapel Hill and the National Institute for Nutrition and Health of the Chinese Center for Disease Control and Prevention (2018-004). Participants aged 7 to 17 years provided signed informed consent from themselves and their guardians, while participants aged 18 years and above provided their own signed informed consent forms to participate in the original surveys. The data for our study were completely deidentified and did not contain any information that could be traced back to the individual participants.

Results

In total, 21,921 (77%) out of 28,477 participants, 52.6% (n=11,537) of them male, aged between 7 and 19 (mean 13, SD 3.6) years, with data for at least 4 CVH components, were included in the study analysis. Among the participants, 6071 (27.7%) were from urban areas. Demographic characteristics, as well as CVH status, are detailed in Table 1 by geographic regions, and comparisons of demographic characteristics between the excluded and included children are displayed in Table S4 of Multimedia Appendix 1. The sample distribution at each research wave is displayed in Table S5 of Multimedia Appendix 1.

Table 1. Demographic characteristics of participants by geographic regions.

Characteristics	Overall	North China (n=403)	Northeast China (n=2746)	East China (n=4271)	Central China (n=10,208)	Southwest China (n=3830)	Northwest China (n=463)	Difference (*P* value)

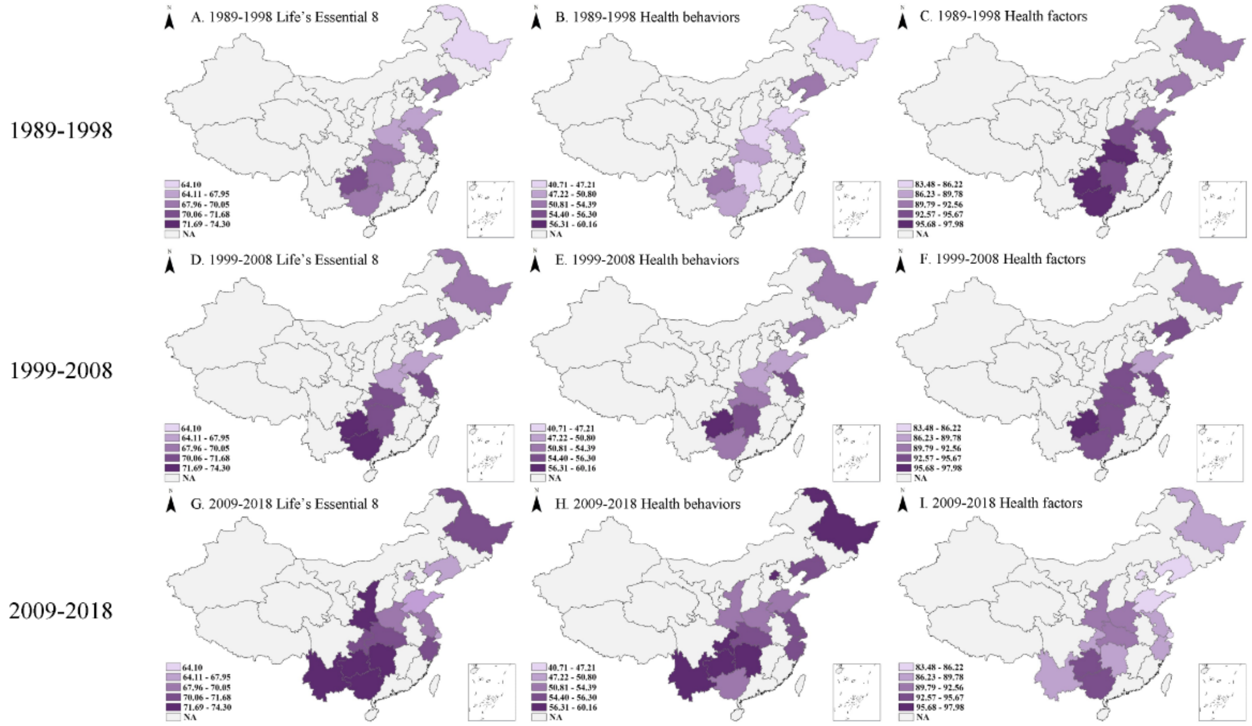
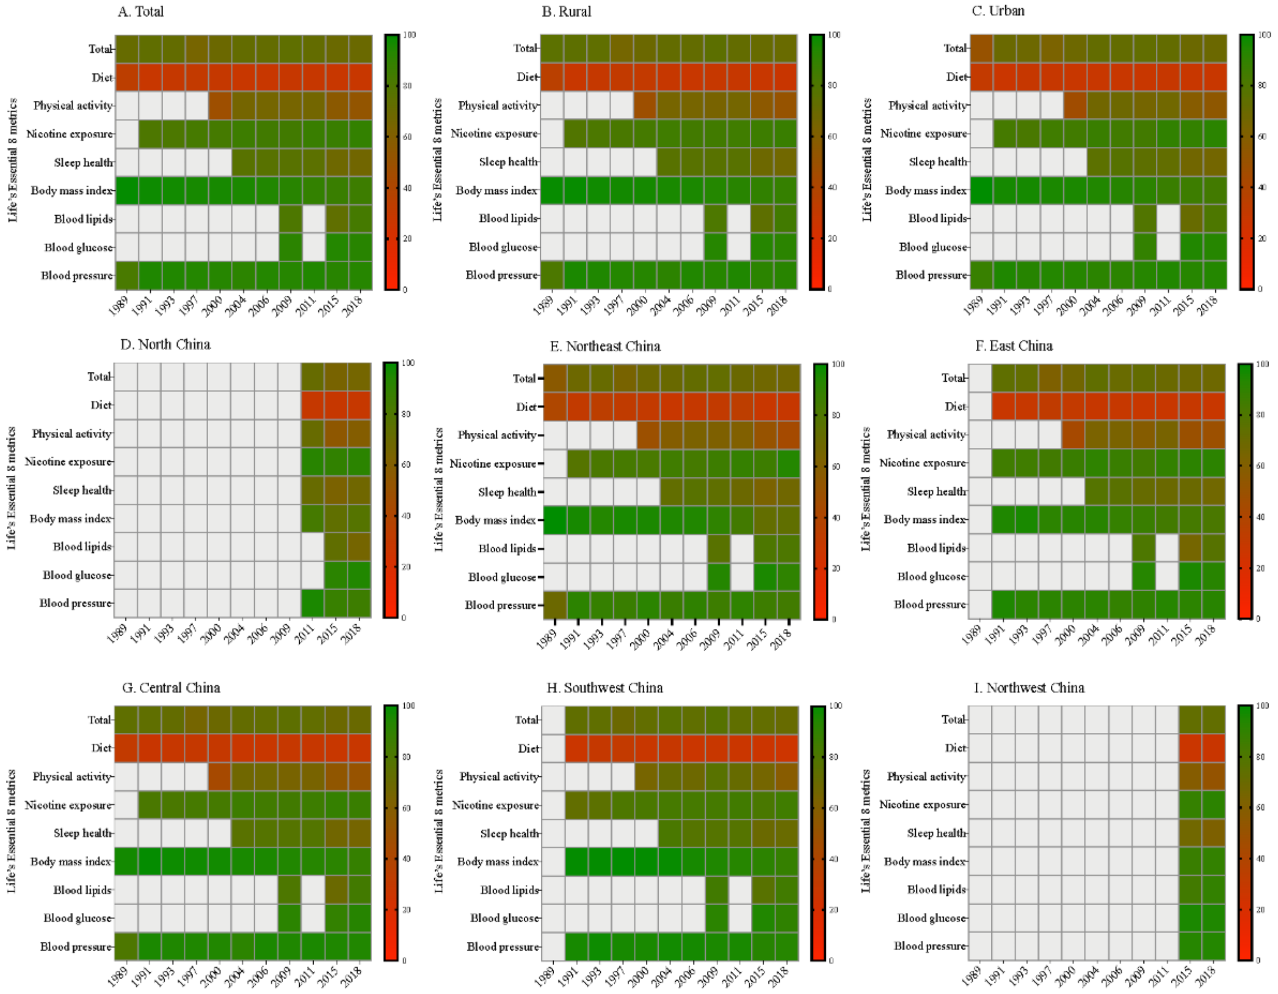
During the past 3 decades, the overall CVH score remained stable in most of the involved provinces, with the lowest score observed in Shandong from East China, with a mean between 67 (SD 10.9) and 67.2 (SD 12.4). The highest score was observed in Guizhou from Southwest China, with a mean between 71.4 (SD 10.8) and 74.3 (SD 10.3). The most significant change in overall CVH status was observed in Heilongjiang from Northeast China, with scores increasing from a mean of 64.1 (SD 11.1) to 71.1 (SD 10.3). Health behavior scores, though much lower than overall scores, showed a gradual increase during the decades. The greatest increase was found in Guizhou from Southwest China and Hunan from Central China, with health behavior scores increasing from a mean of 50.8 (SD 18.1) to 60.2 (SD 14.3) and from 46.8 (SD 17.5) to 56.7 (SD 15.7), respectively. Conversely, health factor scores decreased across all areas, with the biggest decline found in Liaoning from Northeast China (mean 92.3, SD 13.8 to mean 84, SD 17.8) and Shandong from East China (mean 91.6, SD 14.5 to mean 83.6, SD 16.7). Temporal changes in CVH scores by province are shown in Figure 1.

Figure 1. Distribution and temporal change of overall cardiovascular health (CVH) status in Chinese school-aged children and adolescents from 1989 to 2018 based on natural breaks (Jenks) classification. A. Life’s Essential 8 score (1989-1998); B. Health behavior score (1989-1998); C. Health factor score (1989-1998); D. Life’s Essential 8 score (1999-2008); E. Health behavior score (1999-2008); F. Health factor score (1999-2008); G. Life’s Essential 8 score (2009-2018); H. Health behavior score (2009-2018); I. Health factor score (2009-2018).



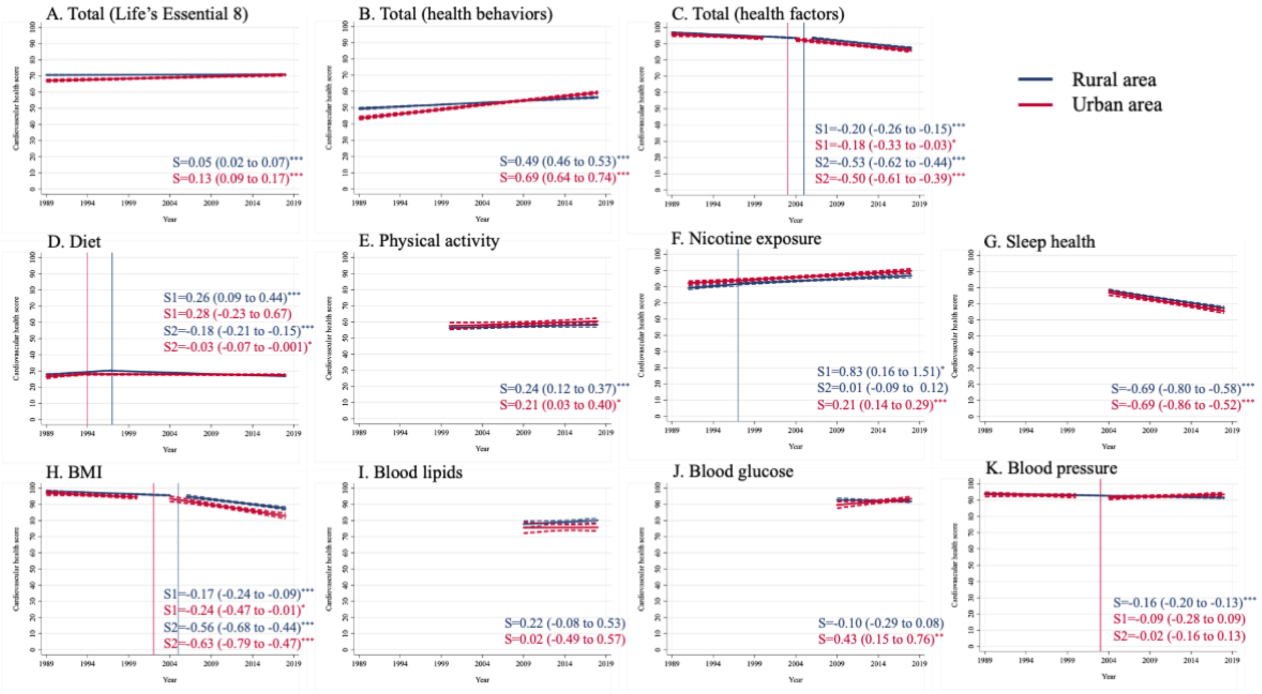
Regarding specific CVH metrics, the healthy diet score consistently remained the lowest for all research waves and in all 6 geographical regions. Worsened sleep health was observed in all geographical regions, while worsened BMI was particularly prominent in North and Northeast China (Figure 2 and Figure S1 in Multimedia Appendix 1).

Figure 2. Changes in cardiovascular health metrics for Chinese school-aged children and adolescents from 1989 to 2018 by geographic region.



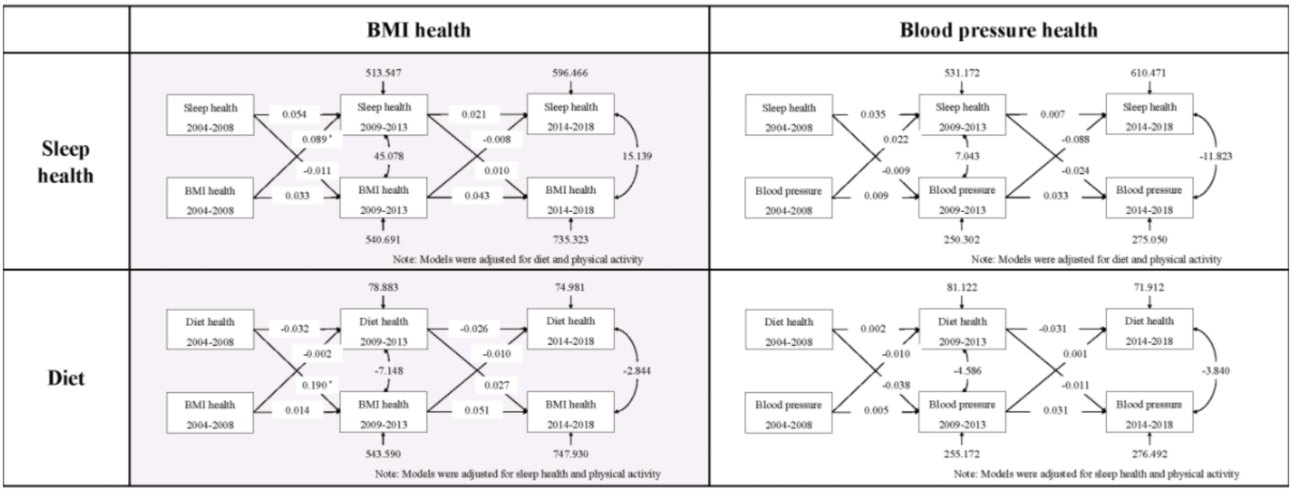
Joint point regression models were then applied to analyze the temporal changes in CVH metrics. Although similar trends were observed in both rural and urban areas, time lags in break points were identified for several metrics (Figure 3). Generally, overall CVH scores and health behavior scores displayed linear growth trends in both rural and urban areas. Total health factor scores decreased faster in rural areas since 2005, with a speed of 0.53 (95% CI 0.44-0.62; *P*<.001) per year, and in urban areas since 2003, with a speed of 0.50 (95% CI 0.39-0.61; *P*<.001). Decreases in diet scores became more significant in rural areas since 1997, with a speed of 0.18 (95% CI 0.15-0.21; *P*<.001) and in urban areas since 1994, with a speed of 0.03 (95% CI 0.001-0.07; *P*=.04). The decrease in BMI scores became more pronounced in rural areas since 2005, with a speed of 0.56 (95% CI 0.44-0.68; *P*<.001) and in urban areas since 2002, with a speed of 0.63 (95% CI 0.47-0.79; *P*<.001). Constant decreases were observed in sleep health scores, with a speed of 0.69 (95% CI 0.58-0.80; *P*<.001) in rural areas and 0.69 (95% CI 0.52-0.86; *P*<.001) in urban areas.

Figure 3. Joint point regression analysis of time trends in cardiovascular health scores in Chinese school-aged children and adolescents from 1989 to 2018. Where a joint point was recognized, S1 referred to the slope before the joint point, and S2 referred to the slope after the joint point. S: slope.



Cross-lagged panel models were constructed between health behaviors (including diet, physical activity, and sleep health) and health factors (including BMI and blood pressure health) during the study waves spanning 2004 to 2008, 2009 to 2013, and 2014 to 2018 (Figure 4). The results indicated that lowered BMI health between 2004 and 2008 resulted in lowered sleep health between 2009 and 2013, with a coefficient of 0.089 (95% CI 0.010-0.168; *P*=.03). Concurrently, lowered diet scores from 2004 to 2008 resulted in lowered BMI health from 2009 to 2013, with a coefficient of 0.190 (95% CI 0.030-0.351; *P*=.02).

Figure 4. Cross-lagged standard regression coefficient of sleep health, diet health, BMI, and blood pressure health between 2009 and 2013 and 2014 and 2018. BP: blood pressure.*Indicated to *P*<.05.



Discussion

Principal Findings

To our knowledge, this is the first study examining CVH status and its temporal changes over the past decades in Chinese school-aged children and adolescents using the new LE8 metrics. From 1989 to 2018, the overall LE8 score remained relatively stable at a moderate level. Simultaneously, the overall score for health behaviors moderately increased, while that of health factors declined significantly over time. Therefore, we inferred that Chinese children and adolescents may face a prolonged downward trend in overall CVH status in the future.

The overall level of CVH scores in Chinese children in the recent decade was compatible with those of children in the United States, ranging between 64.6 and 74.1, depending on the metrics used for calculation [16]. Both groups shared suboptimal performance in diet, but Chinese children and adolescents had relatively lower scores in health behaviors such as physical activity and sleep health. The initiation of CVD and related diseases in childhood underscores the critical importance of LE8 metrics, turning childhood and youth into new frontiers for CVD prevention [17]. As the behavioral change theory has emphasized, changes in human behavior should be based on education, enhanced self-motivation, and adequate external support, eventually resulting in changes in health outcomes [18,19]. Early and sustained multicomponent educational programs that focus on health promotion in children and adolescents could represent a critical window of opportunity to potentially prevent disease in later life [20].

The results of our analysis indicated that the overall CVH level was lower in the eastern part of China compared to the western part, similar to findings reported for Chinese adults from the 2021 Report on Cardiovascular Health and Disease in China [21,22]. In contrast with reports from countries in North America, where lower CVH status is typically associated with less favorable economic conditions [23], we found poorer CVH status in areas with better economic conditions in China. This may be attributed to wider socioeconomic gaps and the prevalence of unhealthy lifestyles in urban and higher-income areas [24]. However, further research is needed for a more detailed exploration of the social determinants of CVH.

Several metrics in the LE8 were particularly noteworthy in this study, highlighting persistently low diet quality, fluctuating levels of physical activity, and persistent declines in sleep and BMI health. Of more concern is that although there was a time lag between urban and rural areas, the trend and speed of the simultaneous decline in rural areas for these indicators were comparable—or even greater than—that of urban areas.

Enhancing physical fitness in school-aged children and adolescents has been a top priority for the Chinese government. The State Council of the People's Republic of China's initiatives "Suggestions on Strengthening Youth Sports and Enhancing Youth Physical Fitness," released in 2007 [25], and the "Sunshine Sports Program," which encourages all school-aged children and adolescents to have at least 1 hour of outdoor physical activity, have been implemented. Nationwide survey findings from both our analysis and the Chinese National Survey on Students' Constitution and Health showed a significant improvement in weekly exercise hours and physical fitness during the following years [26,27]. However, our analysis reveals that physical activity scores have continued to decline since 2011, primarily due to lower scores in Northwest China. The geographical imbalance in policy implementation is evident and should be addressed in future efforts.

Sleep health has drawn attention in some high-income countries, and public health initiatives have been implemented to promote better sleep health [28,29]. In the United States, national surveys indicate an improvement in sleep duration due to earlier bedtimes and longer sleep durations in various segments of the population [30]. Insufficient sleep can directly impact growth and development in children and adolescents, acting as a medium to spread the adverse effects of modern social development on CVH through its impact on the endocrine system [31-34].

A population-based analysis found a causal cycle between poor diet, worsened BMI, and shortened sleep time, as all 3 metrics have experienced significant decreases during the latest decade. This suggests that overall CVH in Chinese children and adolescents could soon worsen. The LE8 guideline emphasizes that overall CVH status depends not on a single metric but on a combination of all 8 metrics. Emphasizing certain aspects when policymaking could lead to joint improvements in other metrics, making it crucial to avoid geographical biases in policy implementations.

Our study results indicate that it might be cost-effective and quicker to prioritize diet health interventions for CVH promotion, as diet could impact other CVH metrics both directly and indirectly. Moreover, comprehensive intervention strategies tailored to specific regional conditions are needed for further CVH promotion, emphasizing the need for developing evidence-based behavior change techniques [35].

It is important to note that our study only reflects the temporal change and distribution of CVH status in school-aged children and adolescents until 2018. Since then, a series of government policies, including the "Healthy China Initiative (2019-2030)," "Implementation Plan for Obesity Prevention and Control in Children and Adolescents," and "Implementation Plan for Comprehensive Prevention and Control of Myopia in Children and Adolescents," have been released to guide health promotion programs targeting Chinese children and adolescents. Key factors such as the prevalence of obesity and myopia were listed as part of assessment indicators to ensure that local governments attach enough importance to them. Dietary health was also addressed in nearly all the aforementioned policies, with related health education packages to aid in implementation. With such a strong driving force, we anticipate significant improvements in CVH and overall health status for Chinese school-aged children and adolescents by 2030, setting a valuable example for other countries.

Limitations

This study has several limitations. First, although the study data originated from one of China's largest and longest-standing nationwide studies of child and adolescent health status, there is an inherent bias in sample selection. Approximately 23% (n=6556) of the participants from the original data set were excluded due to missing data (mainly from blood samples or surveys before 2000). Although the excluded participants were not likely to have influenced the findings of this study, which focuses on CVH changes in the past 20 years, we are unable to ascertain if they would influence the overall CVH scores and their trends before 2000. Nevertheless, the original CHNS sample was not designed to be representative of China but rather to capture a diverse range of economic and demographic circumstances [12] Therefore, caution should be taken when generalizing these findings. Despite these limitations, based on the setting of the original survey, our study results still provide valuable insights into the changing trends of CVH status among children and adolescents from different socioeconomic development levels in China.

Second, although the original CHNS was designed to be a prospective cohort study, our study adopted a multiwave cross-sectional study design due to the lack of personal information. Therefore, the analyses were conducted at the population level, and further studies with individual-level data could provide confirmation of the reported population-level data. Third, concerns about the reliability of the self-reported dietary data have been raised in the scientific community, and we observed lower reported energy intakes in many Chinese children in our previous studies. However, given the complexity of the Chinese diet, objective dietary survey methods are still being developed.

Conclusions

Based on the latest LE8 metrics, Chinese school-aged children and adolescents generally exhibited a moderate level of CVH over the past decades. Poor performance in health behaviors, including diet, sleep, and physical activity may contribute to worsening overall CVH in the future. Therefore, policies and interventions addressing diet health may be the breakthrough point for promoting overall CVH status in Chinese children and adolescents.

Acknowledgments

The China Health and Nutrition Survey (CHNS) survey was supported by the Eunice Kennedy Shriver National Institute of Child Health and Human Development (R01-HD30880 and R01-HD38700); National Institute on Aging (R01-AG065357); National Heart, Lung, and Blood Institute (R01- HL108427I); National Institutes of Health (NIH) Fogarty International Center (D43-TW009077); Carolina Population Center (P2C-HD050924 and P30-AG066615) from 1989 to 2019; and the Ministry of Finance of the People’s Republic of China. This work was supported by the National Natural Science Foundation (81673192 to JM, 81903344 to BD and 82204067 to XW) and Postdoctoral Research Specialization of Vanke School of Public Health, Tsinghua University (2022BH011 to XW).

The authors greatly appreciated the colleagues and primary health care staff from the CHNS investigation groups for their hard work on data collection. We would also like to express our gratitude to Professor Zhiqiang Wang, who provided generous support when drafting this manuscript.

Data Availability

Partial data from 1989 to 2011 are available upon request to the corresponding author. The remaining data are not publicly available.

Abstract

Background: The COVID-19 symptom-monitoring apps provide direct feedback to users about the suspected risk of infection with SARS-CoV-2 and advice on how to proceed to prevent the spread of the virus. We have developed the CoronaCheck mobile health (mHealth) platform, the first free app that provides easy access to valid information about the risk of infection with SARS-CoV-2 in English and German. Previous studies have suggested that the clinical characteristics of individuals infected with SARS-CoV-2 vary by age, gender, and viral variant; however, potential differences between countries have not been adequately studied.

Objective: The aim of this study is to describe the characteristics of the users of the CoronaCheck mHealth platform and to determine country-specific and sociodemographic associations of COVID-19–related symptoms and previous contacts with individuals infected with COVID-19.

Methods: Between April 8, 2020, and February 3, 2022, data on sociodemographic characteristics, symptoms, and reports of previous close contacts with individuals infected with COVID-19 were collected from CoronaCheck users in different countries. Multivariable logistic regression analyses were performed to examine whether self-reports of COVID-19–related symptoms and recent contact with a person infected with COVID-19 differed between countries (Germany, India, South Africa), gender identities, age groups, education, and calendar year.

Results: Most app users (N=23,179) were from Germany (n=8116, 35.0%), India (n=6622, 28.6%), and South Africa (n=3705, 16.0%). Most data were collected in 2020 (n=19,723, 85.1%). In addition, 64% (n=14,842) of the users were male, 52.1% (n=12,077) were ≥30 years old, and 38.6% (n=8953) had an education level of more than 11 years of schooling. Headache, muscle pain, fever, loss of smell, loss of taste, and previous contacts with individuals infected with COVID-19 were reported more frequently by users in India (adjusted odds ratios [aORs] 1.3-8.3, 95% CI 1.2-9.2) and South Africa (aORs 1.1-2.6, 95% CI 1.0-3.0) than those in Germany. Cough, general weakness, sore throat, and shortness of breath were more frequently reported in

India (aORs 1.3-2.6, 95% CI 1.2-2.9) compared to Germany. Gender-diverse users reported symptoms and contacts with confirmed COVID-19 cases more often compared to male users.

Conclusions: Patterns of self-reported COVID-19–related symptoms and awareness of a previous contact with individuals infected with COVID-19 seemed to differ between India, South Africa, and Germany, as well as by gender identity in these countries. Viral symptom–collecting apps, such as the CoronaCheck mHealth platform, may be promising tools for pandemics to support appropriate assessments. Future mHealth research on country-specific differences during a pandemic should aim to recruit representative samples.

Introduction

The emergence of COVID-19, caused by SARS-CoV-2 infection, has led to a major ongoing public health crisis worldwide [1]. By April 2022, the COVID-19 pandemic had been associated with more than 6 million deaths out of more than 500 million confirmed cases worldwide [2]. To contain the spread of the virus, various prevention strategies, such as lockdowns, quarantine, and stringent hygiene practices, have been adopted in countries worldwide [3]. The transmission of SARS-CoV-2 occurs primarily through contact with infected individuals via respiratory droplets and aerosols [4,5]. Symptoms vary widely, with fever, cough, and fatigue among the most common [6,7], while loss of smell and loss of taste were described as the most prominent COVID-19 symptoms until 2021, before the Omicron variant became prevalent [7-9]. Symptoms may appear after an incubation period of 2-18 days after contact with the virus [3,10]. Viral shedding may occur 3 days before the onset of symptoms, and more than 50% of SARS-CoV-2 transmissions are reported to occur in asymptomatic infected individuals [11]. Therefore, early identification and isolation of individuals infected with COVID-19 is particularly important to reduce transmission [12,13]. To effectively prevent and manage COVID-19 cases (eg, by detecting clusters) at the population level, various mobile health (mHealth) apps have been developed [3,14]. Symptom-monitoring apps aim to determine whether the user may be infected with SARS-CoV-2 by asking a series of screening questions that include symptoms, such as fever, cough, and pain, and by documenting potential contacts with infected individuals. These apps aim to provide the user with information about the potential risk of being infected and to give advice about further behavior, such as avoiding physical contact with others or wearing a face mask to reduce the spread [3]. Some evidence exists suggesting that the reported clinical characteristics of individuals infected with SARS-CoV-2 vary by age, gender, variant of the virus, and type of reporting system (eg, self-reports vs clinician reported) [7,11,15-17]; however, possible differences between countries have not yet been sufficiently investigated. Since health systems operate differently worldwide (eg, centralized vs decentralized) and have responded differently to the pandemic itself, such country-specific comparisons are important [18]. Official COVID-19 data often do not reflect differences between countries, because they are subject to various uncertainties, such as small numbers of COVID-19 tests and shortcomings in the monitoring systems of countries with limited resources. Therefore, studies comparing cross-national cases run the risk of arriving at incorrect conclusions [19].

In the beginning, the CoronaCheck app was intended to enable symptom monitoring to offer quick advice to those affected. This advice needed to follow the official recommendations of the Robert Koch Institute as the National German Public Health Institute so that those affected could assess their symptoms to the best of the current knowledge and to complement the official support hotlines. Another goal was to provide certain segments of the population with easier access to information than through a telephone hotline. These included adolescents, people with hearing problems who may not fully understand the telephone voice, and migrants or tourists without sufficient language skills for a hotline in the local language.

CoronaCheck is an open-science mHealth platform with 109,603 installations and 88,537 completed questionnaires as of February 3, 2022. The app was developed in the first months of the COVID-19 pandemic in Germany in collaboration with university partners from Bavaria and software companies. The app is based on the TrackYourHealth platform [20,21] and is guided by the information and official recommendations of health authorities. The goal is to provide users with quick and easy-to-perform symptom screening and documentation of contact information to identify their risk of infection with SARS-CoV-2 [22]. CoronaCheck adheres to the Medical Device Regulations (MDR) and has been released on the official app stores of Google (April 30, 2020, 8:25 p.m.) and Apple (April 24, 2020, 12:47 p.m.). The app collects anonymous information about users' sociodemographic characteristics, COVID-19–related symptoms, and recent close contact with an infected individual to provide direct feedback to users. This includes recommendations on how individuals should act, such as seeking medical advice, avoiding contact with others, and taking other protective measures. This study aims to describe the CoronaCheck user characteristics based on data from Germany, India, and South Africa and to determine associations of self-reports of COVID-19–related symptoms and previous contacts with individuals infected with COVID-19 with country, sociodemographic characteristics (gender identity, age group, educational level), calendar year, and user status (reported for oneself vs reported for another person).

Methods

Ethical Considerations

The study was approved by the Ethics Committee of the University of Würzburg (ethical approval no. 71/20-me) and the university's data protection officer and was carried out in accordance with the General Data Protection Regulations of the European Union [23]. To have their anonymous data included in this study, all app users had to provide informed consent and agree that the data can be used for research purposes. With regard to data protection, users were also given comprehensive information at the beginning, and this information can also be viewed at any time [24].

Experimental Design

CoronaCheck was developed in a scientific collaboration between 2 German university partners from Bavaria and software companies and is based on the openly available information about SARS-CoV-2 and corresponding recommendations of the Robert Koch Institute, the German national health authority [22]. CoronaCheck combines the ideas of patient-reported outcomes and mobile sensing with direct feedback from the app to users based on their answers to the questions. The overall goal is to provide a quick test that can be easily performed at any time and with any change in symptoms. In developing the app, it was important to comply with the MDR. The app was released in the official app stores of Google and Apple and complies with the MDR.

On April 8, 2020 (10 weeks after the first COVID-19 cases were reported in Germany), data collection from this app began in Germany, followed by the first data from South Africa and India on April 24 and 28, 2020, respectively.

Ascertainment of Demographic Information

We collected data on age (years, categorized in 10-year intervals up to 79 years, ie, ≤9, 10-19, 20-29, 30-39, 40-49, 50-59, 60-69, 70-79, ≥80 years), gender identity (male, female, diverse, not specified), educational level (defined by years of schooling in 4 categories: ≤9 years, 10-11 years, ≥12 years, and "not reported" if users did not answer this question), and the information for whom the questionnaire was filled out (oneself, another person, not specified).

Ascertainment of COVID-19–Associated Symptoms

Participants were asked about the presence of 11 different COVID-19–related symptoms in the past 24 hours (yes/no): fever (defined as a temperature of 37.5 °C or more), sore throat, stuffed or runny nose, cough, loss of smell, loss of taste, shortness of breath, headache, muscle or joint pain, diarrhea, and general weakness. In the case of diarrhea, the symptom was assessed only in the first 2 months (April-June 2020), before it was deleted in accordance with the recommendations of the Robert Koch Institute.

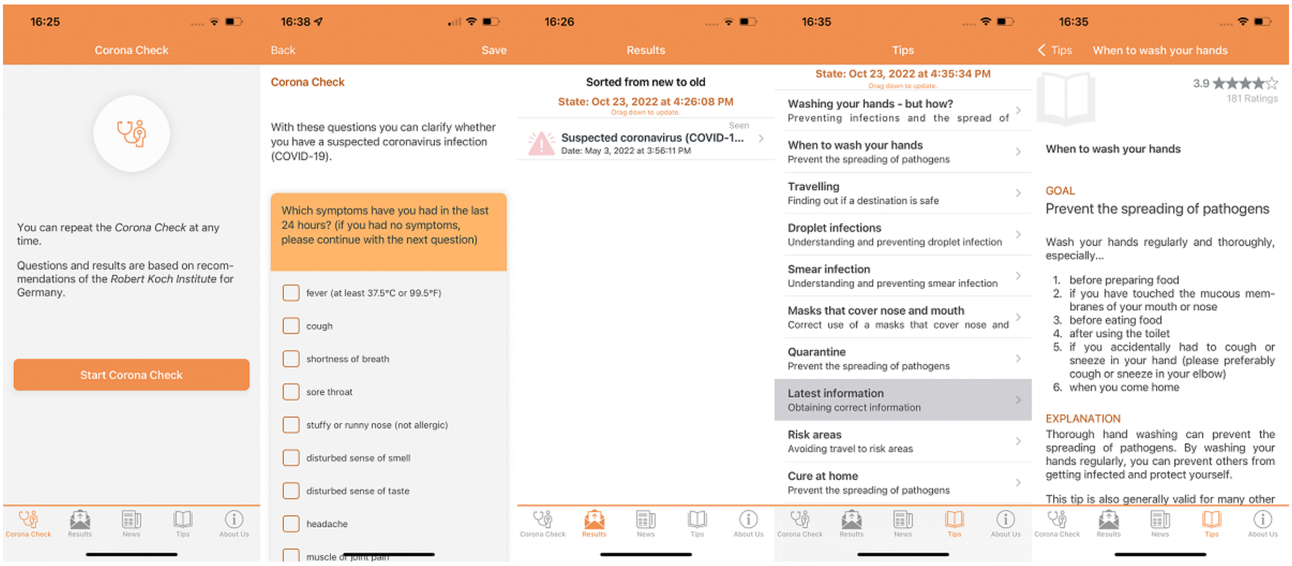
Assessment of Close Contact With a Confirmed Case of COVID-19

We asked participants whether they or the person for whom they completed the questionnaire had had close contact with a person with confirmed COVID-19 in the past 14 days (yes, no, or not specified). We did not ask whether this confirmed case was based on a polymerase chain reaction (PCR) test, a medical diagnosis (including clinical radiology tests), or other information.

App Development and Illustrations

The app was developed based on the TrackYourHealth platform [20,21]. This always consists of a native iOS (Objective C) and a native Android (Java) app as well as a server backend. The latter includes a relational database and interface for mobile apps. The interface is based on the representational state transfer (REST) architectural style, and the connection to the apps is carried out via an encrypted secure sockets layer (SSL) channel [25]. The apps include a questionnaire for the COVID-19 self-check and a module that calculates the feedback for the symptoms. The module consists of the server-side calculation and a component in the apps that displays the feedback. Furthermore, 2 other modules are enabled in the app, one that displays general news located on the server and one that provides tips about COVID-19. The tips are intended to make everyday life easier and can also be evaluated by users in terms of their usefulness. Finally, the app provides information about the team, privacy, and declarations of conformity. The server for the data acquisition is located at the Service Center Medical Informatics at the University Hospital in Würzburg (SMI), and the app has been published in the official stores of Apple and Google. The last thing to mention is that all information (ie, the questionnaire, feedbacks, tips, news) is cached on the mobile devices, but server-side changes appear as an update in the app. Figure 1 shows screenshots of the app. The first screenshot shows the screen to start the test, the second the test in action, the third the feedback screen, the fourth the list of tips, and the fifth a detail page for a tip.

Figure 1. App illustration: screenshots of (1) Start Check, (2) Questionnaire, (3) Feedback Module, (4) Tips, and (5) Detailed Tip.



You can repeat the *Corona Check* at any time.

Questions and results are based on recommendations of the *Robert Koch Institute* for Germany.

With these questions you can clarify whether you have a suspected coronavirus infection (COVID-19).

Which symptoms have you had in the last 24 hours? (if you had no symptoms, please continue with the next question)

- ☐ fever (at least 37.5°C or 99.5°F)
- ☐ cough
- ☐ shortness of breath
- ☐ sore throat
- ☐ stuffy or runny nose (not allergic)
- ☐ disturbed sense of smell
- ☐ disturbed sense of taste
- ☐ headache
- ☐ muscle or joint pain

Prevent the spreading of pathogens

When to wash your hands

GOAL

Prevent the spreading of pathogens

Wash your hands regularly and thoroughly, especially...

1. before preparing food
2. if you have touched the mucous membranes of your mouth or nose
3. before eating food
4. after using the toilet
5. if you accidentally had to cough or sneeze in your hand (please preferably cough or sneeze in your elbow)
6. when you come home

EXPLANATION

Thorough hand washing can prevent the spreading of pathogens. By washing your hands regularly, you can prevent others from getting infected and protect yourself.

This tip is also generally valid for many other

Data Management

Only participants who met the following criteria were included in the final analysis: provided consent to use data for research purposes; answered questions about age, user status, and gender identity; provided GPS data; and answered questions about previous contacts (in the past 14 days) with a person infected with COVID-19 and the presence or absence of the 11 symptoms listed before. In case the app was used multiple times by a single person, only the first recording was used. It should be noted that every time a questionnaire is filled out, the GPS location is saved, provided that the user gives their consent. The location permission is regulated by the operating system (Android or iOS). We do not store the raw location, but we process the data we receive from the operating system to make it more coarse-grained, and only store a value with an accuracy of 11.1 km. The level of detail with which we store the GPS sensor data was determined in discussions with all stakeholders, the institutional review board, and relevant laws and regulations. Further, only data from countries with more than 3000 users (Germany, India, and South Africa) were included in the statistical analyses. Data from other countries were comparatively small (each <600 users). The educational level was categorized into 3 groups (<12 years, ≥12 years, missing). Since most reports were collected in 2020 and the first variants of concern emerged around the turn of 2020/2021 [26], we defined 2 categories (2020 and 2021/2022) for the calendar year variable.

Statistical Analysis

Descriptive statistics were conducted to describe the CoronaCheck user characteristics. To compare sociodemographic characteristics (gender identity, age, education), calendar year, and user status among app users from Germany, India, South Africa, and other countries, chi-square tests were applied. Chi-square tests and Fisher exact tests were performed to compare the proportion of users who reported COVID-19–related symptoms and contact with a person infected with COVID-19 between 3 countries (Germany, India, and South Africa), gender identity (3 categories), educational level (3 categories), calendar years (2020 vs 2021/2022), and user status (symptoms reported for oneself vs another person). Univariate logistic regressions were calculated to assess the associations between reporting COVID-19–related symptoms and reporting contact with a person who tested positive for COVID-19 with country, gender, age (in 10-year categories), calendar year, educational level, and user status. Multivariable logistic regression was conducted to adjust the data for country, gender identity, age, calendar year, education level, and user status. Odds ratios (ORs) and their 95% CIs were estimated to assess the statistical uncertainty. All statistical analyses were performed using SPSS version 26 (IBM Corp), and all tests were 2-tailed.

Results

Study Population

From April 8, 2020, to February 3, 2022, we received a total of 88,537 recordings. Recordings with missing GPS data (n=29,449, 33.3%), missing consent that data can be used for research purposes (n=30,836, 34.8%), or missing information about age (n=2001, 2.3%), gender identity (n=1927, 2.2%), or user status (n=10,039, 11.3%) were excluded. Only the first recording per person was included in the case of multiple use. After applying these exclusion criteria, 23,179 recordings remained. All recordings included answers on the questions about previous contact (in the past 14 days) with a person infected with COVID-19 and the presence or absence of the 11 symptoms listed before. Most recordings were from Germany (n=8116, 35.0%), India (n=6622, 28.6%), and South Africa (n=3705, 16.0%). Recordings from 131 other countries ranged from 1 (0.004%) to 595 (2.6%) per country and were summarized into 1 group, "other countries" (n=4736, 20.4%).

The characteristics of the sample stratified by country are summarized in Table 1. In short, about half of the users were younger than 30 years old, with a higher proportion of young people using the app in India than in Germany. On average, 35.5% (n=8218) of the users were women, with the lowest proportion of women using the app in India.

The 4736 (20.4%) app users from “other countries” were excluded from further analysis, yielding a final analytic cohort of 18,443 (79.6%) individuals.

Table 1. Characteristics of CoronaCheck app users stratified by country.

Characteristics	Country				Total (N=23,179), n (%)
	Germany (n=8116, 35.0%), n (%)	India (n=6622, 28.6%), n (%)	South Africa (n=3705, 16.0%), n (%)	Other countries (n=4736, 20.4%), n (%)

Occurrence of COVID-19–Related Symptoms and Close Contact With an Infected Person

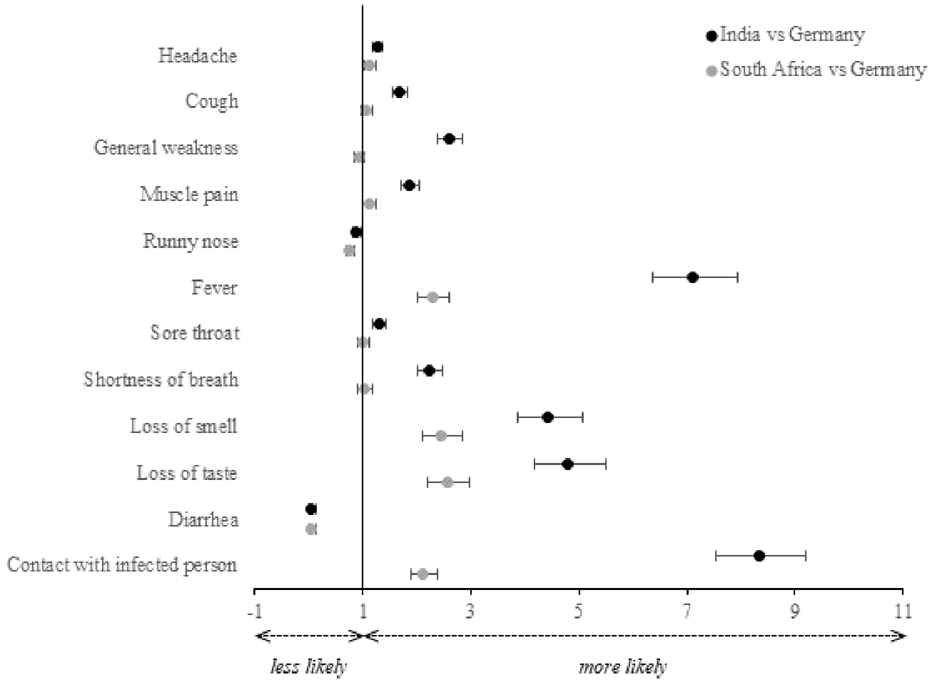
Of the 18,443 recordings collected in Germany, India, and South Africa, the 3 most frequent self-reported symptoms were headache (n=5351, 29.0%), cough (n=5219, 28.3%), and general weakness (n=4592, 24.9%), followed by muscle pain (n=4131, 22.4%), runny nose (n=3984, 21.6%), fever (n=3815, 20.7%), and sore throat (n=3646, 19.8%). Shortness of breath (n=2852, 15.5%), loss of smell (n=2224, 12.1%), loss of taste (n=2161, 11.7%), and diarrhea (n=136, 0.7%) were reported less frequently.

In 5105 (27.7%) of the 18,443 recordings collected in the 3 countries, the app users reported close contact with someone infected with SARS-CoV-2 in the past 14 days.

Exploration of Country Differences

We found differences between the 3 countries in all symptoms (Figure 2 and Multimedia Appendix 1, Tables S1 and S2). We observed higher odds of reporting headache, cough, general weakness, muscle pain, fever, sore throat, shortness of breath, and loss of smell and taste: the adjusted odds ratios (aORs) were 1.27-7.10 (95% CI 1.17-7.95) for app users from India compared to Germany. In contrast, app users from India reported diarrhea less frequently than those from Germany (aOR 0.05, 95% CI 0.02-0.12). App users from South Africa were more likely to report headache, muscle pain, fever, and loss of smell and taste (aORs 1.11-2.56, 95% CI 1.00-2.98), while they were less likely to report runny nose (aOR 0.76, 95% CI 0.68-0.84) and diarrhea (aOR 0.03, 95% CI 0.01-0.12) than users from Germany. App users from India were significantly more likely to have knowledge of close contact with a person positive for SARS-CoV-2 in the past 14 days compared to Germany (aOR 8.33, 95% CI 7.53-9.21). To a lesser extent, this was also the case for app users from South Africa compared to Germany (aOR 2.12, 95% CI 1.89-2.38).

Figure 2. aORs and their 95% CIs stratified by the country of the CoronaCheck app users. aOR: adjusted odds ratio.

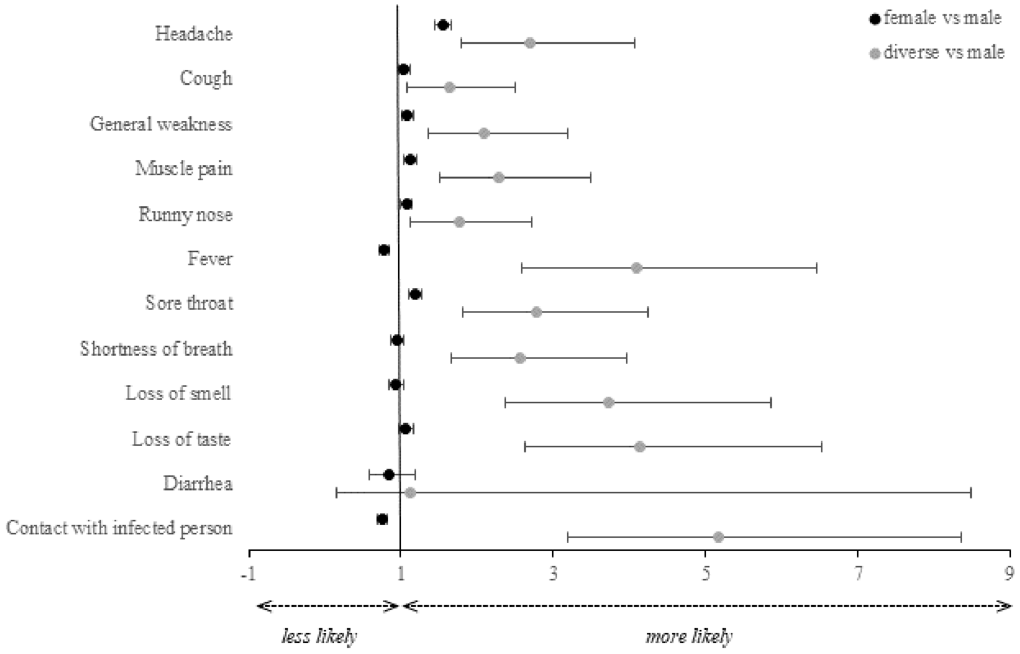


Exploration of Sociodemographic Differences

Gender Identity Differences

Our results showed gender identity differences for all symptoms except diarrhea (Figure 3 and Multimedia Appendix 1, Tables S3 and S4). Women app users reported fever less often (aOR 0.78, 95% CI 0.72-0.85) and headache, general weakness, muscle pain, runny nose, and sore throat more often (aORs 1.07-1.55, 95% CI 1.00-1.65) compared to men. Except for diarrhea, gender-diverse users reported COVID-19–related symptoms more often compared to men (aORs 1.64-4.14, 95% CI 1.08-6.53). Women were less likely than men to know of recent contact with a person infected with SARS-CoV-2 (aOR 0.76, 95% CI 0.70-0.82). Gender-diverse users had 5.16 times higher odds (95% CI 3.18-8.36) of reporting close contact with a person infected with SARS-CoV-2 in the past 14 days compared to app users who were men.

Figure 3. aORs and their 95% CIs stratified by the gender identity of the CoronaCheck app users. aOR: adjusted odds ratio.



Age Effects

Older persons were less likely to report headache, cough, general weakness, runny nose, fever, sore throat, and loss of smell (aORs 0.86-0.96, 95% CI 0.84-0.99, per 10-year category), whereas they were more likely to report muscle pain (aOR 1.03, 95% CI 1.01-1.05, per 10-year category; Table 2). Older persons were less likely to report close contact with a person positive for SARS-CoV-2 in the past 14 days (aOR 0.87, 95% CI 0.85-0.89, per 10-year category).

Table 2. Unadjusted ORs[a] and aORs[b] by 10-year age category (N=18,445).[c]

Variable	Unadjusted OR (95% CI)	aOR (95% CI)
Headache	0.84 (0.82-0.86)	0.87 (0.85-0.89)
Cough	0.85 (0.84-0.87)	0.90 (0.89-0.92)
General weakness	0.87 (0.86-0.89)	0.96 (0.94-0.99)
Muscle pain	0.96 (0.94-0.98)	1.03 (1.01-1.05)
Runny nose	0.87 (0.85-0.89)	0.86 (0.84-0.88)
Fever	0.76 (0.74-0.77)	0.92 (0.90-0.94)
Sore throat	0.84 (0.82-0.86)	0.87 (0.85-0.89)
Shortness of breath	0.91 (0.89-0.93)	0.99 (0.97-1.02)
Loss of smell	0.81 (0.79-0.83)	0.95 (0.92-0.98)
Loss of taste	0.83 (0.81-0.86)	0.98 (0.95-1.02)
Diarrhea	1.17 (1.08-1.28)	0.92 (0.84-1.01)
Contact with infected person	0.71 (0.70-0.73)	0.87 (0.85-0.89)

[a] OR: odds ratio.

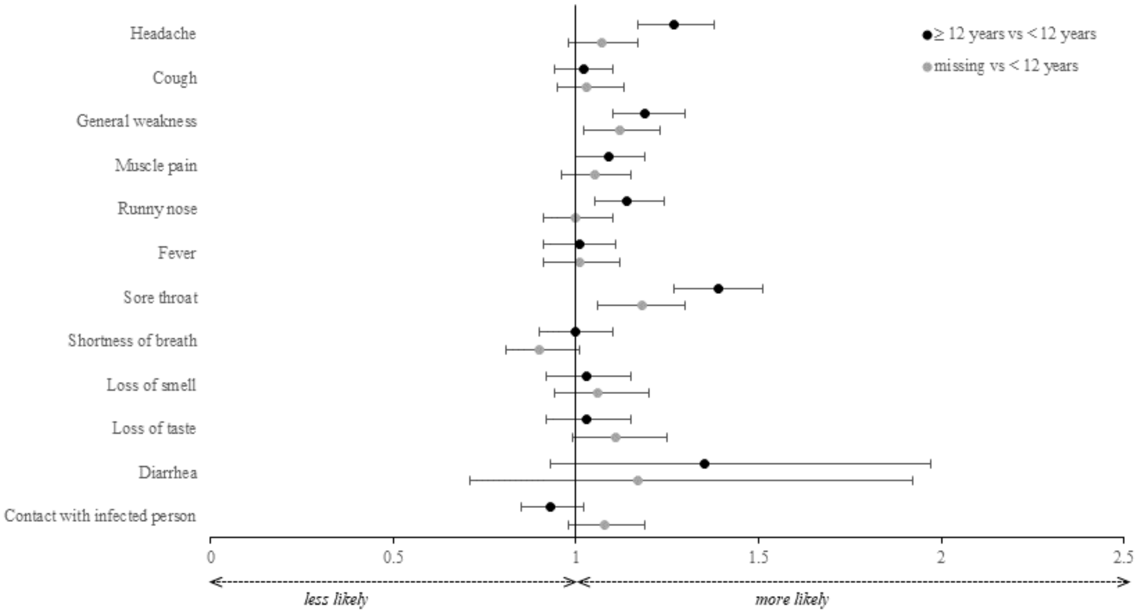
[b] aOR: adjusted odds ratio.

[c] The multivariable regression model was adjusted for country, gender identity, calendar year, education, and user status.

Differences Concerning the Educational Level

App users with at least 12 years of school education reported headache, general weakness, muscle pain, runny nose, and sore throat more often compared to users with 11 or fewer years of education (aORs 1.09-1.39, 95% CI 1.00-1.51; Figure 4 and Multimedia Appendix 1, Tables S5 and S6).

Figure 4. aORs and their 95% CIs stratified by educational level (years of schooling). aOR: adjusted odds ratio.

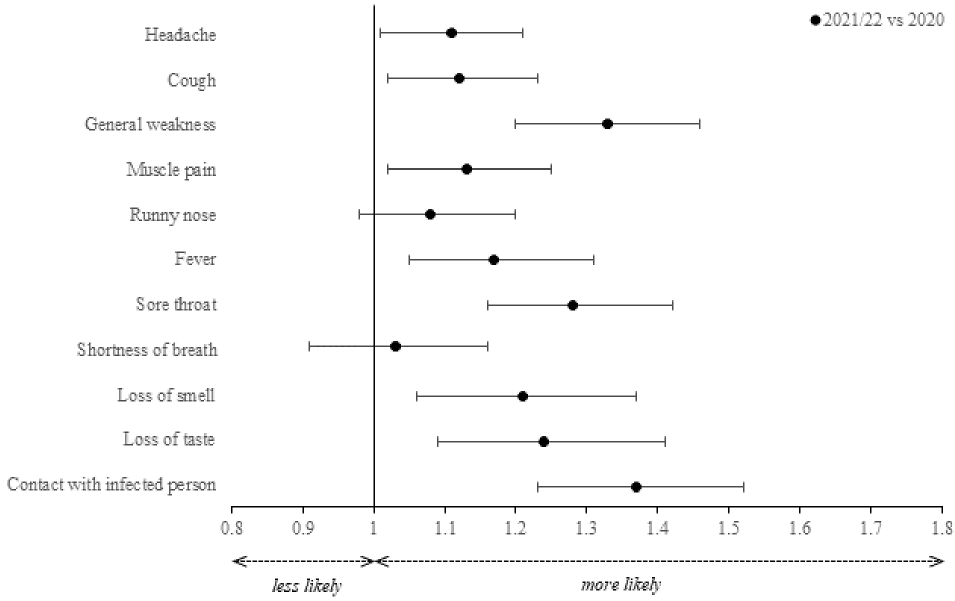


Exploration of Differences Between Calendar Years

Most COVID-19–associated symptoms were more likely to be reported by app users in 2021/2022 compared to 2020 (aORs 1.11-1.33, 95% CI 1.01-1.46; Figure 5 and Multimedia Appendix 1, Tables S7 and S8). The occurrence of runny nose and shortness of breath was not associated with the calendar year.

The reporting of close contact with someone infected with SARS-CoV-2 in the past 14 days was more likely in 2021/2022 compared to 2020 (aOR 1.37, 95% CI 1.23-1.52).

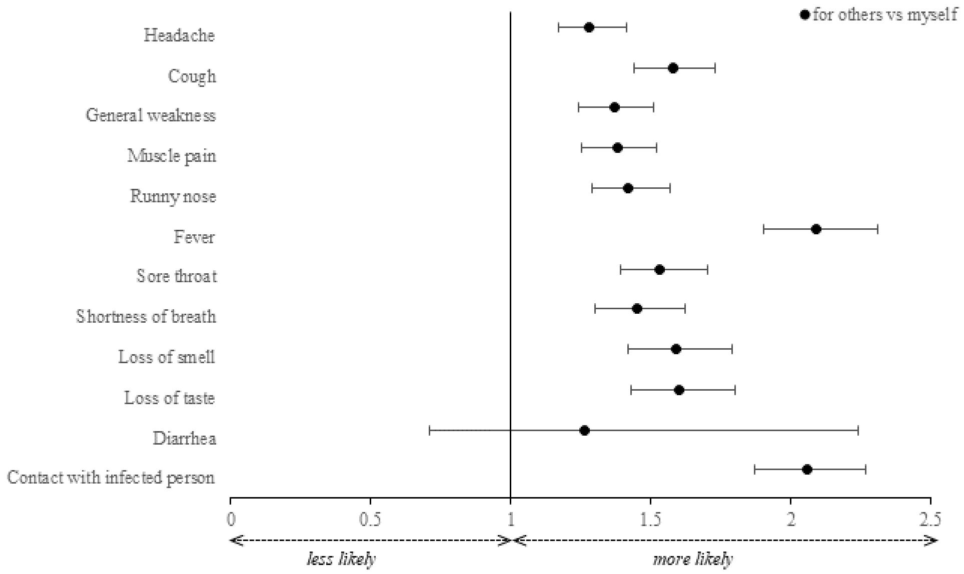
Figure 5. aORs and their 95% CIs stratified by the year of using the CoronaCheck app. aOR: adjusted odds ratio.



Exploration of Differences Concerning the Status of the Person (Reported for Oneself vs for Others)

We found differences between persons for whom symptoms were reported for all symptoms except diarrhea (Figure 6 and Multimedia Appendix 1, Tables S9 and S10). Symptoms as well as close contact with a person positive for SARS-CoV-2 in the past 14 days were more often reported when the data were entered for another person compared to for oneself (aORs 1.28-2.09, 95% CI 1.17-2.31).

Figure 6. aORs and their 95% CIs stratified by user status (ie, user-reported symptoms for another person or for oneself). aOR: adjusted odds ratio.



Discussion

Principal Findings

Our study showed that self-reported COVID-19–related symptoms and reports of previous contact with individuals infected with COVID-19 vary by country, gender identity, age, calendar year, education, and user status.

Overall, the most frequently reported symptoms were headache, cough, and general weakness. Symptoms commonly included in COVID-19 case definitions, such as shortness of breath and fever [27,28], were less frequently reported by app users. Especially app users from India (compared to Germany), as well as gender-diverse (compared to men) users were more likely to report COVID-19–related symptoms and previous close contact with infected individuals.

Comparison With Prior Work

Our findings regarding the occurrence of common symptoms, such as headache, general weakness, and runny nose, are consistent with previous studies. Specifically, previous studies in individuals infected with PCR-confirmed SARS-CoV-2 have shown that fatigue, headache, malaise, myalgia, and upper respiratory symptoms (sore throat, cough, sneezing, rhinitis) occur early after symptom onset, whereas symptoms considered more characteristic of COVID-19, such as lower respiratory and chemosensory symptoms, occur later [17,29,30].

Our study showed differences in self-reported COVID-19 symptoms primarily between Germany, India, and South Africa. App use from India and South Africa was associated with a disproportionately high likelihood of experiencing COVID-19–related symptoms and knowledge of close contact with an infected person. Specifically, the likelihood of reporting contact with a person infected with COVID-19 was 8.3-fold higher among users from India compared to Germany. Most symptoms were also more likely to be reported by users from India than by German users. World Health Organization (WHO) official data on confirmed COVID-19 cases show conflicting results, with higher numbers of confirmed cases and deaths per capita in Germany than in India and South Africa [2]. In more detail, by the beginning of February 2022, the cumulative confirmed COVID-19 cases amounted to 15% of the German population, higher than in South Africa (6%) and India (3%). The discrepancy is likely due to several factors of uncertainty in the COVID-19 data, such as the low number of COVID-19 tests and deficiencies in surveillance systems in India that result in underreporting of infections and deaths [31]. Studies that compare cross-national cases run the risk of reaching incorrect conclusions [19]. Thus, a higher likelihood of reporting a previous contact with a person testing positive for COVID-19 in our study and the reporting of symptoms associated with COVID-19 suggest that there is substantial underreporting bias in the existing data from India. In addition, higher odds of reporting previous contact with a person positive for COVID-19 (OR 2.12) as well as higher odds of reporting several symptoms were observed for app users from South Africa compared to Germany. Although South Africa is the country that performs the most COVID-19 testing among African countries and is one of the few countries that produces vital statistics, it is likely that the number of COVID-19 cases and deaths is underestimated [32]. The findings suggest that effective management of the pandemic is particularly difficult in countries with limited resources, inadequate testing, and weak health systems.

Gender identity differences were found in this study. Several symptoms were more likely to be reported by women and gender-diverse users than by men. Exceptions to the general assumption that women are more likely to report symptoms than men were observed for fever. Previous studies of individuals testing positive for COVID-19 support the assumption that women are more likely than men to be affected by headache and sore throat, as well as rhinitis [15,17,33,34]. Results regarding muscle pain [15,17] are equivocal, and fever seems to be less prevalent in women [33]. Female users less frequently reported contact with a person positive for COVID-19 compared to male users. Previous studies highlight that women are more willing to adhere to protective measures [35,36], which might be 1 explanation for the lower odds of self-reported contact with an infected person in women individuals and possibly also to the overall lower proportion of women app users.

The impact of COVID-19 on COVID-19 symptoms in gender-diverse individuals has not been well captured; however, the more than 5-fold increase in the likelihood of gender-diverse users reporting prior contact with an individual who tested positive for COVID-19, as well as the higher odds of reporting symptoms observed in this study, is supported by the notion that gender-diverse individuals are more vulnerable to COVID-19, which extends to the areas of increased barriers to COVID-19 transmission prevention strategies, decreased physical and mental health, and barriers to health services [37]. As such, the higher odds of reporting contact with persons infected with COVID-19 corroborates the reported reduced options of gender-diverse individuals to practice physical distancing, as they are more likely to be essential workers, requiring in-person work and often commuting by public transport [37]. Other discussed aspects are the higher behavioral risks, such as substance use and smoking, which are common among gender-diverse people [38]. Studies have also reported a higher risk for chronic health conditions, such as diabetes, in gender-diverse individuals [39], and they often face barriers to health care services [40]. Greater vaccination hesitancy has also been reported, likely associated with medical mistrust due to the historical mistreatment of gender-diverse individuals [37]. Thus, all these factors might place this population at greater risk for COVID-19–related illness. Considering these previous reports as well as the findings of the study at hand, gender-diverse individuals seem to be among those minorities most strongly affected by the COVID-19 pandemic.

Older age was found to be associated with a lower likelihood of reporting contact with a person infected with COVID-19. In support of this finding, previous studies have found an association between older age and self-reported adherence to COVID-19 public health measures [41]). Reports of age-related differences in the clinical presentation of patients with COVID-19 suggest that older patients with COVID-19 are more likely to have general symptoms (fever, fatigue, gastrointestinal symptoms) than specific symptoms (loss of smell and taste) [17,33,34]. In this study, the odds of reporting almost all COVID-19–related symptoms decreased with increasing age. Given the lower likelihood of being a contact in older individuals, it can be surmised that the proportion of app users infected with COVID-19 was lower among older users, which likely contributed to their lower frequency of reported symptoms.

The increased odds of reporting contact with someone who tested positive for SARS-CoV-2 in 2021/2022 compared to 2020 is supported by the increased transmission of the variants of concern, which predominated from 2021 onward. The Alpha variant (B.1.1.7), first identified in the United Kingdom at the end of 2020; the Beta variant (B.1.351), first identified in South Africa at the end of 2020; the Delta variant (B.1.617.2), first identified in India at the end of 2020; and the Omicron variant (B.1.1.529), first identified in South Africa at the end of 2021, have roughly 50% increased transmission [11]. In addition, the higher odds of reporting symptoms after 2020 compared to the year in which the SARS-CoV-2 wild-type virus was dominant might be due to the increased disease severity of the Alpha, Beta, and Delta variants [26].

In this study, the person for whom the symptom check was used affected the outcome: the likelihood of reporting contact with a person positive for COVID-19 and various COVID-19–related symptoms was higher when the app was used to check symptoms for another person. Thus, it appears that the app was used more frequently for other individuals when there was a specific suspicion of infection. Differences in reporting systems have been observed previously, with a higher percentage of symptoms reported in self-reports than in physician reports [7]. Therefore, the use of a self-report app seems to be an appropriate method for recording COVID-19–related symptoms.

Strengths

Our study had several strengths. First, data were collected over a long time interval that began early in the pandemic. Data were collected across different countries, with considerable differences in health care systems, economic status, and governmental regulations to combat the spread of the virus, therefore increasing the generalizability of the findings. The number of gender-diverse individuals among app users also allowed us to identify the specifics of symptoms reported by COVID-19 among gender minorities. In addition, it was possible to develop the app in a relatively short period and adapt it to the MDR, which meant that, among other things, special consideration was given to the risks involved in using the app. The app made use of GPS measurements when users allowed it, which shows that such measurements are also welcomed by many users. Finally, the content of the app was based on the recommendations of the Robert Koch Institute, the national public health institute in Germany. We therefore regularly adapted the app to the changing official recommendations.

Limitations

Our study also had some limitations that need to be noted. First, objective data on whether app users tested positive for COVID-19 or not were not available. Thus, we were not able to validate the subjectively reported information about COVID-19 test positivity. Moreover, no objective data were available if the infected contact person of the user had a positive COVID-19 test; however, the corresponding question asked specifically about contact with a person who was a confirmed case.

Second, all information about specific symptoms was self-reported by the users, which was not validated by, for example, doctors' diagnoses. In those cases where the questionnaire was filled out for another person, the validity of the data is further limited. This especially applied to the youngest and oldest app users, where a higher proportion of reported information was not entered by themselves (51.5% among children ≤9 years old and 21.1% among the elderly ≥80 years old vs 12.1% among 10-79-year-old persons).

Third, participants' socioeconomic status was limited to the information about the years of education in school. This information was further limited by the high number of missing entries as well as by differences in the educational systems between countries.

Fourth, we had to adjust the app several times to meet the changing official recommendations of the German public health authority, the Robert Koch Institute, over the course of the pandemic. Therefore, during the overall time of app usage, especially in the early phase of the pandemic, some information was slightly differently presented to users. For example, the question regarding diarrhea was only administered for the first 2 months before it was removed.

Furthermore, as data collection was based on a mobile app, results might not be generalized to individuals with lower affinity for digital health apps. In concrete terms, this also means that information and selection bias must be taken into account. However, observer and recall bias can be reduced to some extent by an app in terms of patient-reported outcomes. Therefore, app-based data have strengths as well as weaknesses that need to be considered. Moreover, mHealth apps are always not just tools but also social phenomena that create a feedback loop between app and user, which means that users continuously adjust their behavior as they use the app. However, since the CoronaCheck app has collected a comparatively large amount of data in different cultures compared to other mHealth apps, certain differences may have been balanced out in the sense of generalization. Finally, it should be mentioned that apps that are made available on multiple mobile operating systems will also always generate differences in the resulting data, as the user interface is never completely identical.

Conclusion

Our app-based results indicated country-specific differences in COVID-19–related symptom patterns. It seems that self-reported COVID-19–related symptoms and awareness about previous contacts with individuals infected with COVID-19 are more likely among app users from India and South Africa (compared to users from Germany), as well as in gender-diverse (compared to male) users. Symptom assessment tools could play a positive role in the context of widespread infectious diseases. In general, with COVID-19, we saw that the way symptoms were reported and the way infection and COVID-19 deaths were defined were different [42]. For future pandemics, app-based global data collection, such as that of CoronaCheck, is another tool to better equip us and support appropriate assessments.

Future mHealth research on country-specific differences during a viral pandemic should aim to recruit representative samples. If pseudonymous assessments are possible, studies should collect information about symptoms, confirmed testing, and adherence to public health recommendations longitudinally.

Acknowledgments

We are grateful to all app users for providing data for research purposes. We thank Rachel Dale for proofreading the manuscript and Marc Schickler for his help in visualizing the results.

Data Availability

The data presented in this study are only available on request from the corresponding author. The data are not publicly available, because participants' informed consent did not cover public deposition of data.

Authors' Contributions

EH analyzed the data and drafted the manuscript. TK was the coprincipal investigator, supervised the development of the app regarding the medical content, planned and developed the questionnaire, and participated in the planning of the statistical analyses and writing of the manuscript. CS participated in the development of the study design and questionnaire and updated the medical content and corresponding recommendations by state and nationwide health authorities. WS and MW participated in the development of the study design. PH spent resources and provided advice. MW participated in the statistical analyses. TP analyzed the data and drafted the manuscript. RP was the principal investigator, was responsible for the study design and technical development, and drafted the manuscript. All coauthors have reviewed and approved the manuscript for submission. The corresponding author attests that all listed authors meet authorship criteria and that no others meeting the criteria have been omitted.

Conflicts of Interest

None declared.

Abstract

Background: Long COVID induces a substantial global burden of disease. The pathogenesis, complications, and epidemiological and clinical characteristics of patients with COVID-19 in the acute phase have been evaluated, while few studies have characterized the epidemiology, symptomatology, and risk factors of long COVID symptoms. Its characteristics among patients with COVID-19 in the general population remain unaddressed.

Objective: We examined the prevalence of long COVID symptoms, its symptom patterns, and its risk factors in 4 major Chinese cities in order to fill the knowledge gap.

Methods: We performed a population-based, multicenter survey using a representative sampling strategy via the Qualtrics platform in Beijing, Shanghai, Guangzhou, and Hong Kong in June 2022. We included 2712 community-dwelling patients with COVID-19 and measured the prevalence of long COVID symptoms defined by the World Health Organization (WHO), and their risk factors. The primary outcomes were the symptoms of long COVID, with various levels of impact. A descriptive analysis of the prevalence and distribution of long COVID symptoms according to disease severity was conducted. A sensitivity analysis of increasing the number of long COVID symptoms was also conducted. Univariate and multivariate regression analyses were performed to examine the risk factors of severe long COVID symptoms, including age, gender, marital status, current occupation, educational level, living status, smoking habits, monthly household income, self-perceived health status, the presence of chronic diseases, the use of chronic medication, COVID-19 vaccination status, and the severity of COVID-19.

Results: The response rate was 63.6% (n=2712). The prevalence of long COVID, moderate or severe long COVID, and severe long COVID was 90.4% (n=2452), 62.4% (n=1692), and 31.0% (n=841), respectively. Fatigue (n=914, 33.7%), cough (n=865, 31.9%), sore throat (n=841, 31.0%), difficulty in concentrating (n=828, 30.5%), feeling of anxiety (n=817, 30.2%), myalgia (n=811, 29.9%), and arthralgia (n=811, 29.9%) were the most common severe long COVID symptoms. From multivariate regression analysis, female gender (adjusted odds ratio [aOR]=1.49, 95% CI 1.13-1.95); engagement in transportation, logistics, or the discipline workforce (aOR=2.52, 95% CI 1.58-4.03); living with domestic workers (aOR=2.37, 95% CI 1.39-4.03); smoking (aOR=1.55, 95% CI 1.17-2.05); poor or very poor self-perceived health status (aOR=15.4, 95% CI 7.88-30.00); ≥3 chronic diseases (aOR=2.71, 95% CI 1.54-4.79); chronic medication use (aOR=4.38, 95% CI 1.66-11.53); and critical severity of COVID-19 (aOR=1.52, 95% CI 1.07-2.15) were associated with severe long COVID. Prior vaccination with ≥2 doses of COVID-19 vaccines was a protective factor (aOR=0.35-0.22, 95% CI 0.08-0.90).

Conclusions: We examined the prevalence of long COVID symptoms in 4 Chinese cities according to the severity of COVID-19. We also evaluated the pattern of long COVID symptoms and their risk factors. These findings may inform early identification of patients with COVID-19 at risk of long COVID and planning of rehabilitative services.

KEYWORDS

COVID-19; epidemiology; symptom; risk factor; long COVID; multicenter survey; general population

Introduction

COVID-19 has posed an unprecedented challenge to public health worldwide. As of July 9, 2022, more than 551 million cases and 6.3 million deaths have been reported [1]. Apart from the acute phase of the infection, the disease may also manifest as persistent, lingering symptoms known as long COVID [2-5]. The World Health Organization (WHO) has defined long COVID as a condition that occurs in patients with COVID-19 usually 3 months from the onset of the disease, with symptoms that last for at least 2 months and that the symptoms could not be attributed to an alternative diagnosis [6]. These long-term symptoms could exert a devastating effect [7], as they could involve multiple organ systems, and have been linked to psychosocial consequences [8]. A study has found that almost 10% of people with COVID-19 reported long COVID stmptoms 4-12 weeks after the infection [9,10].

The impact of long COVID symptoms has been observed even in patients with mild COVID-19, patients who do not require respiratory support or intensive care, moderate-to-severe cases among hospitalized patients who turn out to have cleared SARS-CoV-2 and have been discharged from hospitals, mild-to-moderate cases in outpatient clinics, and even children [11]. It has been reported that a substantial proportion of patients with COVID-19 continue to suffer from long-term adverse effects involving almost all bodily systems, including respiratory, gastrointestinal, neuropsychiatric, cardiovascular, and dermatological systems [12]. A recent study performed by our team showed that approximately 76% of patients with COVID-19 suffered from long COVID symptoms, including fatigue, poor memory, and hair loss, within 6 months of hospital admission [13].

The prevalence of long COVID symptoms appeared not only in Hong Kong and other Chinese cities but also across different countries [14]. For example, a study in Germany described different symptoms of long COVID, including headache, cough, shortness of breath, fatigue, dysosmia or anosmia, brain fog, or cognitive impairment [15]. Similar to these studies, the pattern of long COVID symptoms and their impacts have been investigated. For example, fatigue was the most common symptom in patients who had long COVID irrespective of the severity of their initial infection. Patients who had severe fatigue between 3 and 6 months might not encounter symptom improvement or resolution in the long term. Even those patients who had mild COVID-19 could develop long-term symptoms, including cough, fatigue, low-grade fever, shortness of breath, headaches, chest pain, muscle pains and weakness, metabolic disruption, neurocognitive difficulties, and gastrointestinal upset [3]. Long COVID symptoms could largely affect health-related quality of life and activities of daily living [16,17].

There could be many contributing factors that lead to prolonged patient recovery, such as deconditioning, relapse or reinfection, weak or absent antibody response, inflammatory and other immune reactions, and posttraumatic stress [3]. Risk factors that are associated with sociodemographic characteristics are important. These include gender, employment status, marital status, religion, multimorbidity, and living status [18-21].

Although the pathogenesis, complications, and epidemiological and clinical characteristics of patients with COVID-19 in the acute phase have been evaluated [22,23], few studies have characterized the epidemiology, symptomatology, and risk factors of long COVID. Previous studies examining these attributes are relatively few, mainly focused on hospitalized patients, or used a convenience sampling strategy [8]. In addition, the timing of assessment varied from 14 days to 6 months—or was not even reported—which is not consistent with the time frame of long COVID proposed by WHO, which is 3 months after COVID-19 infection [6]. In a recent review by Crook et al [8], 1 of the top priorities of research includes the precision epidemiology and risk factors of long COVID.

Hence, we aimed to fill these knowledge gaps by evaluating the prevalence of long COVID symptoms in 4 major Chinese cities using a representative sampling methodology. We also examined the distribution of COVID-19 symptoms and explored the risk factors of long COVID symptoms. We hypothesized that age, gender, the presence of chronic diseases, the use of chronic medications, the severity of COVID-19, and not receiving COVID-19 vaccines are associated with the occurrence of long COVID symptoms based on findings from recent studies [18,24,25].

Methods

Study Design

This was a cross-sectional survey of patients with COVID-19, aged ≥18 years, and residing in 4 cities of China: Beijing, Shanghai, Guangzhou, and Hong Kong. The study was launched on June 2, 2022, and closed on June 28, 2022. We used Qualtrics [26], an online survey platform. Inclusion criteria included age ≥18 years, with a diagnosis of COVID-19 from January 2020 to June 2022 in Beijing, Shanghai, Guangzhou, or Hong Kong. We excluded subjects without a history of COVID-19 infection. The survey collected the dates of COVID-19 vaccination, COVID-19 diagnosis, and recovery.

Ethical Considerations

The Survey and Behavioural Research Ethics Committee of the Chinese University of Hong Kong approved the study (approval no. SBRE-21-0730). All eligible participants provided digital informed consent via electronic means at the beginning of the survey. The survey did not collect personally identifiable information, and we encrypted email addresses collected for survey distribution as anonymized respondent identities. All respondents' data were recorded in an anonymous manner with a unique internally generated reference key. We assured the respondents of the anonymous, confidential nature of the study, where only aggregate data would be reported. We strictly adhered to the data privacy policy in the approved study protocol.

Survey Instrument

An expert panel consisting of epidemiologists, physicians, public health professionals, professors, and biostatisticians composed and validated the survey. The survey was pilot-tested to optimize coherence and clarity and was subsequently revised according to the pilot findings. During the curation of survey items, we referred to published studies that used validated survey instruments for long COVID symptoms [13,27]. The survey comprised 31 questions and required a median of 13 minutes to complete. The information sheet of the survey provided background information about COVID-19. The survey was delivered in traditional Chinese for participants in Hong Kong and simplified Chinese for respondents in the other 3 cities of mainland China. Before commencement of the survey, prospective participants confirmed that they were aged 18 years or older and had previously been diagnosed with COVID-19.

The survey collected respondents' sociodemographic information, past medical history, use of chronic medications, history of COVID-19 vaccines received, and severity of COVID-19. The survey contained several parts: First, we collected the respondents' sociodemographic information, including gender, marital status, employment status, types of jobs, educational level, living status, smoking habits, income level, self-reported health status, and long-term medication. In addition, we asked for the dates of positive and negative COVID-19 tests, the severity of COVID-19, the number of COVID-19 vaccines that were received, and the dates of taking vaccination. To identify the severity of COVID-19, we used the COVID-19 WHO severity classification [28] to assign respondents to 4 categories (mild, moderate, severe, and critical) based on the presence of pneumonia (eg, adults with clinical signs of pneumonia, respiratory rate>30 breaths/minute, severe respiratory distress, or SpO_2<90% on room air; WHO mentioned that a diagnosis can be made on clinical grounds with the assistance of chest imaging, such as radiograph, computed tomography (CT) scan, or ultrasound), hypoxia requiring oxygen, the need for mechanical ventilation, and a history of admission to the intensive care unit (ICU) due to COVID-19.

The respondents' medical history before and after the diagnosis of COVID-19 was also collected. Respondents were asked whether they had certain types of diseases before diagnosis (yes or no), the year of disease diagnosis, whether they took medications for the diseases (yes or no), and an open-ended field allowing them to document their medications. Medical conditions on the survey were infection, tumor, metabolic diseases, hematological disorders, mental illness, nervous system disease, circulatory system disease, respiratory disease, digestive disease, reproductive and urinary diseases, pregnancy complications, immune system disease, skin and subcutaneous tissue diseases, and musculoskeletal and connective tissue disease, which have been used in previous studies on the association between comorbidities and COVID-19 infection [29].

We also inquired about the presence of COVID-19 symptoms encountered by the respondents that were persistent for at least 3 months after COVID-19 infection. Referring to previous surveys [13,27], we listed 30 common symptoms: fatigue, fever, chills, inability to perform exercise, night sweats, hair loss, headache, dizziness, chest pain, rapid heartbeat, cough, sputum, sore throat, runny nose, dyspnea, arthralgia, myalgia, nausea, vomiting, diarrhea, abdominal pain, stomachache, anosmia, loss of taste, blurred vision, difficulty in concentration, difficulty in fall into asleep, feeling anxious, feeling sad, and memory problems. An open-ended field allowed the respondents to document other symptoms. These symptoms also appeared in "Symptoms of Infection with Coronavirus-19 (SIC)," which is a comprehensive patient-reported outcome measure developed to evaluate vaccines and treatment for COVID-19 [30]. To capture clinically meaningful symptoms, we assigned a 4-point Likert scale to assess the impact of the symptoms on the respondents' activities of daily living: 1 (no impact), 2 (little impact), 3 (moderate impact), and 4 (high impact). In addition, we classified the symptoms according to the bodily systems involved.

Sampling Strategy

The sample partners of Qualtrics randomly selected eligible respondents for the study, aiming for national representation through routers and a sophisticated application programming interface (API). To enhance the representativeness of the survey, we used a simple random sampling strategy to recruit potential participants by trying to match population demographics to our survey. The study collected data on the population of each city, and eligible participants were randomly selected and invited to complete the survey. The survey was accessed through the website, a smartphone, or other e-devices. Data scrubbing was subsequently performed after receiving all survey responses to remove unfavorable data, optimizing data accuracy and reliability. A more detailed survey methodology has been described elsewhere [26].

Outcome Variables and Sample Size

The primary outcome variable was the prevalence of long COVID symptoms, moderate or severe long COVID symptoms, and severe long COVID symptoms. We defined these 3 outcome variables as having at least 1 symptom with any degree of impact, at least 1 symptom with moderate or severe impact, and at least 1 symptom with severe impact, respectively. The secondary outcomes included the distribution of long COVID symptoms and their patterns. We assumed the proportion of the primary outcome as 50%, which provided a maximum sample size for each group. From the formula precision=1.96 × √[(p) × (1 – p)/N], where "p" refers to proportion of the primary outcome, a sample size of approximately 550 respondents would achieve a precision level of 0.04 for each city, so a total of 2200 respondents were required.

Statistical Analysis

We conducted a descriptive analysis of the prevalence and distribution of long COVID symptoms according to their severity. As the prevalence of self-reported long COVID symptoms was high, we also conducted a sensitivity analysis of increasing the number of long COVID symptoms. The proportion of long COVID symptoms, moderate or severe long COVID symptoms, and severe long COVID symptoms was computed for each city. To examine the risk factors of severe long COVID symptoms, we performed univariate and multivariate regression analyses with the primary outcome as a binary variable. The covariates included age, gender, marital status, current occupation, educational level, living status, smoking habits, monthly household income, self-perceived health status, the presence of chronic diseases, the use of chronic medication, COVID-19 vaccination status, and the severity of COVID-19. We classified the respondents’ occupations based on the recommendation by the Environmental Modelling Group (EMG) [31]. We entered all covariates with $P<.25$ in univariate analysis into the regression model and evaluated their statistical significance defined as $P<.05$. We tested for variable interaction and multicollinearity in the regression analysis.

Results

Participant Characteristics

We received 7161 total entries and screened out 3862 (53.9%) surveys due to ineligibility. A total of 830 (11.6%) surveys were overquota, and quality control was performed on 248 (3.5%) surveys. There were 4024 (56.2%) complete surveys, and 1312 (32.6%) were removed by data scrubbing. The total sample size achieved was 2712 (37.9%), with a response rate of 63.6%. The number of respondents from Beijing, Shanghai, Guangzhou, and Hong Kong was 725 (26.7%), 718 (26.5%), 715 (26.4%), and 554 (20.4%), respectively. Among them, the majority (n=2182, 80.5%) were aged 25-44 years, female (n=1626, 60.0%), married (n=2422, 89.3%), engaged in full-time jobs (n=2612, 96.3%), and with a tertiary or higher educational level (n=2547, 93.9%). Most respondents engaged in occupations at high risk for COVID-19, including the catering industry (n=533, 19.7%), followed by transportation, logistics, and the discipline workforce (n=344, 12.7%) and the health care sector (n=201, 7.4%) [18]. Most were living with their spouse (n=2400, 88.5%) or children (n=2230, 82.2%), were nonsmokers (n=1817, 67.0%), and were approximately equally distributed according to their monthly household income in the strata HK $10,000 to ≥$60,000 (US $1275.04-$7650.22). The majority perceived their health as good (n=994, 36.7%) or average (n=952, 35.1%), followed by very good (n=466, 17.2%), poor (n=256, 9.4%), and very poor (n=44, 1.6%). Around 2515 (92.7%) respondents did not use chronic medications, and 335 (12.3%) reported at least 2 chronic conditions before COVID-19 diagnosis (Table 1).

Table 1. Respondent characteristics (N=2712).

Characteristics	Respondents, n (%)
Age (years)	
18-24	139 (5.1)

Severity of COVID-19

Most respondents suffered from pneumonia at the time of COVID-19 diagnosis (n=2141, 78.9%), required hospital admission for COVID-19 management (n=1944, 71.7%), needed oxygen due to COVID-19 (n=1427, 52.6%), and received antiviral agents (n=1747, 64.4%); see Multimedia Appendix 1, Table S1. A significant proportion necessitated artificial ventilation (n=986, 36.4%) and admission to the ICU (n=940, 34.7%). Up to 1552 (57.2%) of them had severe or critical COVID-19, and 1160 (42.8%) had mild or moderate severity of COVID-19. Most of the respondents had received vaccination before COVID-19 diagnosis, with the majority having taken 3 or more doses of Coronavac-Sinovac (n=1525, 56.2%), following by those who had taken 2 doses of Coronavac-Sinovac (n=786, 29.0%). There were about 169 (6.2%) respondents who had taken 2 or more doses of Pfizer-BioNTech.

Long COVID Symptoms

Multimedia Appendix 1, Table S2, shows the distribution of long COVID symptoms. The highest proportion of respondents suffered from fatigue (n=914, 33.7%), cough (n=865, 31.9%), sore throat (n=841, 31.0%), difficulty in concentrating (n=828, 30.5%), feeling of anxiety (n=817, 30.2%), myalgia (n=811, 29.9%), arthralgia (n=811, 29.9%), sputum production (n=789, 29.4%), and difficulty in falling asleep (n=792, 29.2%); see Figure 1. The prevalence of having long COVID symptoms of any severity, moderate or high severity, and high severity was 90.4% (n=2452), 62.4% (n=1692), and 31.0% (n=841), respectively. The symptoms were qualified in terms of self-perceived severity, and sensitivity analysis of using 2 or more symptoms showed a better estimate of long COVID syndrome/disorder (Figure 2). These prevalence figures were the highest in Hong Kong (n=541, 97.7%, n=385, 69.5%, and n=194, 35.0%, respectively) and Shanghai (n=662, 92.2%, n=461, 64.2%, and n=287, 40.0%, respectively), followed by Guangzhou (n=630, 88.1%, n=451, 63.1%, and n=212, 29.7%, respectively) and Beijing (n=619, 85.4%, n=395, 54.5%, and n=148, 20.4%, respectively); see Figure 3. The prevalence figures were the highest in the second wave (from July to December 2020; n=67, 91.8%, n=48, 65.8%, and n=16, 21.9%, respectively) and the third wave (from January to June 2021; n=453, 91.7%, n=329, 66.6%, and n=175, 35.4%, respectively), followed by the first wave (from January to June 2020; n=122, 90.4%, n=64, 47.4%, and n=36, 26.7%, respectively), the fifth wave (from January to June 2022; n=1446, 90.1%, n=998, 62.2%, and n=503, 31.3%, respectively), and the fourth wave (from July to December 2021; n=364, 89.9%, n=253, 62.5%, and n=111, 27.4%, respectively); see Multimedia Appendix 1, Figure S1. A slightly negative correlation was found between the timing of COVID-19 and the number of long COVID symptoms (β=–.046, *P*=.016), supporting that long COVID symptom numbers decline with a longer duration of follow-up.

Figure 1. Distribution of long COVID symptoms. The highest proportion of respondents suffered from fatigue (n=914, 33.7%), cough (n=865, 31.9%), sore throat (n=841, 31.0%), difficulty in concentrating (n=828, 30.5%), feeling of anxiety (n=817, 30.2%), myalgia (n=811, 29.9%), arthralgia (n=811, 29.9%), sputum production (n=789, 29.4%), and difficulty in falling asleep (n=792, 29.2%).

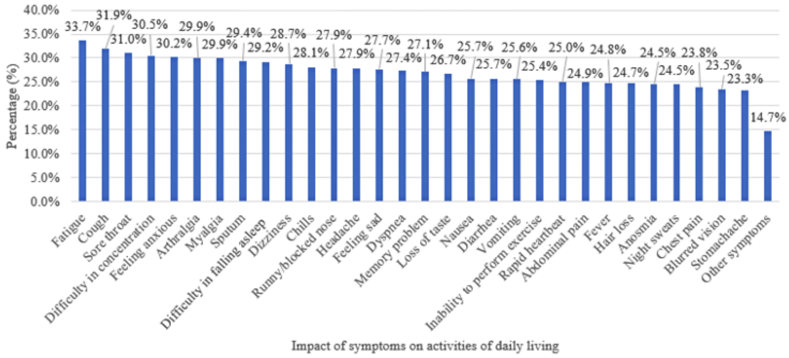

Figure 2. The prevalence of having long COVID symptoms of any severity, moderate or high severity, and high severity was 90.4% (n=2452), 62.4% (n=1692), and 31.0% (n=841), respectively. The symptoms were qualified in terms of self-perceived severity, and sensitivity analysis of using more than 1 symptom showed a better estimate of long COVID syndrome/disorder.

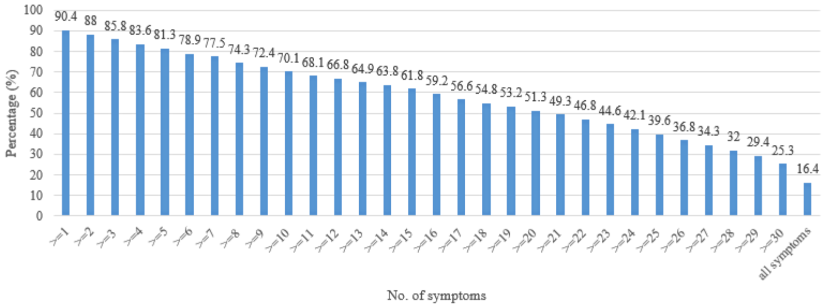

Figure 3. Prevalence of long COVID with severity. These prevalence figures were the highest in Hong Kong (n=541, 97.7%, n=385, 69.5%, and n=194, 35.0%, respectively) and Shanghai (n=662, 92.2%, n=461, 64.2%, and n=287, 40.0%, respectively), followed by Guangzhou (n=630, 88.1%, n=451, 63.1%, and n=212, 29.7%, respectively) and Beijing (n=619, 85.4%, n=395, 54.5%, and n=148, 20.4%, respectively).

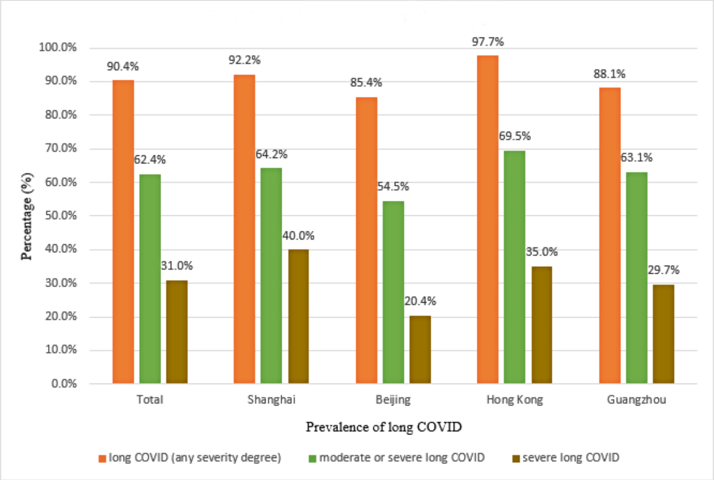

Factors Associated With Long COVID Symptoms of Moderate-to-High Severity

From multivariate regression analysis (Table 2), female subjects (adjusted odds ratio [aOR]=1.49, 95% CI 1.13-1.95); patients engaged in transportation, logistics, or the discipline workforce (aOR=2.52, 95% CI 1.58-4.03); patients living with domestic workers (aOR=2.37, 95% CI 1.39-4.03); smokers/ex-smokers (aOR=1.55, 95% CI 1.17-2.05); respondents with poor or very poor self-perceived health status (aOR=15.4, 95% CI 7.88-30.00); those with more chronic diseases (1 chronic disease: aOR=1.92, 95% CI 1.24-2.97; 2 chronic diseases: aOR=2.71, 95% CI 1.21-6.05; ≥3 chronic diseases: aOR=2.71, 95% CI 1.54-4.79); chronic medication use (aOR=4.38, 95% CI 1.66-11.53); and critical severity of COVID-19 (aOR=1.52, 95% CI 1.07-2.15) were associated with the development of severe long COVID. Prior COVID-19 vaccination with Coronavac-Sinovac (aOR=0.35, 95% CI 0.14-0.90, *P*=.03) or Pfizer-BioNTech (aOR=0.22, 95% CI 0.08-0.63, *P*=.005) for at least 2 doses was a protective factor.

Discussion

Principal Findings

This multicenter survey involving 4 Chinese cities showed that the prevalence of long COVID symptoms was high for symptoms of any severity, moderate or high severity, and high severity. We reported the most common long COVID symptoms and their distribution, as well as the risk factors of long COVID symptoms. Notably, COVID-19 vaccination was associated with a protective effect on the development of long COVID symptoms.

The prevalence of long COVID symptoms was high across different cities. Several studies have reported different incidence rates of long COVID symptoms at different observation periods, including 76% of patients at 6 months [5], 32.6%-87.0% of patients at 60 days [32,33], and 96% of patients at 90 days [34]. A study conducted in the Chinese city of Wuhan included 2469 patients who had confirmed COVID-19 and were discharged from the hospital between January and May 2020. Those who required high-flow nasal cannula (HFNC), noninvasive mechanical ventilation (NIV), or invasive mechanical ventilation (IMV) were more likely to suffer from long COVID symptoms and complications that affected their quality of life, including limitations in their mobility, usual activities, and mental health [14]. These findings were compatible with our results in which patients with critical severity of COVID-19 were more likely to have severe long COVID symptoms. The prevalence of long COVID symptoms was also common in other countries. For instance, a study found that 62% of 89 interviewed patients in the United Kingdom had long COVID symptoms for over 3 months, 52% for 6 months, and 49% for 9 months after their hospital admission [35]. In France, 51% of patients presented with at least 1 symptom after their COVID-19 diagnosis. Regarding severity, 20% of the patients required ICU care, including IMV, vasopressors, and extracorporeal membrane oxygenation during COVID-19 [31]. By using the same WHO definition of COVID-19 severity, a study in Turkey reported 47.5% of the participants suffering from 1 or more persistent symptoms, including outpatient and inpatient clinics, irrespective of disease severity. Most studies have reported high prevalence rates of long COVID symptoms, including Spain, Bangladesh, the United Kingdom, the United States, Nigeria, and Denmark [5].

In addition, research on the prevalence of long COVID symptoms has begun. Apart from respiratory symptoms, fatigue and neuropsychiatric symptoms have been the most frequently reported manifestations of long COVID. The UK Office for National Statistics (ONS) estimated the 5-week prevalence of fatigue to be 11.9% among patients with COVID-19 [36]. One cross-sectional study concluded that 92.9% and 93.5% of hospitalized and nonhospitalized patients with COVID-19, respectively, suffered from ongoing fatigue for 79 days following illness onset [17]. The exact mechanism of its appearance after COVID-19 is currently speculative. This has been attributed to dysfunctional inflammatory response pathways [37]. In addition, a repertoire of central, peripheral, and psychological factors might play a role [8], including congestion of the glymphatic system, hypometabolism in the frontal lobe and cerebellum, and direct SARS-CoV-2 infection of skeletal muscle fibres and neuromuscular junctions [8]. With regard to neuropsychiatric symptoms, the underlying mechanism may be related to glial cell activation, which damages neurons, in addition to hyperinflammatory and hypercoagulable states leading to increased risk of thrombotic events. These could lead to infiltration of blood-derived substances and leukocytes to the brain parenchyma [8].

The risk factors of long COVID symptoms have not been extensively studied. In some studies, certain factors that increase the risk of COVID-19 do not seem to increase the risk of long COVID [8]. For instance, although the male sex has been found to be a risk factor for contracting COVID-19, the ONS reported that the prevalence of any long COVID symptoms is higher in women than that in men (23.6% vs 20.7%) [36]. This observation is consistent with our findings where the female gender was associated with a significantly higher risk of severe long COVID symptoms.

Across different regions, studies have shown that particular occupational groups may be at higher risk of contracting COVID-19, which in turn may affect the risk of long COVID symptoms. High-risk occupations included those engaged in health care, public service, public transportation, material moving, elementary services, and other essential sectors with workers reporting higher rates of mortality. A study conducted across 46 states in the United States found that the per capita age-standardized mortality rate among essential workers was 30.4 per 100,000 individuals compared to workers in nonessential industries (15.5 per 100,000 individuals) [38]. As the risk of long COVID symptoms was associated with employment in transportation, logistics, and the discipline workforce in this study, this could be attributed to increased exposure to SARS-CoV-2, leading to a higher likelihood of experiencing persisting symptoms.

Living status, which was also regarded as an environmental risk factor, has also been examined by other studies on COVID-19 infection and long COVID symptoms. Despite a poor living environment, such as low air quality and transportation insecurity, environmental exposure to social contact that was affected by sociodemographic characteristics is also associated with the risk of COVID-19 infection. This might increase the risk of suffering from long COVID symptoms. These exposures include cohabitation and living in overcrowded housing [18]. There is a lack of studies that investigate the relationship between COVID-19 infection or long COVID symptoms and the living status of domestic workers, while our study showed that it is a significant risk factor. This may be due to environmental exposure to social contact.

Previous meta-analyses have demonstrated an increased risk of severe COVID-19 and death in current and former smokers compared to nonsmokers [39,40]. However, smoking is not a confirmed risk factor for long COVID symptoms and has only been shown to be a predictor (P>.001) of longer symptom duration [41]. Our findings also demonstrated that smoking prevalence is associated with a higher risk of long COVID symptoms. Smoking may potentially be a risk factor for some long COVID symptoms as smokers tend to have a greatly weakened immune and cardiovascular system, thus increasing their susceptibility to various health complications.

Multimorbidity with pre-existing health conditions [42], particularly asthma [43], has displayed a heightened risk of developing persistent symptoms and increased risk of COVID-19 fatality [44]. Multimorbidity has been positively associated with medication use, with 50% of adults in high-income countries taking up to 5 medications or more [45,46]. Poorer perceived health status may be considered a risk factor for long COVID symptoms, as observed in a study wherein 87% of the participants had a good self-reported health status before the pandemic but 83.3% reported moderate-to-poor self-reported health 6 months after initial onset [24]. This is further supported by a cohort study conducted in the Netherlands 3 months following recovery, where the health status of patients with COVID-19 was generally reported to be poor, with significant impairment in the domains of functional impairment (64%), fatigue (69%), and quality of life (72%) [47].

COVID-19 vaccination, including Coronavac-Sinovac and Pfizer-BioNTech, had protective effect on the development of long COVID symptoms. A community-based study in the United Kingdom that included 6729 patients with any severity of long COVID symptoms found that vaccine doses are associated with significant reduction in experiencing long COVID symptoms (first vaccine dose: 12.8% decrease, P<.001; second vaccine dose: 8.8% decrease, P=.003) [48]. Vaccination is able to prevent reinfection among patients with long COVID symptoms, as persons who take a single vaccine dose have equal or higher antibody titers than those who do not take any vaccination, which is consistent with our study findings [25]. The impact of vaccination on long COVID symptoms could vary among respondents or between different vaccine types; however, the vaccinated population does have a lower chance of suffering from long COVID symptoms compared with those who have not been vaccinated [25,48,49].

Strengths and Limitations

This study was relatively large scale as compared to other surveys, and it adopted a representative sampling strategy involving 4 major cities in China. The response rate was high relative to other similar studies, thus enhancing its generalizability to other settings. Nevertheless, several limitations should be addressed. First, its cross-sectional nature did not allow a cause-and-effect relationship to be established due to the possibility of reverse causality. However, the objective of this study was to identify independent risk factors instead of causes of long COVID. In addition, there existed potential recall bias as some study participants self-reported the presence of long COVID symptoms, especially those with an earlier diagnosis of COVID-19. It should also be noted that the definition of long COVID is different across various authorities, with the National Institute for Health and Care Excellence (NICE) and the US Centers for Disease Control and Prevention (CDC) using 4-12 weeks and 4 weeks, respectively, as the time frame of its persistent symptoms. Furthermore, there could be residual confounders in our multivariate regression analysis, and these could vary according to different cities where the management strategies for COVID-19 might be different. In particular, it is unknown whether the study participants received certain treatments to relieve their long COVID symptoms at the initial stage of the development, thus reducing their risk of long COVID symptoms. Lastly, as in most surveys, not all potential study participants in the sampling frame were eligible before the recruitment process. In addition, the older population who may have a substantially higher burden of both COVID-19 and long COVID symptoms were underrepresented in this study. As the survey had to be completed through e-devices, relatively fewer older people were included as a higher proportion of them did not know how to use e-devices. Future study on the prevalence of long COVID in the older population is warranted.

Conclusion

We examined the prevalence of long COVID symptoms in 4 Chinese cities and the effect of the severity of COVID-19. We also examined the pattern of long COVID symptoms, as well as the risk factors, including gender, occupational groups, living status, lifestyle, multimorbidity, and vaccination status. Fatigue, cough, sore throat, difficulty in concentration, feeling of anxiety, myalgia, and arthralgia are the most common severe long COVID symptoms. The female gender; engagement in transportation, logistics, or the discipline workforce; living with domestic workers; smoking; poor self-perceived health status; chronic diseases; chronic medication use; and critical severity of COVID-19 are associated with severe long COVID. Prior vaccination with ≥2 doses of COVID-19 vaccines is a protective factor. Our findings may inform early identification of patients with COVID-19 at risk of long COVID and planning of rehabilitative services.

Abstract

Background: Globally, men who have sex with men (MSM) continue to bear a disproportionately high burden of HIV infection. Rwanda experiences a mixed HIV epidemic, which is generalized in the adult population, with aspects of a concentrated epidemic among certain key populations at higher risk of HIV infection, including MSM. Limited data exist to estimate the population size of MSM at a national scale; hence, an important piece is missing in determining the denominators to use in estimates for policy makers, program managers, and planners to effectively monitor HIV epidemic control.

Objective: The aims of this study were to provide the first national population size estimate (PSE) and geographic distribution of MSM in Rwanda.

Methods: Between October and December 2021, a three-source capture-recapture method was used to estimate the MSM population size in Rwanda. Unique objects were distributed to MSM through their networks (first capture), who were then tagged according to MSM-friendly service provision (second capture), and a respondent-driven sampling survey was used as the third capture. Capture histories were aggregated in a 2k–1 contingency table, where k indicates the number of capture occasions and “1” and “0” indicate captured and not captured, respectively. Statistical analysis was performed in R (version 4.0.5) and the Bayesian nonparametric latent-class capture-recapture package was used to produce the final PSE with 95% credibility sets (CS).

Results: We sampled 2465, 1314, and 2211 MSM in capture one, two, and three, respectively. There were 721 recaptures between captures one and two, 415 recaptures between captures two and three, and 422 recaptures between captures one and three. There were 210 MSM captured in all three captures. The total estimated population size of MSM above 18 years old in Rwanda was 18,100 (95% CS 11,300-29,700), corresponding to 0.70% (95% CI 0.4%-1.1%) of total adult males. Most MSM reside in the city of Kigali (7842, 95% CS 4587-13,153), followed by the Western province (2469, 95% CS 1994-3518), Northern province (2375, 95% CS 842-4239), Eastern province (2287, 95% CS 1927-3014), and Southern province (2109, 95% CS 1681-3418).

Conclusions: Our study provides, for the first time, a PSE of MSM aged 18 years or older in Rwanda. MSM are concentrated in the city of Kigali and are almost evenly distributed across the other 4 provinces. The national proportion estimate bounds of MSM out of the total adult males includes the World Health Organization’s minimum recommended proportion (at least 1.0%) based on 2012 census population projections for 2021. These results will inform denominators to be used for estimating service coverage and fill existing information gaps to enable policy makers and planners to monitor the HIV epidemic among MSM nationally. There is an opportunity for conducting small-area MSM PSEs for subnational-level HIV treatment and prevention interventions.

population size; men who have sex with men; nationwide; capture-recapture; RDS; three-source; Rwanda; HIV

Introduction

Globally, men who have sex with men (MSM) continue to bear a disproportionately high burden of HIV infection [1]. In sub-Saharan Africa, same-sex behaviors have become an area of interest for HIV research. The results from recent studies indicate the widespread existence of MSM groups across sub-Saharan Africa and high rates of HIV infection among this population [2]. As countries approach HIV epidemic control in sub-Saharan Africa, attention has shifted to key affected populations, including female sex workers (FSW), people who inject drugs (PWID), transgender women, and MSM who are at a higher risk of HIV acquisition [3].

These key populations account for less than 5% of the global population, but they and their sexual partners comprised 70% of new HIV infections in 2021 [4]. MSM living in sub-Saharan African countries, where homosexual activity has often been severely criminalized, are hard to reach with HIV prevention programs. Currently, the risk of getting an HIV infection is nearly five times higher among MSM in countries where there is criminalization for homosexuality compared to that for MSM in countries where no criminalization for homosexuality occurs [5].

Biologically, unprotected receptive anal sex poses a much higher risk than unprotected receptive vaginal sex, whether the receptive partner is male or female; the risk of HIV transmission during anal intercourse may be approximately 18 times greater than that during vaginal intercourse [1]. By this fact, MSM are at an extremely high risk of becoming infected with HIV. The global estimated HIV prevalence among MSM is 21%, with 6% in sub-Saharan countries, ranging from 3.8% up to 31% [6,7]. In addition, people with marginalized sexual or gender identities or behaviors sometimes lack the ability to protect themselves from HIV infection due to structural factors, including self-stigmatization, discrimination, and lack of access to information and services [8]. The prevalence ratios are particularly elevated in West and Central Africa as well as in low-prevalence countries [9].

Rwanda is in the East African region, bordering four countries: Tanzania, Uganda, the Democratic Republic of the Congo, and Burundi. The country is divided into five administrative regions, including four provinces, the city of Kigali, and 30 districts as another subnational unit level. Rwanda experiences a mixed HIV epidemic, which is generalized in the adult population, with an adult (15-49 years) HIV prevalence stabilized at around 2.6%, and aspects of a concentrated epidemic among specific key populations at higher risk of HIV infection, with a rate of 45% among FSWs [10] and 6.5% among MSM [11]. In Rwanda, MSM are considered one of the key populations for HIV prevention and care in the HIV and AIDS national strategic plan [12].

Although the national strategic plan suggests a special emphasis on key populations and that the epidemic is likely concentrated among these populations, limited data exist to estimate the actual population size at the national scale [12]. To date, no nationwide study has been performed to estimate the number of MSM in Rwanda. However, the Project San Francisco study performed in 2018 using a service multiplier and unique object identifier approach estimated the size of MSM in the city of Kigali and surrounding areas to be 8411, ranging between 6760 and 11,151 [11]. Lack of reliable estimates of the MSM national population size misses important information to determine the denominators to estimate need, coverage, and the spread of new infections that policy makers and planners use to monitor HIV epidemic control.

In response to this information gap, we performed a national population size estimation of MSM in Rwanda from October to December 2021, aimed at providing national-level and provincial-level estimates.

Methods

Study Population

The study population included adult males aged 18 years and older who self-reported as gay/bisexual or having had anal sex with a male in the last 12 months and lived primarily in Rwanda during the past 12 months. By living primarily in Rwanda, we refer to having spent most of their time in Rwanda over the last 12 months, regardless of any possibility of traveling out of the country. The study excluded any MSM who were not willing to voluntarily participate.

Study Design and Setting

Estimating the size of hard-to-reach populations has long been a challenging task due to the fact that sampling frames often do not exist for these populations, some populations are dynamic both in time and space, and members may be afraid to identify themselves in the community. There are multiple methods suggested to estimate the size of populations without a sampling frame, including venue-based sampling [13], time-location sampling [14], respondent-driven sampling (RDS) [15], multiplier methods [16], the network scale-up method [17], successive sampling-population size estimation [18], and capture-recapture (CRC) [19]. No gold-standard method currently exists, and many methods have been used, each with different strengths and weaknesses.

The CRC method has been shown to be useful in estimating the size of hard-to-reach populations [20-22]. Based on its statistical foundation, CRC, as an empirical population size estimate (PSE) method, produces PSEs with higher precision. Research suggests that, compared with two-source CRC, conducting CRC with multiple (three or more) sampling/capture rounds strengthens the design, produces more robust estimates, and relaxes the CRC requirement (assumption) of sample independence [23]. The CRC method is increasingly being used by several researchers in epidemiology and public health [24-26], and this method was previously used to estimate the national size estimate of FSWs in Rwanda, demonstrating that acquired implementation experiences are crucial for such estimates [27].

We used the three-source capture-recapture (3S-CRC) method to estimate the size of MSM in Rwanda. CRC consists of marking a random portion of the population of interest at the first encounter. Subsequently, another portion of the population is drawn to observe how many were marked initially. The greater the number of those tagged, the smaller the PSE. Tagging can be replicated multiple times as desired. The 3S-CRC approach has been shown to be a robust method in estimating a population without a sampling frame, such as FSWs, MSM, and PWID [28], and is described elsewhere in more detail [29]. The MSM 3S-CRC began with a capture stage. During this stage, members of the MSM population were “encountered” and then “marked” by providing a memorable and easily identifiable gift with a specific design that is hard to find on the local market. After a 1-week interval, a second capture (recapture) was initiated by offering MSM-friendly services to MSM countrywide. During the third capture (recapture), an RDS approach was used [30,31] with specific questions incorporated to identify those MSM encountered during the previous capture occasions.

During capture one, MSM key informants were selected by MSM community-based organizations (CBOs) to facilitate the distribution of unique objects within MSM associations and groups and those who are neither members of any association nor MSM group. A list of MSM associations and groups was developed with their corresponding numbers of members in all provinces of the country: 14 from Eastern province, 12 from the city of Kigali, 10 from Southern province, and 8 from each of the Northern and Western provinces. Each province was assigned a different unique color of the unique objects to be distributed. The number of objects to be distributed within each association or group was determined by the probability proportional to the association or group size; within an association or a group, systematic sampling was found to be appropriate to determine who receives the unique object according to the existing list of MSM association or group members. The approach comprises determining a sampling interval as well as a random start on the list of MSM association or group members.

Each selected MSM member within an association or a group was given three unique objects: one for himself and another two to hand out to other MSM he knows but who do not belong to any association or group. The distribution process for unique objects within an MSM association or group was facilitated by a well-trained team of distributors with MSM key informants’ support. Branded keychains valued at no more than US $3 were used as unique objects. MSM were provided with the study objectives and advised to keep the received unique objects in a safe place as they may be asked to show them later for verification. This activity took 1 week to be completed.

There were possibilities that some objects could not be successfully distributed and not returned as well as multiple objects given to the same person. To minimize any related bias on the PSEs, a debrief was given to the MSM key informant as well as the MSM association/group members focusing on study objectives; eligibility criteria to receive the object; object distribution process; and key considerations, including prompting the object receiver to check if he had not been approached by someone else in the same study context to avoid duplication. In addition, the monetary value of the unique object was set to US $3 to minimize the intention for the object distributor to keep the objects for themselves or the object receiver being willing to receive more than one object. The object distribution process was monitored daily by the object distributor and MSM key informant to report the number of objects distributed successfully as well as those not successfully distributed, which were returned physically.

The following week, capture two was initiated, where MSM were tagged using selected specific MSM-friendly services. The selection process for services was facilitated by MSM key informants and their CBOs. Given that MSM are given health services through usual health facilities but equipped with MSM-friendly settings and packages, the latter were used to offer specific MSM-friendly services, including distribution of condoms and lubricants. For this purpose, 23 health facilities were selected across the country where an MSM key informant and a health worker who usually serve MSM at the same facility were assigned to provide the selected service to MSM and to record corresponding information in the study purposes. The key informant role was to serve as the receptionist and to facilitate screening to create a welcoming and friendly environment for MSM, while the health worker served to provide services and record necessary information. Prior to the second capture, community mobilizers served on the mobilizing of upcoming service provision to MSM to increase awareness and to break the fear and stigma of participation. Those who accepted the offered services were counted as captured and were asked whether they had received the distributed unique object during the previous week. Responses (yes/no) were recorded depending on whether the MSM had the gift with him or was able to correctly identify the unique object received.

Capture two was followed by the Integrated Behavioral and Biological Surveillance Survey (IBBSS) using RDS [32], which served as the opportunity for the third capture. RDS is a variant of chain-referral sampling that employs Markov-chain theory and the theory of biased networks to reduce biases generally associated with chain-referral methods [31]. It was proven that even though sampling begins with a purposively chosen group of initial subjects, as is the case for most chain-referral samples, the composition of the ultimate sample is wholly independent of those initial subjects [33]. During capture three, all MSM recruited by their peers using the RDS approach were counted as captured. There were eight study sites distributed according to the administrative provinces: one in each of the Northern, Southern, and Eastern provinces; two in the Western province; and three in the city of Kigali. MSM who met the study eligibility criteria and were well-connected and respected among their MSM peers were selected as seeds and marked the beginning of each referral chain. During this study, the investigator contacted the seed via the implementing partners, including nongovernmental organizations and CBOs working with the MSM population. Three seeds were selected at each study site for a total of 24 seeds.

During the RDS survey, participants were asked whether they had received unique objects during capture one and/or had received provided services during capture two during the second week of study implementation. Several prompts were used to confirm prior participation, including having received the object physically or being able to correctly identify the received object on a laminated card with images of multiple objects. MSM were not allowed to participate more than once in the same round; an interoperable fingerprint system was used to verify that each participant was recorded only once during capture three and to detect any duplication within the same site and across all study sites.

Fingerprint machines were installed at each study site and connected to the internet for easy and real-time data synchronization. Once a fingerprint was recorded, it was automatically converted into alpha-numerical codes and transferred to the central server to synchronize all study site–level data. With this installed system, we could identify any MSM trying to reregister his fingerprint at the same site or at a different site. The fingerprint machines converted the recorded fingerprints into alpha-numerical codes with no reverse backway possibility, and then the alpha-numerical codes were stored as participant identifiers to ensure participants' confidentiality.

Sample Size and Sampling

For the first two initial captures, the sample size was based on Rwanda Population-Based HIV Impact Assessment 2019 [34], where the proportion of all males aged 18+ years with at least one male sexual partner in the last 12 months by province (0.30% for the city of Kigali, and 0.16%, 0.08%, 0.24%, and 0.24% for the Eastern, Northern, Southern, and Western provinces, respectively) was obtained to estimate the pooled and provincial-level stratified sample size. Assuming a design effect of 1.5, a precision of 0.5%, and adjusting for a 15% loss of coupons estimated from a previous CRC-related study [27], we calculated the required minimum sample size. We estimated a total of 2705 objects needed to be distributed across provinces as follows: 803 in the city of Kigali, 586 in Western province, 658 in Southern province, 219 in Northern province, and 439 in Eastern province during each of the first two captures.

For the RDS survey, the sample size calculation was based on the results from the previous IBBSS conducted in Rwanda in 2020. The formula for the sample size calculation for an RDS study was used according to the method of Salganik [35], assuming an MSM HIV prevalence of 11.3% in the city of Kigali, 6.4% in Western province, 1.4% in Southern province, 3.1% in Northern province, and 1.2% in Eastern province; a design effect of 1.5; precision *w* 0.025; and a nonresponse rate of 10%. We estimated the required minimum total sample size of 2210 across the country distributed by province as follows: 1027 in the city of Kigali, 613 in Western province, 141 in Southern province, 308 in Northern province, and 121 in Eastern province.

All of the estimated sample sizes for each capture and the statistical power were validated using MS-CRC Power Analysis of the shinyrecap application [36].

Data Management

Data were captured using 3 electronic forms (capture one, capture two, and capture three forms) using tablets with data-entry forms designed using Open Data Kit (ODK) [37]. The tablets were password-protected to ensure that only the study team had access to the data. Other data were captured using Microsoft Excel sheets, which were also password-protected. Data cleaning, entailing deduplication, review of data consistency, and completion of any missing data, was performed daily.

Unique identifiers were used to ensure that study participants were only enrolled once. Once data were deduplicated, all identifiers were removed prior to creating the final data sets for analysis.

Statistical Analysis

In preparation for analysis, participant-level data from ODK were exported into R v.4.0.5 for Windows, and cleaning steps were performed based on preset exclusion criteria and logical flow. Data were analyzed by province. Aggregated data sets detailing counts of each capture/recapture combination were produced for each subset. The Bayesian nonparametric latent-class model, which is flexible and able to accommodate various forms of heterogeneity in capture probabilities, was used to produce the final PSE with 95% credible sets (CS) from aggregate data sets.

All analyses were performed using the latent-class model for capture-recapture (LCMCR) package in R v.4.0.5 for Windows [38,39]. LCMCR is a novel Bayesian nonparametric method for estimating the size of hard-to-reach populations from CRC data. This method is based on a Dirichlet process mixture, capable of accommodating complex patterns of heterogeneity of captures, and can transparently modulate its complexity without a separate model selection step [40,41]. The Bayesian nonparametric latent-class approach posits that the population is divided into several groups with members in each group having the same homogeneous capture probability. The number of homogeneous strata in a population is uncertain and covariates that identify those classes may not be available. Thus, the strata are said to be latent and strata identities are treated as missing data. Estimation is naturally accomplished using mixtures of distributions [42].

Uninformative priors (ie, those with minimal influence on the inference and dominated by the likelihood function) were specified for the Dirichlet process parameters α and γ (0.25, 0.25). We used K=5 latent classes; 10,000 samples from the posterior distribution were drawn with a burn-in of 10,000 iterations and a thinning interval of 1000 iterations to specify the Markov Chain Monte Carlo (MCMC) sampling. Convergence of the MCMC sampling was assessed using trace plots and a histogram of the posterior probability distribution for population size.

Median PSEs with 95% CS for 3S-CRC were produced overall and by province. To facilitate the interpretation of results and application of estimates for programs, the highest density intervals (HD Interval package in R) are presented. Analysis outputs include the median PSEs with 95% CS.

Ethical Considerations

The survey received ethical approval from the local Institutional Review Board, Rwanda National Ethics Committee. It was also reviewed in accordance with the US Centers for Disease Control and Prevention (CDC) human research protection procedures and was determined to be research with CDC nonengaged. For the PSE study component, we received a waiver of the informed consent requirement for all MSM participants because no personally identifiable information was collected; however, verbal consent was sought since the data collected were restricted to only recording whether the MSM accepted the gift during subsequent capture.

Since same-sex relationships remain stigmatized in Rwanda, we anticipated a small risk of physical and/or verbal violence in cases where a study participant was identified in the community. Therefore, the study investigator ensured that the study was conducted anonymously to protect the identity of participants and ensure confidentiality of the data collected; no names or any other personally identifiable information were recorded anywhere. Completed questionnaires (identifying individuals by only identification numbers) were kept with the study coordinator during the fieldwork. All forms containing any study information were kept in a locked cabinet accessible by only authorized study personnel. Additionally, the electronic data set identified by the unique code was password-protected and accessed by authorized personnel using a computer backed up to a server located at Rwanda Biomedical Center. Furthermore, for all study members participating in human subjects research and data collection, it was a requirement for the study team to have participated in trainings on human subjects research, confidentiality, and interviewing techniques before commencing study activities. A confidentiality agreement was signed by all study investigators, coinvestigators, and data collectors.

Results

Capture One

Keychains with unique designs were distributed to the MSM through their corresponding associations, groups, and key informants (Figure 1). Table 1 summarizes the results from capture one; a total of 2465 out of the 2723 objects (90.53%) were successfully distributed.

Figure 1. Example of a unique object (keychain) distributed in capture one.

Table 1. Provincial-level object distribution breakdown.

Location	Objects assigned, n	Objects successfully distributed, n	Objects not distributed successfully and returned, n
Eastern province	636	558	78
City of Kigali	894	885	9
Northern province	166	150	16
Southern province	585	515	70
Western province	442	357	85
Total	2723	2465	258

Capture Two

MSM-friendly services were provided at 23 health facilities that typically have a key population service package countrywide. Lubricants and condoms were distributed during the capture-two period, during which a total of 1340 of the anticipated 2705 MSM (49.54%) came for health services at health facilities. Out of the 1340 MSM who came for the services, 1314 (98.06%) met the inclusion criteria and were offered the services, and among them, 721 (54.87%) were identified as having received the distributed unique object during the previous week. Table 2 provides the province-level breakdown for capture two.

Table 2. Provincial-level service provision among men who have sex with men (MSM) in capture two.

Location	Health facilities, n	Anticipated MSM to be offered services, n	MSM received at health facility, n	MSM received offered services, n	MSM received distributed unique object during the previous week, n
Eastern province	5	439	343	337	211
City of Kigali	5	803	510	497	185
Northern province	1	219	28	25	4
Southern province	7	658	291	291	195
Western province	5	586	168	164	126
Total	23	2705	1340	1314	721

Capture Three

During capture three, RDS was used for participant recruitment. Every MSM recruited during RDS was screened for eligibility and considered as captured during capture three once he consented to participate. A total of 2211 MSM were captured during this capture occasion. Among those captured during capture three, 422 (19.09%) were identified as having received distributed unique objects during capture one, whereas 415 (18.77%) were identified as having received MSM-friendly services during capture two. Table 3 provides the provincial-level breakdown for capture three.

Table 3. Provincial-level data among men who have sex with men (MSM) in capture three.

Location	Anticipated MSM to be captured, n	MSM captured, n	MSM received distributed unique object, n	MSM received provided MSM-friendly services, n	MSM received both unique object and MSM-friendly services, n
Eastern province	121	126	50	64	36
City of Kigali	1027	1,021	128	124	42
Northern province	308	303	20	18	4
Southern province	141	152	42	54	28
Western province	613	609	182	155	100
Total	2210	2211	422	415	210

Population Size Estimation

Overall, we sampled 2465, 1314, and 2211 MSM in capture one, two, and three, respectively. There were 721 recaptures between captures one and two, 415 recaptures between captures two and three, and 422 recaptures between captures one and three. There were 210 MSM captured in all three captures. The Venn diagram in Figure 2 provides the summary results for all three capture occasions and overlaps.

Before conducting the CRC analysis, we explored dependency between captures by testing for homophily in the RDS recruitment chain based on the capture history variable, finding a homophily value of 1.016596, which indicates nondependency.

The trace plot in Figure 3 presents the simulation results over 10,000 samples, demonstrating the population size distribution for a converging simulation result based on the random noise shape observed between the values 10,000 and 20,000 on the Y-axis. Figure 4 presents the posterior distribution (ie, population size distribution) provided by the model.

The final MSM PSEs for the overall and provincial levels are presented in Table 4. The median from the posterior probability distribution is used as the point estimate and 95% CS are used to describe uncertainty.

We estimated the overall population of MSM in Rwanda to be 18,100 (95% CS 11,300-29,700), with the majority living in the city of Kigali (7842, 95% CS 4587-13,153). The MSM PSEs were similar for the remaining 4 provinces (Northern, Southern, Eastern, and Western provinces).

[b] CS: credibility set.

Discussion

This MSM PSE presents the first use of the 3S-CRC approach to estimate MSM population size on a nationwide scale in Rwanda. The 3S-CRC method provided an estimate for MSM in the city of Kigali of 7842 (95% CS 4587-13,153), which was similar to the previous estimate obtained by “Project San Francisco” of 8411 (95% CS 6760- 11,151) [11]. The slight differences in the 2018 and 2021 Kigali MSM PSEs can be explained by considering the geographical coverage and difference in methodologies used. The distribution of MSM in each of the remaining 4 provinces was fairly uniform and lower than the estimates in Kigali. Differences in estimates of the MSM population size distribution across the country may also reflect long-term movement patterns among MSM, from rural to urban as well as from smaller to larger urbanized contexts [43].

To some degree, MSM size estimates are influenced by the proportion of MSM who may have decided to not participate in the study due to potential privacy concerns, a potentially significant element given the burden of stigma and heteronormative behavioral expectations (eg, marriage and parenting) for MSM in Rwanda. Our overall MSM PSE represents 0.7% (95% CI 0.4%-1.1%) of the total adult male population in Rwanda based on 2012 Census data collected by National Institute of Statistics of Rwanda 2021 population size projections. The 2020 World Health Organization (WHO) and Joint United Nations Program on HIV/AIDS (UNAIDS) technical brief recommends the revision of the MSM PSE for those countries, using an MSM PSE less than 1% of total adult males based on the region [28]. The UNAIDS monitoring system through 2019 estimated a global median proportion of adult men who had sex with another man in the previous year of 1.9% across 38 low- or middle-income countries, and this proportion was estimated at 1.45% in Eastern and Southern Africa, where Rwanda is located [44,45]. Accordingly, the estimate from the current study aligns with the WHO recommendation regarding MSM PSEs [7].

Different approaches are being used for size estimation of hidden populations, each with various strengths and limitations, and there is currently no consensus on a gold-standard method [46]. The traditional CRC method employs two captures; however, extra captures can be added to increase the number of data points from which estimates are created, resulting in more stable and robust PSEs [47]. The 3S-CRC method has been commonly used in epidemiology to estimate the size of key populations targeted by health interventions for certain health conditions owing to its mathematically grounded and defensible results [23,48,49]. Several studies have used the 3S-CRC method to estimate the size of certain population groups without a sampling frame, including FSW, MSM, and PWID [28,50-52]. The final estimate for this study was based on the 3S-CRC data set. In summary, four major assumptions must be met for CRC to give reliable population estimates: individual captures are independent, the population is closed, the capture history is correct for all members of the target population, and the chance of getting caught is homogeneous [53].

To minimize dependencies between captures, we used different distribution settings for each capture occasion. During the first capture, members of the MSM population were tagged by the keychain provided through their corresponding associations, groups, and key informants. In the second capture, MSM were tagged by being offered MSM-friendly services through health facilities that usually serve MSM nationwide. In the third capture, we used the RDS method, in which all recruited MSM were considered as captured. For all three captures, a 1-week time interval was used between two consecutive capture occasions to minimize recall bias and to fulfill the population closeness assumption. At each capture of the first two capture rounds, unique object distribution and MSM-friendly services provision procedures included a random aspect to ensure that the chance of getting caught was homogeneous. However, our estimates might be limited with missing a random sampling aspect during the third capture round where RDS was used.

There are several plausible constraints to the design of our estimation activity. A possible limitation is the underlying 3S-CRC assumptions that might have influenced the validity of our findings, leading to reduced accuracy of population sizes and wide confidence ranges. In particular, we employed unique objects as a tagging strategy to protect the anonymity of sampled populations. However, not all individuals were carrying the received object at the subsequent capture occasion, complicating the identification of recaptures. Furthermore, we had to assume that the person presenting the object is the same person who received the object (an essential limitation present in anonymous sampling–based CRC). We tried to mitigate these limitations by offering the opportunity to identify the correct object from a laminated card with several pictures including the correct unique object for those presenting without unique objects. There was a possibility of guessing or having seen the object and therefore biasing the PSE downward. To overcome possible participation duplicates at enrollment during the third capture, a biometric system using fingerprint identification was installed and employed across all study sites. We also acknowledge any possible selection bias that might have been influenced by the established study inclusion criteria.

The key strength of our study is that it is powered to provide national- and provincial-level PSEs for MSM in Rwanda for the very first time. Sampling considered administrative provinces as strata and targeted 28 (out of 30) districts in Rwanda, which are nationally representative and reflective of the demography. The selected districts included key urban areas with a high likelihood of expanding the catchment to include participation by MSM based in rural areas. Furthermore, during the third capture occasion, RDS was used giving more confidence in reaching MSM with lower social visibility.

The final estimate of the MSM population size in Rwanda is based on a Bayesian approach to account for the complex patterns of heterogeneity between captures and the aggregation of homogeneous strata into latent classes. While other statistical techniques make reasonably strong assumptions about the structure of the joint distribution of capture patterns, the latent-class Bayesian method is a model-averaging strategy that seeks to estimate the joint distribution as directly as feasible from the data [40].

In conclusion, this study provides, for the first time, an estimated population size of MSM aged 18 years and above in Rwanda. The results will allow national programs and implementation partners to invest in HIV services at a level that is commensurate with need, coverage, and new infections. These data enable policy makers and planners to monitor HIV epidemic control nationwide, specifically among the MSM population, and to plan for other health services such as the prevention and treatment of sexually transmitted infections, among others. While these estimates are usable at the national and provincial levels, further work is needed on small-area estimation to align the PSE results with the intended HIV treatment and prevention interventions at subnational levels among MSM. Furthermore, we acknowledge that there are still limitations of estimating some hard-to-reach MSM groups, which is another potential area for further research.

Acknowledgments

The authors would like to thank all those that made valuable contributions to the success of this project. This population size estimation of men who have sex with men has been supported by the President’s Emergency Plan for AIDS Relief (PEPFAR) through the Centers for Disease Control and Prevention (CDC) under the terms of GH002203. The findings and conclusions in this paper are those of the authors and do not necessarily represent the official position of the funding agencies.

Data Availability

Data are owned by Rwanda Biomedical Center (RBC); all data access enquiries should be directed to RBC through the following email address: info@rbc.gov.rw.

Authors' Contributions

All authors made significant contributions to the study’s design, conduct, or data analysis and interpretation, as well as writing or editing portions of the work and approving the final version for publication.

Abstract

Background: Gout is a common and debilitating condition that is associated with significant morbidity and mortality. Despite advances in medical treatment, the global burden of gout continues to increase, particularly in high–sociodemographic index (SDI) regions.

Objective: To address the aforementioned issue, we used age-period-cohort (APC) modeling to analyze global trends in gout incidence and prevalence from 1990 to 2019.

Methods: Data were extracted from the Global Burden of Disease Study 2019 to assess all-age prevalence and age-standardized prevalence rates, as well as years lived with disability rates, for 204 countries and territories. APC effects were also examined in relation to gout prevalence. Future burden prediction was carried out using the *Nordpred* APC prediction of future incidence cases and the Bayesian APC model.

Results: The global gout incidence has increased by 63.44% over the past 2 decades, with a corresponding increase of 51.12% in global years lived with disability. The sex ratio remained consistent at 3:1 (male to female), but the global gout incidence increased in both sexes over time. Notably, the prevalence and incidence of gout were the highest in high-SDI regions (95% uncertainty interval 14.19-20.62), with a growth rate of 94.3%. Gout prevalence increases steadily with age, and the prevalence increases rapidly in high-SDI quantiles for the period effect. Finally, the cohort effect showed that gout prevalence increases steadily, with the risk of morbidity increasing in younger birth cohorts. The prediction model suggests that the gout incidence rate will continue to increase globally.

Conclusions: Our study provides important insights into the global burden of gout and highlights the need for effective management and prophylaxis of this condition. The APC model used in our analysis provides a novel approach to understanding the complex trends in gout prevalence and incidence, and our findings can inform the development of targeted interventions to address this growing health issue.

Introduction

Background

Gout is a ubiquitous chronic disease caused by an elevation of urate concentrations in articular and nonarticular structures. It can lead to highly intensive pain, lingering discomfort, and inflammation, as well as limited range of motion at the joints, with a high population burden [1]. With a high recurrence rate, many patients cannot undergo standard therapy, which leads to poor health-related quality of life [2]. Besides the increased personal financial burden, direct and indirect annual financial burdens exist for those who cannot control gout well [3]. Patients with cardiovascular disease who have also been diagnosed with gout have higher mortality rates, regardless of age, sex, and comorbidities factors [4]. The mortality gap of gout, which is the association with premature death, has stayed consistent over 2 decades [5,6].

Despite the heavy population burden, especially in the high–sociodemographic index (SDI) countries, the latest studies only focused on the regional or short-period gout burden [7-10]. Because of technological advancements, people's lifestyles have changed dramatically over the past 2 decades. The tendency and pattern of gout have changed owing to the lifestyle changes worldwide, even with treatment recommendations by many rheumatological societies. However, health policies have not provided any effective action strategies to cope with the steadily increasing trend of gout incidence [11-13]. To break through the barrier, it is essential to provide different approaches regarding the epidemiology of gout to evaluate public health development over time. In this regard, an analysis of prevalence trends, with a particular focus on their associations with age-period-cohort (APC) effects, has the potential to delineate the success of different aspects of health care delivery and identify the remaining treatment gaps [14,15].

Using the APC model, we can potentially mine ethnic disparities and geographic differences, as well as the effectiveness of the monitoring system. As the comparison of collinearity factors should be determined through the additional constraints [16]. This is a valid model for providing valuable insight into various public health issues. It could compare the efficiency of health care provision of different regions and identify the emblematic countries or regions that have acted efficiently on gout prevalence [17-20].

Objectives

This study aims to use the APC model to analyze the global-, regional-, and national-level prevalence of gout. The *Nordpred* and Bayesian APC (BAPC) prediction models were used to estimate future gout incidence. Although Jeong et al [21] have analyzed the global burden of gout and its associations with various factors such as sex, age, and region, as well as risk factors such as obesity and potential genetic factors, using Global Burden of Disease (GBD) Study 2019 data, this study aims to analyze global trends in gout incidence and prevalence and discuss local health care delivery to learn what may lead to novel action for better management in the future [21]. Therefore, by analyzing the GBD Study 2019 data from 1990 to 2019 by age, sex, and SDI, we have provided an in-depth gout report.

Methods

Overview

All data were extracted from the GBD Study 2019 [22], which provides descriptive epidemiological data on 369 diseases and injuries in 204 countries and territories from 1990 to 2019, including incidence, prevalence, mortality, years of life lost, years lived with disability (YLD), and disability-adjusted life years [23]. To identify the data source from a systematic review of published studies, searches of government and international organization websites, published reports, and primary data sources were undertaken, and librarians reviewed each data source. Diagnosis codes from both the International Classification of Diseases, Ninth Revision (ICD-9; 274.x), and the International Classification of Diseases, Tenth Revision (ICD-10; M10.x), were used to identify cases of gout in the GBD Study 2019 data set. The search terms used included *acute gout*, *gouty arthropathy*, *gouty neuritis*, and *primary gout*. According to the American College of Rheumatology diagnostic criteria for gout, the gold standard consists of checking for the presence of monosodium urate crystals in the synovial fluid of the affected joint.

Ethical Considerations

This study used data from the GBD Study 2019, which was approved by the institutional review board of the University of Washington School of Medicine. As this is a secondary analysis of existing data, no additional human participant research ethics review or informed consent was required. The original data collection obtained informed consent from study participants or was granted exemptions by the institutional review board. Study data were anonymized and deidentified to protect the privacy and confidentiality of study participants.

Analysis of Overall Temporal Trends

Using all-age prevalence (number) and age-standardized prevalence rates, we assessed the temporal trend in gout prevalence over the study period from 1990 to 2019. Age-standardized population prevalence was calculated using the global data from the GBD Study 2019. Measuring age-standardized population prevalence can provide a method that compares prevalence among countries and SDI quantiles with different populations. As they provide an indirect insight into epidemiological severity, YLD data were examined using an age-standardized YLD rate for the study period from 1990 to 2019. YLD refers to the number of years that an individual with an illness that affects their quality of life, in this case, a patient with a confirmed diagnosis of gout, survives until death [24].

APC Analysis

The APC model was used mainly to analyze gout morbidity trends and predict future gout burden. The model considers 3 factors: age, period, and cohort. Time trends of diseases are usually explained by age effects, period effects, and cohort effects, as well as random variation. The critical problem of descriptive epidemiology in this case was to describe the APC results of disease occurrence under the condition of gout rates. In the APC model, the period effect refers to the change of human factors affecting the gout rate in the population, such as the development of disease diagnosis technology, screening and early detection, changes in disease definition and registration, and treatment improvement. These human factors may affect disease rates in different periods, resulting in period effects. The age effect is one of the most critical determinants of disease occurrence. The cohort effect refers to changes in disease rates caused by different levels of exposure to risk factors in different generations. The APC model estimates the APC effects by SDI quintiles. The age effect uses longitudinal and cross-sectional age curves, representing age-related gout prevalence; fitted temporal trends display the period effect, period risk ratio, and period deviations; and cohort effects are displayed using cohort RR, local drifts, and cohort deviations. In the APC model, net drifts represent the overall trend in prevalence or incidence over time, whereas local drifts reflect the trends within a specific time period or age group. Age effects measure the changes in prevalence or incidence associated with aging, period effects refer to changes that affect all age groups at a particular time point, and cohort effects reflect the changes in prevalence or incidence for individuals born in the same year. The model also included the issue of covariance among age, period, and cohort, which was addressed by the identifiability constraint that the sum of the APC coefficients must equal 0. However, this constraint can lead to difficulties in estimating the separate APC effects. To address this issue, the estimable functions approach is used, which involves combining linear constraints on the APC coefficients to estimate these effects. Specifically, the sum-to-0 constraint is used to estimate the net drifts (long-term trends) and local drifts (deviations from the long-term trends) for each effect. The net drifts correspond to the overall change in the outcome over time, whereas the local drifts correspond to the deviations from the overall change. The APC model can thus provide insights into the unique APC effects on gout prevalence and incidence over time. In the case of gout, the model grouped age effect into 10-year intervals, period effect into 5-year intervals, and cohort effect into 5-year intervals to simplify the analysis. The x intercept for the cohort effect is set at the year 1945, and the reference choice (the baseline for comparison) is indicated with a dashed line.

Prediction Model

To reflect the trends in gout burden, the number of new cases of gout from 2019 to 2042 was predicted using a *Nordpred* APC analysis by sex. The R software (R Foundation for Statistical Computing) package *Nordpred* was used for this analysis, which takes into account changing rates and changing population structures, as demonstrated in previous studies [25]. In addition, to facilitate comparison with the predicted results, we calculated the absolute number of events that would occur if the rates remained stable (baseline reference), decreased by 1% per year (optimistic reference), or increased by 1% per year (pessimistic reference) based on actual observed rates in 2019. To validate the stability of the prediction results, we performed a sensitivity analysis using the BAPC model integrated nested Laplace approximations (INLA) with the *BAPC* and *INLA* packages in R.

Statistical Analysis

Our study used the APC model to analyze gout morbidity and mortality trends and predict future gout burden. The APC model estimates the time trend of prevalence within each age group, expressed as the annual percentage change of age-specific prevalence, reflecting the birth cohort effect trend, whereas Jeong et al [21] used counts, age-standardized rates, age-standardized percentage changes of prevalence, incidence, and YLD to quantify global trends in the burden of gout using the GBD Study 2019 standard population from 1990 to 2019. The Wald chi-square test results indicate whether there is a birth cohort effect and whether the test results are statistically different. An important implication is that a single age-standardized rate curve and estimated annual percentage change value do not adequately describe the time trend in each age group. A drift absolute value of >1% is considered a material change, which is tested by the Wald chi-square test. All analyses were 2-sided, and statistical significance was considered at *P*<.05. Statistical analysis was conducted using R software (version 3.6.3), and the result was presented using 95% uncertainty intervals (UIs).

Results

Global and Regional Trends in Gout Incidence From 1990 to 2019

The global population of individuals with gout increased in the past 30 years from 22 million (95% UI 17.52-27.37) to 53 million (95% UI 43.38-66.34). The growth rate of gout *incidence* was 63.44% (95% UI 57.33%-68.78%). YLD increased from 0.69 million (95% UI 0.44-99.37) to 1.67 million (95% UI 1.07-2.39). The growth rate of global YLD was 51.12% (95% UI 45.91%-56.51%). The sex ratio stayed consistent at 3:1 (male to female), but the gout *incidence* kept increasing over time. The number of male individuals with gout increased from 16 million (95% UI 13.22-20.68) to 40 million (95% UI 32.75-50.10). The growth rate of gout incidence in male individuals was 70.15% (95% UI 64.55%-75.74%). The number of female individuals with gout increased from 5.3 million (95% UI 4.25-6.75) to 13.2 million (95% UI 106.03-163.79), and the growth rate of gout incidence in female individuals was 68.70% (95% UI 63.70%-73.43%). In the high- and middle-SDI regions, the number of individuals with gout skyrocketed from 7 million (95% UI 5.67-8.84) to 17 million (95% UI 14.19-20.62) and from 6 million (95% UI 4.64-7.26) to 15 million (95% UI 12.28-19.40), respectively, with growth rates of 94.3% (95% UI 84.33%-107.15%) and 90.46% (81.34%-98.45%), respectively (Figure 1; Table 1).

Figure 1. The age effect for gout is shown with all sociodemographic index (SDI) quantiles on total prevalence cases (number) and prevalence rate per 100,000 population from (A) 1990 to (B) 2019. The age effect is shown with all SDI quantiles on years lived with disability (YLD; number) and the YLD rate per 100,000 population from (C) 1990 to (D) 2019. The global tendency under the age effect on both gender.

[a] Age-standardized mortality rate is computed by direct standardization with the global standard population in the Global Burden of Disease Study 2019.

[b] UI: uncertainty interval.

[c] APC: age-period-cohort.

[d] Net drifts are estimates derived from the age-period-cohort model and denote overall annual percentage change in mortality, which captures the contribution of the effects from calendar time and successive birth cohorts.

Global and Regional Trends in Gout Prevalence From 1990 to 2019

The gout prevalence trends are similar to the incidence trends. The global all-age prevalence rate increased from 412.42 (95% UI 327.46-511.67) to 696.25 (95% UI 857.42-6634.23) per 10,000 population, and the age-standardized prevalence rate increased from 532.99 (95% UI 425.35-657.86) to 652.24 (95% UI 528.56-798.60) per 10,000 population (Figure 2; Table 1). The high-SDI quantiles have the highest increase in prevalence from 711.83 (95% UI 565.01-887.95) to 1041.01 (95% UI 862.79-1244.91) per 10,000 population, an increase of 47.95%, followed by the high-middle–SDI quantiles, where the age-standardized prevalence increased from 492.64 (95% UI 393.93-611.45) to 624.81 (95% UI 495.85-778.15) per 10,000 population. The prevalence depends on the regions' SDI development (Figure 3; Table 1).

Figure 2. The period effect for gout is shown with all sociodemographic index (SDI) quantiles on (A) total prevalence cases (number) and age-standardized prevalence rate per 100,000 population and (B) years lived with disability (YLD; number) and standardized YLD rate per 100,000 population. The global tendency under the age effect on both sexes is shown as line charts.

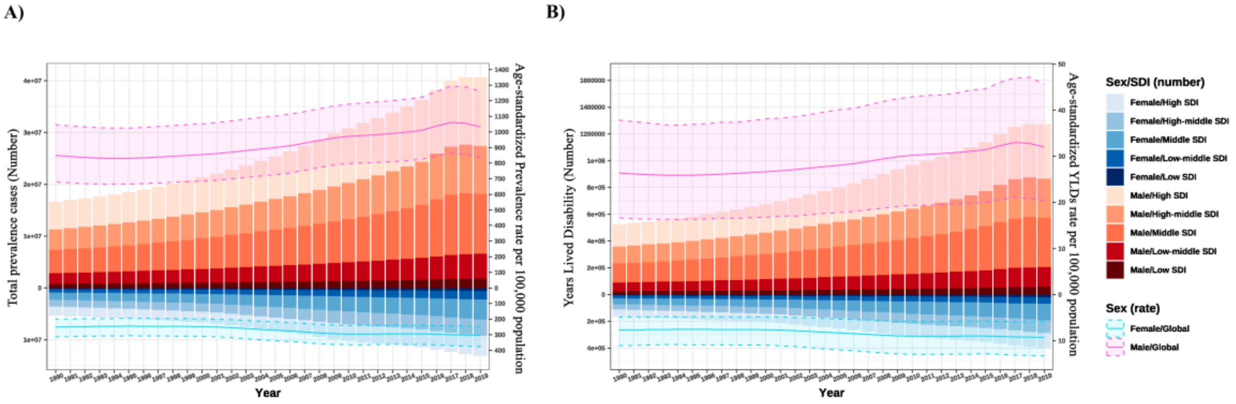

Figure 3. (A) The all-age prevalence for gout in 2019 in 204 countries and territories. (B) Net drift of gout prevalence from 1990 to 2019 in 204 countries and territories.

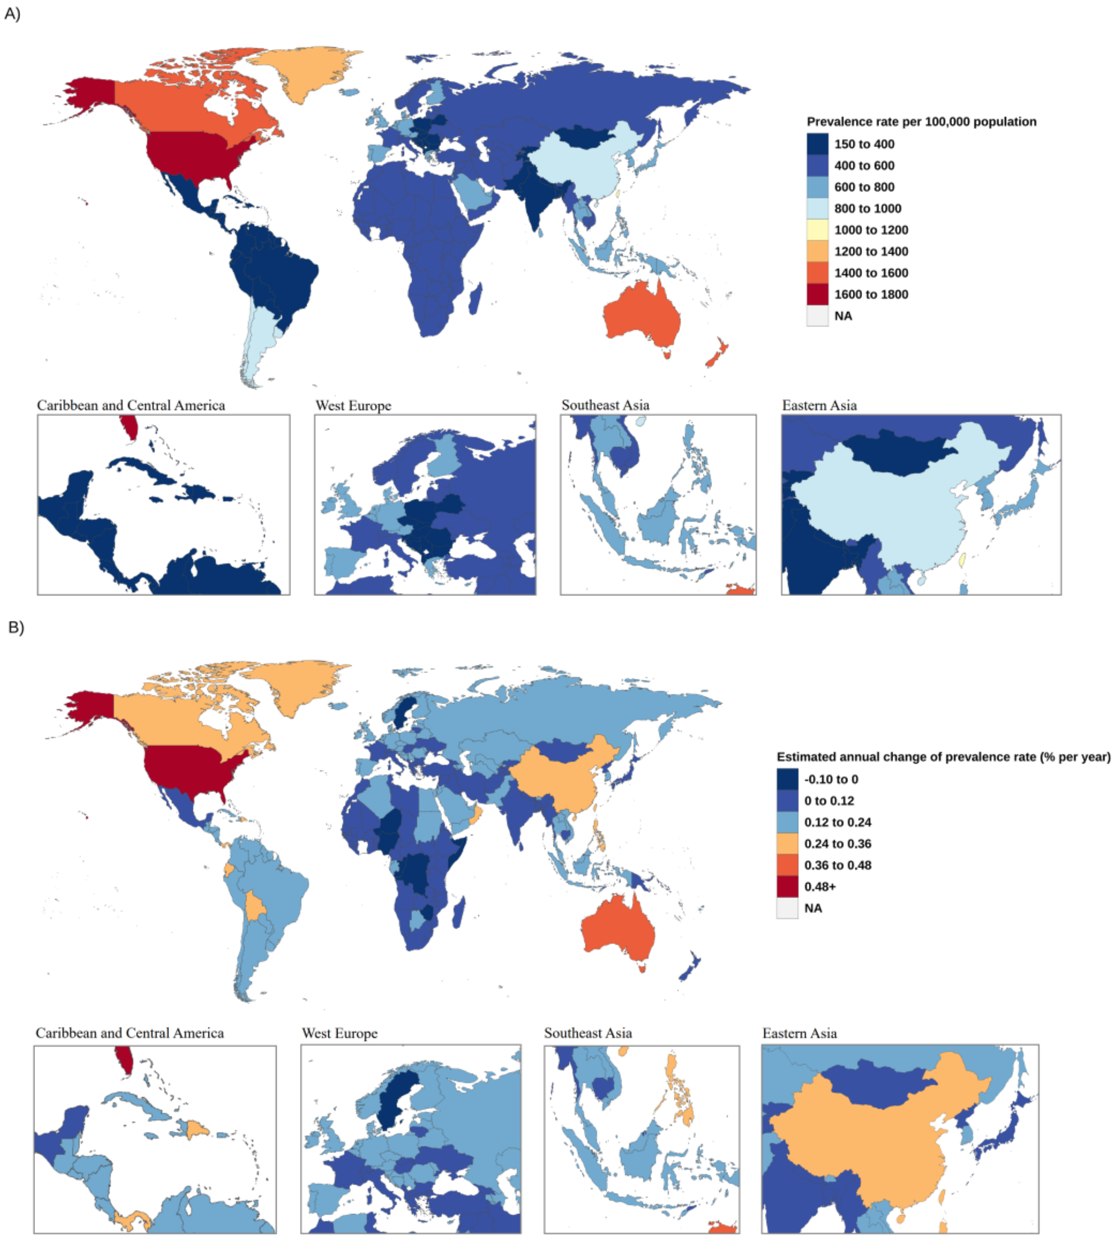


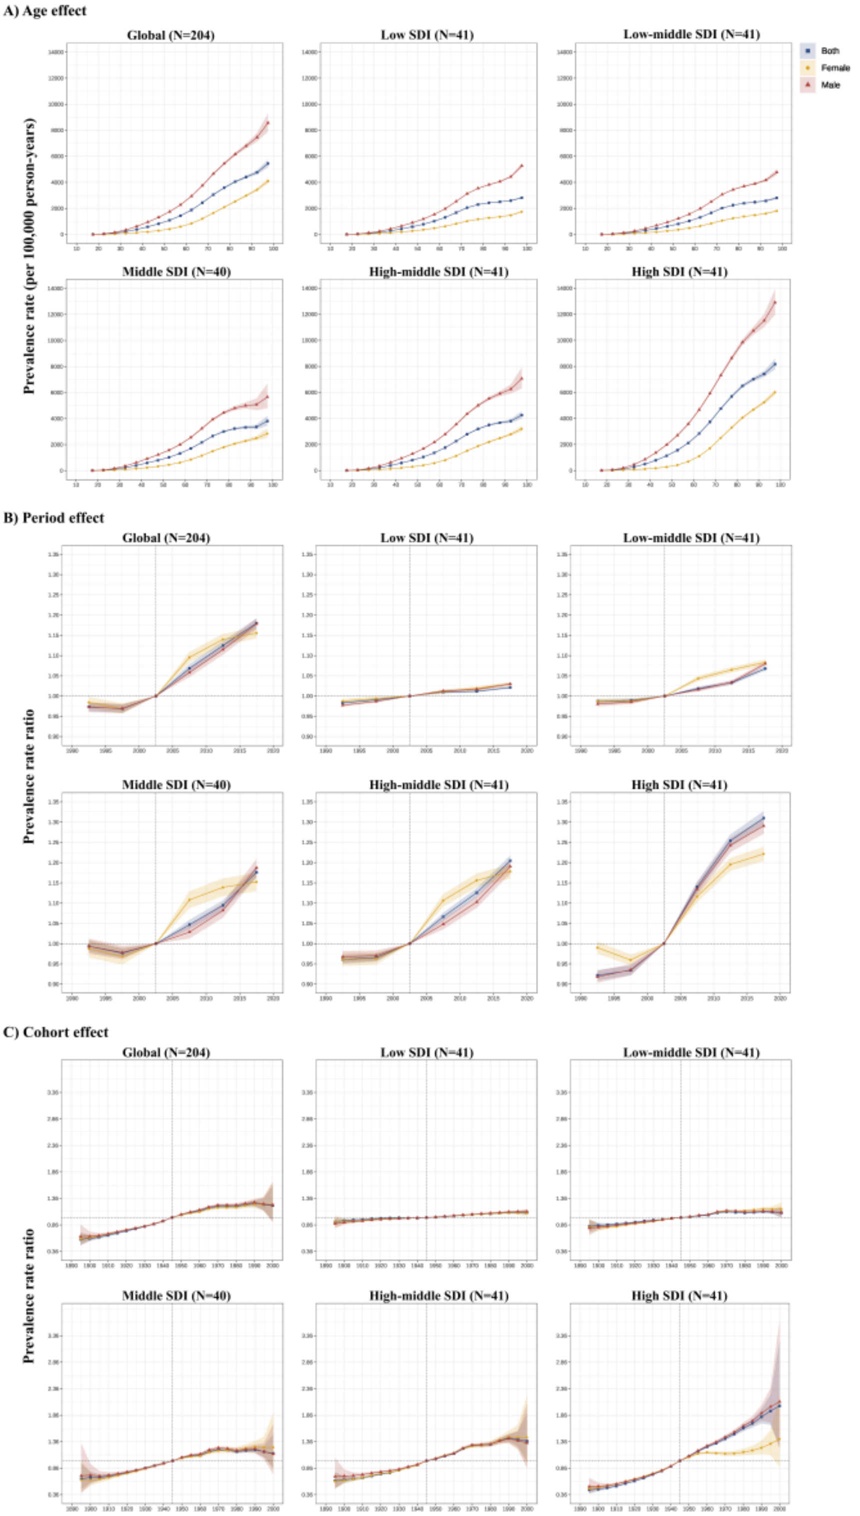
APC Effects on Gout Prevalence

To extend the previous studies, we used the APC model to analyze gout burden [21]. Globally, the prevalence of the age effect increases steadily from the age of 30 years in both sexes. The prevalence rises the most readily in high-SDI quintiles across all age groups compared with other quintiles.

Regarding the period effect, gout prevalence witnessed a growth tendency across most SDI quintiles over the study period, with only low-SDI countries remaining nearly constant over the past 2 decades. High-SDI, high-middle–SDI, and middle-SDI countries had the most notable increase in period prevalence rates across the period from 1990 to 2019. By contrast, low-SDI and low-middle–SDI countries stayed relatively stable in terms of prevalence rates. Surprisingly, in terms of the period effect, the gout prevalence rate in female individuals was higher than that in male individuals across the period from 2003 to 2015 in low-middle–SDI, middle-SDI, and high-middle–SDI countries. Still, the data showed that the gout prevalence rate in male individuals was higher than that in female individuals (Figure 1).

The morbidity is increased and the younger age population is readily exposed to the risk factor. The growth of cohort effects was remarkable in high-SDI countries. High-SDI countries had progressively increasing morbidity rates among those born after 1900. The sex ratio has shifted in middle-SDI and high-middle–SDI countries, where female individuals have a higher morbidity rate than male individuals in terms of the cohort effect (Figure 4).

Figure 4. Age-period-cohort effects on gout prevalence by sociodemographic index (SDI) quintiles. (A) Age effects are shown by the fitted longitudinal age curves of prevalence (per 100,000 person-years) adjusted for period deviations. (B) Period effects are shown by the relative risk of prevalence (prevalence rate ratio) and computed as the ratio of age-specific rates from 1990 to 1994 (the referent period) to 2015-2019. (C) Cohort effects are shown by the relative risk of prevalence and computed as the ratio of age-specific rates from the 1925 cohort to the 2015 cohort, with the referent cohort set at 1960. The dots and shaded areas denote prevalence rates and prevalence rate ratios, respectively, and their corresponding 95% CIs.

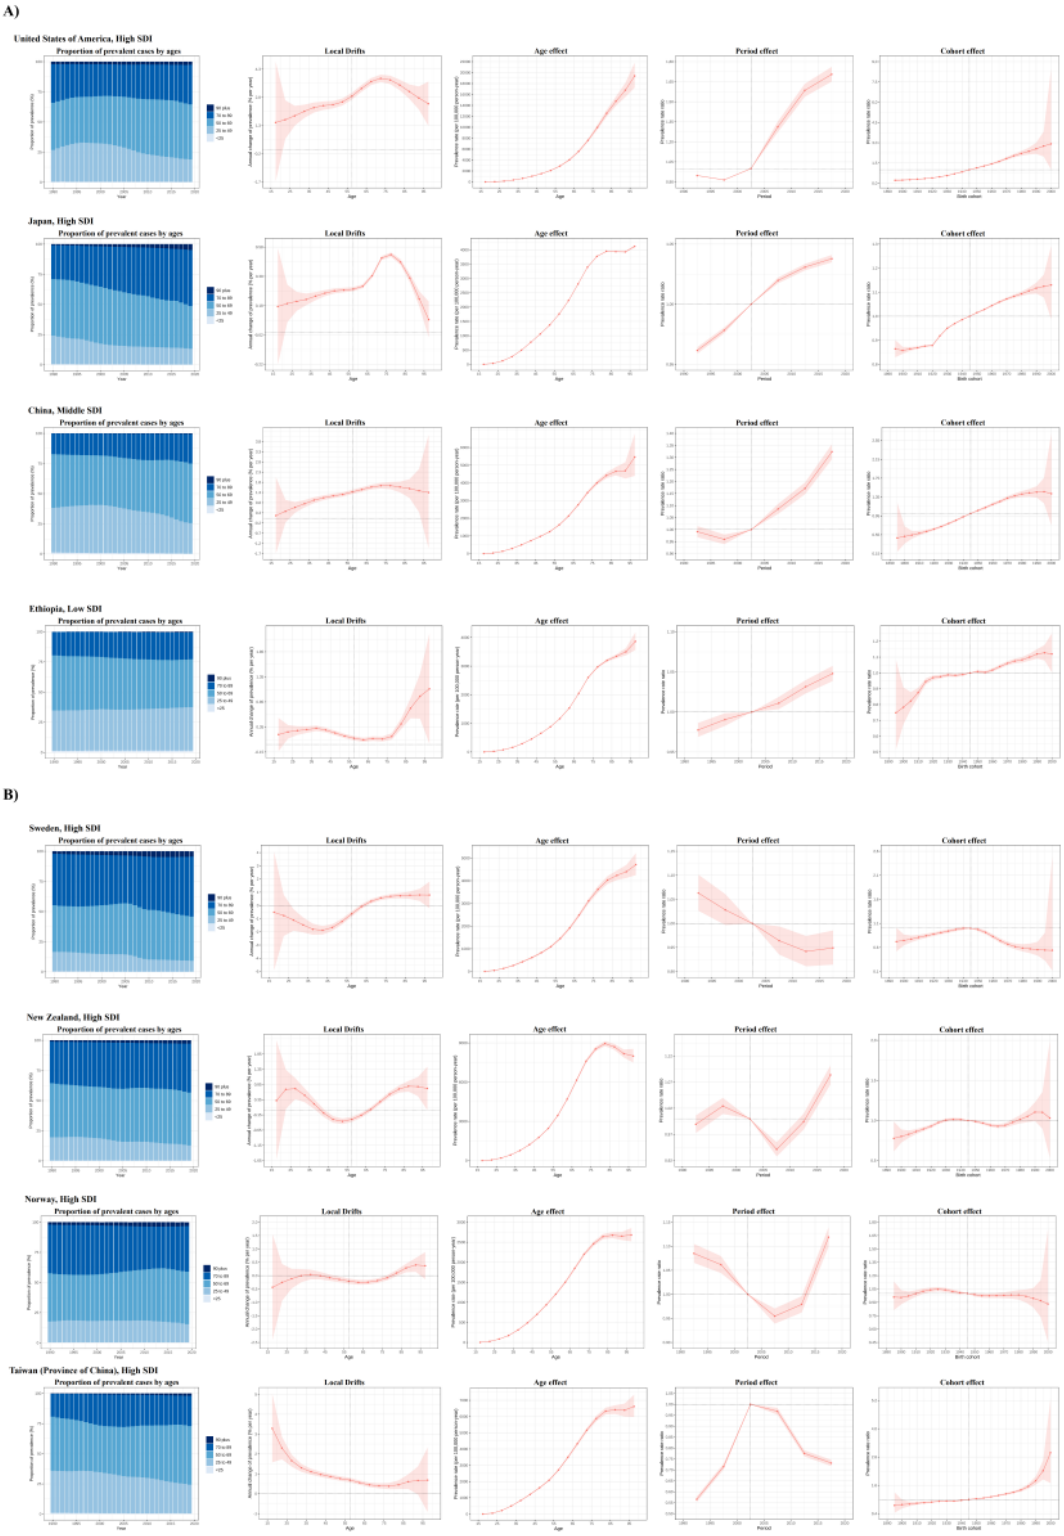


APC Effects in Typical Countries or Regions

Several countries or regions across SDI quintiles displayed significant developments in gout morbidity by APC effects around the world. The United States showed a trend typical of high-SDI countries, where growing gout prevalence was measured across all age groups. In Japan, another example of a high-SDI country, increased morbidity stood out for its notable net drift and demonstrated an emerging transition in the age distribution of morbidity. Moreover, China had a shift in the age distribution of morbidity, with significantly increased risk in those born after 1970, and the gout prevalence increased dramatically after 2003 in this middle-SDI country. Regarding low-SDI countries, Ethiopia showed a similar phenomenon to that in high-SDI countries because the prevalence kept growing over time. People aged <75 years had significant local drift in terms of being diagnosed with gout. People born after 2000 had a significantly higher risk of developing gout (Figure 5A).

Countries displaying relatively unfavorable APC effects on prevalence are shown in Figure 5B. Sweden, a high-SDI country, showed increasing risk throughout the age effect, but the period effect reduced the prevalence. In addition, people born after 2000 in Sweden have a lower risk of developing gout. New Zealand and Norway showed a descending trend in the period effect but rebooted the prevalence rate after 2008. By contrast, Taiwan showed the opposite result, with the prevalence rate consistently decreasing after 2003.

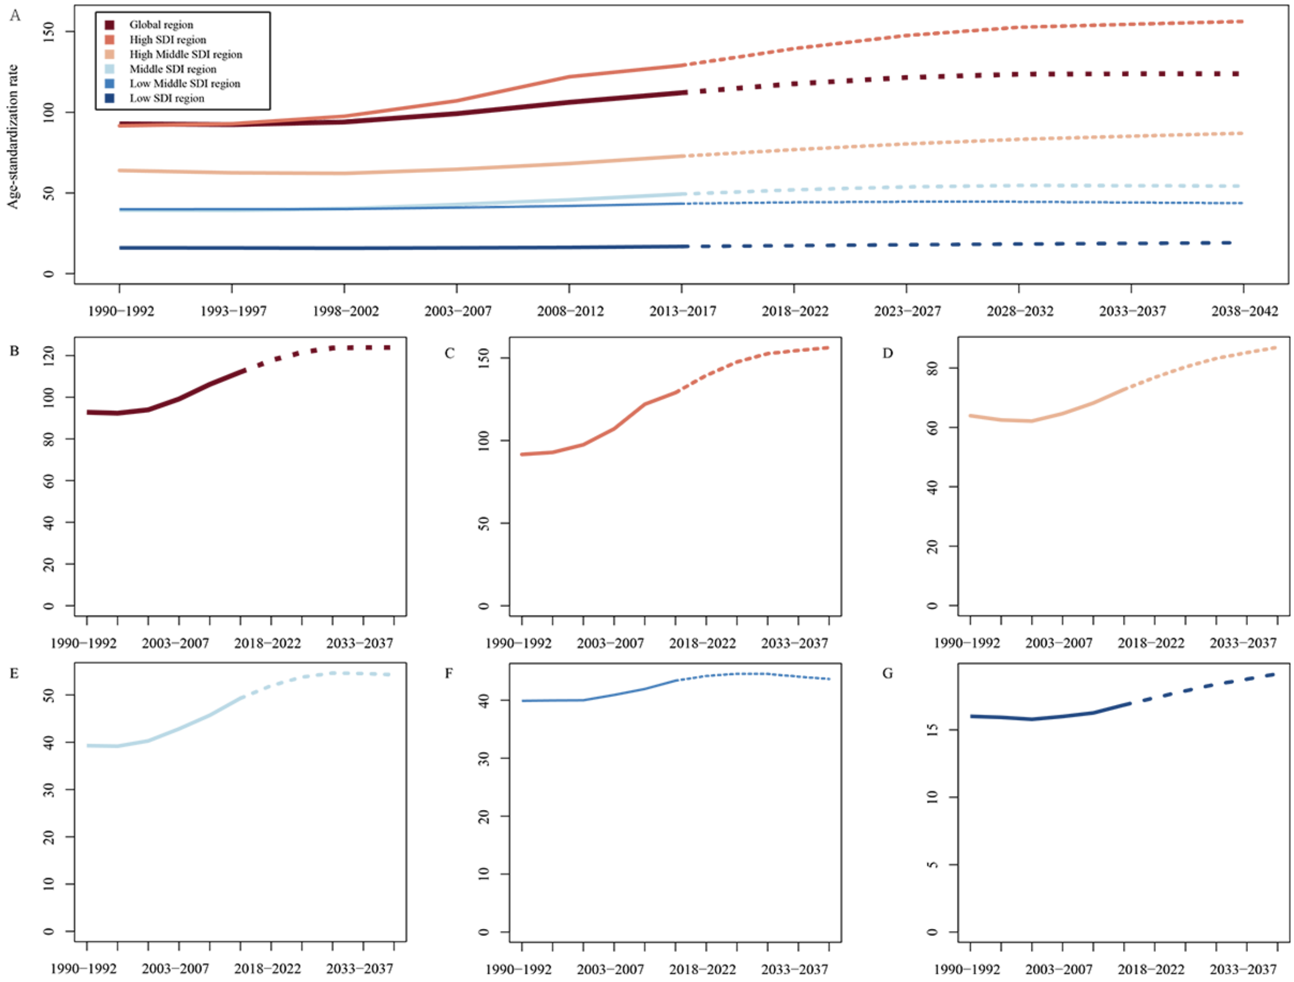
Figure 5. Favorable (A) and unfavorable (B) age-period-cohort effects on exemplar countries across sociodemographic index (SDI) quintiles. Age distribution of deaths shows the relative proportion of morbidity from each age group from 1990 to 2019. Local drifts indicate the annual percentage change in prevalence rate (%) across 5-year age groups (from 0-4 to 65-69 years). Age effects are represented by the fitted longitudinal age curves of prevalence (per 100,000 person-years) adjusted for period deviations. Period effects are represented by the relative risk of prevalence (prevalence rate ratio) and computed as the ratio of age-specific rates in each period compared with the referent period from 1990 to 1994. Cohort effects are represented by the relative risk of prevalence (prevalence rate ratio) and computed as the ratio of age-specific rates in each cohort compared with the referent 1960 cohort. The shaded areas indicate the corresponding 95% CIs of each point estimate. See high-resolution image in Multimedia Appendix 1.



Trends in Gout Incidence Over Time

The predicted incidence rates of gout per 100,000 population were calculated using the *Nordpred* APC prediction for different SDI regions (Figure 6). Overall, the predicted incidence rates of gout increased over time in all regions. The global predicted incidence rate increased from 92.79 per 100,000 population in the period from 1990 to 1992 to 123.83 per 100,000 population in the period from 2038 to 2042. The highest predicted incidence rate was observed in the high-SDI quantiles region, with a predicted incidence rate of 156.28 per 100,000 population in the period from 2038 to 2042. The lowest predicted incidence rate was observed in the low-SDI quantiles region, with a predicted incidence rate of 19.16 per 100,000 population in the period from 2038 to 2042. There were also notable differences in the predicted incidence rates among regions; for instance, the predicted incidence rates in the high-middle–SDI quantiles region were consistently lower than those in the high-SDI quantiles region but higher than those in the middle-SDI quantiles and low-middle–SDI quantiles regions. Similarly, the predicted incidence rates in the low-middle–SDI quantiles region were consistently lower than those in the middle-SDI quantiles region but higher than those in the low-SDI quantiles region.

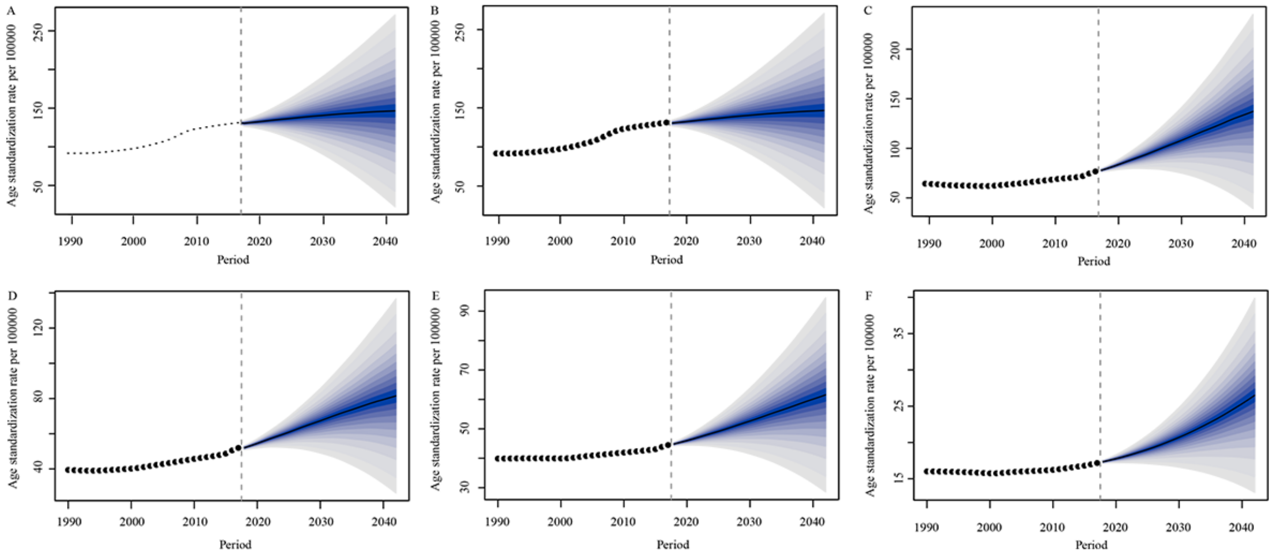
Figure 6. Trends in gout by Nordpred age-period-cohort prediction model in (A) global scale. To minimize the scale bias, the plots were separated as follows: (B) global scale, (C) high–sociodemographic index (SDI) quantiles, (D) high-middle–SDI quantiles, (E) middle-SDI quantiles, (F) low-middle–SDI quantiles, and (G) low-SDI quantiles.



Overall, the number of cases of gout increased over time in all regions. Globally, in 2023, a total of 10,016,336 cases were reported, which is projected to increase to 12,082,807 cases in 2035. The low-SDI quantiles region had the lowest number of cases, with 490,786.4 cases reported in 2018, which is projected to increase to 788,807.5 cases in 2042. There were also notable differences in the number of cases among regions; for instance, the high-SDI quantiles region had the second highest number of cases, with 2,242,423 cases reported in 2018, which is projected to increase to 2,395,031 cases in 2035. The low-middle–SDI quantiles region had a slightly higher number of cases than the middle-SDI quantiles region, but the trend is expected to reverse by 2035, with the middle-SDI quantiles region projected to have more cases (Multimedia Appendix 2).

The BAPC prediction model was used as a sensitivity analysis to validate the findings from the APC analysis. Consistent with the APC analysis, the BAPC prediction model suggested that there would be an overall increase in the age-standardized incidence of the disease from 1990 to 2042 across all 6 regions. The highest increase in age-standardized incidence is expected to occur in the high-middle–SDI quantiles, with the incidence increasing from 64.30 per 100,000 population to 137.14 per 100,000 population. The high-SDI quantiles are also expected to experience a significant increase in age-standardized incidence, from 91.68 per 100,000 population to 146.51 per 100,000 population. The middle-SDI quantiles are expected to see an increase from 39.44 per 100,000 population to 81.48 per 100,000 population. The low-middle–SDI quantiles are expected to experience an increase from 39.86 per 100,000 population to 61.54 per 100,000 population. The low-SDI quantiles are expected to experience the smallest increase in age-standardized incidence, from 15.99 per 100,000 population to 26.49 per 100,000 population. Overall, the BAPC prediction model suggests that there will be a significant increase in the incidence of the disease across all regions, with the highest increases occurring in regions with higher-SDI quantiles (Figure 7).

Figure 7. Trends in gout by Bayesian age-period-cohort prediction model in (A) global scale, (B) high–sociodemographic index (SDI) quantiles, (C) high-middle–SDI quantiles, (D) middle-SDI quantiles, (E) low-middle–SDI quantiles, and (F) low-SDI quantiles.



Discussion

Principal Findings

Gout is among the most common chronic rheumatic and inflammatory arthritis diseases worldwide. Understanding trends in gout prevalence is key for governments to distribute health care resources better [26]. Despite gout having a low mortality rate and high *curable* rates without comorbidities, gout prevalence has steadily increased globally owing to inadequate management by both medical professionals and patients in many countries [27,28]. The net drift in the majority of high-SDI quantiles increased most readily in terms of both period and cohort effects. To our knowledge, this is the first study using the APC model to analyze global trends in gout prevalence, enabling comparisons among different countries and predictions of future incidence. Compared with previous publications [7,21], our study advances the field by providing a more comprehensive and nuanced understanding of gout prevalence trends and contributing to public health knowledge through future burden estimations. To be precise, the analysis of age effects, period effects, and cohort effects allowed us to determine the prevalence trends by period and birth cohort in individual regions, providing an in-depth evaluation of the quality of the health care system with regard to gout management. The model allowed a comparison among countries and the discovery of some countries or regions with effective interventions. By highlighting these responsive quantiles, we hope that inspiration will strike for a novel or potential idea to better manage gout.

This study illustrates the increase in gout prevalence over time from 1990 to 2019. This tendency would not change, according to our APC model prediction. The major challenge was that the highest gout prevalence occurred in the high-SDI quantiles where the quality of medical care is outstanding. This is an indication, perhaps, that advanced interventions and techniques are not sufficient to solve the problem; rather, this points to the need for the entire medical system to work together. With populations increasing worldwide and with an increase in the aging population, the situation regarding gout prevalence is delicately poised. This analysis of the gout burden in different regions, therefore, is important from the point of view of learning how the medical system works in countries that have demonstrated superior management of gout.

A previous study reported the global gout burden during the period from 1990 to 2010 [8]. With a 9-year data gap, it is necessary to perform updated research to learn trends in gout prevalence and identify the challenges our health system may face in the future. In addition, it is essential to evaluate the effectiveness of the gout management strategies used during the period from 2010 to 2019. Compared with the Disease Modelling Meta-Regression model, the APC model could divide data into 3 spatially varying parameters with conditioning. The conditioning order-dependent model was validated on the spatially varying coefficients; therefore, the model was available for the individual country calculations [16]. Consequently, the APC model was more favorable with regard to the Watanabe-Akaike information criterion than the model with independent random effects [29].

Our analysis of gout prevalence estimates suggests that many low- and middle-income countries, especially those with a high SDI, have had an increasing gout prevalence tendency. Still, the low-SDI countries have relatively stable conditions regarding gout prevalence. We also found that people born after 2000 were more likely to develop gout than those born after 1900, suggesting that awareness of health care resources and education for gout are insufficient [7]. It is possible that patients who experience gout flares may be ashamed of admitting their lifestyles, including the excessive intake of purine-rich foods and alcohol, and this may be combined with low health literacy, because of which they do not receive sufficient information on gout [30]. Most patients with gout visit inpatient clinics only for relief of gout flares, and it has been suggested that the weak relationship between the physician and the patient with gout is leading to treatment nonadherence [31,32]. Another possible explanation for the higher likelihood of gout development among individuals born after 2000 compared with those born after 1900 is the improvement in people's standard of living and dietary habits, which may have led to an earlier onset of gout [33]. This highlights the importance of considering multiple factors when analyzing the trends in gout prevalence and the burden of gout.

Age-standardized prevalence and YLD can provide a clear picture for comparisons among different economic countries or regions. Because of the varying population structure in different SDI countries and regions, we should interpret the results carefully. In lower-SDI countries, citizens tend to have shorter life expectancy and higher birth rates; therefore, the all-age prevalence is relatively lower than the standardized-age prevalence [34,35]. To cope with the actual situation, health care systems may consider investing more resources in *gout flare* services, especially effective treatment. However, the aging population structure is one of the common social issues in higher-SDI countries. Although the standardized-age prevalence is lower than the all-aged prevalence, because older adults have become a prominent part of the population and also because of rising obesity rates, the health burden would keep increasing. Prevention and long-term management are key to coping with the situation [36,37].

Although the standardized-age prevalence of chronic diseases is lower among younger age groups, the increasing prevalence of obesity and the aging population in the United States has contributed to a considerable health burden. As one of the high-SDI countries, the United States has experienced the most substantial incidence and prevalence rates in the world, with an estimated 1 million cases [38]. Although the United States provides one of the best medical services in the world, gout is the most common inflammatory arthritis disease with significant morbidity and mortality [39]. Gout management strategies, including monitoring and treatment options, are far from enough. According to our results, gout prevalence in the United States has yet to plateau. The rates of obesity, hypertension, and chronic kidney disease keep rising because of the aging population and longer life expectancy [40-42]. As a result, the quality of life may not be improved even with advanced medical services.

In contrast to the United States, Japan, a high-SDI country, has a lower prevalence rate, despite a steadily increasing trend. Japanese traditionally favor purine-rich foods, including seafood, miso, soy sauce, and umami broth [43]. A possible reason for Japan having a lower prevalence rate than the United States is the country's treat-to-target approach to gout [44,45]. The Japanese medical profession has suggested that patients who present with hyperuricemia and those without symptoms should undergo urate-lowering therapy because hyperuricemia is the etiology causing gout flares [46]. This approach is one of the breakthrough ideas for gout prevention. Checking for the presence of urate in the blood during routine examination may be a possible way to control and prevent gout.

China is the world's second most populous country, with a population of 1.4 billion. The prevalence of gout in China was lower than that of the United States and European countries in 1990, the reasons for which are differences in genetic factors and exposure [7]. In addition, in 1990, China's public health institutions were undeveloped, and most public health workers had a poor opinion of the whole system [47]. Therefore, it became a challenge to collect national-level data; as a result, detection accuracy was unsatisfactory, and it remained so until the public health system was reformed. Subsequently, because of rapid westernization and urbanization, the Chinese changed their lifestyles; thus, gout prevalence kept rising in this large-population country with higher diagnosis accuracy. However, various degrees of urbanization and levels of quality of hospitals in different regions or provinces could lead to an extensive range of prevalence [48-50]. It has been reported that the obesity rate could reflect gout prevalence indirectly [51]; thus, it may be an index for the public health professional for the surveillance and prediction of gout prevalence. In low and middle tropical countries, the focus is mainly on infectious diseases and parasites, with insufficient epidemiological surveillance. Because of the younger population, the noncommunicable disease burden is underestimated in these regions. After age standardization, the mortality rate in low and middle tropical countries is more severe than that in high-income countries owing to lack of proper management and health education [52]. To better distribute resources, governments should financially support public health institutions to screen for a *curable* chronic disease, which is gout in this case [53].

A few countries such as Sweden and Taiwan showed a descendant trend in gout prevalence in terms of the period effect. However, several studies have reported that gout management in these countries was not satisfactory owing to the low rate of urate-lowering therapy use, long-term management issues, and poor gout management education [54-56]. Kuo et al [56] explained that the phenomenon could be due to statistical bias, including the delay in prevalence reaction time, short follow-up time, and overestimation of incidence rates from previous studies. However, our APC model presented the period effect from 1990 to 2019; therefore, the length of the follow-up period is sufficient. Besides the education level, ethnic differences, income, and occupation, the possible reason for the aforementioned phenomenon is the different levels of diagnostic certainty [26,57]. In addition, these countries have improved health care systems with regard to gout management because the government provides public data for researchers to study the disease. In Sweden, the Skåne Healthcare Register provides nationwide data for rheumatologists to study gout. Therefore, the rheumatologists could analyze the data with different dimensions, including by region and population [54,58-62]. In Taiwan, the researchers focused on the comorbidities caused by gout [63-68]. As mentioned previously, the mortality gap has stayed consistent over 2 decades. Gout complications could also affect the quality of life catastrophically. Research is necessary to understand and analyze the relationship between gout and its complications. It is also essential to explore the correlations between gout and other diseases. These studies are not only for academic use but also for practical use in the future. Although gout prevalence showed a descendant trend in Sweden, the Swedish public health professional is not satisfied regarding the prevalence and incidence of gout in the country [69]. Therefore, awareness should be created of chronic inflammatory arthritis prevalence on a worldwide level, and immediate action should be taken, including gout management education for both patients and healthy populations.

Although gout is a chronic disease, the primary management involves short-term symptomatic treatment [70,71]. Chronic diseases are often established integrated health care systems with multidisciplinary input [72]. It could prevent comorbidity effectively with the advanced policy science [73]. Primary health care for chronic diseases involves different approaches. At outpatient clinics, patients receive comprehensive advice regarding, for example, nutrition intake, individual susceptibility, body weight, and behavior changes. As gout is caused by multiple factors, the individual approach, such as nursing case management, shows significantly positive results [74]. Regarding health care system approaches, a medical record network set up among hospitals can play an important role. A patient's medical history could track gout flare frequency, which could enable evaluation of the effectiveness of the management strategy. Of note, a patient's medical history is a record of their lifestyle in the past (eg, alcohol use and body weight). Hence, the establishment of a medical record network may help to provide effective support for, and monitoring of, patients with gout [75]. It has been reported that low medication adherence among patients with gout is due to time constraints, cost, and scarcity of incentives [76]. Technology could help to overcome these barriers; for example, mobile phone apps and personal activity tracker tools could provide a novel approach to helping patients to change health behaviors [77]. Monitoring patients' health state remotely, improving patient convenience, and protecting patient privacy could enhance patient medication adherence. It may also be meaningful for health care departments to refer to the policy on, and the management of, other common chronic disease (eg, cardiovascular disease, diabetes mellitus, and asthma).

Limitations

This study includes limitations. First, limited primary data could be obtained for analysis because the data was modeled in a higher setting by the Institute for Health Metrics and Evaluation, an independent global health research center at the University of Washington, which coordinated the GBD Study 2019. Therefore, the results are heavily dependent on the GBD Study 2019 results data. It is essential to ensure the quality of country-level data collection for a health system because the public health professional can evaluate the effectiveness of the local guideline and policy with in-depth studies. Cohort studies and prospective studies are essential for studying health issues in various populations. An epidemiological study could be combined with pharmacology, mental health, etiology, and genetic studies. Second, the APC model was the mathematical approach used. However, it does not fully reflect the realistic situation. Therefore, the results should be interpreted with caution.

Conclusions

Our study provides important insights into the global burden of gout and highlights the need for effective management and prophylaxis of this condition. The APC model used in our analysis provides a novel approach to understanding the complex trends in gout prevalence and incidence. Gout prevalence in the global population has increased significantly over the past 3 decades, particularly in high-SDI regions. Our study also identified an increasing trend in gout incidence, which is predicted to continue in the coming years. These findings emphasize the urgency of addressing the inadequate strategies for management and prevention of gout in many countries. To cope with the increasing gout prevalence, we recommend the integration of multidisciplinary input and the establishment of medical record networks to improve gout management.

Acknowledgments

This study was supported by Chinese Academy of Medical Sciences (CAMS) Innovation Fund for Medical Sciences (CIFMS; No. 2022-I2M-C&T-B-031), the National High Level Hospital Clinical Research Funding (No. 2022-PUMCH-A-124), the National Natural Science Foundation in China (No. 81871740), and the City University of Hong Kong New Research Initiatives/Infrastructure Support from Central (APRC; 9610589).

Data Availability

All data were obtained via the Global Burden of Disease 2019 study.

Authors' Contributions

QH, T-NM, and BF contributed to the conception and design of the study. SL organized the database. YY performed the statistical analysis. T-NM and QH wrote the first draft of the manuscript. T-HS wrote sections of the manuscript. W-KM and BF supervised the research. W-KM and BF were the cocorresponding authors. All authors contributed to manuscript revision and read and approved the submitted version.

Abstract

Background: Men who have sex with men (MSM) who practice chemsex have a higher likelihood of engaging in risky sexual behaviors and higher rates of HIV infection and other sexually transmitted infections (STIs) than those who do not.

Objective: This trial aimed to evaluate the effectiveness of a web-based intervention in reducing the sexual harms of chemsex among MSM.

Methods: The study was a 2-arm, assessor-blinded, randomized, parallel-group trial with a 3-month follow-up period. The study was conducted in the year 2021 in Hong Kong. Underpinned by the theory of planned behaviors and a harm reduction approach, the intervention consisted of interactive components and knowledge-based information about chemsex. Participants in the control group received brief information and content about sexual violence. The primary outcome was self-efficacy in refusing risky sexual behaviors and chemsex, as measured by the Condom Self-Efficacy Scale (CSES), Self-Efficacy for Sexual Safety (SESS) instrument, and Drug Avoidance Self-Efficacy Scale (DASES). The secondary outcomes included intentions to have chemsex, actual engagement in chemsex, HIV and other STI testing, and condom use in the last 3 months. All outcomes were self-reported. An online structured questionnaire was used to collect data.

Results: In total, 316 MSM enrolled in the study. The intervention group demonstrated a significantly larger improvement in condom-use self-efficacy (as measured by CSES scores; time-by-group interaction: β=4.52, 95% CI 2.03-7.02; *P*<.001), self-efficacy for sexual safety (as measured by SESS scores; time-by-group interaction: β=2.11, 95% CI 0.66-3.56; *P*=.004), and drug avoidance self-efficacy (as measured by DASES scores; time-by-group interaction: β=6.98, 95% CI 1.75-12.22; *P*=.009). Regarding the secondary outcomes, participants in the intervention group demonstrated a significantly larger reduction in the likelihood of having engaged in chemsex in the last 3 months (time-by-group interaction: odds ratio [OR]=0.23, 95% CI 0.10-0.53; *P*=.001) and likelihood of having had the intention to engage in chemsex in the last 3 months (time-by-group interaction: OR=0.37, 95% CI 0.18-0.78; *P*=.009). Participants in the intervention group also showed a significantly larger increase in the likelihood of having undergone HIV testing in the last 3 months (time-by-group interaction: OR=3.08, 95% CI 1.72-5.54; *P*<.001).

Conclusions: This study suggests that a web-based intervention with a harm reduction approach can enhance the self-efficacy of MSM in refusing risky sexual behaviors and chemsex and improve the uptake of HIV testing. We also provide initial evidence that such interventions can reduce both the intention of MSM to engage in chemsex and their actual engagement in chemsex.

Introduction

"Chemsex" is defined as the use of psychoactive substances before or during planned sex to facilitate, initiate, prolong, sustain, or intensify the sexual encounter [1,2]. There is no universal and systematic definition of types of chemsex drugs because the drugs used might vary based on place and time [3]. Nonetheless, there are 4 substances typically associated with chemsex: methamphetamine, mephedrone, γ-butyrolactone/γ-hydroxybutyric acid, and ketamine [4]. Chemsex occurs across sexual orientations and genders but is considerably more common among men who have sex with men (MSM) [5-7]. A systematic review reported that the prevalence of recent (within the last 6 months) engagement in chemsex among MSM populations is high, with estimates ranging from 9.9% to 93.7% (according to 12 studies) [8]. Motivations for engagement in chemsex vary. A systematic review reported that MSM engage in chemsex because it can increase their stamina and arousal levels, allowing them to engage in sex for sustained periods; the lowering of inhibitions induced by chemsex can also provide a more immediate and sustained interaction with sex partners [2].

Empirical studies have reported that the practice of risky sexual behaviors is prevalent among MSM who engage in chemsex. A systematic review reported that the prevalence of condomless sex ranged from 17% to 100% among MSM who engaged in chemsex [8]. A study in the Netherlands also reported that the participating MSM who engaged in chemsex were significantly more likely to practice condomless anal sex than the MSM who did not (84.3% vs 61.1%, respectively; $P<.001$) [9]. According to a qualitative study conducted in the United Kingdom, MSM perceive condomless sex as the norm during chemsex [10]. Chemsex is also associated with group sex, fisting, and a higher number of sexual partners [8,11,12]. Robust evidence suggests that chemsex is strongly associated with high-risk sexual behaviors linked to the risk of acquisition of HIV and other sexually transmitted infections (STIs).

MSM who engage in chemsex experience higher rates of HIV infection, other STIs, and hepatitis C infection than those who do not [4]. A cohort study in Canada reported that practicing chemsex is linked to an increased incidence of gonorrhea and chlamydia and that this effect is stronger for people who use multiple chemsex substances [13]. A study in the United Kingdom reported that the rate of new HIV diagnoses is significantly higher in MSM who practice chemsex than in those who do not (8.6% vs 1.8%, respectively) [12]. The study also reported that MSM who practice chemsex have higher odds of having a serodiscordant HIV-positive sex partner (adjusted odds ratio [OR]=6.83) [12]. The high frequency of STIs among chemsex users highlights the importance of primary, secondary, and tertiary prevention of STIs and chemsex among MSM.

Globally, "undetectable equals untransmittable (U=U)" and pre-exposure prophylaxis (PrEP) have become important elements in HIV prevention programs [14]. However, the uptake of U=U and PrEP has been limited and slow in the Asia-Pacific region [14]. It was reported that U=U has not yet been widely applied in clinical settings in the Asia-Pacific region to empower people living with HIV to use antiretroviral treatments to achieve and maintain their untransmittable status and to live normal sexual and social lives [14]. However, there has been no systematic study evaluating the use of U=U in Hong Kong. According to the most recent review of the HIV/AIDS situation in Hong Kong, sexual transmission remained the major mode of HIV transmission [15].

In addition, even though PrEP is a very effective HIV prevention method [16], unequal access to PrEP services continues to negatively affect many people who could benefit from it worldwide. It was estimated that just under 1 million people had initiated oral PrEP by 2020, which is far less than the 2020 Joint United Nations Programme on HIV/AIDS target of 3 million [17]. Furthermore, access to PrEP is still highly concentrated in a small number of countries. By the end of 2020, fewer than 20 countries recorded more than 10,000 PrEP initiations [17]. In Asia, which was the source of nearly 20% of the world's HIV infections in 2019, only a few countries (eg, Thailand and Vietnam) have implemented national guidelines outlining PrEP as an HIV prevention strategy [17,18]. Moreover, another study estimated that Southeast Asia contributes less than 5% of all the PrEP initiations recorded worldwide [19]. Despite increasing scientific evidence on its effectiveness and safety, international recommendations, and the rising global adoption of PrEP in HIV prevention, PrEP is currently not available as a part of public health care services in Hong Kong. People in Hong Kong can only obtain PrEP in the private sector at a very high cost (about HK $8000/month [US $1032]) or purchase it from other countries [20]. In areas where the availability of PrEP is still limited, behavioral interventions to promote safer sexual practices, such as consistent condom use and regular HIV testing, still play an important role in HIV prevention.

eHealth, health services and information delivered electronically through the internet (eg, through a website) [21], has become a commonly used modality for health promotion. A systematic review of the process evaluation of 8 eHealth interventions reported that eHealth interventions targeting sexual risk and substance use are acceptable for MSM across different sociodemographic groups [22]. Another systematic review and meta-analysis of 46 studies supported the effectiveness of eHealth privacy interventions in promoting HIV-preventive behaviors, such as condom use and STI testing, among MSM [23]. Thanks to the well-established internet access that most people have worldwide, one of the most important advantages of eHealth is the high degree of accessibility it offers by granting access to remotely located people [24]. Moreover, compared with face-to-face interventions, eHealth interventions provide greater anonymity, privacy, and accessibility, which are particularly relevant and important for promoting sexual health among MSM.

Although several systematic reviews have provided robust evidence about the effectiveness of eHealth interventions in improving sexual health among MSM [23,25,26], there has been no study related to chemsex and its prevention. To address this knowledge gap, this study aimed to evaluate the effectiveness of a web-based intervention in reducing the sexual harms of chemsex among MSM, with the objectives of strengthening the self-efficacy of MSM in refusing risky sexual behaviors and chemsex, reducing both their intention to engage in chemsex and their actual chemsex behaviors, enhancing consistent condom use during both sober and drug-influenced sex, and increasing motivation toward the practice of regular HIV and STI testing.

We hypothesized that the web-based intervention could increase participants' self-efficacy in refusing risky sexual behaviors and chemsex, reduce both the intention to engage in chemsex and actual chemsex behaviors, enhance consistent condom use, and increase the uptake of HIV and STI testing.

Methods

Study Design

This study was a 2-arm, assessor-blinded, randomized, parallel-group trial with a 3-month follow-up period. The trial protocol has been published [27] and registered. There were no important changes to the methods and study content after trial commencement.

Study Participants and Setting

The study participants were enrolled using convenience sampling from June 15, 2021, to November 5, 2021. To ensure that we could recruit the required number of study participants from diverse backgrounds, potential participants were approached using social media (eg, Instagram). Local nongovernmental organizations that target MSM populations in Hong Kong also helped recruit potential participants based on their existing networks. Participants were eligible for inclusion in the trial if they self-identified as cis-male MSM aged ≥18 years with internet access and the ability to read and understand Chinese.

Screening, Baseline Assessment, and Randomization

An online screening questionnaire was used to screen the study participants for eligibility. Eligible participants were asked to sign an electronic consent form and use their email addresses to register for the study. They also needed to set a personal password to gain access to the study intervention. After completing these steps, the participants were asked to complete an online baseline questionnaire. After completing the baseline questionnaire, participants were randomly assigned to either the intervention group or the control group via a computer-generated block randomization procedure (with a block size of 4 with no stratification) with a 1:1 randomization ratio. The computer-generated sequence was created by the independent programmer who developed the online platform. The online platform conducted masking and allocation concealment. All participants and research team members were blinded to the allocation sequence before the allocation. After randomization, the study participants were automatically guided to the web content associated with their allocation.

Interventions

The intervention was divided into 2 parts. The first part involved an interactive component. Enrolled participants were first invited to complete 2 quizzes to review their level of understanding of chemsex. The quizzes assessed how much the participants knew about chemsex. Each quiz contained 10 multiple-choice questions. The 2 sets of quizzes differed in terms of the level of difficulty. Participants received their score after completing the quiz. In the second part, participants were given knowledge-based information about chemsex and its potential risks and legal consequences. The side effects of different chemsex substances were also covered. Additionally, the participants were presented with information about how they could protect themselves from contracting HIV and other STIs and regarding local resources for emotional support and HIV and STI testing.

The contents of the intervention were developed based on the theory of planned behaviors [28,29]. For example, the interventions aimed to (1) lower participants' desire to engage in chemsex by enhancing their knowledge of chemsex (eg, regarding its side effects, risks, and legal consequences) and (2) improve the consistency of participants' condom use by enhancing their attitude toward and knowledge about condom use. Also, the contents of the intervention aimed to intervene from the perspective of harm reduction, primarily with regard to sexual harm. Because it is difficult for current chemsex users to withdraw from drug use over a short period, being empowered to carry out safer sex practices, even in drug-influenced situations, may be a more realistic way to lower the risks associated with HIV and STI transmission. For example, checklists of what to pay attention to before, during, and after chemsex were provided to foster responsible attitudes toward and practices of chemsex. The safety precautions an individual can take to reduce harm related to chemsex practice were also emphasized. Participants in the intervention group were expected to spend only 30 minutes to 45 minutes to complete the overall intervention.

The control group was offered brief information and educational content about sexual violence, which was not relevant to the chemsex intervention component. There was no interactive component in the control group. The details of the intervention and control groups are shown in Multimedia Appendix 1.

Study participants had unlimited access to their allocated content during the study period. However, the content was only available to participants with a registered email address and password to minimize contamination between the intervention and control groups.

Outcomes

The primary outcome was self-efficacy in refusing risky sexual behaviors and chemsex. As there was no well-established study instrument to specifically assess this primary outcome, the traditional Chinese version of the Condom Self-Efficacy Scale (CSES) [30], Self-Efficacy for Sexual Safety (SESS) instrument [31], and Drug Avoidance Self-Efficacy Scale (DASES) [32] were used to measure the primary outcome.

The CSES is a 14-item instrument covering 3 domains: (1) consistent condom use, (2) correct condom use, and (3) condom use communication. The total score ranges from 14 to 70, with a higher score indicating a higher level of condom use efficacy [30]. The Cronbach alpha coefficient of the CSES was 0.94 in the current sample. The SESS is a 7-item instrument for assessing participants' confidence in practicing safer sex. The total score ranges from 7 to 35, with a higher score indicating a higher level of self-efficacy for safe sex [31]. The Cronbach alpha coefficient of the SESS was 0.89 in the current sample. The DASES was used to assess drug avoidance self-efficacy. It includes 16 items assessing abstinence self-efficacy across different high-risk situations. The total score ranges from 16 to 112, with a higher score indicating a higher level of self-efficacy for resisting drug use [32]. The Cronbach alpha coefficient of the DASES was 0.89 in the current sample.

The secondary outcomes included (1) an intention to have chemsex in the last 3 months, (2) actual engagement in chemsex in the last 3 months, and (3) HIV and other STI testing in the last 3 months. We assessed and evaluated participants' intentions to have chemsex in the last 3 months because we wanted to supplement the outcomes relating to their actual engagement in chemsex. It is known that people who intend to have chemsex do not necessarily eventually engage in chemsex. Therefore, their intentions to have chemsex in the past 3 months were assessed. For participants who engaged in chemsex in the last 3 months, data were collected on the (4) practice of condomless sex during non-chemsex in the last 3 months and (5) practice of condomless sex during chemsex in the last 3 months.

All study outcomes were self-assessed at baseline and 3-month follow-up interviews through an online structured questionnaire. The online questionnaire was pilot tested. A trained research assistant would send reminders (via email or instant messaging) to the study participants to ask them to complete the follow-up interview. There was no change to trial outcomes after the study commenced.

Sample Size

To detect a small-to-moderate between-group difference (Cohen d=0.4) in the primary outcome through an independent samples *t* test and to achieve a power of 80% at a .05 level of 2-sided significance, at least 200 participants (100 participants in each group) were required. Based on a systematic review of eHealth interventions about HIV and STI prevention among MSM [26], we estimated that the dropout rate would be 20%. Therefore, at least 250 participants would need to be recruited. G*Power was used to calculate the sample size.

Statistical Analysis

Descriptive statistics were used to summarize the sociodemographic characteristics and study outcomes of the participants at each time point. Baseline characteristics and study outcomes (1) between the intervention and control groups and (2) between participants who completed the study and those who did not (dropouts) were compared using Fisher exact tests for categorical variables or an independent samples *t* test for continuous variables.

The intention-to-treat principle was applied. Linear mixed effects models were used to assess the differential change in continuous outcomes (ie, scores on the CSES, SESS, and DASES). Similarly, generalized linear mixed effects models with logit links were used to analyze the binary outcomes (ie, intention to have chemsex, actual engagement in chemsex, undergone HIV testing, undergone other STI testing, practice of condomless sex during non-chemsex, and practice of condomless sex during chemsex in the last 3 months). Time, group, and interaction between group and time were included as independent variables. Mixed effects models can accommodate missing data and do not require imputation of missing observations, providing a natural way to deal with missing values or dropouts. For the main analysis, no covariates were put in the models. To supplement the main analysis, complete case analysis was conducted. Statistical analysis was performed using SPSS version 25.0 (IBM Corp, Armonk, NY). All statistical tests were 2-tailed, with a 5% level of statistical significance. The data set and analyses were checked by 2 researchers.

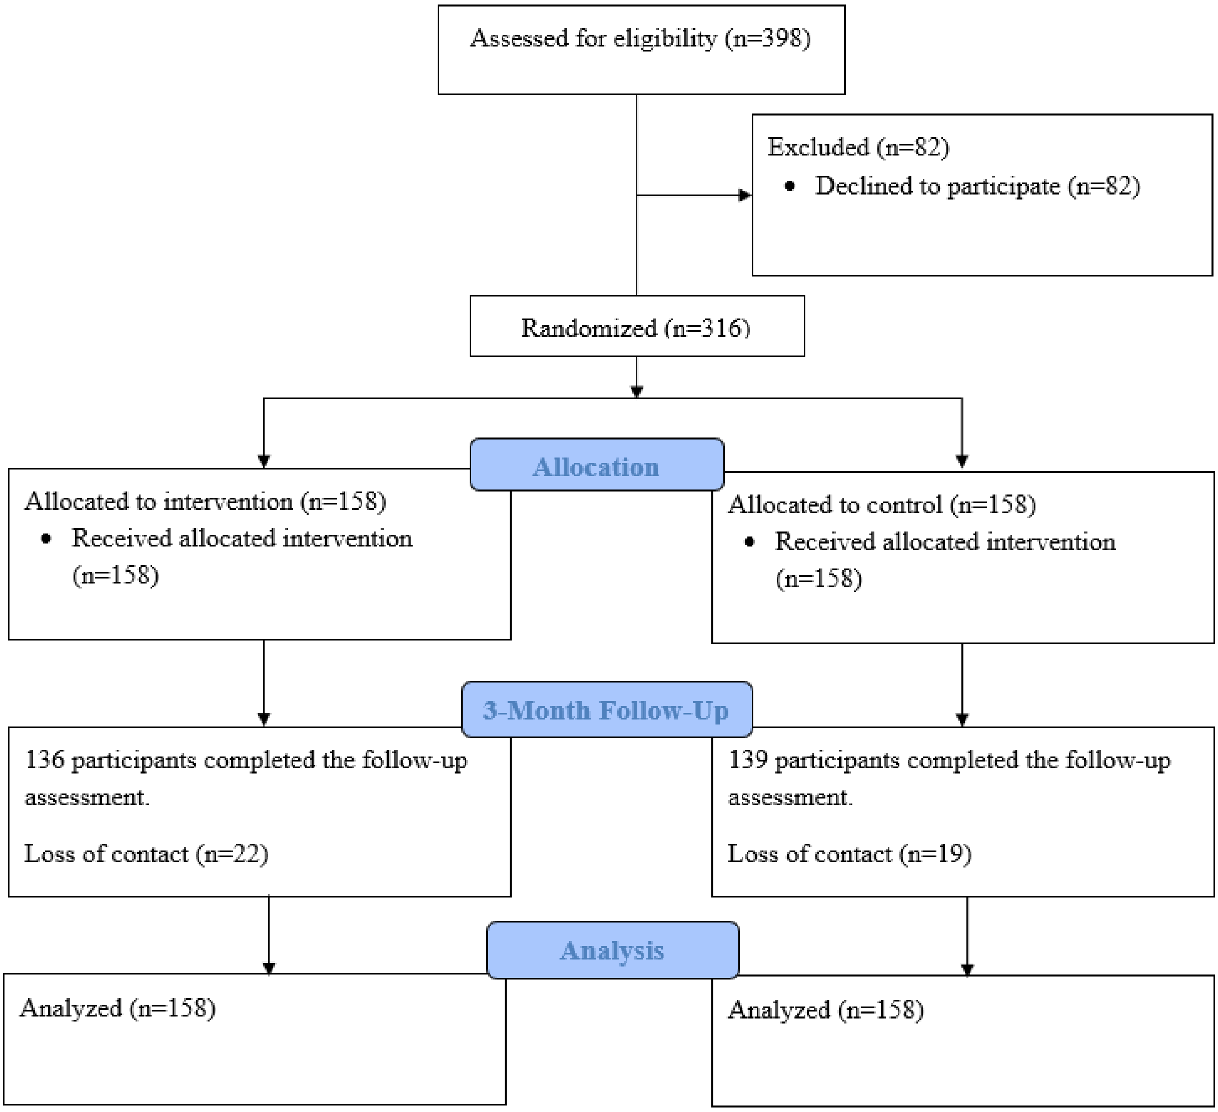
Ethics

The study was approved by the Institutional Review Board of the University of Hong Kong/Hospital Authority Hong Kong West Cluster (HKU/HA HKW IRB; reference number: UW 20-650). Electronic informed consent was obtained from each study participant. Study information such as aims, nature of the study, and brief overview of the content of the intervention were provided in the consent form. This trial followed the CONSORT-EHEALTH statement (Multimedia Appendix 2) and the International Conference of Harmonisation Guidelines for Good Clinical Practice. Study data were de-identified. Only the research team had access to the study data. We established a hotline and email account for enquiries and support.

Results

In total, 316 participants were enrolled and randomized into intervention (n=158) and control (n=158) groups. However, 41 participants (22 participants in the intervention group and 19 participants in the control group) did not complete the follow-up survey. The overall dropout rate was 13.0%, (41/316), and there was no significant difference in the dropout rate between the intervention group and control group. Figure 1 shows the CONSORT flow diagram.

Figure 1. CONSORT flow diagram.



Participant Characteristics

Table 1 shows the study participants' baseline characteristics. The mean age was 27.34 (SD 6.77) years. Of the 316 participants, 265 (83.9%) were homosexual, and 51 (16.1%) were bisexual. Regarding relationship status, 172 (54.4%) of the 316 participants were in a relationship or married, and 144 (45.6%) participants were single. Of the 316 participants, 199 (63.0%) were employed full-time, and 117 (37.0%) were not employed full-time. Regarding income, 167 (52.8%) of the 316 participants had a monthly personal income less than HK $20,000, and 149 (47.2%) had a monthly personal income of at least HK $20,000.

In total, 104 (32.9%) of the 316 participants had undergone HIV testing in the last 3 months, while 64 (20.3%) of the 316 participants had undergone other STI testing in the last 3 months. Regarding chemsex, 57 (18.0%) of the 316 participants had intended to have chemsex in the last 3 months, while 84 (26.6%) of the 316 participants had engaged in chemsex during their lifetime and 51 (16.1%) of the 316 participants had engaged in chemsex in the last 3 months.

No significant heterogeneity of the demographic data and study outcomes was found between the intervention group and control group, except for relationship status and HIV testing in the last 3 months. No significant heterogeneity of the demographic data and study outcomes was found among those who completed the study (non-dropout) versus those who did not complete the study (dropouts), except for sexual orientation and chemsex in the last 3 months (Multimedia Appendix 3).

[a] Fisher exact test for categorical variables or independent *t* test for continuous variables.

[b] STI: sexually transmitted infection.

[c] Only participants who engaged in chemsex in the last 3 months answered the questions about condom use. At the baseline assessment, 51 participants had chemsex in the last 3 months.

Primary Outcomes

The effects of the intervention on the study outcomes are summarized in Table 2. Regarding the SESS, the intervention group demonstrated significantly larger improvement in self-efficacy for sexual safety (time-by-group interaction: β=2.11, 95% CI 0.66-3.56; *P*=.004). The intervention group also demonstrated significantly larger improvement in condom use self-efficacy (as measured by their total CSES score; time-by-group interaction: β=4.52, 95% CI 2.03-7.02; *P*<.001) and drug avoidance self-efficacy (as measured by the DASES; time-by-group interaction: β=6.98, 95% CI 1.75-12.22; *P*=.009). The results of the CSES subscale scores are shown in Multimedia Appendix 4.

[a] Primary outcomes.

[b] Secondary outcomes, with “no” as the reference category.

[c] OR: odds ratio.

[d] Linear mixed effects models for primary outcomes, with the control group as the reference category. Baseline characteristics were not adjusted in the models.

[e] Generalized linear mixed-effects models for secondary outcomes, with logit links that were used to analyze the binary outcomes and the control group as the reference category. Baseline characteristics were not adjusted in the models.

[f] The total score ranges from 7 to 35, with a higher score indicating a higher level of self-efficacy for safe sex.

[g] N/A: not applicable.

[h] The total score ranges from 14 to 70, with a higher score indicating a higher level of condom use efficacy.

[i] The total score ranges from 16 to 112, with a higher score indicating a higher level of self-efficacy to resist drug use.

[j] Participants who reported being HIV-positive at the baseline assessment were excluded from the analysis.

[k] STI: sexually transmitted infection.

[l] Only participants who engaged in chemsex in the last 3 months answered the questions about condom use. At the follow-up assessment, only 31 participants had chemsex in the last 3 months.

Secondary Outcomes

Participants in the intervention group demonstrated significantly larger reductions in the likelihood to have engaged in chemsex in the last 3 months (time-by-group interaction: OR=0.23, 95% CI 0.10-0.53; *P*=.001) and intention to engage in chemsex in the last 3 months (time-by-group interaction: OR=0.37, 95% CI 0.18-0.78; *P*=.009). Participants in the intervention group also showed a significantly larger increase in the likelihood to have undergone HIV testing in the last 3 months (time-by-group interaction: OR=3.08, 95% CI 1.72-5.54; *P*<.001). However, no significant group-by-time interaction effect was observed on the outcome of other STI testing in the last 3 months (*P*=.23). During the follow-up interviews, only 31 participants reported engaging in chemsex in the last 3 months. A statistically significant group-by-time interaction effect was observed for the outcome of condomless sex during non-chemsex in the last 3 months (*P*<.001). No significant group-by-time interaction effect was observed on the outcome of condomless sex during chemsex in the last 3 months (*P*=.41). The results of the between-group differences in all study outcomes at each time point are shown in Multimedia Appendix 5. Given that there was a statistically significant difference in relationship status between the intervention group and control group at the baseline assessment, an adjusted analysis was conducted (Multimedia Appendix 6). The results of the complete case analysis (n=275) are shown in Multimedia Appendix 7. The results are consistent with those of the main analysis.

Discussion

Principal Findings

In this randomized controlled trial, we found that a web-based intervention with a harm reduction approach could enhance the self-efficacy of MSM in refusing risky sexual behaviors and chemsex. The intervention enhanced HIV testing but had no effects on other STI testing. Importantly, we found that the intention of MSM to engage in chemsex and their actual engagement in chemsex can also be reduced by the intervention. However, it should be noted that, given the small sample size of participants who reported engaging in chemsex in the last 3 months during the follow-up interviews, the findings related to condom use might not be reliable and should be interpreted with caution. Nonetheless, the clinical significance and academic merits of the findings are substantial because this study has provided one of the very first pieces of evidence on the effectiveness of eHealth interventions in reducing the sexual harm of chemsex among MSM, which echoes the recent review by Strong and colleagues [33] that called for more action and identified a need for more harm reduction interventions related to chemsex. In addition, one important feature of the trial was that the contents of the intervention were relatively brief. Participants in the intervention group were expected to spend only 30 minutes to 45 minutes to complete the overall intervention. Such digitally delivered brief interventions can be easily disseminated to hard-to-reach populations such as MSM who practice chemsex, in a cost-effective manner.

The intervention in the current trial was developed through a harm reduction approach because most qualitative evidence suggests that many MSM prefer reducing the harm associated with drug use (eg, by learning how to better manage their use) instead of abstaining altogether [33,34]. Furthermore, while highlighting what kinds of tailored interventions can assist in the reduction of harm, Herrijgers and colleagues [35] showed in their schematic overview that MSM were exposed to different degrees of harm before, during, and after chemsex events. To meet the actual needs of MSM, the intervention contents of the current trial were developed in a comprehensive manner, addressing the different aspects of harm related to chemsex [33,35]. We also added interactive content (quizzes and instant feedback) to the intervention because a meta-analysis of 12 studies reported that a new media intervention using interactive components yielded significant effects on condom use, while interventions using only static content did not yield positive effects on enhancing condom use [36].

Compared with the control group, the intervention group demonstrated statistically significant effects on the primary outcomes with a small-to-moderate effect size (in Multimedia Appendix 7) and on most secondary outcomes (ie, HIV testing, intention to have chemsex, and actual engagement in chemsex). Our findings are in line with those reported by a systematic review and meta-analysis of 46 studies, which supported the effectiveness of eHealth interventions in promoting HIV-preventive behaviors among MSM with a small effect size [23]. Coupled with previous studies [23], our study further supports the benefits of eHealth interventions to reduce risky sexual behaviors among MSM, which ultimately decreases the burdens of HIV and other STIs in the MSM population.

Even though PrEP has provided a new means of harm reduction (ie, primary HIV prevention) in the context of chemsex [33], the uptake of PrEP has remained low in some regions, such as Southeast Asia. A study reported that only 1% had ever used PrEP among MSM in Hong Kong [20]. In geographic areas where the availability of PrEP and access to it are still limited, eHealth interventions to promote safer sexual practice and regular HIV testing still play an important role in HIV prevention. Therefore, this trial still has significant public health implications for helping to control the burgeoning HIV epidemic among MSM.

Another important benefit of the current study is that the intervention was found to reduce the participants' intention to have chemsex and their actual engagement in chemsex. Given that chemsex tends to be hidden and private and that those who practice chemsex are difficult to reach [37], eHealth interventions can provide MSM with a private, anonymous, and easily accessible platform offering supportive care and useful information. The current study provides empirical evidence for governments, health authorities, and other stakeholders to put more resources into delivering chemsex-preventive interventions and care using online platforms. Also, more implementation research is needed to plan how to position and scale up eHealth interventions regarding chemsex alongside other community-based HIV-preventive interventions.

This study found no significant effect on other STI testing, implying that future interventions should strengthen the components intended to encourage MSM to undergo regular STI testing. Nonetheless, the negative result could be explained by the substantial reduction in the availability of sexual health services during the COVID-19 pandemic [38]. A study in Australia reported that chlamydia and gonorrhea testing dropped significantly during the COVID-19 pandemic [39]. Unlike HIV self-testing, which is available through the government, community-based organizations, and registered pharmaceutical stores [40], MSM in Hong Kong might have experienced difficulty undergoing other forms of STI testing during the pandemic. Also, the attitudes and perceptions toward the consequences of other STIs among MSM could have led to the insignificant finding [41]. Specifically, according to a qualitative study among MSM in Hong Kong, the MSM community is less cautious about other STIs because they are curable and treatable [42]. However, given the rising number of other STIs in MSM, there is an urgent need to strengthen STI screening and care for MSM [43].

Limitations

There are several limitations and implications for further studies. First, social media, such as Instagram, was used to recruit participants. An online screening survey and electronic consent forms were also used in this study. Participants who were not technology-savvy may thus have been excluded in the recruitment phase. Therefore, the study findings may not be applicable to those who are not technology-savvy and those with low eHealth literacy. Second, study participants were not blinded to group allocation. The study might be subject to performance bias, as participant knowledge of group allocation may have affected their behaviors. Third, we only evaluated participants' intention to have chemsex in the last 3 months. Further studies should assess their intention to have chemsex in the future such as in the next 3 months. Fourth, the study outcomes were measured 3 months after the baseline, so the long-term sustainability of the intervention remains unknown. Trials with a longer follow-up period are needed to evaluate the sustained effect of eHealth interventions in enhancing the self-efficacy of MSM in refusing risky sexual behaviors and chemsex. Also, an analysis of the cost-effectiveness of eHealth interventions for chemsex should be considered. Fifth, we did not record information about the study participants' engagement, such as the duration or frequency of their visits. These parameters should be recorded in the future to further investigate how study engagement impacts the effectiveness of interventions. Sixth, during the follow-up interviews, the number of people who had engaged in chemsex in the last 3 months was small (n=31), which might have affected the statistical power and precision of some of the secondary outcomes. Seventh, qualitative interviews should be conducted to obtain qualitative feedback from study participants in the future. Finally, similar trials should be developed and tested in other geographic areas to provide more empirical evidence to support the effectiveness of such interventions in enhancing the self-efficacy of MSM in refusing risky sexual behaviors and chemsex.

Conclusion

This study suggests that a web-based intervention with a harm reduction approach can enhance the self-efficacy of MSM in refusing risky sexual behaviors and chemsex and improve HIV testing in the 3-month follow-up interview. We also provide initial evidence that such interventions can reduce both the intention of MSM to engage in chemsex and their actual engagement in chemsex.

Abstract

Background: Health-related research on sexual minority populations in China is lacking, and research on sexual and gender minority women (SGMW, including transgender women and persons of other gender identities assigned female at birth of all sexual orientations, and cisgender women with nonheterosexual orientations) is even less. Currently, there are limited surveys related to mental health in Chinese SGMW, but there are no studies on their quality of life (QOL), no studies comparing the QOL of SGMW with that of cisgender heterosexual women (CHW), and no studies on the relationship between sexual identity and the QOL as well as associated mental health variables.

Objective: This study aims to evaluate the QOL and mental health in a diverse sample of Chinese women and make comparisons between SGMW and CHW and then investigate the relationship between sexual identity and the QOL through the role of mental health.

Methods: A cross-sectional online survey was conducted from July to September 2021. All participants completed a structured questionnaire containing the World Health Organization Quality of Life–abbreviated short version (WHOQOL-BREF), the 9-item Patient Health Questionnaire (PHQ-9), the 7-item Generalized Anxiety Disorder scale (GAD-7), and the Rosenberg Self-Esteem Scale (RSES).

Results: In total, 509 women aged 18-56 years were recruited, including 250 (49.1%) CHW and 259 (50.9%) SGMW. Independent *t* tests showed that the SGMW reported significantly lower levels of QOL, higher levels of depression and anxiety symptoms, and lower self-esteem than the CHW. Pearson correlations showed that every domain and the overall QOL were positively associated with mental health variables, with moderate-to-strong correlations (r range 0.42-0.75, *P*<.001). Multiple linear regressions found that participants belonging to the SGMW group, current smokers, and women with no steady partner were associated with a worse overall QOL. The mediation analysis found that depression, anxiety, and self-esteem significantly completely mediated the relationship between sexual identity and physical, social, and environment domains of the QOL, while the relationship between sexual identity and the overall QOL and psychological QOL was partially mediated by depression and self-esteem.

Conclusions: The SGMW had poorer levels of QOL and a worse mental health status than the CHW. The study findings affirm the importance of assessing mental health and highlight the need to design targeted health improvement programs for the SGMW population, who may be at higher risk of a poor QOL and mental health.

Introduction

Public health surveillance systems, to date, have focused on cisgender heterosexual (CH) individuals, whose gender identity is consistent with their sex assigned at birth and who are sexually or romantically attracted to people of the opposite sex, while people with other gender and sexual orientation identities have historically been less visible [1]. In general, all non-CH individuals could be characterized as sexual and gender minority (SGM) populations. Specifically, gender minorities include but are not limited to people who are transgender (whose gender identity and sex assigned at birth do not correspond), gender queer (whose gender identity falls outside the traditional gender), gender fluid (whose gender identity is not fixed), gender questioning (who are unsure about or are exploring their gender identity), and other nonbinary genders outside of the traditional gender binary of male and female. Similarly, sexual orientation minorities include but are not limited to homosexual (gay and lesbian, people who are primarily sexually or romantically attracted to people of the same sex or gender as themselves), bisexual (attraction to multiple genders), pansexual (attraction to all genders/regardless of gender), and asexual (who experience little or no sexual attraction to others) or other nonheterosexual orientations.

A growing body of research has explored health disparities among people of different sexual orientations, and sexual minority populations have consistently been found to report worse health outcomes than their CH peers, especially in the area of mental health [2-9]. Specifically, studies investigating mental health and its relationship with sexual orientations have shown that sexual minority populations are more likely to experience mental health problems than CH individuals, with depression and anxiety being the most commonly diagnosed mental health disorders [3,10-16]. In a comprehensive meta-analysis of large samples, sexual minority populations were twice as likely to suffer from depression and anxiety as CH individuals [17]. It is worth noting that from a gender perspective, mental disorders are more commonly diagnosed in women than in men globally [18,19], so relevant research on women is crucial. Even in the field of research on SGM populations, more attention has been paid to males than females [20]; therefore, sexual and gender minority women (SGMW, including transgender women and persons of other gender identities assigned female at birth of all sexual orientations, and cisgender women with nonheterosexual orientations) need more public health attention.

As emphasized by the World Health Organization (WHO), mental health is “not just the absence of mental disorder” but “a state of well-being in which individuals realize their own potential and can cope with normal stresses of life” [19]. In other words, a healthy mental state is not only the absence of depression, anxiety, or other symptoms but also the presence of positive components of well-being. Self-esteem, literally defined as the degree to which individuals believe themselves to be valuable or adequate [21], is one such essential component and strongly related to happiness [22]. Similar to gender differences in mental disorders, a meta-analysis of self-esteem also revealed that women report lower levels of self-esteem than men [23]. Although high levels of self-esteem are associated with positive self-attitudes and are protective against adverse mental health outcomes [24], low levels of self-esteem, more commonly reported by people belonging to sexual minority populations [25], increase the likelihood of mental health difficulties.

In addition to mental health, a poor quality of life (QOL) has been shown to be positively associated with adverse mental health outcomes [26]. The QOL is widely used to present individuals’ perceptions of their physical and psychological health, social relationships, and environment [27]. However, there is compelling evidence that sexual minority populations are more likely to report a poorer QOL than CH individuals [28], especially psychological QOL [29]. To promote the overall health of SGM populations, it is not sufficient to only examine differences in the incidence of mental disorders and levels of the QOL without understanding the in-depth relationships and mechanisms among them. A recent review examining mediators of the depression disparities between sexual minority and CH populations suggested that the psychological process may also play a role, but this has been understudied to date [30], and more mediation analyses are needed.

Health-related research on SGMW is growing slowly worldwide [31-33], but there is less research on Chinese SGMW. According to published data from Western countries, sexual minority women experience a higher incidence of mental health disorders, including anxiety and depression, and also generally report a worse QOL than cisgender heterosexual women (CHW) [34,35]. A recent scoping review summarizing the holistic health of homosexual and bisexual Chinese over the past 20 years showed that the academic attention given to the male population is much higher than that given to female groups (96.46% vs 1.32%, respectively) [20]. Although there are limited surveys investigating the mental health of SGMW in China, results regarding depression and anxiety are less consistent among women from different countries with varied sexual identities [13,36-38]. Furthermore, there is currently no research on the QOL of Chinese SGMW and the relationship between sexual identity and the QOL, highlighting the need to research the health of women, especially SGMW in China.

The associations between sexual identity and the QOL as well as mental health vary across studies conducted in different countries, and there are currently no studies aimed at explaining these relationships among Chinese SGM populations, let alone SGMW. Therefore, this study aims to first examine the QOL and mental health of Chinese adult women of different sexual identities, with mental health variables including depression and anxiety as well as self-esteem, and then investigate the relationships between sexual identity and the QOL through the role of mental health variables in the Chinese context. Our main hypotheses were as follows: (1) SGMW in China may report lower levels of the QOL and more mental health disorders compared to CHW, (2) a better mental health status may positively be associated with higher levels of the QOL, and (3) mental health variables mediate the effect of sexual identity on the QOL.

Methods

Participants and Procedures

This was a cross-sectional study conducted online in China. Given the relative sensitivity and invisibility of our study population under the influence of traditional Chinese culture, multiple recruitment methods were used, including (1) convenient recruitment via 4 popular nongovernmental organizations (NGOs) serving female or SGM populations in mainland China (TrueSelf, r&B bisexual community, Period Pride China, and the Wuhan LGBT Center); (2) respondent-driven recruitment, where respondents were encouraged to help recruit potential peers through their network of connections [39,40]; and (3) social platform recruitment by releasing the study poster to some popular online communities.

Eligible participants included Chinese women who were (1) at least 18 years old; (2) self-identified as "female," either cisgender or transgender women or gender nonbinary individuals whose sex assigned at birth was female; and (3) able to read and understand Mandarin. Data were collected using an online survey platform (Wenjuanxing), and data collection was initiated after informed consent was obtained.

Ethical Considerations

Ethical approval was obtained from the Human Research Ethics Committee (HREC) of the University of Hong Kong (reference no. EA210325). All participants provided informed consent.

Study Instruments

Participants who consented to join the study were asked to fill out all the following questionnaires in Mandarin.

The 9-Item Patient Health Questionnaire

The 9-item Patient Health Questionnaire (PHQ-9) is a depression module that measures the presence and severity of depression symptoms over the past 2 weeks according to the *Diagnostic and Statistical Manual of Mental Disorders IV* (DSM-IV) criteria for assessing symptoms of depression [41]. The PHQ-9 is a self-report questionnaire, and each item ranges from 0 (not at all) to 3 (nearly every day), with a summed score ranging from 0 to 27. The Chinese version of the PHQ-9 has been previously evaluated for reliability and validity, showing that it is a valid and efficient tool for screening depression [42]. This study used this Chinese version of the PHQ-9, and the Cronbach α of the scale among the study sample was .91.

The 7-Item Generalized Anxiety Disorder Scale

The 7-item Generalized Anxiety Disorder scale (GAD-7) is a self-reported screening tool to identify anxiety symptoms in the past 2 weeks. Each of the 7 items is scored from 0 (not at all) to 3 (nearly every day), and the GAD-7 scale score ranges from 0 to 21 [43]. The Chinese version of GAD-7 has been previously validated and is commonly used [44,45]. This study used this Chinese version, and the Cronbach α of the scale among the study sample was .94.

The Rosenberg Self-Esteem Scale

The Rosenberg Self-Esteem Scale (RSES) is a 10-item self-report scale evaluating an individual's self-esteem [21]. Each item is answered using a 4-point Likert scale ranging from 1 (strongly agree) to 4 (strongly disagree), while half items are reverse-scored ranging from 1 (strongly disagree) to 4 (strongly agree). The Chinese version of the questionnaire has been previously validated [46-49], and this study used this Chinese version to measure participants' self-esteem. All scores of the 10 items are summed as a global score on a continuous scale, and higher scores indicate lower overall self-esteem. In this study, the Cronbach α of the scale was .77.

The World Health Organization Quality of Life–Abbreviated Short Version

The World Health Organization Quality of Life–abbreviated short version (WHOQOL) is a QOL assessment tool developed by the WHOQOL Group and includes 100 items on a 5-point scale [27]. Based on that, an abbreviated short version of the WHOQOL instrument (WHOQOL-BREF) has been developed and is widely used in assessing the QOL of the public [50,51]. The WHOQOL-BREF contains 26 items in total, including 2 (8%) overall items and 24 (92%) facet items on 4 domains: physical (7, 29%, items), psychological (6, 25%, items), social relationships (3, 13%, items), and environment (8, 33%, items). Regarding the scoring, there are 3 negatively phrased items (items 3, 4, and 26) that should be reversed before calculating the scores. The mean score of items within each domain is used to calculate the domain score, and each domain score can be transformed into a score ranging from 4 to 20, with higher scores representing a better QOL [27,51,52]. The Chinese version of the WHOQOL-BREF has been previously validated [51] and was used in this study. In this study, the Cronbach α coefficient of the total scale was .93 and of the 4 subscales was .79, .88, .68, and .83, respectively.

Sociodemographic Information

All participants completed a set of sociodemographic items, including their basic information (age, employment, race/ethnicity, education level, income, relationship status) and their sexual identity (gender identity and sexual orientation identity).

Sample Size Justification

The sample size calculation was performed using G*Power 3.1 [53]. To detect a statistically significant difference between CHW and SGMW using the independent samples *t* test with 80% power, 5% level of significance (2-tailed), and a Cohen *d* effect size of 0.3, a minimum sample size of 352 participants was needed.

Statistical Analysis

Descriptive statistics (counts and percentages, means, and SDs) were used to illustrate participants' demographic characteristics, QOL, and mental health outcomes.

Comparisons Between SGMW and CHW

To compare the scores of mental health variables (PHQ-9, GAD-7, RSES) and the QOL (WHOQOL-BREF) between SGMW and CHW, independent *t* tests were conducted and the Cohen *d* effect size was also calculated, with cut-offs of 0.2, 0.5, and 0.8 for small, medium, and large effect sizes, respectively [54]. To compare the percentages of participants' demographic characteristics, chi-square tests were conducted. Pearson correlations were used to identify the correlations between mental health variables and the QOL, and the correlations were defined as strong (≥0.5), moderate (≥0.3 and <0.5), or weak (<0.3). One-way ANOVA was performed to compare the mean scores in 5 sexual orientation groups. Next, multiple linear regression analyses were performed to identify factors associating mental health and the QOL separately.

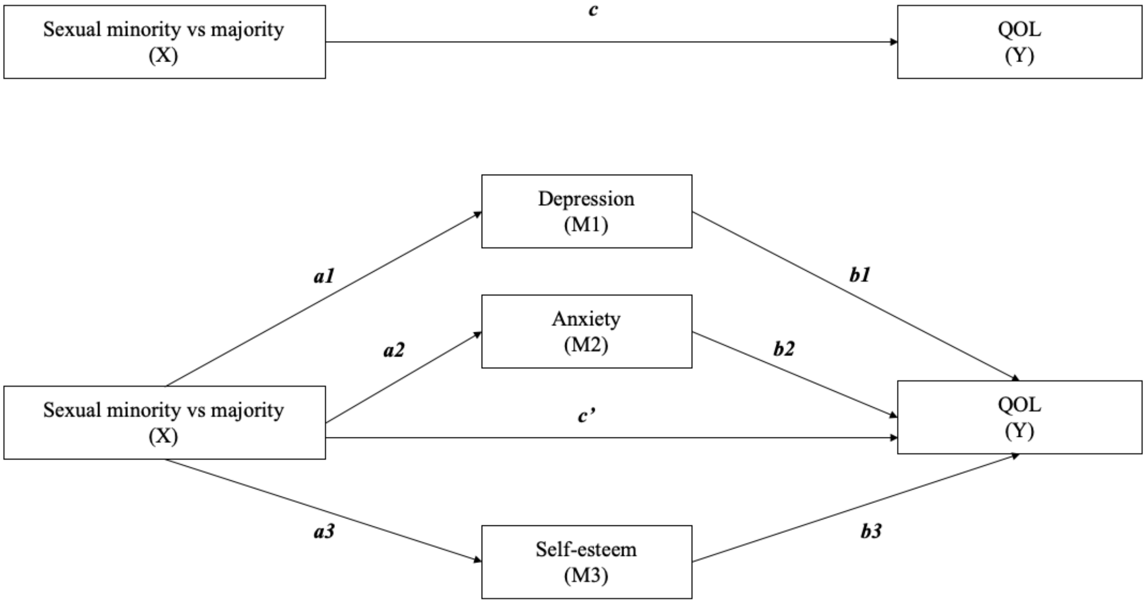
Parallel Mediation Analysis

To examine mediating effects, we used a bootstrapping technique using the PROCESS macro [55], and parallel mediation models were assessed. We implemented 5000 bootstrap samples for the percentile bootstrap CI, and a 95% confidence level was used. We proposed the effects of sexual identity (independent X: sexual minority vs majority) through 3 mediating mental health variables (parallel mediators: M1, depression; M2, anxiety; and M3, self-esteem) on the QOL (dependent Y: physical QOL, psychological QOL, social relationship QOL, environment QOL, and overall QOL). The existing literature has suggested that many sociodemographic factors are associated with the QOL [55-57], so age, income, alcohol use, smoking status, and relationship status were included as covariates to control for their potential effects in the mediation analysis.

As shown in Figure 1, “a” is the effect of the independent variable (X) on mental health (mediators M1-M3), “b” is the effect of mental health (M1-M3) on the QOL (Y), “c” is the total effect of X on Y, and c’ is the direct effect of X on Y. An indirect effect was considered significant if the CI did not contain 0. If the indirect effect is significant, it means that there is a mediation effect. Meanwhile, if the direct effect disappears, then there is complete mediation, whereas if the direct effect remains, then there is partial mediation [58]. Thus, we expected that sexual minority status would be positively associated with mental disorders (higher levels of depression and anxiety but lower levels of self-esteem) and, in turn, be negatively associated with the QOL.

Data were analyzed using IBM Statistical Package for the Social Sciences (SPSS) version 27.0, and the PROCESS macro version 4.1 for SPSS was used to conduct the mediation analysis [55]. All significance tests were 2-tailed, and findings with *P*<.05 were considered statistically significant.

Figure 1. Proposed parallel mediation model; a: effect of the independent variable (X) on mental health (M1-M3), b: effect of mental health on QOL (Y), c: total effect of X on Y, c’: direct effect of X on Y. M: mediator; QOL: quality of life.



Results

Demographic Characteristics of Study Participants

Of the 524 questionnaires collected between July and September 2021, 15 (2.9%) were unqualified since they were cisgender male (9/15, 60%) or less than 18 years old (4/15, 27%) or invalid data with all same answers (2/15, 13%), resulting in a total of 509 (97.1%) adult women enrolled in the study with no missing data. Specifically, 250 (49.1%) were CHW and categorized as the CHW group, while 259 (50.9%) were either sexual orientation or gender minority women and categorized as the SGMW group. The sexual orientation and gender identity of participants are shown in Table 1.

The mean age of the overall sample was 25.57 (SD 5.77) years, ranging from 18 to 56 years (Table 2). The mean age of the CHW was 26.75 (SD 6.31) years and was 24.43 (SD 4.94) years for the SGMW. Most participants were Han people (n=466, 91.6%) in the age group of 21-30 years (n=347, 68.2%) and had college or bachelor’s degrees (n=284, 55.8%), and around two-fifths were full-time students (n=222, 43.6%). About half of the women were single, and half had a steady partner (n=258, 50.7%, vs n=251, 49.3%), and a total of 248 (48.7%) women had full-time jobs. One-third of the women (n=178, 35.0%) never had a drink before, and the majority (n=428, 84.1%) had never smoked or had already quit smoking. Notably, 9 (1.8%) participants had a history of drug use.

Table 1. Frequency distribution of participants by gender and sexual orientation identity (N=509).

Gender identity	Sexual orientation identity, n (%)					
	Homosexual	Heterosexual	Bisexual	Pansexual	Others[a]	Total
Cisgender women	51 (10.0)	250 (49.1)[b]	74 (14.5)	33 (6.5)	28 (5.5)	436 (85.7)
Transgender women	8 (1.6)	1 (0.2)	1 (0.2)	1 (0.2)	2 (0.4)	13 (2.6)
Gender queer	10 (2.0)	1 (0.2)	4 (0.8)	12 (2.4)	1 (0.2)	28 (5.5)
Gender fluid	0	0	4 (0.8)	2 (0.4)	1 (0.2)	7 (1.4)
Other gender nonbinary[c]	2 (0.4)	7 (1.4)	5 (1.0)	4 (0.8)	7 (1.4)	25 (4.9)
Total	71 (13.9)	259 (50.9)	88 (17.3)	52 (10.2)	39 (7.7)	509 (100.0)

[a] Other minority sexual orientation identities, including asexual, gynephilia/femininity, and all other nonheterosexual orientations.

[b] The cisgender heterosexual women (CHW) group in this study comprised 250 (49.1%) women. Correspondingly, the other 259 (50.9%) sexual orientation and gender minority women were categorized as the sexual and gender minority women (SGMW) group.

[c] This group included gender questioning (someone who is unsure about or is exploring their gender identity), no gender, and other nonbinary genders that are noncisgender and beyond social norms.

[a] SGMW: sexual and gender minority women. The percentages for this column were all calculated with 259 SGMW as the denominator.

[b] CHW: cisgender heterosexual women. The percentages for this column were all calculated with 250 CHW as the denominator.

[c] All *P* values were reported by conducting comparisons performing independent *t* tests or chi-square tests.

[d] CNY 1=US $0.15.

QOL and Mental Health Among Study Participants With Comparisons

Table 3 shows the mean scores of the QOL (as measured by the WHOQOL-BREF) and mental health outcomes (as measured by the PHQ-9, GAD-7, and RSES) for our study participants. The mean QOL scores of each domain in the overall sample were ranked as follows: physical QOL (mean 14.05, SD 2.71), psychological QOL (mean 13.74, SD 3.13), environment QOL (mean 13.74, SD 2.68), and social relationship QOL (mean 13.62, SD 3.07). The mean scores of mental health variables in the overall sample were 7.85 (SD 5.92) for depression, 6.00 (SD 5.23) for anxiety, and 28.86 (SD 4.66) for self-esteem. All comparisons indicated that compared to the CHW group, the SGMW group reported significantly lower levels of overall QOL (52.77 vs 57.61) and QOL in all domains, lower levels of self-esteem (28.04 vs 29.72), but higher levels of depression (9.16 vs 6.50) and anxiety (5.49 vs 4.77) symptoms (all *P*<.01). The comparisons among 5 different sexual orientation groups were also conducted (Multimedia Appendix 1).

Table 3. QOL[a] and mental health of the study participants with comparisons.

QOL and mental health	Overall (N=509)	SGMW[b] (n=259, 50.9%)	CHW[c] (n=250, 49.1%)	*P* value	Cohen *d* (SGMW-CHW)
QOL (WHOQOL-BREF[d]), mean (SD)

[g] RSES: Rosenberg Self-Esteem Scale.

Correlations Between the QOL and Mental Health

Pearson correlations between the QOL and depression, anxiety, and self-esteem are displayed in Table 4. As hypothesized, both depression and anxiety symptoms were significantly negatively associated with all domains of the QOL as well as the overall QOL, with moderate-to-strong correlations (*r* range –0.42 to –0.68, all *P*<.001). Self-esteem was significantly positively associated with all domains of the QOL as well as the overall QOL, with all strong correlations (*r* range 0.52-0.75, all *P*<.001).

Table 4. Correlations between the QOL[a] and mental health variables.

Mental health	QOL (WHOQOL-BREF[b])				
	Physical	Psychological	Social relationship	Environment	Total score
Depression (PHQ-9[c])

Regressions of the QOL and Mental Health

Tables 5-12 display the results of multiple linear regressions. The identity of being a sexual minority woman had a significant negative association with the QOL in all domains as well as the overall QOL (all *P*<.01). In the regression models of mental health variables, belonging to the SGMW group was associated with more severe depression (*P*=.002) and anxiety (*P*=.02) symptoms as well as lower self-esteem levels (*P*=.02). The current smoking status was significantly negatively associated with the overall QOL and all other domains of the QOL except social relationship QOL. Regarding the regressions of mental health variables, the current smoking status was significantly associated with higher levels of depression (*P*<.001) and anxiety (*P*=.006) and lower levels of self-esteem (*P*=.002). Furthermore, having a steady partner was found to be significantly positively associated with the overall QOL (*P*=.006), psychological QOL (*P*=.02), and social relationship QOL (*P*<.001).

Table 5. Regressions of sexual identity on the physical QOL[a].

Characteristics	Physical QOL (R-square=7.9%)

Mediation Effects Between Sexual Identity and the QOL via Mental Health

Figures 2-6 and Table 13 show the effects of parallel mediation analyses and the corresponding unstandardized effect coefficients of mental health on the relationship between sexual identity status and the QOL. As demonstrated, individuals' sexual identity was significantly associated with depression (β=–1.72, *P*=.002), anxiety (β=–1.12, *P*=.02), and self-esteem (β=.93, *P*=.03). As mediators, depression and self-esteem were significantly associated with the QOL in all domains as well as the overall QOL (β ranging from –.07 to –.68 and .19 to .98, respectively; all *P*<.05), while anxiety was only significantly associated with the QOL in the environment domain (β=–.07, *P*=.04). Likewise, the indirect effects of depression, anxiety, and self-esteem were only significant (95% CI did not contain 0) in the environment domain of the QOL, while the indirect effects of depression and self-esteem were significant in all other domains of the QOL as well as the overall QOL, indicating that anxiety is only a mediator in the environment domain but not in other aspects. After considering the mediation effects of depression, anxiety, and self-esteem, the direct effects (c') between sexual identity and the physical QOL (β=.20, *P*=.28), social relationship QOL (β=.35, *P*=.14), and environment QOL (β=.21, *P*=.32) were no longer statistically significant, supporting complete mediation effects. In contrast, the direct effects between sexual identity and the psychological QOL (β=.44, *P*=.02) and the overall QOL (β=1.20, *P*=.04) remained statistically significant, supporting partial mediation effects.

[a] QOL: quality of life.

[b] M: mediator.

[c] a1, a2, and a3 are the effects of the sexual identity (X) on the mental health mediators depression (M1), anxiety (M2), and self-esteem (M3), respectively.

[d] Correspondingly, b1, b2, and b3 are the effects of M1, M2, and M3, respectively, on the QOL (Y).

[e] Unstandardized coefficients (β) are reported. Bootstrap sample size=5000.

[f] Not applicable.

Discussion

Principal Findings

The QOL is widely used to describe individuals' perceptions of general and holistic health [27,52]. SGMW in this study reported significantly lower levels of overall and domain-specific QOL, higher levels of depression and anxiety, and lower levels of self-esteem compared to CHW. Our findings are consistent with several large-scale reviews of the mental health of sexual minority populations in Western countries [3,10], all suggesting that people belonging to sexual minorities are at higher risk of mental health disorders. Meanwhile, our study findings are consistent with the findings in Hong Kong, both showing that Chinese sexual minority populations report poorer levels of the QOL than CH people [28]. In terms of positive mental health, the CHW in our study reported significantly higher levels of self-esteem than the SGMW, which may be related to the fact that the CH identity is mainstreamed and encouraged in Chinese society, suggesting the need to consider specific social contexts when exploring the health of SGM populations.

In terms of cultural issues affecting the QOL and mental health of SGMW in China, it is critical to consider the deep-rooted traditional Confucian Chinese culture that highly values family and inheritance. Specifically, being a member of SGM populations in China is associated with internalized homophobia and stressful feelings in the face of social expectations [25,59,60], which is found to be negatively correlated with lower self-evaluation [61] and social well-being [62]. Compared to the twentieth century, the living conditions of sexual minority populations in China do not seem to have changed much and lesbians have always been more hidden and invisible than gays [63]. According to a recent national survey on sexuality in China, for women born in the 1980s and 1990s (similar to the age group of the population surveyed in this study), 30.3% and 18.1%, respectively, believe homosexual sex is always wrong, and both rates are higher among men in the same age groups [64].

Furthermore, despite a similar cultural background, the overall participants in our study (mainly from mainland China) scored lower than SGMW in Taiwan using the same RSES [25], which may be related to the differences in policy—same-sex marriage has been legalized in Taiwan since 2019 [65]. However, governments in mainland China, Hong Kong, and Macau do not recognize same-sex marriage, which may further lead the sexual minority populations to feel isolated and fear social condemnation [60]. Despite the fact that homosexuality is no longer classified as a pathology under the *Chinese Classification of Mental Disorders* since 2001 [66], the SGMW in our study reported a more worrisome QOL and mental health disorders than the CHW. Thus, future researchers should not only pay attention to SGM populations' current health status but also fully consider social contexts and living environments before designing adaptive health improvement interventions.

Both correlation and regression analyses in this study showed that the overall QOL as well as the QOL in each domain are significantly associated with depression, anxiety, and self-esteem, which is in line with previous studies. Specifically, depression was shown to negatively impact the QOL in our study, as has been seen in similar pathway analysis studies in other populations [67]. Previous studies have also suggested that people with anxiety report an impaired QOL compared to the general population [68], and both depression and anxiety play an important role in the QOL [69], supporting our study results. On the hypothesized mediation effects of mental health, our results indicated that sexual identity not only directly affects the QOL but also indirectly impacts the QOL through the complete or partial mediating effects of mental health variables, which is consistent with previous studies supporting the mediation effects of mental health [56,70]. The pathways from sexual identity to a reduced QOL shown in our study can be attributed to depression, anxiety, and self-esteem. SGMW reported higher levels of depression and anxiety but lower levels of self-esteem than CHW, which was subsequently related to lower levels of the QOL. To minimize the negative effects of sexual identity on the QOL, mental health may be promoted through interventions targeting SGMW.

Given the prior neglect of the health status of SGM populations and the worrisome levels of the QOL and mental health among SGMW, the participants in this study, our results also have significant implications for professional practice. It is recommended that health and social care professionals proactively attend to the mental health of people belonging to sexual minorities when designing or providing interventions. Notably, we found that the proportions of current smokers and alcohol users were significantly higher in SGMW than in CHW, which is supported by previous studies [71-74]. As shown in the multiple linear regressions, current smokers had poorer levels of the QOL in each domain as well as the overall QOL, which is also consistent with the review conclusions that smoking is negatively associated with the QOL [75]. In addition, the current smoking status was significantly associated with all mental health outcomes in this study, as indicated by higher levels of depression and anxiety and lower levels of self-esteem in current smokers compared to nonsmokers, so the substance use among SGMW in China requires more attention and corresponding improvement programs are needed. Existing evidence shows that smoking cessation is associated with reduced depression and anxiety and could significantly improve the QOL as well [76]. With regard to specific smoking cessation programs for SGM populations, a review summarized that interventions targeting SGM populations are more effective than those targeting the general population [74] and a connection to specific sexual minority communities could protect young sexual minority women in the United States from the risk of smoking [71]; therefore, further research to examine whether sexual minority community engagement can reduce the likelihood of smoking among Chinese SGM populations is warranted.

Although there were no significant associations between having a steady partner and mental health variables in our study, being in a steady relationship was found to be significantly positively associated with the overall QOL, psychological QOL, and social relationship QOL. Such findings that the relationship status could positively affect the QOL are consistent with a published review showing that being in a relationship with a regular partner is a protective factor for health [77], so future interventions that take relationship factors into account may be promising. There is also ample evidence that social support has protective effects on the mental health and QOL of sexual minority populations [9,29,78,79], and perceived support from participants' partners is related to lower risk of depression among SGMW [25]. In contrast, stressors, such as victimization and lower social or family support, may contribute to higher levels of depression among sexual minority populations compared to CH individuals [30]. However, there are few studies examining the comprehensive factors influencing the holistic health of Chinese SGM individuals, and studies only on Chinese SGMW are basically nonexistent; thus, it is strongly recommended that future researchers conduct specific explorations targeting female minority populations.

Sexual minority populations have been found to experience higher rates of physical and mental health disorders and poorer levels of the QOL [2-9,80]; thus, interventions should be designed to help improve their holistic health, especially the QOL. The finding of this study that mental health could mediate the association between sexual identity and the QOL highlights the need for all relevant stakeholders to assess SGM populations' mental health when providing health care or social service. Based on our findings, we also recommend that future interventions aimed at improving the QOL of sexual and gender minorities also emphasize positive mental health components, such as self-esteem, thereby improving their QOL.

To sum up, this is the first study to examine both the QOL and mental health among Chinese adult women with diverse sexual identities and also the first to conduct comparisons between SGMW and CHW, showing that SGMW experience worse levels of the QOL and mental health compared to CHW. Although the associations between the QOL and mental health are well established in general populations, there has been little research on these relationships in people of different gender and sexual orientation identities, so this study is also the first to report the interrelationships between sexual identity and the QOL as well as mental health (depression, anxiety, and self-esteem). Moreover, our study is also the first to explore and confirm the mediating role of mental health in the impact of sexual identity on the QOL.

Limitations

This study had several limitations. First, although the QOL and mental health variables explored in this study are generally investigated as separate constructs, this has certain limitations as the meanings of these concepts are intertwined and may influence each other. Although due to the cross-sectional design of this study, the comprehensive relationships within these concepts could not be adequately explored, further studies using more diverse research methodologies, such as qualitative approaches or longitudinal designs, are needed. Second, most of our study participants were young, and nearly half had no paid employment or were still full-time students; therefore, the results might not be generalizable to the broader Chinese female population. Third, although the sample size was sufficient for comparisons between SGMW as a whole and CHW, subgroup analyses by specific sexual orientation may not be powerful enough. Future studies with larger, more diverse, and representative samples are needed.

Conclusion

This study demonstrated that SGMW have lower levels of the QOL, higher levels of depression and anxiety symptoms, and lower levels of self-esteem than heterosexual women. The overall QOL and QOL in each domain were found to be positively associated with good mental health outcomes, with moderate-to-strong correlations. Multiple linear regressions found that being a sexual or gender minority, current smoker, and woman with no steady partner are associated with a worse overall QOL. Mediation analysis showed that depression, anxiety, and self-esteem play significant mediating roles in the relationship between sexual identity and the QOL in Chinese adult women, affirming the importance of assessing mental health when investigating or improving the QOL. Longitudinal studies and evidence-based intervention programs are further needed, with a particular focus on sexual minority women.

Acknowledgments

We are grateful to all the participants for sharing their experiences with us. We also thank TrueSelf Shenzhen, Period Pride China, Wuhan LGBT Center, the r&B bisexual community, and all those who helped transfer this survey to their friends for their contribution to the questionnaire distribution.

Publication made possible in part by support from the University of Hong Kong (HKU) Libraries Open Access Author Fund sponsored by the HKU Libraries.

Conflicts of Interest

None declared.

Abstract

Background: Bullying victimization is highly prevalent among sexual minority youths, particularly in educational settings, negatively affecting their mental health. However, previous studies have scarcely explored the symptomatic relationships among anxiety, depression, and posttraumatic stress disorder (PTSD) among sexual minority youths who experienced bullying on college campuses.

Objective: The objectives of our study were to (1) characterize the anxiety-depression-PTSD network structures of gay or lesbian, bisexuals, and other sexual minority youths previously bullied on college campuses; and (2) compare symptomatic associations in the anxiety-depression-PTSD networks among bullied sexual minority youths and heterosexual youths' groups.

Methods: This cross-sectional study recruited college participants from Jilin Province, China. Data were analyzed using a subset of the data extracted after screening for sexual orientation and history of bullying victimization. Sexual minority youths were then divided into 3 subgroups: gay or lesbian (homosexual), bisexual, and other. Mental health symptom severity was assessed using scales: the 7-item Generalized Anxiety Disorder Scale measuring anxiety, the 9-item Patient Health Questionnaire measuring depression, and the 10-item Trauma Screening Questionnaire measuring PTSD symptoms. Combining the undirected and Bayesian network analyses, the anxiety-depression-PTSD networks were compared among sexual minority youths subgroups, and the difference between heterosexual youths and sexual minority youths was investigated. Chi-square tests were used to compare the difference in categorical variables, while independent-sample *t* tests were run on continuous variables.

Results: In this large-scale sample of 89,342 participants, 12,249 identified as sexual minority youths, of which 1603 (13.1%, 95% CI 12.5%-13.7%) reported being bullied on college campuses in the past year. According to the expected influence (EI) and bridge expected influence (bEI) index, in the global network structure of anxiety, depression, and PTSD, sad mood (EI=1.078, bEI=0.635) and irritability (EI=1.077, bEI=0.954) were identified as central and bridge symptoms; emotional cue reactivity (EI=1.015) was a central symptom of PTSD in this global network. In the anxiety-depression-PTSD Bayesian network, anhedonia had the highest prediction priority for activating other symptoms; and feeling afraid linked symptoms from anxiety to the PTSD community. Compared to their heterosexual counterparts, sexual minority youths exhibited a stronger association between difficulty concentrating and appetite. The “sad mood-appetite” edge was strongest in the gay or lesbian network; the “irritability-exaggerated startle response” edge was strongest in the bisexual network.

Conclusions: For the first time, this study identified the most central and bridge symptoms (sad mood and irritability) within the depression-anxiety-PTSD network of sexual minority youths with past bullying-victim experiences on college campuses. Emotional cue reactivity, anhedonia, and feeling afraid were other vital symptoms in the comorbid network. Symptomatic relationships existed showing heterogeneity in bullied heterosexual youths and sexual minority youth networks, which also was present within the sexual minority youth subgroups. Consequently, refined targeted interventions are required to relieve anxiety, depression, and PTSD symptoms.

KEYWORDS

sexual minority youths; bullying victimization; anxiety; depression; posttraumatic stress disorder; network analysis; Bayesian network

Introduction

Bullying is defined as the intent or behavior that seeks to harm another person repeatedly, with an imbalance of power [1,2]. It is reported in the literature that the rate of bullying in higher education (on college or university campuses) varies across cultures, ranging from 1.7% to 25.2% [3-5]. Particularly, sexual minority youths, who identify their sexual orientations as nonheterosexual, such as lesbian, gay, or bisexual, are vulnerable to discrimination and bullying [5,6], and have higher odds of experiencing bullying on campus than their heterosexual counterparts [7-10]. A national survey in the United States further reported that sexual minority youths experience a high rate of verbal harassment (76.1%), sexual harassment (53.7%), physical harassment (31.2%), and physical assault (12.5%) [11]. In addition, after being bullied, sexual minority youths may experience adverse physical health and persistent negative effects on their mental health [12].

A considerable amount of literature has reported that sexual minority youths exhibit higher rates of anxiety, depression, and posttraumatic stress disorder (PTSD) than their heterosexual counterparts [13-16]. As a recent meta-analysis noted [17], compared to heterosexual counterparts, lesbian or gay, as well as bisexual individuals yielded a higher risk of anxiety and depression. In addition, sexual minority individuals were found to be vulnerable to adverse experiences, such as being harassed and even bullied in school, increasing the risk for anxiety, depression, and PTSD than those participants who have not experienced adverse life events [18].

Past research has found differences in mental health problems among subgroups of sexual minorities [17,19]. For example, the result from a longitudinal study suggests that bullying victimization is connected to stronger depressive symptoms among bisexual women, and stronger anxiety symptoms among bisexual men [20]. Bisexual individuals are also more likely to report PTSD than their gay or lesbian counterparts [21]. Pansexual women appear to be more open about their sexuality but with a higher consciousness in regard to their sexual orientation-based stigma than bisexual women, which is linked to poorer mental health [22]. Further, asexual men are suggested to have higher scores of depression and psychiatric disturbance than their homosexual and bisexual counterparts [23]. The above studies show a high heterogeneity of mental health outcomes among sexual minority subgroups. However, whether these differences remain consistent among sexual minority youths who are being bullied on college campuses requires further exploration.

Minority stress theory provides a conceptual model that the mental health issues of sexual minorities are partially derived from minority stressors, which are defined as the excess stress to which individuals from stigmatized social categories are exposed to due to their minority position [24], such as higher rates of bullying and discrimination. Furthermore, minority stress can cause biological responses that are related to mental health symptoms [25]. For example, exposure to general minority stress can affect one’s gene expression, which is connected to cardiovascular function [26] and exerts an interactional effect between anxiety, depression, and PTSD [27-29]. Meanwhile, it may increase the dysregulation of the hypothalamus-pituitary-adrenal axis, directly adding to the risk of depression, anxiety, and PTSD [30,31]. Nevertheless, the symptomatic relationship between anxiety, depression, and PTSD among sexual minority youths who are bullied on college campuses lacks investigation.

In recent years, several published studies have adopted network analysis in both clinical psychology or psychiatric fields to explore the relationship between symptoms of various disorders [32-34]. The undirected network analysis depicts the interactions between individual symptoms, with a symptom being termed a “node,” and the partial correlation coefficient between 2 nodes determining their “edge” [35]. According to the expected influence (EI) index and the bridge expected influence (bEI) index, the central and bridge symptoms of the network structure could be identified, respectively [36,37]. Furthermore, in this study, Bayesian network analysis was applied to clarify the directed relationship between symptoms further. Based on the completed partially directed acyclic graph (CPDAG), Bayesian network analysis can unclose the putative directions of the potential causal relationship between 2 nodes [38], and it could help to discover activating paths among symptoms of anxiety, depression, and PTSD network [33].

Given these premises, this study was implemented using undirected and Bayesian network analyses to achieve 2 main objectives: first, to characterize the symptomatic relationships in the anxiety-depression-PTSD network among bullied sexual minority youths and sexual minority youth subgroups; second, to compare the network structures among bullied sexual minority youth subgroups. For aim 1, based on previous results [34,39,40], the researchers hypothesized that depressive and anxious symptoms would be the most central and bridge among all symptoms. For aim 2, considering sexual minority youth subgroups have various prevalence and symptomatic manifestations of anxiety, depression, and PTSD [14,21], the researchers hypothesized that different strengths of symptomatic associations would exist among sexual minority youth subgroups who had disclosed experiences of being bullied. In addition, the researchers aimed to enrich the field, as well as help offer targeted suggestions and interventions for specific symptoms associated with poor mental health.

Methods

Participants and Settings

This study was designed with a cross-sectional approach, recruiting College students from 63 Universities or Colleges in Jilin Province, China, from October to November 2021. Students completed an electronic questionnaire with a Quick Response code, delivered by their teachers with their classmates. The inclusion criteria for recruitment were (1) being 15 years old or older; (2) studying at universities or colleges in Jilin Province, China; (3) understanding the Chinese questionnaire and having the ability to provide informed consent.

Ethical Considerations

Ethical approval for this study was granted by the Ethics Committee of Jilin University (NO20210929 [11 October 2021]), following the 1964 Helsinki Declaration and its amendments in 2013. Electronic informed consent was provided by all participants, with consent that their answers could be applied to any secondary analyses.

Measurements

Participants' sexual orientation was measured by a single-option question with 6 items: "Which of the following better describes your sexual orientation?" Except for heterosexuality, all other sexual orientations are combined to form the sexual minority youth group [41,42], which was then further divided into 3 subgroups, including homosexuality (gay or lesbian), bisexuality, and others (asexuality, pansexuality, and uncertain). Anxiety was measured by the 7-item Generalized Anxiety Disorder Questionnaire [43], depression by the 9-item Patient Health Questionnaire [44], and PTSD by the 10-item Trauma Screening Questionnaire [45]. The experience of being bullied during higher education was measured by a single question: "Have you ever been bullied on campus in the past year?" Details of measurements are presented in the Section S1 in Multimedia Appendix 1, Additional information for networks.

Statistical Analysis

Descriptive Analysis

In total, 117,769 participants were recruited and 89,342 were included according to the criteria and completion of the questionnaire. A descriptive analysis was run on the subdata extracted from screening for sexual orientation and history of bullying victimization. In the data set of those who had been bullied on college campuses in the past, they were divided into groups of heterosexual and sexual minority youth groups. Sociodemographic variables included participants' age, sex, residence, ethnicity, family type, current annual income, and whether they were an only child. The categorical variables in heterosexual or sexual minority youth groups were compared by chi-square tests, while continuous variables were compared by two-tailed independent-sample *t* tests.

Undirected Network Estimation

This study used R programming [46] to structure the undirected network, with the R package "qgraph" (R Foundation for Statistical Computing) to visualize the Graphical Gaussian Model [35]. The R package "mgm" assessed the predictability of a node, referring to the variance of a node that could be explained by all others [47]. The differences between the sexual minority youths and heterosexual network structures and among sexual minority youth subgroups were compared using the R package "Network Comparison Test" with 1000 permutations [48]. For more detail on the method, see Section S2 in Multimedia Appendix 1, Additional information for networks.

Bayesian Network Estimation

In this study, DAG was modelled by the R package "bnlearn," with the hill-climbing algorithm [49]. To further obtain a clear direction among symptoms, the Markov equivalence classes of the DAG were drawn, which can be described uniquely by a CPDAG [50]. In CPDAG, all arrows of undirected edges can be invertible, while all directed edges cannot be converted into undirected edges. Finally, in the determined CPDAG, the direct activating paths in the Bayesian network are more conclusive. More details are shown in Section S2 in Multimedia Appendix 1, Additional information for networks.

Results

Descriptive Statistics

Table 1 presents the sociodemographic characteristics of participants. Within groups, 5063 (6%) heterosexual participants and 1603 (13.1%) sexual minority youth participants reported being bullied on college campuses in the past year. The prevalence of bullying among heterosexual youths was 6% (95% CI 5.9%-6.2%), and 13.1% (95% CI 12.5%-13.7%) among sexual minority youths. Furthermore, among gay participants, the prevalence of bullying was 19.9% (95% CI 17.1%-23.1%), 12.2% (95% CI 9.8%-15.1%) among lesbians, 15.6% (95% CI 13.6%-17.9%) among bisexual males, and 12% (95% CI 11.2%-12.9%) among bisexual females. The odds of being bullied among sexual minority males was 14.4% (95% CI 12.7%-16.2%), and 11.8% (95% CI 10.6%-13%) among sexual minority females.

[a] X^2: used to compare differences between heterosexual and sexual minority youth groups among specified demographic variables.

[b] There was a significant difference existing with *P*<.001.

[c] N/A: Not applicable.

[d] T: used to compare differences between heterosexual and sexual minority youth groups among specified demographic variables.

[e] GAD-7: the 7-item Generalized Anxiety Disorders Scale.

[f] PHQ-9: the 9-item Patient Health Questionnaire.

[g] PTSD-10: measured by the 10-item Trauma Screening Questionnaire.

Compared to their heterosexual counterparts, more sexual minority females, and more sexual minority youths living in urban residences reported being bullied on the campuses. In addition, experiences of being bullied were more likely to occur among participants from nuclear families, with lower annual family income, or among those who had siblings. Bullied sexual minority youths also reported higher rates of anxiety, depression, and PTSD symptoms than bullied heterosexual youths.

Undirected Network Structure

As seen in Figure 1, according to the centrality index EI, GAD2 (Generalized Anxiety Disorders Scale; “control worry,” EI=1.134) had the highest EI, followed by PHQ4 (Patient Health Questionnaire; “energy,” EI=1.116), GAD3 (“worry a lot,” EI=1.085), PHQ2 (“sad mood,” EI=1.078), GAD6 (“irritability,” EI=1.077), and PTSD4 (“energy,” EI=1.015). These 6 symptoms played the most central role in the global network of anxiety, depression, and PTSD symptoms among all bullied sexual minority youths. The central network structures of the 3 sexual minority youth subgroups and their centrality index EI are shown in Table S1 and Figures S1, S2, S3, and S4 in Multimedia Appendix 1, Additional information for networks.

As seen in Figure 2, according to bEI, GAD6 ("irritability," bEI=0.954), PHQ8 ("motor," bEI=0.883), GAD7 ("feeling afraid," bEI=0.758), GAD5 ("restless," bEI=0.718), GAD1 ("nervous," bEI=0.694), and PHQ2 ("sad mood," bEI=0.635) had crucial bridging roles in connecting to the other symptoms of anxiety, depression, or PTSD, which may possibly transform from 1 community to another. The bridge network structures of the 3 sexual minority youth subgroups and their bridge bEI index are shown in Table S1 and Figures S5, S6, S7, and S8 in Multimedia Appendix 1, Additional information for networks.

Figure 1. The global network structure of central symptoms among all bullied sexual minority youths (N=1603). GAD: the 7-item Generalized Anxiety Disorders Scale; LGB: homosexuality (gay or lesbian), bisexuality and other sexual minority youths; PHQ: the 9-item Patient Health Questionnaire; PTSD: posttraumatic stress disorder measured by the 10-item Trauma Screening Questionnaire.

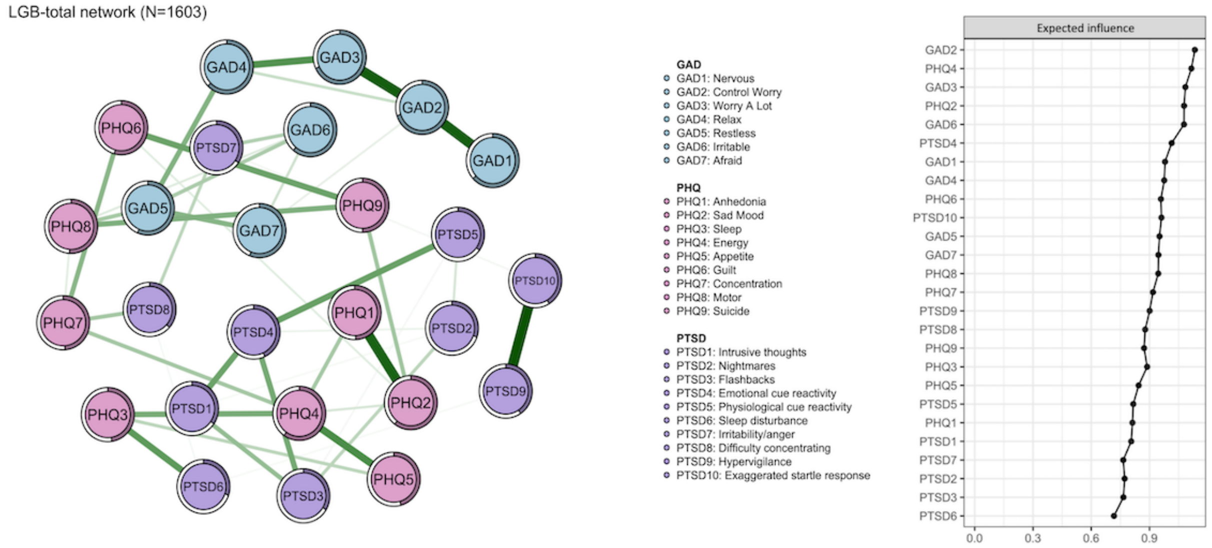

Figure 2. The global network structure of bridge symptoms among all bullied sexual minority youths (N=1603). GAD: the 7-item Generalized Anxiety Disorders Scale; LGB: homosexuality (gay or lesbian), bisexuality and other sexual minority youths; PHQ: the 9-item Patient Health Questionnaire; PTSD: posttraumatic stress disorder measured by the 10-item Trauma Screening Questionnaire.

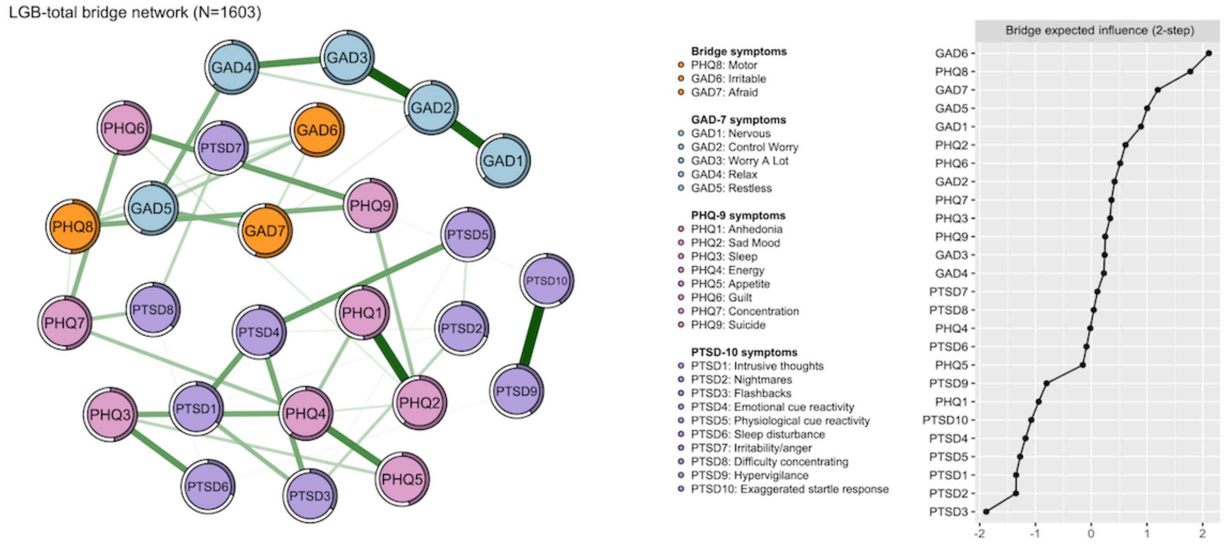


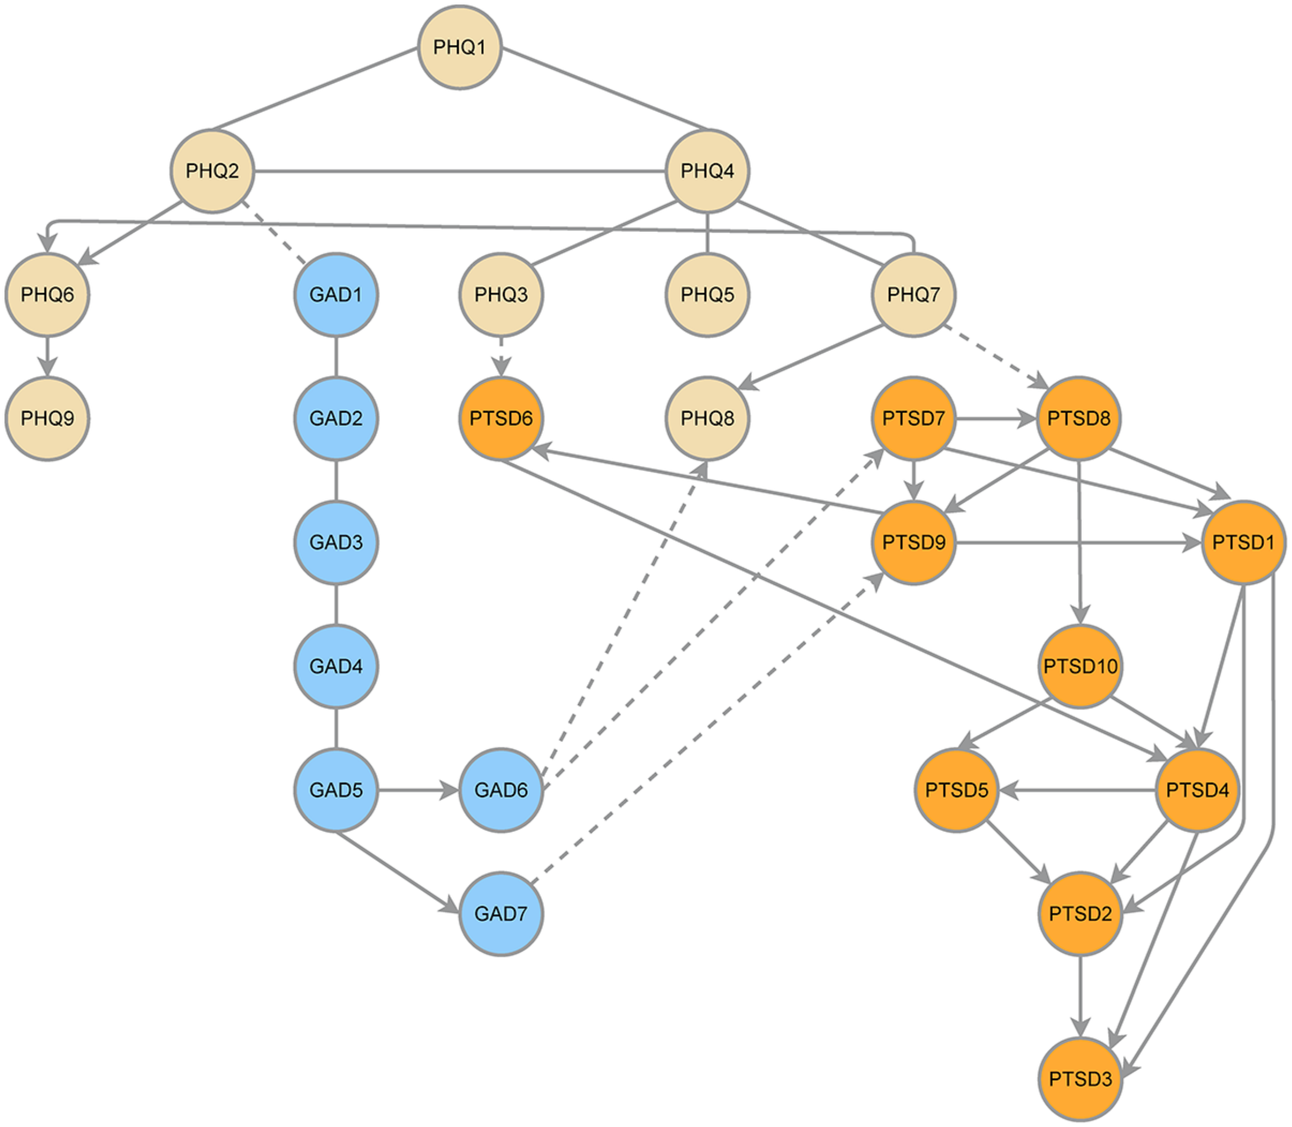
The average predictability of nodes was 48.67%, which means that, on average, the variance of 48.67% per node could be explained by its neighbors. In addition, all networks show good stability in this study (see in Figures S9, S10, S11, and S12 in Multimedia Appendix 1, Additional information for networks).

Bayesian Network Structure

Figure 3 shows the CPDAG results, indicating that PHQ1 ("anhedonia") had the highest predictive priority for other symptoms occurring in the anxiety-depression-PTSD network. PHQ2 ("sad mood"), GAD6 ("irritability"), and GAD7 ("feeling afraid") were identified as 3 crucial bridge symptoms, whose downstream symptoms had more branches and could activate more pathways. In addition, there were reversible connections between PHQ1 ("anhedonia"), PHQ2 ("sad mood"), and PHQ4 ("appetite"). Whereas, the edges between PHQ2 ("sad mood") and PHQ6 ("guilt"), between GAD6 ("irritability"), PHQ8 ("motor"), and PTSD7 ("irritability or anger"), and between

GAD7 (“feeling afraid”) to PTSD9 (“hypervigilance”) were unidirectional and irreversible. These results indicate the most likely direction from both depression and anxiety symptoms to PTSD symptoms, rather than vice versa. More results of CPDAG can be found in Figure S13 in Multimedia Appendix 1, Additional information for networks.

Figure 3. The Bayesian network of anxiety, depression, and posttraumatic stress disorder among bullied sexual minority youths, based on a completed partially directed acyclic graph. GAD: the 7-item Generalized Anxiety Disorders Scale; PHQ; the 9-item Patient Health Questionnaire; PTSD: posttraumatic stress disorder measured by the 10-item Trauma Screening Questionnaire. The edges without directions refer to reversiblity. The solid edges with direction refer to irreversiblity. The dotted edges with direction refer to irreversibility and arrowing to a node in another symptom community.

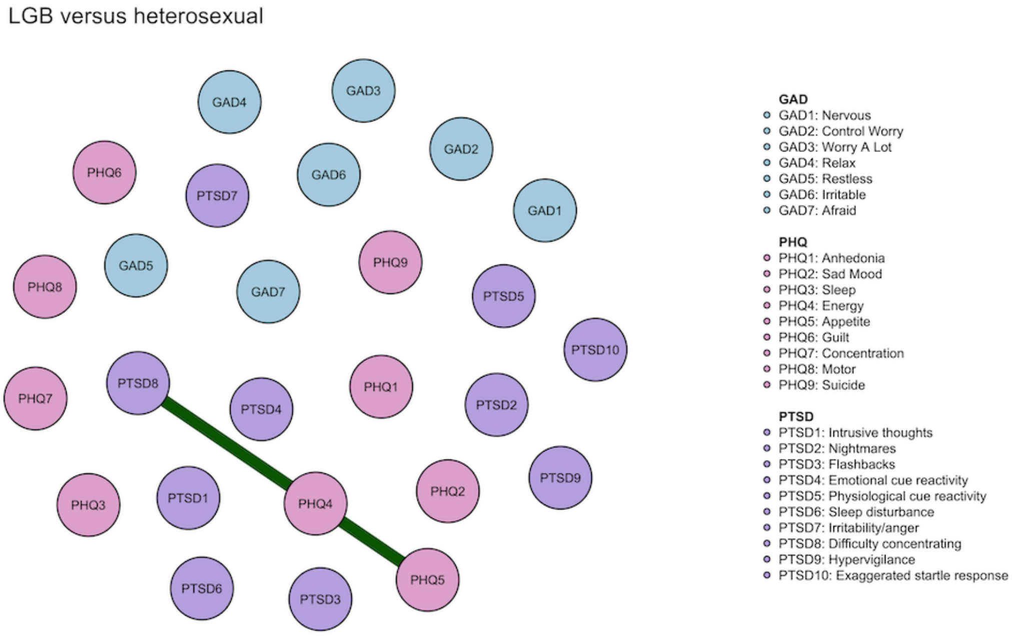


Network Comparison Structures

Figure 4 shows the results when comparing the network structures between the sexual minority youths and heterosexual groups. The edge of PTSD8 (“difficulty concentrating”)-PHQ5 (“appetite”) was significantly stronger in the sexual minority youth network structure than in the heterosexual.

Among the 3 subgroups of sexual minority youths, there was no significant difference in edges between the gay or lesbian network and the other sexual minority youth networks. However, the edge of PHQ2 (“sad mood”)-PHQ5 (“appetite”) was strongest in the gay or lesbian network and the edge of PTSD7 (“irritability”)-PTSD10 (“exaggerated startle response”) was strongest in the bisexual sexual minority youth networks (Figure S14 in Multimedia Appendix 1, Additional information for networks).

Figure 4. The comparison of network structure between sexual minority and heterosexual youths. GAD: the 7-item Generalized Anxiety Disorders Scale; PHQ: the 9-item Patient Health Questionnaire; PTSD: posttraumatic stress disorder measured by the 10-item Trauma Screening Questionnaire.



LGB versus heterosexual

Discussion

Principal Findings

This is the first study based on a large-scale sample to investigate the symptomatic relationship of anxiety, depression, and PTSD among sexual minority youths bullied on college campuses in the past. The results partly supported hypothesis 1: sad mood and irritability were identified as the most frequently crucial activating symptoms of poor mental health, where emotional cue reactivity was the most central symptom of the PTSD community. In the Bayesian network, anhedonia had the highest predictive priority to activate the occurrence of all other symptoms; feeling afraid played a bridging role in the anxiety-depression-PTSD network. The results supported hypothesis 2: compared to heterosexuals, sexual minority youths exhibited a stronger association between difficulty concentrating and appetite. The "sad mood-appetite" edge was strongest in the gay or lesbian network, and the "irritability-exaggerated startle response" edge was strongest in the bisexual network.

Sexual minority youths has been frequently reported to experience discrimination, prejudice, and stigma-bias because of their sexual orientation [6,51], associated with bullying victimization of sexual minority youths [52,53]. Our study further reported a high prevalence of being bullied on college campuses among sexual minority youths, which was 13.3% (95% CI 12.5%-13.7%, n=1603). Consistent with previous findings, exposure to bullying on college campuses was found to be related to the onset of mental health problems among sexual minority youths [53]. As a meta-analysis supported, individuals who experience bullying victimization had increased odds of depression, anxiety, and PTSD [54].

Sad mood and irritability were the most crucial symptoms (both central and bridge) in all anxiety-depression-PTSD network models. Previous network analyses have consistently identified sad mood as the central and bridge symptom in the structure of the anxiety-depression network [36,55]. This result may be explained by the external stressors that sexual minority youths face, making them feel sad [51,56]. According to a US national survey on youths' risk behavior, high rates of in-school bullying victimization for homosexuals (28.22%, n=91) and bisexuals (34.03%, n=318) occurred because of external discrimination [7]. When under stressful conditions, if those bullied students experience insufficient support from teachers, they could feel abandoned and hopeless [57]. In terms of irritability, 2 prior studies also noted that irritability had a high betweenness index (another bridge centrality index) [34], and was identified as one of the central symptoms in the depression-anxiety-PTSD network [58]. Research has indicated that, once bullied, an inability to find a coping strategy or resist bullying behaviors can make individuals feel frustrated, which may trap them in rumination anger [9]. Moreover, traumatic memories of bullying victimization could generate severe distress and irritability as well [59]. Our results showed irritability also had a high predictive priority of the occurrence of PTSD symptoms. Findings indicate that for those who do withstand cumulative bullying victimization, their subjective aggression can be triggered, potentially increasing their irritable mood and PTSD symptoms simultaneously [60]. Notably, emotional cue reactivity (in this study referring to feeling upset by reminders of the events) was the most central symptom in the PTSD network. This may be explained by the influences of autobiographical memories (a mixed memory of complicated life events) [61]. Experiences of being bullied incur negative emotional cues, such as insults and physical aggression [62], and these negative memories would, in turn, cause further distress.

In the Bayesian network, anhedonia had the highest predictive priority of activating other symptoms. It parallels a previous network analysis that identified anhedonia as a central symptom in the anxiety-depression network [36]. Previous findings reported that bullying behaviors could lead to poorer mental health for bullying victims [63]. After being bullied, sexual minority youths may form a negative schema about an institution, which influences their interaction with others, decreasing their interest in participating in activities with their peers [64]. Another possible explanation could be a lack of support from teachers and families after exposure to being bullied, which further hinders sexual minority youths' mental health [65] and also makes it harder for them to perceive pleasure [66]. Additionally, being bullied may negatively influence the release of dopamine, a chemical produced by neuronal receptors that relate to feeling good, in the case of bullying, this causes a lack of pleasure [67]. Feeling afraid also played a significant bridging role in the Bayesian network, pointing to the occurrence of hypervigilance in the PTSD community. On the one hand, past bullying victimization could lead sexual minority youths to be afraid of reoccurring bullying [68]; on the other hand, without efficient support from others, exposing perpetrators of bullying could trigger their fear of retaliation [69]. In addition, feeling afraid is linked to the symptoms of PTSD in this study. As early findings stated, those bullied could incur idiopathic nightmares and sleep problems, leading to hypervigilance [70]. From the neuropsychological perspective, fear-related threats increase the steady-state visual evoked amplitudes, thus heightening individuals' vigilance [71]. Based on this fear of repeated bullying, sexual minority youths' visual attention to possible danger may present with over-heightened reactions.

Compared to the heterosexual network structure, difficulty concentrating was found to be more closely associated with appetite in the sexual minority youth network structure. As previous findings stated, sexual minority youths were more vulnerable to weight-based bullying by peers than heterosexual youths [72,73]. Moreover, a motivation to avoid or prevent bullying may be a key driver for those who seek treatment for obesity [74]. Thus, the ideal body image and weight bias may result in more sexual minority youths choosing to diet in order to lose weight or engage in harmful weight-control strategies, such as purging, to maintain a satisfactory appearance [75]. It should be noted that over-preoccupation with body shape might impair concentration in other areas, supported by a previous study in which those who experienced bullying reported that they perceived their attention was distracted due to the fear associated with the experience, which led to difficulty concentrating when learning and during academic achievement, further hindering their state of mental well-being [76].

Differently, compared to bullied bisexual youths, sad mood had a stronger correlation with appetite among bullied gay or lesbian youths. Researchers consistently report more disordered eating behaviors in gay or lesbian youths than in bisexuals [77]. In addition, gay or lesbian youths were reported to have more body dissatisfaction, driven by an ideal body shape [78,79]. Negative mood also relates to subjective appetite, causing poor appetite or overeating [80]. Since discrimination and bullying incur a sad mood for gay or lesbian youths, they may choose binge eating to elevate their mood momentarily [81]. Furthermore, compared to other sexual minority youths, bisexual youths exhibited a stronger correlation between irritability and exaggerated startle response. This may be due to bisexual youths experiencing dual discrimination from homosexual and heterosexual communities [82]. Since bullying shapes a threatening context for bisexual youths, they may become irritable and exhibit a high startle reactivity [83]. Meanwhile, higher irritability can alter attention bias, with decreased functional connectivity between the left inferior frontal gyrus and a periaqueductal grey area, which may increase the response to frustrating stimuli [84].

Limitations

Several limitations should be noted in this study. First, as a cross-sectional study, it is hard to explore the dynamic process of psychopathological networks [85], thus, further longitudinal research is required to obtain causal conclusions. Second, the replicability and generalizability of network structures are still limited across various samples [86]. In the future, neuroimaging studies are required to explore the organic effects on the brain. Third, measurements were limited in several aspects: (1) the minority stressors, such as lacking peers or family support, were not directly measured, and the results could be biased because of other potential influences. (2) There may be a part of the youths who have hesitancy toward or concealment of being identified as sexual minority youths for fear of being exposed in the context. (3) In addition, the interaction of gender identity and sexual orientation should be considered in future investigations. For example, a transgender man attracted to a cisgender man could also consider himself gay. Further studies should be conducted covering diverse gender identities in detail. (4) Because the experience of being bullied on college campuses in the past was measured by a self-report as well, in which the standard to determine the conceptualization of bullying varies across individuals, it was inevitable to include samples with different severities of bullying victimization. Future research should provide more detailed standards to define bullying and explore the underlying mechanism between various types or levels of bullying behaviors and the impact this has on the mental health of sexual minority populations. Bullying off-campus perpetrated by peers should be measured, and its impacts must be explored. (5) The bias of recall errors or social desirability effects is unavoidable for data from subjective reporting scales. Finally, other psychiatric disorders, such as obsessive-compulsive disorder or eating disorders, were not measured directly, which may affect the results.

Conclusions

This cross-sectional study based on a large-scale sample, combined the undirected network analysis and Bayesian network analysis, for the first time, identifying the most central and bridge symptoms (sad mood and irritability), as well as the central role of emotional cue reactivity within the depression-anxiety-PTSD network of sexual minority youths who were bullied on college campuses in the past. CPDAG results also indicated the vital roles of anhedonia and feeling afraid in the global Bayesian network in this study. In addition, the comparisons of networks supported three findings: (1) compared to heterosexuals, the edge of "difficulty concentrating" was stronger than in the global sexual minority youth network, (2) the edge of "sad mood-appetite" was strongest in the gay or lesbian network, and (3) the edge of "irritability-exaggerated startle response" was strongest in the bisexual network. These findings should be considered when offering targeted support for improving the physical health and mental well-being of sexual minority youths. Consequently, refined targeted interventions could be formulated [6] to relieve the symptoms of anxiety, depression, and PTSD comorbidity among sexual minority youths.

Acknowledgments

The conception and design of this study was done by YW and SX. SX and XS did the data collection. Data quality control was done by SX. Data analysis and all figures were done by YJ, CC, XLuo, YL, and XLing. This study's write-up was performed by JL, YJ, and SX. Critical comments were made by YW and AW. This study was supervised by YW and SX. We thank all the participants and staff involved in this study. This study was supported by the National Natural Science Foundation of China (82201708).

Abstract

Background: Opioid-related overdose mortality has remained at crisis levels across the United States, increasing 5-fold and worsened during the COVID-19 pandemic. The ability to provide forecasts of opioid-related mortality at granular geographical and temporal scales may help guide preemptive public health responses. Current forecasting models focus on prediction on a large geographical scale, such as states or counties, lacking the spatial granularity that local public health officials desire to guide policy decisions and resource allocation.

Objective: The overarching objective of our study was to develop Bayesian spatiotemporal dynamic models to predict opioid-related mortality counts and rates at temporally and geographically granular scales (ie, ZIP Code Tabulation Areas [ZCTAs]) for Massachusetts.

Methods: We obtained decedent data from the Massachusetts Registry of Vital Records and Statistics for 2005 through 2019. We developed Bayesian spatiotemporal dynamic models to predict opioid-related mortality across Massachusetts' 537 ZCTAs. We evaluated the prediction performance of our models using the one-year ahead approach. We investigated the potential improvement of prediction accuracy by incorporating ZCTA-level demographic and socioeconomic determinants. We identified ZCTAs with the highest predicted opioid-related mortality in terms of rates and counts and stratified them by rural and urban areas.

Results: Bayesian dynamic models with the full spatial and temporal dependency performed best. Inclusion of the ZCTA-level demographic and socioeconomic variables as predictors improved the prediction accuracy, but only in the model that did not account for the neighborhood-level spatial dependency of the ZCTAs. Predictions were better for urban areas than for rural areas, which were more sparsely populated. Using the best performing model and the Massachusetts opioid-related mortality data from 2005 through 2019, our models suggested a stabilizing pattern in opioid-related overdose mortality in 2020 and 2021 if there were no disruptive changes to the trends observed for 2005-2019.

Conclusions: Our Bayesian spatiotemporal models focused on opioid-related overdose mortality data facilitated prediction approaches that can inform preemptive public health decision-making and resource allocation. While sparse data from rural and less populated locales typically pose special challenges in small area predictions, our dynamic Bayesian models, which maximized information borrowing across geographic areas and time points, were used to provide more accurate predictions for small areas. Such approaches can be replicated in other jurisdictions and at varying temporal and geographical levels. We encourage the formation of a modeling consortium for fatal opioid-related overdose predictions, where different modeling techniques could be ensembled to inform public health policy.

Introduction

Opioid-related overdoses continue to be at crisis levels in communities across the United States, with more than 75,673 fatal overdoses in the 12-month period ending in April 2021 [1-7], worsening during the COVID-19 pandemic [8]. Opioid-related deaths increased more than 5-fold in Massachusetts between 2000 and 2016, with more than 2000 per year from 2016 to 2021 [9,10]. Fatal opioid-related overdose rates above the national level have been ubiquitous across communities in Massachusetts [11]. Despite this crisis, public health responses to the opioid overdose epidemic have been limited by an inability to rapidly identify current fatal overdose patterns, predict future local clusters, and evaluate the effectiveness of interventions.

Identification and prediction of local fatal opioid overdoses require a comprehensive and high-quality surveillance system that provides data sources to capture granular geographic information of the fatal opioid overdose cases across space and time. Ideally, additional information such as individual demographics, past medical history (particularly mental health history), local drug supply, and other risk factors should be included as well to enhance our understanding of the opioid crisis. Many states have established surveillance systems to monitor opioid-related morbidity and mortality to inform planning and evaluate control efforts. Some surveillance systems include unlinked individual data sources for different opioid-related reporting (eg, vital records and prescription drug monitoring programs), and some aim to provide an individually linked database across various data sources [12]. While the latter provides much enhanced data capacity for a wide range of opioid-related research, creating such linked databases takes substantial time and financial resources.

Accurate identification and prediction of fatal opioid-related overdose trends also requires sophisticated spatial and predictive analytical approaches, as noted in a recent review of methodological approaches for the prediction of opioid use–related epidemics in the United States [13]. Most published literature has focused on the identification of community- or neighborhood-level risk factors for opioid-related overdose. For example, Bozorgi et al [14] explored different machine learning and spatial analytical approaches to identify leading contextual risk factors for drug overdose at the block group level in South Carolina. A similar study by Schell et al [15] also focused on identifying new neighborhood-level predictors of opioid-related overdose deaths in Rhode Island at the census block group level, using least absolute shrinkage and selection operator and random forest algorithms. Abell-Hart et al [16] identified counties with a high number of underserved opioid overdose patients in New York state. Basak et al [17] detected spatiotemporal hot spots (ie, counties) at high risk of prescription opioid misuse and overdose using regression models that relied on Medicare claims data in Virginia, North Carolina, and West Virginia.

Statistical models or machine learning techniques proposed specifically for prediction purposes are limited, with most previous studies performed at the US county or state level [18,19], lacking the spatial granularity needed to guide local public health departments for preemptive actions. Bayesian spatiotemporal models have received substantial attention in the past several years in opioid-related research, given their ability to include temporal and spatial correlations and improved precision in small area estimation [20-22]. Sumetsky et al [20] for instance, developed a Bayesian logistic growth model for opioid overdose mortality predictions for 146 counties in North and South Carolina.

In this study, we developed and validated several Bayesian spatiotemporal dynamic predictive models designed for small area forecasting of opioid-related overdose mortality at the ZIP Code Tabulation Area (ZCTA) level. We investigated the benefits of including various area-level demographic and socioeconomic factors in improving the prediction. The predictive performance was assessed using opioid-related overdose mortality data from Massachusetts between 2005 and 2019. We identified the top ZCTAs with the highest predicted fatal opioid overdose rates or counts and by urban and rural areas. Our prediction results can help inform local public health departments' planning and targeting of resource allocations.

Methods

Opioid-Related Mortality Data

Opioid-related mortality data were obtained from the Massachusetts Department of Public Health's (MDPH's) Registry of Vital Records and Statistics (RVRS) for 2005 through 2019. International Classification of Disease, Tenth Revision, codes for mortality were used to select from the *underlying cause of death* field by RVRS staff and identify poisonings or overdoses: X40-X44, X60-X64, X85, and Y10-Y14. All multiple *underlying cause of death* fields were then used to define opioid-related death with T40.0, T40.1, T40.2, T40.3, T40.4, and T40.6. We excluded opioid-related deaths for individuals younger than 20 years, since fatal opioid-related death was rare in this age group (n=191). This age grouping also allows for comparison of opioid-related overdose rates with other drug overdose studies [23]. We used the ZCTA of the reported residential address for decedents at the time of the fatal overdose and excluded those either with missing addresses or those with addresses outside of Massachusetts' boundaries (n=642). The final analytic sample included 16,377 fatal opioid-related overdoses from 2005 to 2019. The flowchart for deriving the analytic samples used for this analysis, summarized by each year, is presented in Figure S1 in Multimedia Appendix 1. We also developed a web-based dashboard to present the map and summaries of these data [24]. Requests for the opioid-related decedent data should be made directly to the MDPH's RVRS.

ZCTA Demographic and Socioeconomic Factors

ZCTA-level demographic and socioeconomic variables were obtained from 2005 to 2019 from the American Community Survey 5-year estimates (2005-2009, 2010-2014, and 2015-2019, respectively) [25]. We used the total population counts and characteristics for people aged 20 years or older at the ZCTA level to account for differences in population size. The ZCTA-level demographic variables included race or ethnicity (proportions of White and Hispanic individuals), education (proportion of individuals with a bachelor's degree), employment (proportion of unemployed individuals), poverty level (proportion of individuals living under the federal poverty level), income (per capita income in US $), living conditions (proportion of renters), transportation (proportion of individuals without vehicles), and English speaking (proportions of individuals with limited English). A detailed summary of these covariates, for all ZCTAs and those stratified by urban or rural areas, is presented in Table S1 in Multimedia Appendix 1. These covariates were considered from a larger set of community-level covariates and were selected on the basis of the literature and our prior research. Following calculation of descriptive statistics and bivariate analyses, we further narrowed the list to a subset of population-level measures at the ZCTA level. The final set of covariates included in this analysis was chosen after fitting a simple Poisson regression model and selecting those with a significant association with opioid-related overdose mortality (see Figure S5 in Multimedia Appendix 1).

Urban and Rural ZCTAs

The Massachusetts State Office of Rural Health uses a composite scoring system to categorize rurality for each ZCTA. Among the 537 ZCTAs included in this analysis, 390 (73%) were classified as urban areas, and the rest as rural areas. A map of the ZCTAs, color-coded by their urban or rural status, is provided in Figure S2 in Multimedia Appendix 1.

Statistical Models

Our choice of dynamic spatiotemporal model was motivated by a previous study of drug overdose rates across US counties, which showed that the strongest predictor of overdose rates was overdose rates in nearby counties from the previous year. We considered the following Bayesian dynamic spatiotemporal models [26,27]. Y_{it} denotes the number of opioid-related fatal overdose counts in ZCTA i (i=1, …, I=537) and year t (t=2005, …, t=2019). We assumed a Poisson distribution with mortality rate μ_{it}; that is, $Y_{it}|\mu_{it} \sim Poisson(N_{it}\mu_{it})$, with N_{it} representing the population size as an offset. The mortality rate μ_{it} was then decomposed using the following models:

Model 1: $\log(\mu_{it}) = \alpha_i + S(t) + \eta_t$, $\eta_t \sim AR(1)$,

Model 2: $\log(\mu_{it}) = \alpha_i + S(t) + \omega_{it}$, $\omega_{it} \sim GMRF(\tau\Sigma_{AR(1)} \otimes \Sigma_I)$, and

Model 3: $\log(\mu_{it}) = \alpha + S(t) + \omega_{it}$, $\omega_{it} \sim GMRF(\tau\Sigma_{AR(1)} \otimes \Sigma_{CAR})$

In all 3 models, $S(t)$ captured the overall (or marginal) temporal trend and could be modeled via linear or quadratic terms or spline functions. The major differences among the 3 models were how random effects (η or ω) were modeled in the spatiotemporal interactions. In model 1, α_i was the random effect accounting for the difference of the opioid-related mortality at the ZCTA level, and η_t was a first-order autogressive latent effect $AR(1)$ for the temporal trend. Essentially, model 1 regressed the opioid-related mortality rate at time t, on the log scale, over the previous time point t–1; however, instead of running one model for each ZCTA, the Bayesian framework allowed pooling of the ZCTAs to improve prediction. In models 2 and 3, α was the overall intercept, and the ZCTA-level differences of the opioid-related mortality rates were absorbed in the spatiotemporal interaction term ω_{it}, which now accounted for the spatial dependency between ZCTAs. Models 2 and 3 were inseparable spatiotemporal models, where the interaction term ω_{it} had a Gaussian Markov Random Field (GMRF) with mean 0 and covariance matrix $\tau\Sigma_T \otimes \Sigma_S$ [28]. The interaction term was the Kronecker product of the temporal structure Σ_T and the spatial structure Σ_S, and τ was the precision parameter (ie, reciprocal of the variance parameter). We again used the $AR(1)$ temporal structure in models 2 and 3 but considered different structures for the spatial dependency. In model 2, the spatial structure was an $I \times I$ identity matrix. Although the identity matrix may appear to assume independence of the areas, the hierarchical structure of the model imposed borrowing information from the neighboring areas. In model 3, we assumed a conditional autoregressive model (CAR) [29] as the spatial structure, which assumed that ZCTAs that were geographically adjacent were more similar than those that were far away. We note that other spatial or temporal structures (eg, random walk models) can also be considered in the proposed model framework.

Models 1, 2, and 3 were referred to as the respective base models. We then added ZCTA-level demographic and socioeconomic variables x_{it} and the urban or rural indicator variable described above, to each of the base models to assess potential improved prediction performance. All models were fit in a Bayesian framework, with the priors chosen as the noninformative priors commonly used in spatiotemporal models [28]. In our application, it turned out that the interaction term was sufficient to capture the spatial-temporal variation, so we dropped the marginal temporal term. We used the posterior median and 90% credible intervals (CrIs) for inference. The

90% CrI was preferred over the commonly used 95% CrI, as the former was better suited for prediction purposes to avoid overly wide uncertainty. All analyses were performed in RStudio [30] and R package integrated nested Laplace approximation [31].

To assess the predictive performance of the models, we used a one-year ahead approach: assuming we observed data from 2005 to year *t*, we predicted the opioid-related mortality rates and counts for year *t*+1. We started by considering the observed data from 2005 to 2015, and the prediction was carried out for 2016. Then we considered observed data from 2005 to 2016 and predicted counts and rates were calculated for 2017. The one-year ahead prediction procedures were carried out for each year from 2016 to 2019, and the predictions were obtained for each ZCTA, along with the prediction uncertainty (posterior 90% CrI). We used the following metrics to compare the predictive performance across different models: mean absolute error (MAE), root mean square error (RMSE), and the rank difference (RD). MAE was defined as the average absolute difference between the predictive and the observed values; that is, , for count or rate Y_{it}. RMSE was defined as the average squared difference between the predictive and the observed values; that is, . RMSE has the advantage that it was on the same scale as the outcome variable and was thus easy to interpret. For example, if the prediction was for the ZCTA-level mortality count (ie, how many people would die from fatal opioid-related overdose), then an RMSE of 10 would roughly mean that on average the prediction was off by 10 mortality cases. Smaller MAE and RMSE would indicate better performance. The RD was motivated by the correct classification of opioid mortality by group membership, where we divided the ZCTAs into quintiles Q1 to Q5, based on the observed fatal opioid-related overdose rates and counts, and then compared to the quintiles for the predicted rates and counts. The RD was then calculated by the percentage of times when the classification was correct. Higher values of RD indicated better performance.

Ethical Considerations

This study was reviewed by the Health Sciences institutional review board at Tufts University and was designated as exempt from ethics approval (IRB reference number: 13288).

Results

The number of fatal opioid-related overdoses among people aged 20 years or older increased from 557 in 2005 to 1912 in 2019, corresponding to an increase in rate from 7.95 in 2005 to 34.4 in 2019 per 100,000 population. Out of a total of 16,377 opioid-related fatalities between 2005 and 2019, overall, 91% occurred in urban ZCTAs. The observed rates at the ZCTA level were highly variable (Figure S3 in Multimedia Appendix 1), ranging from 0 to 1316 per 100,000 population. The extreme values in the observed rates tended to occur in areas with small populations. The high instability of the observed rates, commonly known as the small area estimation problem, poses a special challenge in developing accurate prediction models, which our Bayesian spatiotemporal models helped address.

Results of the predictive performance among the proposed candidate models, using the one-year ahead approach, are presented in Table 1 (for the ZCTA-level fatal opioid-related overdose count) and Table 2 (for the ZCTA-level fatal opioid-related overdose rate). Prediction errors were summarized for all ZCTAs and stratified by rural and urban ZCTAs. Overall, model 3 with the inseparable spatiotemporal interaction term of $AR(1)$ and CAR structures performed best for fatal opioid-related overdose predictions, as indicated by smaller MAE and RMSE values. The RMSE showed that the predicted opioid-related death counts, on average, were off only by 2 counts per area. As expected, predictions were better for urban areas than for rural areas, since most of the deaths occurred in urban areas. Addition of demographic and socioeconomic variables generally improved the prediction performance, particularly for model 1; however, the improvement was attenuated in models 2 and 3 where we assumed inseparable spatiotemporal models. The smaller improvement in model 3 was likely because the CAR model already captured the spatial patterns tied to the demographic and socioeconomic factors and hence served as a surrogate of the demographic and socioeconomic variables for predictions. The best performing model using the rank difference showed a less clear pattern, as the values were very similar across the different models. This was particularly true when focusing on the rural ZCTAs, likely due to their small predicted rates or counts and hence very narrow ranges for each quintile.

Table 1. Predictive performance assessment of the ZIP Code Tabulation Area (ZCTA) level opioid-related overdose death count, using the root mean and rank difference, and one-year ahead prediction starting with 2016[a]. The smallest root mean square error, mean absolute difference, and highest rank difference for each row are depicted in italics, indicating the best performing models.

[a] For example, using data from 2005 to 2015, we predicted the fatal opioid-related overdose count in year 2016 for each of the 537 ZIP Code Tabulation Areas (ZCTAs) in Massachusetts, and compared them to the observed data to assess performance. Similarly, for 2017, we used data from 2006 to 2016, and predicted for 2017. The prediction error was assessed for counts for all ZCTAs and stratified by rural and urban status. Base model refers to Bayesian dynamic spatiotemporal models without any covariates; model results with added covariates of area-level contextual factors are included in the column “Add SDOH.”

[b] SDOH: Social determinants of health.

Since our 1-year prediction assessments suggested that the best performing model was model 3 with the included demographic and socioeconomic variables, we used this model for 2020 and 2021 predictions based on the opioid-related mortality data for 2005-2019. We assumed that ZCTA-level population size and demographic and socioeconomic variables had the same values in 2020 and 2021 as those in 2019. We carried out the prediction for each ZCTA and at the state level. Figure 1 presents the fitted temporal trends of opioid-related mortality in Massachusetts between 2005 and 2019, with predictions carried out for 2020 and 2021 (the gray shaded area), both as the rate per 100,000 population (panel A) and total counts (panel B). Each line represents an individual ZCTA, color-coded by urban or rural status. Figure 2 presents the maps of the predicted opioid-related mortality rates and counts for 2020 and 2021. At the ZCTA-level, the predicted opioid-related mortality rate ranged from 6.11 to 162 per 100,000 population for 2020, and 6.05 to 158 per 100,000 population in 2021. Note that because of the “smoothing” effect in Bayesian models, the estimated or predicted rate could be very close to 0 but would never be exactly 0. Therefore, for ZCTAs that may have zero observed deaths, the predicted rate would not be zero but would be skewed toward the average rate. In addition, any ZCTAs that may have low observed rates but were “surrounded” by ZCTAs with high rates would have higher predicted rates, reflecting how the spatial models borrow information from neighboring ZCTAs. Because of the large variation in population size by ZCTA, the spatial patterns seen in the maps in Figure 2 for predicted rate and counts are quite different, where the latter are generally centered around highly populated areas. The predicted count ranges from close to 0 (after rounding up to integers) to 30 (90% CrI 21-41) for 2020, and 29 (90% CrI 19-44) for 2021. We also identified the top 5 ZCTAs with the highest predicted counts, by urban or rural classifications, and presented the prediction results in Figure 3. The urban ZCTAs were located within cities with high fatal opioid-related overdose risks: Lawrence, Lynn, Quincy, Brockton, and New Bedford (Figure 3C). The rural ZCTAs were located in municipalities that were known to have high risks for fatal opioid-related overdoses, including Pittsfield, North Adams, Greenfield, Westfield, and Billerica (Figure 3D).

At the state level, the predicted opioid-related mortality rate for the population aged 20 years and older was 35.79 per 100,000 population (90% CrI 29.4-43.4) for 2020, and 35.81 (90% CrI 26.9-46.0) for 2021. For urban areas, the predicted rate was 36.0 (90% CrI 29.2-43.7) in 2020, and 35.5 (90% CrI 26.8-46.1) in 2021. For rural areas, the predicted rate was 33.9 (90% CrI 26.6-43.3) in 2020, and 34.6 (90% CrI 25.2-53.4) in 2021. The CrIs for the prediction were wider in 2021 than in 2020 and in rural areas than in urban areas. This was expected as the further ahead we attempted to predict outcomes, the less certainty we would have. Our prediction suggested that the opioid-related overdose death counts for 2020 would be 1887 (90% CrI 1549-2285) for the whole state, with 1682 (90% CrI 1364-2041) in urban ZCTAs, and 203 (90% CrI 160-260) in rural ZCTAs, and those for 2021 would be 1888 (90% CrI 1419-2426) for the whole state with 1656 (90% CrI 1253-2149) in urban ZCTAs, and 208 (90% CrI 151-320) in rural ZCTAs.

Table 2. Predictive performance assessment of the ZIP Code Tabulation Area (ZCTA) level opioid-related overdose death rate, using the root mean and rank difference, and one-year ahead prediction starting with 2016[a]. The smallest root mean square error, mean absolute difference, and highest rank difference for each row are depicted in italics, indicating the best performing models.

[a] For example, using data from 2005 to 2015, we predicted the fatal opioid-related overdose rate in 2016 for each of the 537 ZIP Code Tabulation Areas (ZCTAs) in Massachusetts, and compared the predicted rates to the observed rates to assess prediction performance. Similarly, for 2017, we used data from 2006 to 2016 and predicted for 2017. The prediction error was assessed for rates for all ZCTAs and stratified by rural and urban status. Base model refers to Bayesian dynamic spatiotemporal models without any covariates; model results with added covariates of area-level contextual factors are included in the column labeled "Add SDOH."

[b] SDOH: Social determinants of health.

Figure 1. Fitted temporal trends for opioid-related overdose (OD) mortality in Massachusetts between 2005 and 2019, with predictions for 2020 and 2021 (in gray shade). Each line represents a ZIP Code Tabulation Area (ZCTA) color-coded by its urban or rural status. Opioid-related mortality data were obtained from the Massachusetts Registry for Vital Records and Statistics, and predictions were made on the fatal opioid-related overdose rates per 100,000 population (panel A) and count (panel B). These results are from the Bayesian dynamic spatiotemporal Model 3 with ZCTA level demographic and socioeconomic variables.

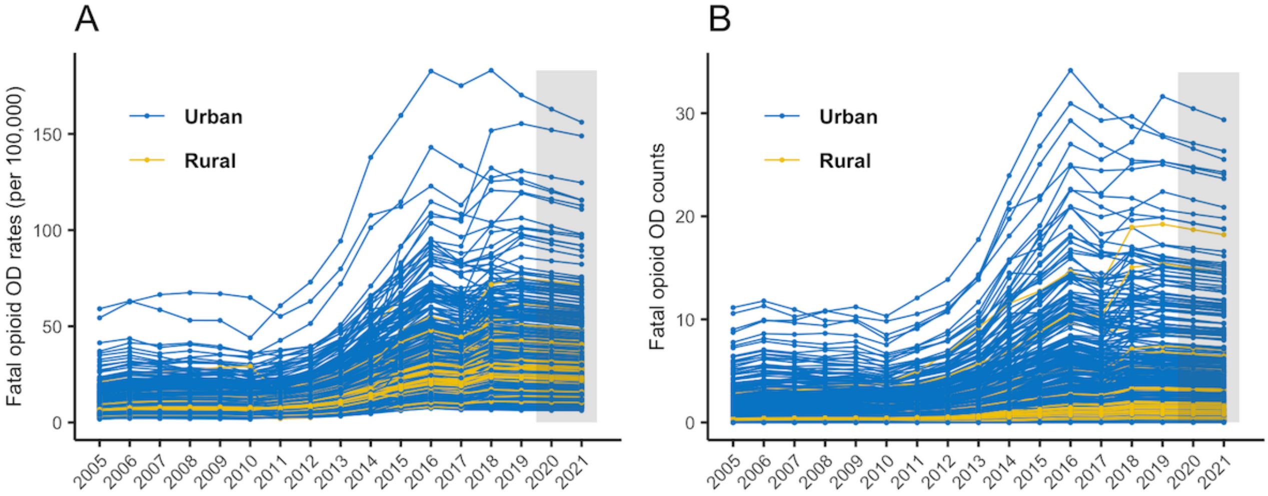

Figure 2. Maps of the predicted ZIP Code Tabulation Area (ZCTA)–level fatal opioid-related overdose (OD) rates (per 100,000 population) and counts for 2020 (A and B) and 2021 (C and D). Data were obtained from Massachusetts Registry for Vital Records and Statistics for 2005 to 2019 and used to predict for 2020 and 2021. These predictions were obtained from the proposed Bayesian dynamic spatiotemporal Model 3 with ZCTA level demographic and socioeconomic variables. In each panel, the embedded histograms present the distribution of the predicted fatal opioid-related overdose rates or counts for that year.

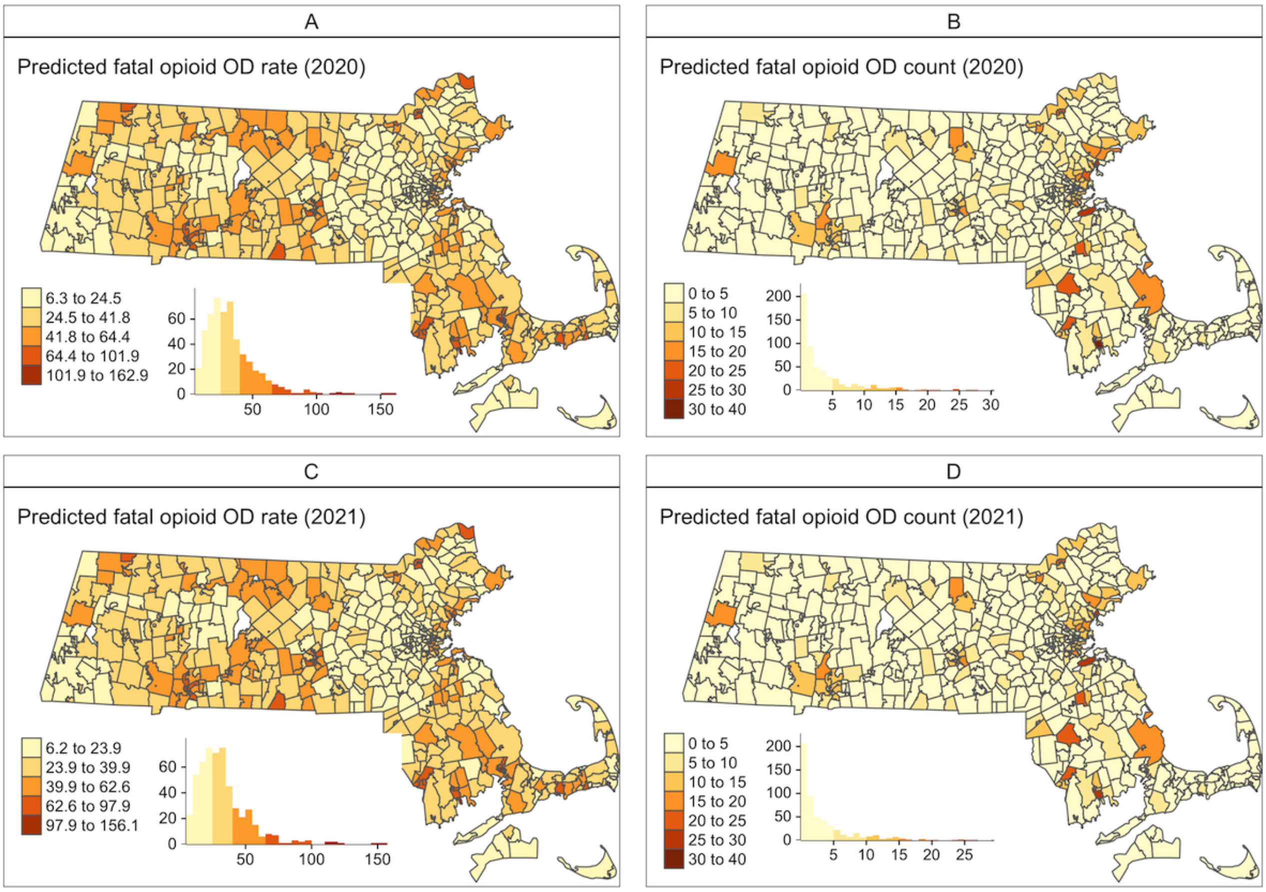

Figure 3. Five selected ZIP Code Tabulation Areas (ZCTAs) with the highest predicted fatal opioid-related overdose (OD) rates or counts for urban (A, C) and rural (B, D) areas. The vertical bars in panels A and B present the 90% posterior credible intervals (CrIs) of the predictions for years 2020 and 2021. Maps (C, D) present the corresponding locations of the identified ZCTAs. Predictions were performed using the proposed Bayesian dynamic spatiotemporal model 3 with ZCTA level demographic and socioeconomic variables and fatal opioid-related overdose data from 2005 to 2019 in Massachusetts.

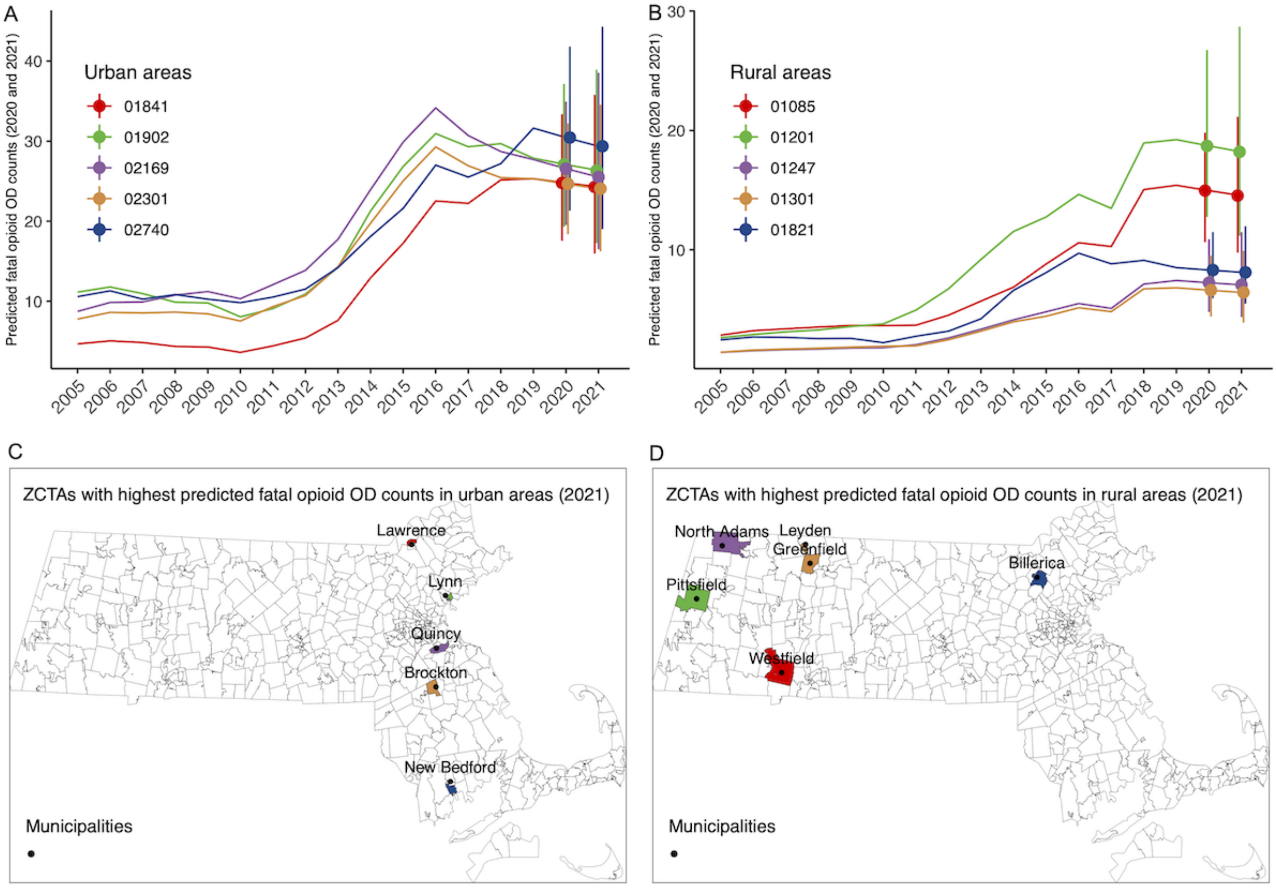

Discussion

In this analysis, we developed and compared several Bayesian spatiotemporal dynamic models for predicting small area opioid-related mortality. The prediction performance was evaluated with data from the MDPH RVRS for 2005 through 2019 using the one-year ahead approach, with and without ZCTA-level demographic and socioeconomic variables. Using data from 2005 through 2019 and the best performing model, we also predicted the fatal opioid-related death rates and counts for 2020 and 2021, respectively, along with uncertainty assessments. We also identified the ZCTAs—by urban and rural status—that had the highest predicted opioid-related mortality, both by rates and by counts.

Our prediction showed that, if there was no interruptive change to the trends observed for 2005-2019, we would observe a stabling trend of the fatal opioid-related overdose in Massachusetts for 2020 and 2021. The stabling trend would be applicable to the entire state (ie, the state-level total fatal opioid-related overdose) as well as for most ZCTAs in Massachusetts. Our prediction also identified the ZCTAs deviating from this stabilizing trend, with continually increasing rates above the state average. Identifying ZCTAs with the predicted high risks allows for the possibility of preemptive and geo-targeted public health interventions. The prediction models presented here allowed for a more granular depiction of existing and expected trends in opioid-related overdose deaths over spatially granular units, which differed from other existing models developed for predication at larger geographical scales (eg, state or county). Such predictions are instrumental for state and local public health departments' planning to identify and address potential service gaps for deploying harm reduction and treatment interventions. Local data are largely limited both in type and quantity; drug seizure data, for example, are often not available at more granular levels than the state, limiting input information in predictive modeling. However, up-to-date data at the local scale are instrumental to developing the prediction models and engaging communities in designing and implementing data-driven responses to reduce opioid-related harms [32].

At the time of this analysis, we only obtained the fatal opioid-related overdose data for Massachusetts from 2005 to 2019 and partial data in 2020 (incomplete data with only the first 6 months). We designed our analysis and prediction evaluation on the basis of the data available to us, but we lacked the official statistics for 2020 and 2021 to assess the prediction accuracy for those years. The latest Massachusetts opioid-related overdose data brief released in December 2022 [33] reported the confirmed opioid-related overdose deaths among Massachusetts residents for 2020 and 2021. Although the data brief reported the total number and rate including all ages, which was different from the adult population we focused on, it was clear that we underpredicted the total number of fatal opioid-related overdose in Massachusetts for 2020 and 2021. The data brief also noted a 9% increase in the opioid-related overdose death rate in Massachusetts for 2021 over 2020. However, since the brief only reported the total opioid overdose death counts at the state level and not by ZCTAs, we were not able to assess the underprediction at a more granular spatial level. The sharp increase in the fatal opioid-related overdose was likely due to the substantive impact of the COVID-19 pandemic [8,34], which disrupted any established trends prior to 2020 that informed our prediction modeling. The time lag in the drug overdose database had been identified as a main barrier to developing fatal overdose predictive models, as reported by Borquez and Martin [35]. Our future work, in collaboration with the MDPH, plans to use the statewide Public Health Data warehouse [36] to obtain timelier and rich data sources with local information in order to improve predictive performance in small areas.

It is important to consider the limitations inherent in the highlighted analyses, and recommendations that should be considered when developing future opioid-related overdose prediction models. First, the spatial units of ZCTAs used in our study may not be the ideal spatial unit for prediction, as the population size within ZCTAs vary substantially, compared to other spatial units of analysis (eg, census tracts) where, by design, the population sizes are much more homogenous. In addition, ZCTAs may not be sufficiently granular, from a spatial perspective, to identify local hot spots. However, they are extensively used in spatial analysis as they are most readily available in many aggregated data sources (eg, surveillance or insurance claims databases). ZCTAs provide useful geospatial information for analyses while often also satisfying data privacy concerns. Second, a better understanding of the contributing factors to local opioid overdose trends and patterns, with reliable measures representing such factors, would clearly improve prediction power and accuracy. For example, toxicology data would have helped us to include the appearance of fentanyl in the local drug supply, to aid the prediction in the shifting “waves” in opioid-related fatal overdose [37]. Third, we used the ZCTA of the decedents’ residences, rather than the injury addresses or the locations where the fatal opioid overdoses were recorded. Injury data generally have a high level of missingness (~50% in MA), and the recorded death location, if not at the decedent’s place of residence, is often recorded at a hospital, even though the injury (ie, overdose event) typically occurred elsewhere. Finally, and perhaps most challenging, is to incorporate the impact of emerging phenomena such as the COVID-19 pandemic into predictions of opioid-related overdose trends, which was not possible for our analyses given the data availability at the time of analyses. This task requires the real-time data inputs and requires a joint effort among researchers and practitioners from multiple agencies, institutions, and sectors. We have seen a lot of progress made on this front during the COVID-19 pandemic, and we hope to see more progress in the drug overdose research in the future.

Despite the abovementioned data source and methodological limitations, our models showed promise in providing reasonable 1-year forecasts of opioid-related mortality in MA with geographic granularity using existing data, as the short-term point estimates for the number of overdoses tended to be close to the true value. Our Bayesian spatiotemporal models further demonstrated the advantages of incorporating inseparable spatiotemporal dependencies over the simpler regression models without such dependence. Since the assumed spatial dependency structure captured the spatial patterns tied to many demographic and socioeconomic factors, such models do not rely on the knowledge of the future measures of these factors in predicting opioid-related mortality. Prediction is a challenging problem in general, and though many models have been developed in various contexts, it is almost impossible to find one single model or approach that universally performs best [38]. Although our analysis could not investigate all possible predictive models for fatal opioid-related overdoses, we provided a novel approach to forecasting overdose events for small geographic areas. Compared to other predictive approaches, Bayesian models provide a natural framework where the prediction can be conveniently included in the model fitting process, by treating predictions as missing values. Our findings demonstrated the utility of sophisticated Bayesian spatiotemporal dynamic models in supporting state and local opioid surveillance and the ability to provide prediction at a granular geographic level, offering a unique opportunity for preemptive public health and policy interventions, replacing reactionary public health responses. Echoing Borquez and Martin [35], we encourage the field to consider a modeling consortium for opioid-related prediction models, where different modeling techniques could be ensembled.

Acknowledgments

This research was partially supported by funding from the Centers for Disease Control and Prevention (Assessing High Risk Opioid Prescribers and Fatal and Non-Fatal Opioid Overdose grant INTF7311HH2 500224100 awarded to the principal investigator TJS), and the National Institute Drug Abuse (grant R01DA054267 awarded to CB and TJS).

Authors' Contributions

CB and TJS conceived and designed the analysis. TJS contributed to the acquisition of the data. CB and KZ contributed to data processing and curation, conducted the data analysis, and drafted the initial manuscript. WL, MRL, DB, and TJS contributed to critical revision of the manuscript. All authors contributed to the interpretation of the findings, and reviewed and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Nasopharyngeal cancer (NPC) is one of the most common head and neck cancers.

Objective: This study describes the global epidemiological profiles of NPC incidence and mortality in 185 countries in 2020 and the projected burden in 2040.

Methods: The estimated numbers of NPC cases and deaths were retrieved from the GLOBOCAN 2020 data set. Age-standardized incidence rates (ASIRs) and age-standardized mortality rates (ASMRs) were calculated using the world standard. The future number of NPC cases and deaths by 2040 were estimated based on global demographic projections.

Results: Globally, approximately 133,354 cases and 80,008 deaths from NPC were estimated in 2020 corresponding to ASIRs and ASMRs of 1.5 and 0.9 per 100,000 person-years, respectively. The largest numbers of both global cases and deaths from NPC occurred in Eastern Asia (65,866/133,354, 49.39% and 36,453/80,008, 45.56%, respectively), in which China contributed most to this burden (62,444/133,354, 46.82% and 34,810/80,008, 43.50%, respectively). The ASIRs and ASMRs in men were approximately 3-fold higher than those in women. Incidence rates varied across world regions, with the highest ASIRs for both men and women detected in South-Eastern Asia (7.7 and 2.5 per 100,000 person-years, respectively) and Eastern Asia (3.9 and 1.5 per 100,000 person-years, respectively). The highest ASMRs for both men and women were found in South-Eastern Asia (5.4 and 1.5 per 100,000 person-years, respectively). By 2040, the annual number of cases and deaths will increase to 179,476 (46,122/133,354, a 34.58% increase from the year 2020) and 113,851 (33,843/80,008, a 42.29% increase), respectively.

Conclusions: Disparities in NPC incidence and mortality persist worldwide. Our study highlights the urgent need to develop and accelerate NPC control initiatives to tackle the NPC burden in certain regions and countries (eg, South-Eastern Asia, China).

KEYWORDS

nasopharyngeal cancer; incidence; mortality; epidemiology; worldwide

Introduction

Background

Nasopharyngeal cancer (NPC) is an epithelial carcinoma that arises from the mucosal lining of the nasopharynx. NPC is one of the most common head and neck cancers and is characterized by remarkable geographic variation. Historically, NPC incidence rates were less than 1 per 100,000 person-years in most parts of the world, but they have been higher than 20 per 100,000 person-years in South-Eastern Asia and Southern China in the past decades [1-3]. In contrast, NPC incidence and mortality rates in most countries worldwide have significantly decreased over the past decades [4,5]. Notably, NPC is usually diagnosed in advanced stages and has a very poor prognosis [6]. For example, the 5-year net survival is estimated to be 47% in China [7].

Risk Factors Associated With NPC Occurrence

NPC is a largely preventable disease due to its many modifiable risk factors. The major etiological factors for NPC include Epstein-Barr virus (EBV) infection, tobacco smoking, intake of salted fish and other salt-preserved food, and occupational exposure to wood dust [8]. EBV infection has been consistently identified as an important risk factor, with a dose-response relationship between EBV antibody level and NPC risk [9,10]. The population attributable fraction for NPC incidence due to EBV infection has been estimated to be 85% [11]. Compared with people who never smoke, people who formerly smoked have a 60% greater risk of developing NPC [12]. The relative risk of NPC associated with weekly consumption of Chinese-style salt-preserved fish ranges from 1.1 to 4, whereas that associated with daily consumption ranges from 1.8 to 20 compared with no or rare consumption [13,14]. Occupational exposure to wood dust is estimated to be associated with a 50% increased risk of NPC [15].

Research Significance and Objective

Given the strong association of NPC with its modifiable risk factors and the changing epidemiological profile due to trends in NPC incidence and mortality, understanding the current epidemiological profile of international variations in NPC incidence and mortality is essential. This would allow public health policy makers to make evidence-based decisions for primary prevention and optimize the allocation of resources to reduce the global burden of NPC. Considering the growing and aging global population, predicting the future NPC burden is vital for better planning of future cancer control programs. We therefore examined the geographic variations in NPC incidence and mortality across world regions and countries worldwide based on the GLOBOCAN estimates for the year 2020 and predict the future NPC burden up to 2040 based on demographic projections.

Methods

Data Sources

The numbers of new cases of and deaths from NPC (International Classification of Diseases, tenth revision C11) were extracted from the GLOBOCAN 2020 database for 185 countries or territories by sex and by 5-year age groups (0-4, 5-9, …, 80-84, 85 years and older) [16-18]. Corresponding population data for 2020 were retrieved from the United Nations website [19]. The population projections used in this study are based on the future fertility rates [19]. The data sources and methods used in compiling the global cancer estimates for 2020 have been described in detail elsewhere [17]. Briefly, the GLOBOCAN national estimates are dependent on the availability of recorded high-quality national and subnational incidence (from population-based cancer registries) and national mortality data (from vital registration systems) [17]. Nine methods were employed depending on the best available data on cancer-specific incidence or mortality data [17]. The hierarchical set of methods includes utilization of short-term and long-term prediction models based on historical observed data, estimated incidence, mortality based on modelled survival, approximation using observed data at the subnational level, or data from neighboring countries [17]. In countries where national mortality data were available but national or subnational cancer registries were not, national incidence estimation relied on national mortality estimates and modelling of the mortality to incidence ratio from neighboring countries [17]. In countries where neither mortality nor incidence data were available, incidence and mortality estimates were based on mortality or incidence data of neighboring countries [17]. Thus, the validity of national cancer incidence and mortality estimates is dependent on the degree of representativeness and the quality of the source information [17]. The methods used to derive the 2020 estimates correspond to those used previously for 2018, 2012, and 2008 [20-22].

Statistical Analysis

We present tables and figures of the estimated new cases and deaths as well as 2 summary measures by using direct standardization, namely, the age-standardized incidence rates (ASIRs) and age-standardized mortality rates (ASMRs) per 100,000 person-years based on the 1966 Segi–Doll World standard population [23,24] and the cumulative risk of being diagnosed with or dying from NPC before the age of 75 years, assuming the absence of competing causes of death [25]. We predicted the future number of NPC cases and deaths worldwide by the United Nation’s 4-tier Human Development Index (HDI), where HDI was used to assess the cancer burden at varying levels of development (low, medium, high, and very high HDI) [26] and in China up to the year 2040 based on demographic projections and scenarios of annually increasing (+1%, +2%, +3%, +4%), stable (0%), or decreasing (–1%, –2%, –3%, –4%) rates from the baseline year of 2020. We did not use scenarios of rates changing by SD 5% or more because such changes would be unlikely to occur in real life [4,5]. Predictions were calculated by applying the age-specific rates for the year 2020 (and each of the increasing or decreasing scenarios described) to the corresponding projected population data as estimated by the United Nations Development Program. The results are presented by country and aggregated across 20 United Nations–defined world regions [19] and according to the HDI group in 2020. Data management and analyses were performed in R software (version 4.0.2; R Foundation for Statistical

Computing) [27]. Figures were plotted using SigmaPlot software (version 12.5; Systat Software Inc) [28]. Global maps of NPC incidence and mortality rates by country are shown using R software (version 4.0.2; R Foundation for Statistical Computing) [27].

Ethical Considerations

This study does not involve human participants and animals. Ethics approval was not required for this study, as this study used existing nonidentifiable data that were aggregated at the population level.

Results

Global Burden of NPC Incidence and Mortality

In 2020, an estimated 133,354 people were diagnosed with NPC worldwide, corresponding to an ASIR of 1.5 per 100,000 person-years (Table 1). More men (96,371 cases) than women (36,983 cases) were diagnosed with NPC, and the ASIRs in men were approximately 3-fold higher than those in women (2.2 vs 0.8 per 100,000 person-years, respectively) (Multimedia Appendix 1). Globally, an estimated 80,008 people died from NPC, corresponding to an ASMR of 0.9 per 100,000 person-years (Table 1). Mortality in men was also higher than that in women, with 58,094 and 21,914 deaths, corresponding to ASMRs of 1.3 and 0.5 per 100,000 person-years, respectively (Multimedia Appendix 1). In addition, the cumulative risk of being diagnosed with and dying from NPC before the age of 75 years was 1 in 476 (0.21%) and 1 in 667 (0.15%), respectively (Table 1).

[a] ASIR: age-standardized incidence rate per 100,000 person-years.

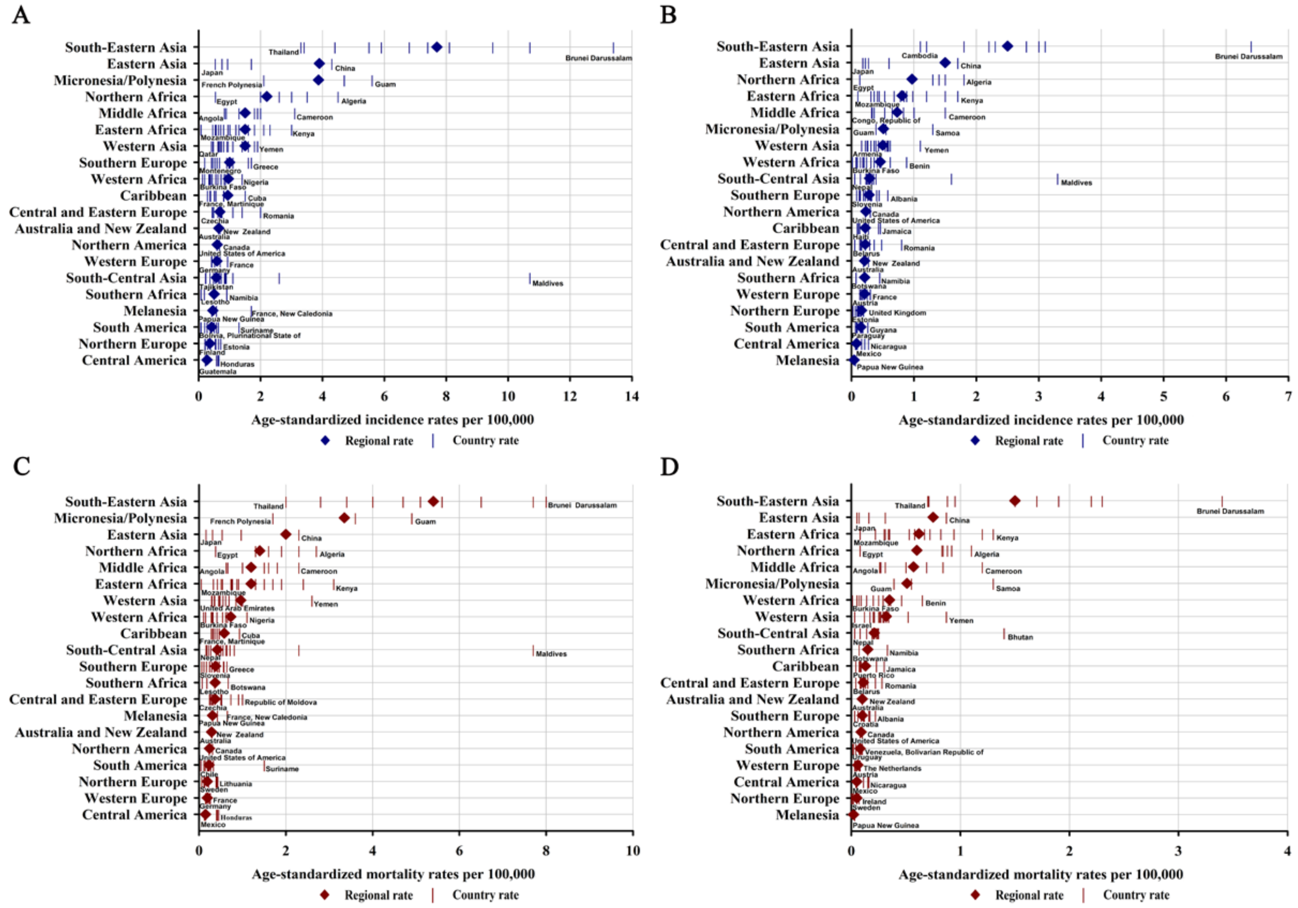
[b] Cumulative risk of being diagnosed with or dying from nasopharyngeal cancer before the age of 75 years in 2020.

[c] ASMR: age-standardized mortality rate per 100,000 person-years.

Geographical Variations in NPC Incidence and Mortality by World Region

The largest numbers of cases and deaths from NPC in both sexes combined were estimated in Eastern Asia (65,866/133,354, 49.39% of total NPC cases and 36,453/80,008, 45.56% of total NPC deaths), followed by South-Eastern Asia (36,747/133,354, 27.55% and 24,219/80,008, 30.15%, respectively) and South-Central Asia (8366/133,354, 6.27% and 6117/80,008, 7.64%, respectively) (Multimedia Appendix 2). A male predominance in NPC cases and deaths was consistent across all world regions (Multimedia Appendix 1). The incidence rates of NPC showed approximately 29-fold variation in men and 63-fold variation in women across world regions (Figure 1A, Figure 1B, and Multimedia Appendix 1). In men, the ASIR per 100,000 person-years was the highest in South-Eastern Asia (7.7), followed by Eastern Asia (3.9) and Micronesia/Polynesia (3.9), but the lowest ASIR was in Central America (0.3). In women, the highest ASIR per 100,000 person-years was detected in South-Eastern Asia (2.5), followed by Eastern Asia (1.5), and Northern Africa (1.0), and the lowest was found in Melanesia (less than 0.1). The mortality rates of NPC varied approximately by 36-fold in men and 75-fold in women among world regions (Figure 1C, Figure 1D, and Multimedia Appendix 1). In men, the highest ASMR per 100,000 person-years was detected in South-Eastern Asia (5.4), followed by Micronesia/Polynesia (3.4) and Eastern Asia (2.0), and the lowest was observed in Central America (0.2). In women, the highest ASMR per 100,000 person-years was found in South-Eastern Asia (1.5), followed by Eastern Asia (0.8) and Eastern Africa (0.6), and the lowest was seen in Melanesia (<0.1). Sex-related disparities were also noted, with NPC ASIRs and ASMRs higher in men than in women across world regions. For example, the male-to-female ASIR and ASMR ratios ranged from 1.9 and 1.9 in Eastern Africa to 11.5 and 15.5 in Melanesia, respectively.

Figure 1. Age-standardized rates per 100,000 person-years of nasopharyngeal cancer incidence in (A) men and (B) women and mortality in (C) men and (D) women, which are ordered according to descending incidence rates by world region. Countries with zero cases are not shown in this figure.

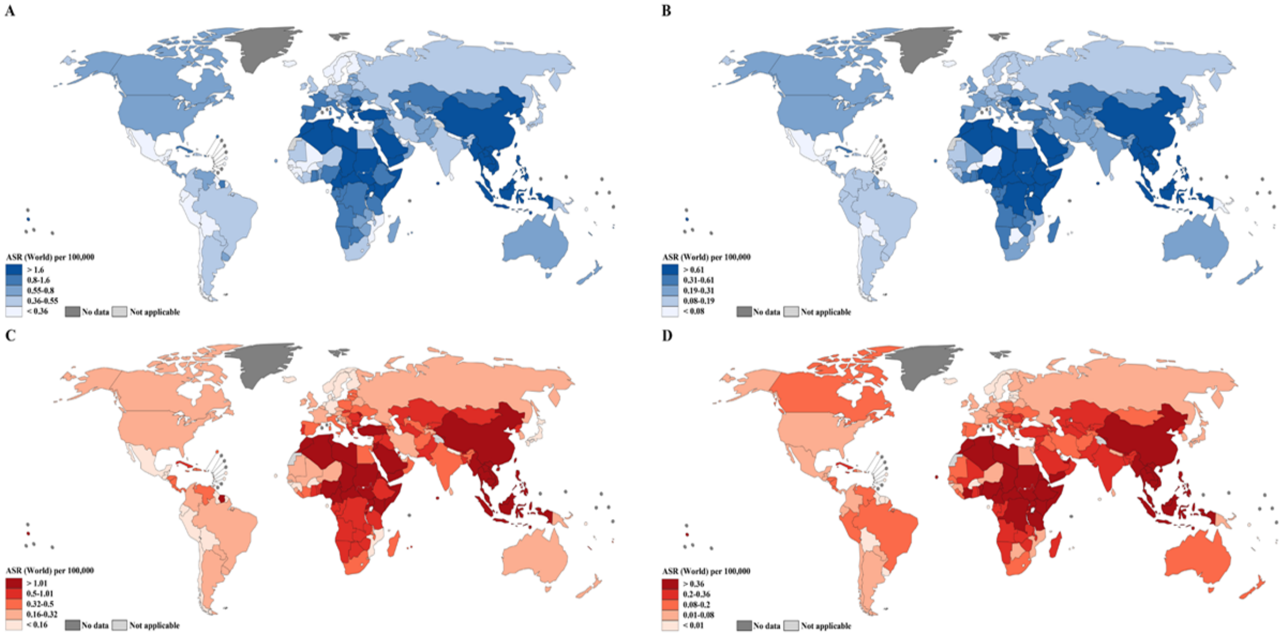


Geographical Variations in NPC Incidence and Mortality by Country

At the national level, China (62,444/133,354, 46.82% of global NPC cases; 34,810/80,008, 43.50% of global NPC deaths) was the greatest contributor to the global NPC burden due to its large population (1,447,470,000/7,794,799,000, 18.56% of the global population) and high incidence and mortality rates (ASIR, 3.0 per 100,000 person-years; ASMR, 1.6 per 100,000 person-years) (Table 1). In terms of incidence rates, the highest ASIR per 100,000 person-years occurred in Brunei Darussalam (13.4), followed by Maldives (10.7) and Indonesia (10.7), in men and in Brunei Darussalam (6.4), followed by Maldives (3.3) and Malaysia (3.1), in women (Figure 1A, Figure 1B, Figure 2A, and Figure 2B). Notably, the incidence rates varied markedly within world regions. For example, in the high-risk region South-Eastern Asia, the ASIRs ranged from 3.3 per 100,000 person-years in Thailand to 13.4 per 100,000 person-years in Brunei Darussalam (high-to-low ASIR ratio = 4.1) in men and from 1.1 in Cambodia to 6.4 in Brunei

Darussalam (high-to-low ASIR ratio = 5.8) in women (Figure 1A and Figure 1B). In terms of mortality rates, the highest ASMR per 100,000 person-years in men was found in Brunei Darussalam (8.0), followed by Maldives (7.7) and Indonesia (7.7), and the highest ASMR per 100,000 person-years in women was found in Brunei Darussalam (3.4), followed by Timor-Leste (2.3) and Lao People's Democratic Republic (2.2) (Figure 1C, Figure 1D, Figure 2C, and Figure 2D). Considerable variations in NPC mortality were also evident within world regions. For example, in South-Eastern Asia, the ASMRs per 100,000 person-years ranged from 2.0 in Thailand to 8.0 in Brunei Darussalam (high-to-low ASMR ratio = 4.0) in men and from 0.7 in Thailand to 3.4 in Brunei Darussalam (high-to-low ASMR ratio = 4.9) in women (Figure 1C and Figure 1D).

Figure 2. Global map of age-standardized rates of nasopharyngeal cancer incidence in (A) men and (B) women and mortality in (C) men and (D) women per 100,000 person-years by country. ASR: age-standardized rate.



NPC Incidence and Mortality by Level of Human Development

By HDI group, the vast majority of NPC cases and deaths occurred among 37.32% (2,909,468,000/7,794,799,000) of the world population living in high HDI countries, representing 69.85% (93,153/133,354) of new cases and 68.55% (54,850/80,008) of deaths globally (Table 1). Both ASIRs and ASMRs were the highest in high HDI countries, with the rates being 2.5 and 1.4 per 100,000 person-years, respectively. Notably, both the lowest ASIRs and ASMRs were observed in very high HDI countries. The ASIRs and ASMRs in low HDI countries were similar to those in medium HDI countries.

Predicted Number and Percentage Increase of Cases and Deaths From NPC

Worldwide, an estimated 179,476 new NPC cases are projected to occur in 2040—an increase of approximately 34.58% (46,122/133,354)—compared with 133,354 cases in 2020, assuming that global incidence rates in 2020 remain stable (Figure 3A). Moreover, a 2% annual increase in incidence rates from 2020 would more than double the total annual NPC cases by 2040 (Figure 3A). Notably, it would require a 2% annual decrease in mortality rates to ensure that there would be fewer NPC cases in 2040 (119,710 cases) than there were in 2020 (133,354 cases). In terms of mortality, NPC deaths were estimated to increase by approximately 42.29% (33,843/80,008), from 80,008 in 2020 to 113,851 in 2040, assuming that mortality rates in 2020 remained unchanged (Figure 3B). An annual decline of 2% in mortality rates would be required to achieve fewer NPC deaths in 2040 compared to the estimated deaths in 2020 (Figure 3B). By HDI group, the largest absolute increase in NPC cases and deaths is estimated to occur in high HDI countries, with 26.7% (24,874/93,153) more cases (24,874 additional cases) and 40.15% (22,024/54,850) more deaths (22,024 additional deaths) per year by 2040 (Multimedia Appendix 3), assuming that incidence and mortality rates in 2020 remain constant, reflecting the already high rates in high HDI countries and its large population, which will continue to grow. However, the greatest relative increases in cases and deaths will occur in low HDI countries (5181/5722, 90.54% and 3808/3996, 95.29% increase, respectively) (Multimedia Appendix 3). Notably, decreases in both incidence and mortality rates would need to be greater than 4%, 3%, 2%, and 1% to retain the predicted NPC burden in 2040 at the level observed in 2020 for low, medium, high, and very high HDI countries, respectively (Figures 4-5).

Figure 3. Predicted number of (A) new cases and (B) deaths from nasopharyngeal cancer, assuming 9 scenarios of annual change in global rates between 2020 and 2040, both sexes combined. Nine scenarios include annually increasing (+1%, +2%, +3%, +4%), stable (0%), and decreasing (–1%, –2%, –3%, –4%) rates from the baseline year of 2020.

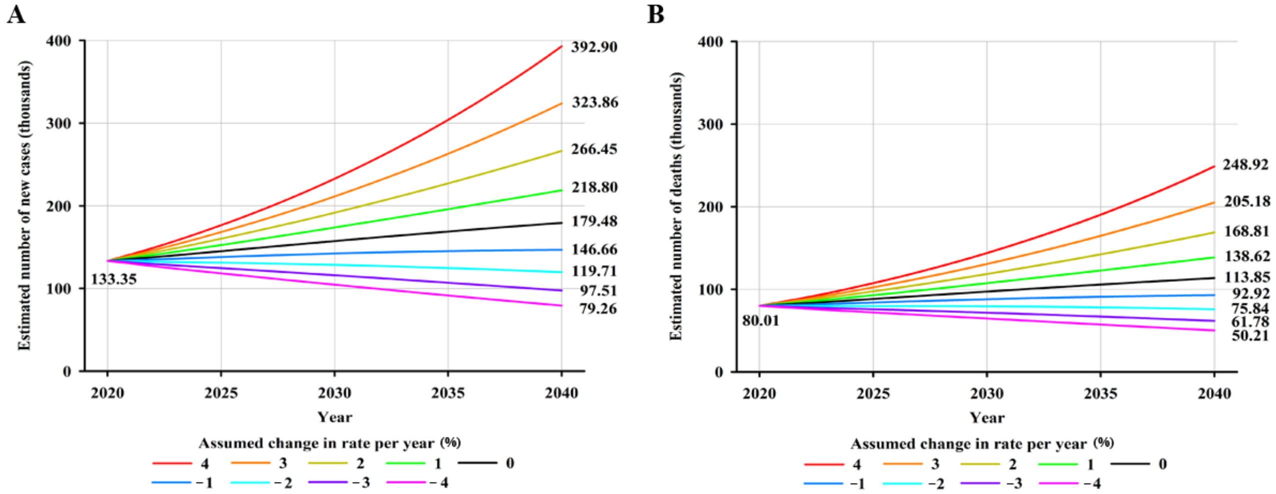


Figure 4. Predicted number of new nasopharyngeal cancer cases, assuming 9 scenarios of annual change in rates between 2020 and 2040, in (A) countries with very high human development index, (B) countries with high human development index, (C) countries with medium human development index, and (D) countries with low human development index, both sexes combined. Nine scenarios consist of annually increasing (+1%, +2%, +3%, +4%), stable (0%), and decreasing (–1%, –2%, –3%, –4%) rates from the baseline year of 2020.

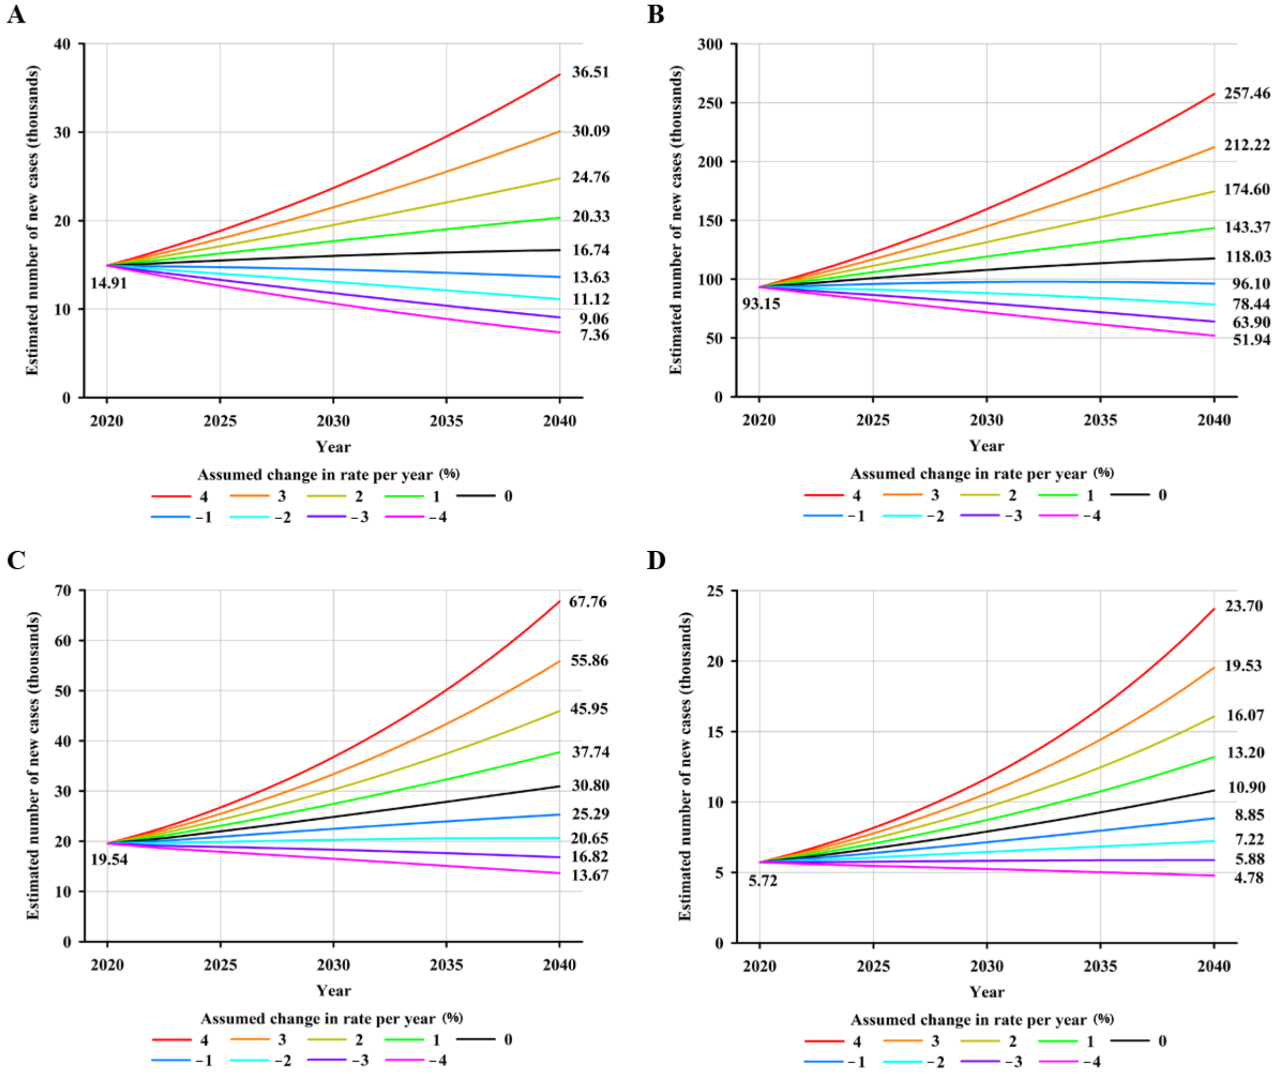

Figure 5. Predicted number of deaths from nasopharyngeal cancer assuming 9 scenarios of annual change in rates between 2020 and 2040 in (A) countries with very high human development index, (B) countries with high human development index, (C) countries with medium human development index, and (D) countries with low human development index, both sexes combined. Nine scenarios consist of annually increasing (+1%, +2%, +3%, +4%), stable (0%), and decreasing (–1%, –2%, –3%, –4%) rates from the baseline year of 2020.

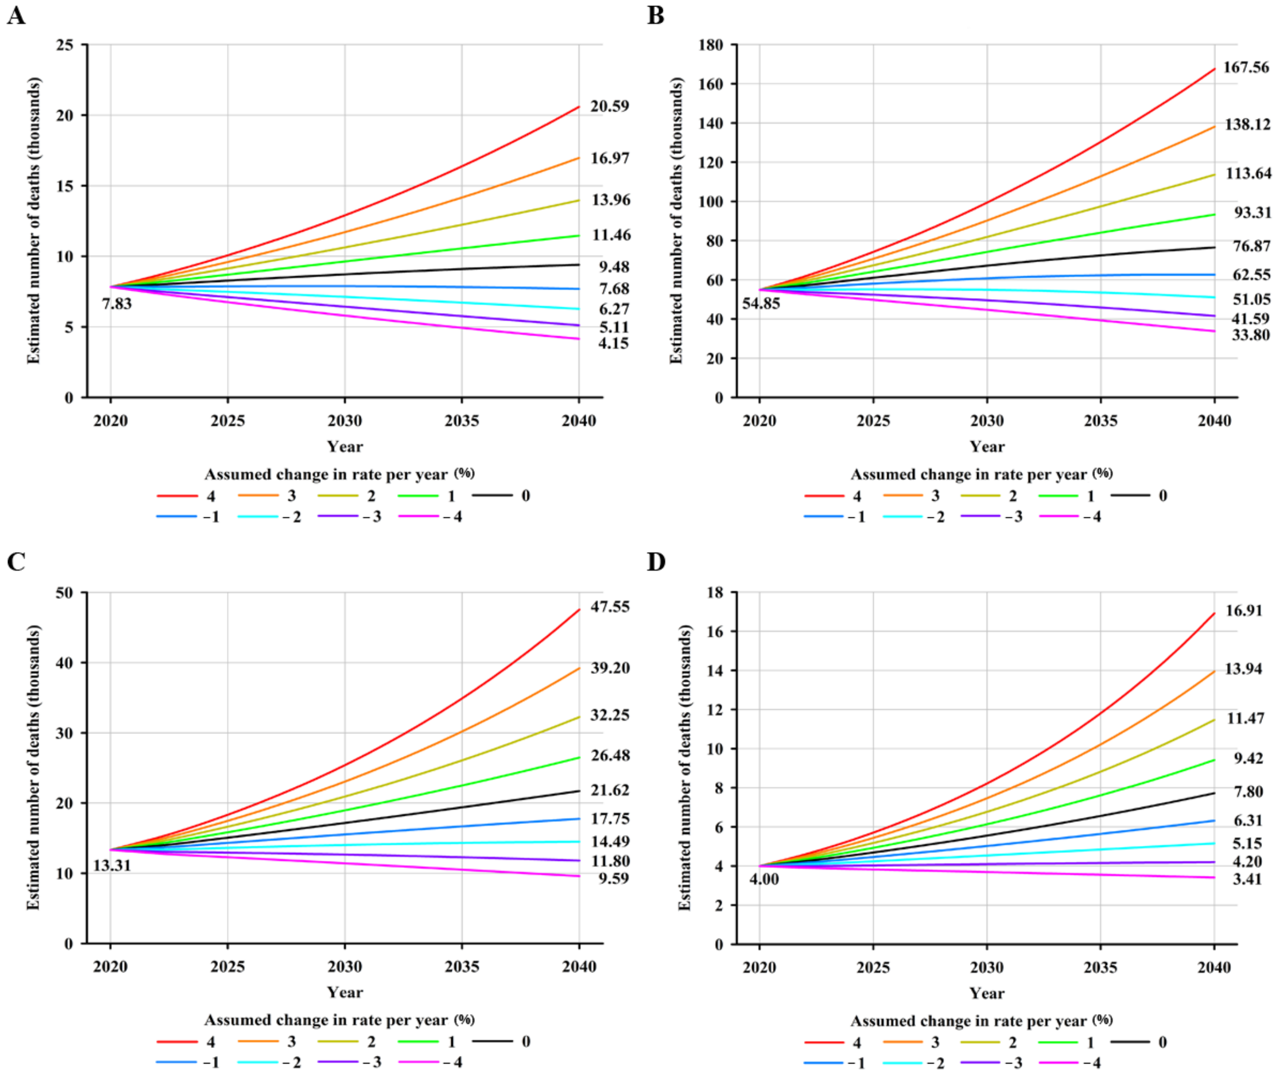
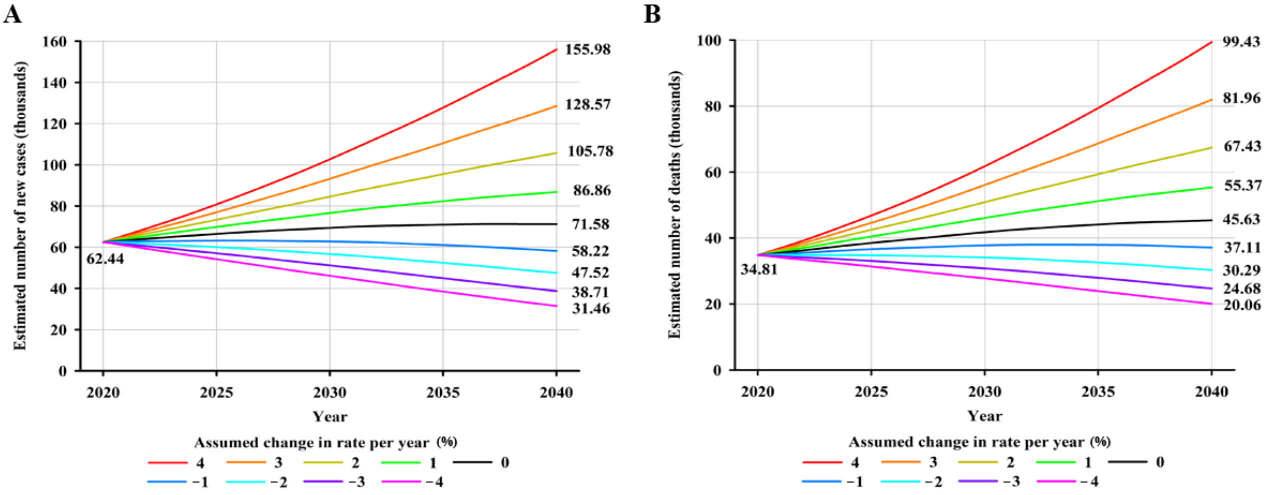


In China, the number of NPC cases was estimated to increase by approximately 13.99% (8742/62,444), from 62,444 in 2020 to 71,186 in 2040, assuming that incidence rates in 2020 remained stable (Figure 6A). Similarly, NPC deaths are set to increase by close to 30.35% (10,568/34,810) based on demographic changes alone, from 34,810 in 2020 to 45,378 in 2040 (Figure 6B). As an illustration, it would take greater than 1% and 2% decline in the annual incidence and mortality rate from 2020 to 2040 to achieve fewer cases and deaths in 2040 compared to the level seen in 2020, respectively.

Figure 6. Predicted number of (A) new cases and (B) deaths from nasopharyngeal cancer assuming 9 scenarios of annual change in rates between 2020 and 2040 in China (both sexes combined). Nine scenarios consist of annually increasing (+1%, +2%, +3%, +4%), stable (0%), and decreasing (–1%, –2%, –3%, –4%) rates from the baseline year of 2020.



Discussion

Principal Findings

Globally, approximately 133,354 new NPC cases were reported and 80,008 deaths occurred in 2020 [16-19]. The largest numbers of cases and deaths of NPC were estimated in Eastern Asia, in which China contributed most to this burden [29]. NPC incidence and mortality rates in men were substantially higher than those in women across all world regions. The highest incidence rates for both men and women were detected in South-Eastern Asia and Eastern Asia, and the mortality rates for both men and women were the highest in South-Eastern Asia. The number of cases and deaths from NPC will increase by more than 35% over the next 20 years worldwide due to population growth and aging alone, with annual NPC cases and deaths expected to almost double in low HDI countries by 2040 [26].

Interpretation of the Disparities of NPC Burden by Geography and by Gender

The changing epidemiological profile and the disparities of NPC burden by geography and by gender might be largely associated with differences in the prevalence of its risk factors and improvement of diagnostic and treatment techniques. Previous studies have shown that NPC incidence and mortality rates have significantly decreased in most European, Northern American, and Eastern and South-Eastern Asian countries over the past decades [4,5]. The declining trends in NPC incidence rates in Europe and Northern America might be related to decreased tobacco smoking prevalence, and the declines in NPC incidence rates in Eastern and South-Eastern Asia might be explained by the decreased intake of salted fish and preserved food [4], while decreases in mortality rates might also be the result of advances in diagnostic (eg, diagnostic imaging accuracy) and radiotherapy techniques (eg, the introduction of intensity-modulated radiation therapy) [5]. In particular, the reduction of NPC burden in China is partly due to the implementation of EBV screening for early detection of NPC since the 1970s [29].

The relatively higher NPC burden in Eastern and South-Eastern Asian countries could be largely related to the high prevalence of EBV infection [30]. In addition, 316 million adults are estimated to smoke in China, who account for nearly one-third of the Chinese who smoke and contribute to 40% of the tobacco consumption worldwide [31]. The higher NPC burden in China could therefore be partly explained by its large tobacco consumption and production. The relatively larger consumption of salt-preserved foods in most Eastern and South-Eastern Asian and Northern African countries might also explain part of the remarkable international variations of NPC burden [2]. The elevated NPC burden observed in men compared with that observed in women across all regions can be partly explained by the higher smoking prevalence and occupational exposure to carcinogens [32,33]. In addition, the decreased NPC burden in women could be related to the potentially protective effect of endogenous estrogens [33,34]. Of note, genetics might also play an important role in the pathogenesis of NPC. Previous studies showed that NPC incidence in Southern China is about 20-50 times higher than that in western countries [1-3]. Despite immigration of second- and third-generation Chinese people to western countries, they are still at a higher risk for NPC, thereby demonstrating a sustained risk for NPC even after changing environments [35,36].

Interpretation of the Projected Number of Cases and Deaths From NPC

Our findings show that the projected number of cases and deaths from NPC are expected to increase to 179,476 and 113,851 by 2040 worldwide, respectively, as a result of population growth and aging alone. A 2% annual decrease in global incidence and mortality rates would be needed to halt the increasing NPC burden by 2040. Notably, our findings show that even larger decreases in incidence and mortality rates would be required to reduce the future NPC burden in low and medium HDI countries. Considering these changes, the reallocation of resources for NPC primary prevention programs aimed at reducing population levels of EBV infection, tobacco smoking, intake of salted fish and other salt-preserved food, and occupational exposure to NPC carcinogens in certain regions and countries and the increased access to early detection modalities (eg, NPC screening) and health care services for high-risk populations identified by our study are crucial for reducing the global NPC burden.

Comparison With Prior Work

To the best of our knowledge, this study is the first to provide a comprehensive picture of the most up-to-date epidemiological profile of NPC incidence and mortality on a global scale based on the GLOBOCAN 2020 data set, which is highly relevant for cancer control and clinical practice. The numbers and rates of NPC presented in this study are estimates based on the best available data (reviewed for their completeness, coverage, and accuracy) from population-based cancer registries.

Limitations

There are several limitations in this study. First, although our findings are based on the best available and high-quality data, caution is warranted when interpreting the findings for countries with limited coverage from population-based cancer registries and where proxy data were used to obtain national estimates [17]. Second, the GLOBOCAN estimates did not account for the impact of the COVID-19 pandemic on cancer diagnoses because the GLOBOCAN estimates were based on extrapolations of previous years of cancer data [17]. Third, the projections of the future burden of NPC in 2040 considered neither the recent changes in NPC incidence and mortality rates nor the heterogeneity in NPC incidence and mortality trends among countries. Thus, the predictions in our study likely represent an overestimate of the future NPC burden, given the declining trends of NPC incidence and mortality rates in recent decades worldwide [4,5] and should be interpreted with caution. Finally, we could not distinguish the required changes in the modifiable risk factors and their corresponding effects on predicted NPC incidence and mortality rates, which suggests the need for further studies to clarify the impact of changes in exposure to modifiable risk factors on the burden of NPC.

Conclusions

NPC remains a considerable public health challenge worldwide. NPC incidence and mortality vary markedly across world regions and countries and between men and women, and this variation is likely related to differences in EBV infection, tobacco smoking, intake of salted fish and other salt-preserved food, and occupational exposure to NPC carcinogens. Given the remarkable geographic disparity of NPC burden across world regions and countries, this study highlights the urgent need to formulate more effective primary NPC prevention strategies and prioritize allocation of NPC prevention and treatment resources for high-risk populations to tackle the NPC burden in certain regions and countries.

Abstract

Background: Accurate estimation of incidence and prevalence is vital for preventing and controlling diabetes. Administrative data (including insurance data) could be a good source to estimate the incidence of diabetes. However, how to determine the look-back period (LP) to remove cases with preceding records remains a problem for administrative data. A short LP will cause overestimation of incidence, whereas a long LP will limit the usefulness of a database. Therefore, it is necessary to determine the optimal LP length for identifying incident cases in administrative data.

Objective: This study aims to offer different methods to identify the optimal LP for diabetes by using medical insurance data from the Chinese population with reference to other diseases in the administrative data.

Methods: Data from the insurance database of the city of Weifang, China from between January 2016 and December 2020 were used. To identify the incident cases in 2020, we removed prevalent patients with preceding records of diabetes between 2016 and 2019 (ie, a 4-year LP). Using this 4-year LP as a reference, consistency examination indexes (CEIs), including positive predictive values, the κ coefficient, and overestimation rate, were calculated to determine the level of agreement between different LPs and an LP of 4 years (the longest LP). Moreover, we constructed a retrograde survival function, in which survival (ie, incident cases) means not having a preceding record at the given time and the survival time is the difference between the date of the last record in 2020 and the most recent previous record in the LP. Based on the survival outcome and survival time, we established the survival function and survival hazard function. When the survival probability, S(t), remains stable, and survival hazard converges to zero, we obtain the optimal LP. Combined with the results of these two methods, we determined the optimal LP for Chinese diabetes patients.

Results: The κ agreement was excellent (0.950), with a high positive predictive value (92.2%) and a low overestimation rate (8.4%) after a 2-year LP. As for the retrograde survival function, S(t) dropped rapidly during the first 1-year LP (from 1.00 to 0.11). At a 417-day LP, the hazard function reached approximately zero (h_t=0.000459), S(t) remained at 0.10, and at 480 days, the frequency of S(t) did not increase. Combining the two methods, we found that the optimal LP is 2 years for Chinese diabetes patients.

Conclusions: The retrograde survival method and CEIs both showed effectiveness. A 2-year LP should be considered when identifying incident cases of diabetes using insurance data in the Chinese population.

diabetes; incident cases; administrative data; look-back period; retrograde survival function

Introduction

Diabetes is a severe, long-term disease that significantly impacts the lives of individuals, families, and societies worldwide [1]. In the past 3 decades, the prevalence of type 2 diabetes has risen dramatically. About 422 million people worldwide have diabetes, and 1.5 million deaths are directly attributable to diabetes each year, as reported by World Health Organization in 2022. In 2013, China had the largest number of patients with diabetes and the second-highest spending on diabetes and its complications worldwide [2,3]. Therefore, to achieve global agreement and halt the worldwide rise in diabetes by 2025, it is crucial to prevent and control diabetes in China.

An accurate estimate of incidence and prevalence plays a crucial role in properly preventing and controlling diabetes. Although large-scale and representative surveys could be used for precise estimation of incidence [4-6], they are expensive, laborious, and time-consuming. Currently, only a few areas have established incident case surveillance systems for chronic diseases in China, and only for some chronic diseases (such as diabetes and hypertension), with short monitoring periods and few sample surveillance points, which limits their usefulness. An alternative method is to use administrative data, such as medical insurance data or disease registration data. Advantages of using these administrative data include easy access, low cost, and large sample size (covering the majority of residents), as well as the ability to follow up with participants longitudinally for many years; this has been confirmed by many researchers in other countries [7-11]. Since medical insurance reforms in 2012 [12], China has vigorously promoted medical policies and expanded coverage of the population [13]. Effective data have gradually accumulated during the past few years, making it possible to conduct research in this population.

However, multiple records of the same patient make it a general challenge to identify true incident cases through medical insurance data, as it is difficult to define the starting point of certain diseases for a patient. Before the index year, a look-back (LP) period is used to deal with this problem. Patients with a diabetes diagnosis in the index year and without a diabetes diagnosis in the LP would be identified as incident cases. Until now, there has been no consensus on the length of the LP. An insufficient LP might cause overestimation of incidence [14], whereas an overlong LP would limit the number of reporting years and the usefulness of the database. Researchers have found that different diseases have different LPs due to specific trajectories [11]. For diabetes, Brameld et al [15] identified an LP of 13 years using data from the Western Australian Data Linkage System, while Asghari et al identified an LP of 5 years using data from the Régie de l’assurance maladie du Québec [7]. We believe that different patterns of medical contact cycles among countries may cause these different findings on LPs. However, there is no study on the optimal LP in the Chinese population for diabetes.

In this study, we will use 2 methods to identify the optimal LP for diabetes in the Chinese population, using data from an insurance database for 2016 to 2020 obtained from the Medical Security Bureau (MSB) of the city of Weifang, China, as an example. Weifang, a prefecture-level city in Shandong province with 9.4 million long-term residents, has a systematic method for ensuring medical service, and the coverage rate for medical insurance reached 96.15% in 2021. The aim of this study is to identify the optimal LP for diabetes for the Chinese population and additionally to compare different results by using different methods to obtain a reference for other diseases in the administrative data.

Methods

Ethical Considerations

The proposal for this study was reviewed by Chinese Academy of Medical Science & School of Basic Medicine (033-2018). The insurance claims data were obtained from the MSB of Weifang. In order to protect the privacy of patients, all personally identifiable information in the database is obfuscated.

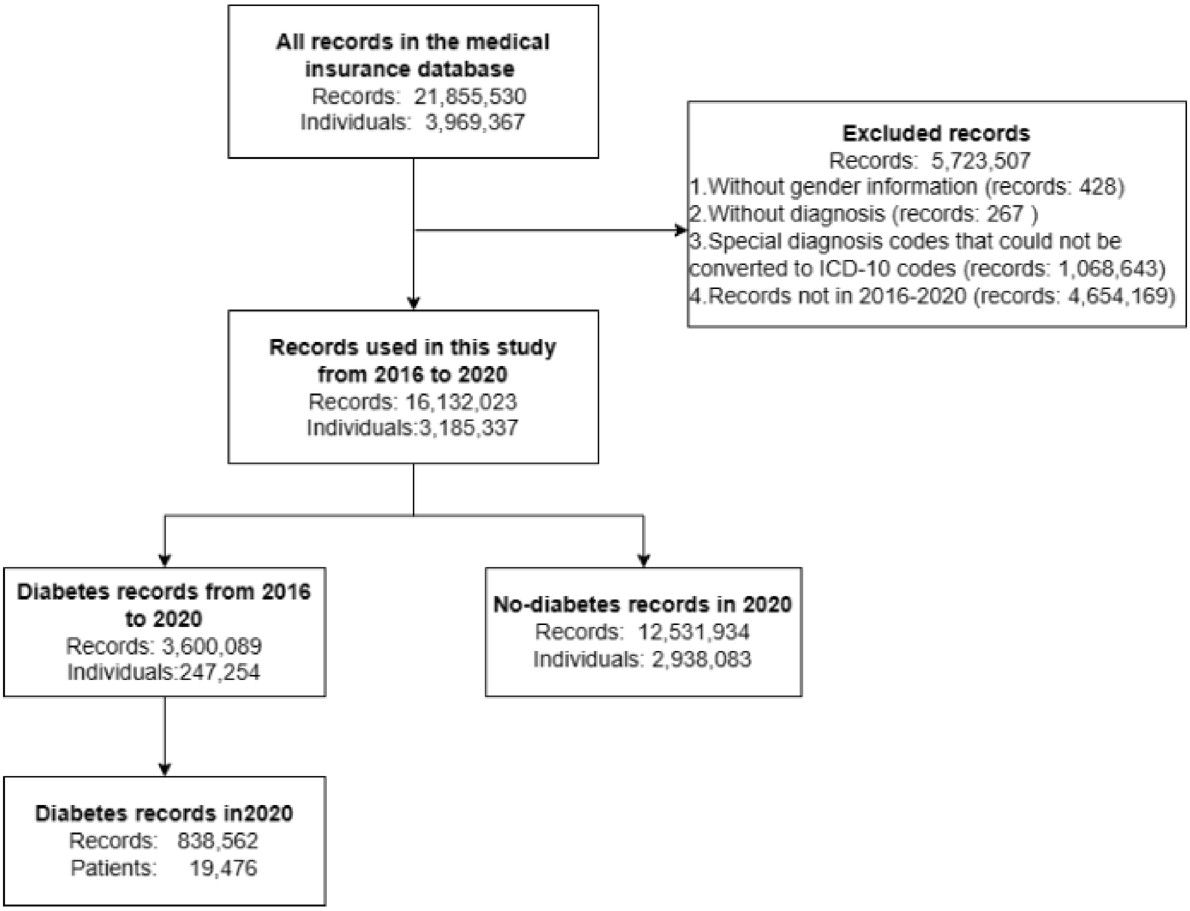
Data Sources

The database used in this study included all in- or outpatient claim records of patients in Weifang for 2016 to 2020 provided by the local MSB. The social health insurance system covered approximately all residents in Weifang (close to 9 million individuals) during the period from 2016 to 2020. Each claim record contains (1) basic information about the patient, including personal identification number, gender, date of birth, and type of medical insurance; (2) medical information, including hospital name and code, admission and discharge time, and diagnosis of disease; and (3) details of medical service expenses, including total expenses, out-of-pocket expenses, and reimbursement expenses.

Data Processing

Firstly, due to the changes in the Weifang disease coding system and the special disease codes in outpatient chronic-disease records, the initial disease codes in the database were partly based on the International Classification of Diseases, 10th Revision (ICD-10). Therefore, the diagnoses were harmonized with the ICD-10 according to the code-disease mapping table provided by the MSB of Weifang. Later, records with critical missing information, such as gender (418/21,855,530, <0.001%) or disease diagnosis (1,068,910/21,855,530, 4.89%), were deleted. The data processing is shown in Figure 1.

Figure 1. Flow chart showing included and excluded records and the process used for data cleaning of the insurance claim data (January 1, 2016, to December 31, 2020). ICD-10: International Classification of Disease, 10th Revision.

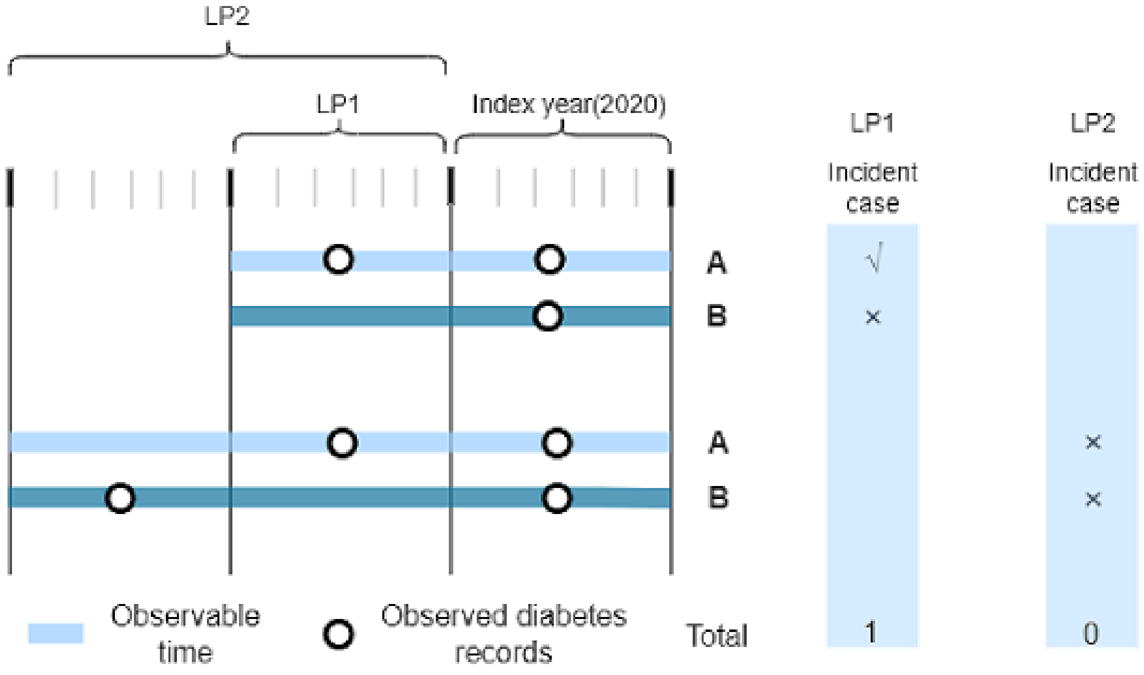


Definition of Incident Diabetes for the Application of Different LPs

First, we defined diabetes (ICD-10 codes E10-E14) cases as those with at least 1 inpatient claim record or 3 outpatient claim records with a diagnosis of diabetes, considering that inpatient records are more reliable than outpatient records [16]. In this database, we found that all patients defined as having diabetes had more than 3 outpatient records, reflecting the regularity of medical contact.

Second, we defined incident diabetes cases. The procedure to identify incident cases was to exclude cases with any in- or outpatient records of diabetes in the given LP, before the index year. Different LPs may classify patients as having different statuses. Two scenarios for assumed different LPs are shown in Figure 2. Scenario 1 (LP1) shows that patient B will be identified as an incident case but patient A will not. Scenario 2 (LP2) shows that with the extension of the LP, more records of patient B might be caught, but patient A and patient B will both be identified as prevalent cases. In order to use as long an LP as possible in this study, we used 2020 as the index year and a 4-year LP (2016-2019) as the longest LP.

Figure 2. Definition of incident cases under 2 scenarios. Scenario 1 (LP1): patient B will be identified as an incident case but patient A will not; scenario 2 (LP2): both patient A and patient B are not identified as incident diabetes cases. LP: look-back period.



Statistical Analyses

Two methods were developed to identify the optimal LP. First, consistency examination indexes (CEIs) were used to determine the level of agreement between different LPs from a quarter of a year to 4 years. Second, a retrograde survival function method was used. Finally, the optimal LP was selected after considering the results from the above approaches.

The CEIs include the κ value, positive predictive values (PPVs), and overestimation value. The relative formulas have been reported in other papers [4,15]. The κ value is categorized as follows: values between –1 and 0 represent “no agreement”; between 0 and 0.20 represent “poor agreement”; between 0.21 and 0.40 represent “slight agreement”; between 0.41 and 0.60 represent “fair agreement”; between 0.61 and 0.80 represent “good agreement”; between 0.81 and 0.90 represent “very good agreement”; and between 0.91 and 1.0 represent “excellent agreement” [17]. The PPVs are used to estimate the probability of identifying a true incident case among those identified as being new cases [18], calculated using the 4-year LP as the reference time. The overestimation of incident cases decreased with extension of the LP, which reflects the impact of the length of the LP impacts on the number of incident cases. All the CEIs mentioned above were calculated at quarter-year intervals during the first year of the LP and 1-year intervals after the first year, since the number of identified incident cases varied greatly within the first year of the LP in previous studies [7,12,16].

With the retrograde survival function method, survival (ie, being an incident case) means not having a preceding record at the given time. In detail, for each record in this study, let *a* represent the date of the last record of diabetes of a patient in 2020, *b* the date of the most recent previous record in the LP, and *c* the first date of the LP. The retrograde survival time is (*a*–*b*) for patients with preceding records. Patients without preceding records during the LP, indicating survival, are defined as censored cases, with the censored time (*a* – *c*). Based on the survival time and censored time, we established the survival function. Survival probability, S(t), the probability of surviving at a specific time, is represented by the equation S(t)=P (T>t), where *T* is the year of the LP, calculated using the Kaplan-Meier estimator. Then, we used the following 2 approaches to determine the optimal LP based on the survival function. For the first approach, we constructed a hazard function. The hazard function represents the instantaneous probability of having the end point event during (t,Δt) conditional on survival up to *t* or later. In actuarial terms, it is calculated by , where $d_{\Delta t}$ is the number of patients with the previous record during (t,Δt) and n_t is the patient at risk during the interval. Since the retrograde hazard of diabetes will decrease and converge to zero and the survival function will converge to the “true” probability of being incident, we assumed that a time point (*tf*) exists where . At this point (*tf*), all cases with preceding records have been found, and the remaining cases are risk-free; this is exactly the optimal LP. To estimate (*tf*), for practical purposes, we defined (*tf*) as the first time point when $h_t \le 0.0005$. For the second approach, we counted the frequency of S(t) corresponding to each day calculated by the retrograde survival function. We assumed that there was a stable S(t), where the frequency was high and increased significantly, representing that S(t) stays at S(t_f) relatively constantly over a long time and that the change in S(t) approaches zero. The t_f will be considered as the point when S(t) first reaches S(t_f).

Statistical analyses were performed using SAS (version 9.4; SAS institute).

Results

After removing records according to the criteria above, 16,132,023 records from medical insurance claims data from 2016 to 2020 were used in this study; these records came from 3,185,337 individuals. There were 3,600,089 records and 247,254 cases of diabetes in total. The insurance record history of 109,476 diabetes prevalent cases in 2020 was screened with the different LPs to identify incident cases. Inclusion and exclusion details are shown in Figure 1, and basic information on the data is shown in Table 1.

Table 1. Basic information on the data used in this study (January 1, 2016, to December 31, 2020). "Insurance records" represents all claims and diabetes records in each year. "Individuals with insurance records" represents the number of persons with claims in each year. "Visits per capita" was calculated as the number of insurance records divided by the number of individuals with insurance records.

	Insurance records, n		Individuals with insurance records, n		Visits per capita, n	
	Inpatient	Outpatient	Inpatient	Outpatient	Inpatient	Outpatient
Entire database						
2016	1,227,374	1,326,862	894,726	128,819	1.37	10.30
2017	1,459,273	1,583,937	1,027,600	151,130	1.42	10.48
2018	1,484,065	1,815,786	1,024,998	168,547	1.45	10.77

2020	1,393,165	2,158,795	947,821	220,560	1.47	9.79
Diabetes cases						
2016	26,597	526,619	23,117	58,703	1.15	8.97
2017	31,053	618,289	26,833	67,542	1.16	9.15
2018	31,668	699,739	27,425	75,361	1.15	9.29
2019	34,131	793,431	29,594	87,197	1.15	9.10
2020	30,604	807,958	27,038	97,396	1.13	8.30

Applying the longest LP identified 19,086 incident cases of diabetes. Only 17% (19,087/109,476) of the prevalent patients in 2020 were identified as incident cases as they did not have preceding records for diabetes in the longest LP before 2020, revealing that around 80% (90,389/109,476) of patients in 2020 were not truly incident cases. The κ coefficient and PPVs for these results rose with extension of the LP. Agreement was good when a quarter-year LP (κ=0.751) was used, changing to very good (κ=0.899) and excellent (κ=0.950) when the 1-year and 2-year LPs were used. As for PPVs, to achieve a PPV of at least 90% (10% of false positives) [19], an LP of 2 years was necessary. The overestimation rate decreased with the extension of the length of the LP and did so especially sharply during the 1-year LP. After a 2-year LP, the overestimation decreased by under 10%. In general, according to the results of these CEIs, the optimal LP is 2 years for the Chinese population. Detailed information on the CEIs is shown in Table 2.

Table 2. Positive predictive values, κ coefficients, and overestimation with different look-back periods, all of which represent the agreement between the incident cases with different look-back periods and the 4-year look-back period as the longest period. Incident cases are defined as those not having previous records in the corresponding look-back period.

LP[a] (years)	Incident cases, n	PPV[b], %	κ	Overestimation, %
0.25	29,407	0.674	0.751	0.485
0.5	26,195	0.756	0.825	0.323
0.75	24,172	0.819	0.876	0.220
1	23,288	0.850	0.899	0.176
2	21,472	0.922	0.950	0.084
3	20,468	0.968	0.980	0.033
4	19,806	1	N/A[c]	0

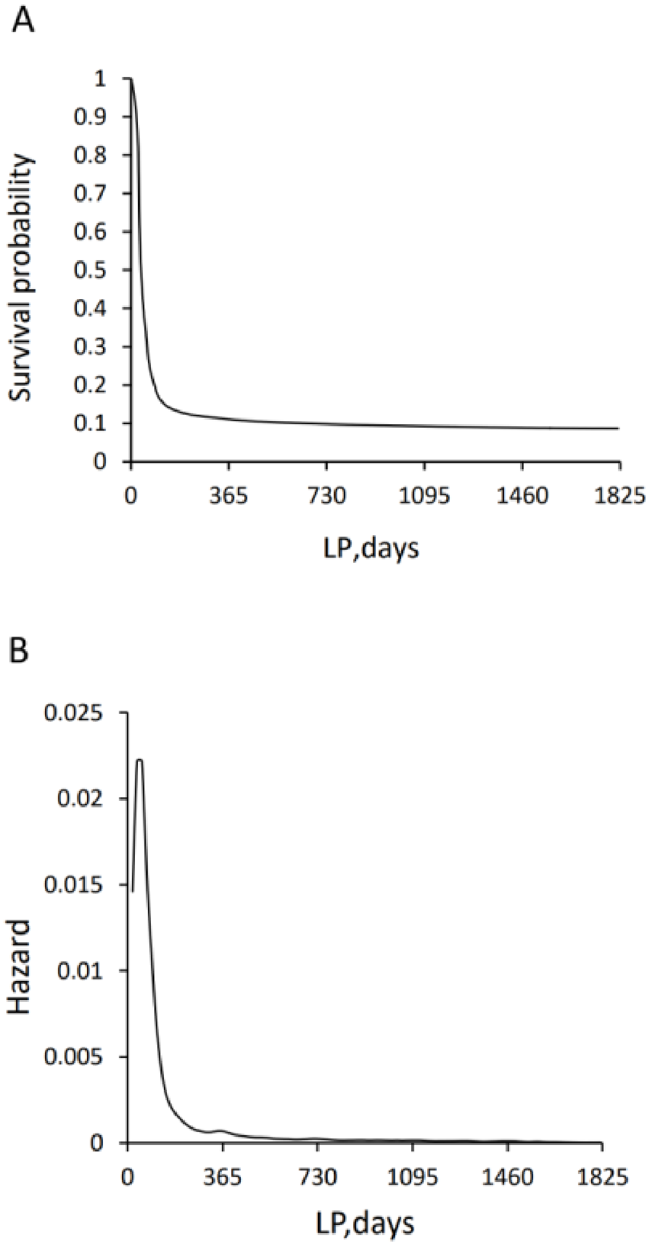
[a] LP: look-back period.

[b] PPV: positive predictive value.

[c] N/A: not applicable.

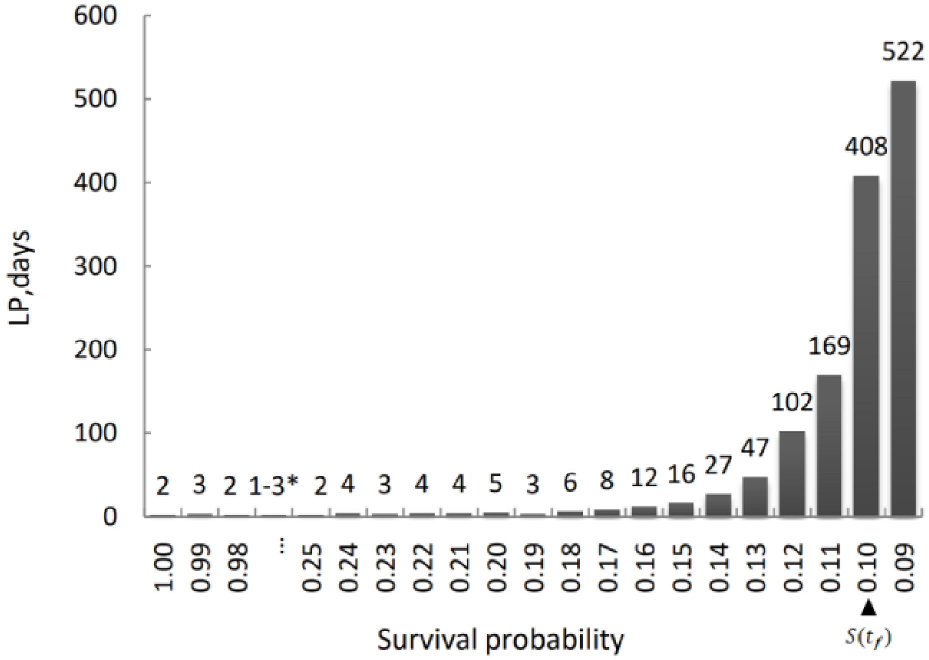
The retrograde survival function graphically represented the exclusion, showing the greatest decrease during the first year of screening (Figure 3). During the first 1-year LP, S(t) dropped from 1.00 to 0.11 (365 days) rapidly. The more days were included in the LP, the more the survival function converged to the “true” probability of being incident [18]. According to the hazard function, the first time point when $h_t \leq 0.0005$ was with a 417-day LP: h_t=0.000459; S(t)=0.11. This meant that the derivative (slope) of the survival function tended toward zero at this time.

Figure 3. (A) Change in survival probability with LPs with different numbers of days. Survival probability represents the probability of being an incident case at a specific day in the LP, which is calculated using the Kaplan-Meier estimator. (B) Change in survival hazard with LPs with different numbers of days. Survival hazard represents the instantaneous probability of having the end point event. LP: look-back period.



The results for frequency showed that the frequency of S(t) was small, from 1.00 to 0.13, indicating that S(t) changed greatly. A change in S(t) from 0.11 to 0.10 means that the frequency has significantly increased, from 169 to 408, which is more than double (Figure 4). This means that the risk for a preceding record at this time remained relatively constant at 0.10 over a very long time, and the first day when S(t) reached 0.10 was 480 days. Combining the results for frequency and hazard function, the retrograde survival function method showed that the optimal LP was more than 400 days, which is closest to 2 years.

Figure 4. The frequency of S(t). *The frequency of S(t) from 0.97 to 0.26 was between 1 and 3. LP: look-back period.



When using 2 years as the optimal LP, there were 21,472 incident cases. The number of female patients (n=10,862) was a little more than that of male patients (n=10,610), and 84.74% (18,192/21,472) of incident cases were between the ages of 45 and 79 years (Table 3).

Table 3. Incident cases applying a 2-year look-back period (ie, using 2018 and 2019 to identify incident cases in 2020) with different ages and genders.

Age group (years)	Male patients, n (n=10,610)	Female patients, n (n=10,862)	Total patients, n (n=21,472)
0-4	4	7	11
5-9	7	16	23
10-14	36	29	65
15-19	34	23	57
20-24	52	45	97
25-29	99	63	162
30-34	308	194	502
35-39	401	178	579
40-44	577	271	848
45-49	961	538	1499
50-54	1432	1073	2505
55-59	1806	1720	3526
60-64	1544	1778	3322
65-69	1504	2061	3565
70-74	1000	1533	2533

80-84	269	394	663
≥85	95	175	270

Discussion

Principal Results

In our study, a 2-year LP had good CEIs with excellent κ agreement (0.950>0.9), a high PPV (92.2%) and a lower than 10% overestimation rate. As for the retrograde survival function, it showed that a 2-year LP can reliably distinguish new cases in a prevalent pool. According to the results of the methods above, we confirmed that the optimal LP for identifying incident cases of diabetes using the Chinese insurance database provided by the MSB of Weifang is around 2 years, and all the methods are effective and stable.

Comparison With Prior Work

Optimal Length of LP Compared to Other Work

A 2-year LP for diabetes incident case identification using administrative data is the same length as used by a few previous studies [20,21]. A study in Manitoba, Canada, also showed a probability of 0.96 for patients with diabetes to have subsequent medical contact for diabetes within 2 years [22]. However, our results differ from those of Asghari et al [7], who reported an LP of 5 years for health insurance data from Quebec, Canada. A possible reason might be different patterns and medical contact cycles among Chinese and Canadian populations caused by the different medical insurance policies. The hazard function figure (Figure 3B) reflects this difference. In our study, the hazard function was not monotonic, indicating that a few diabetes patients had medical contact irregularly in this database, unlike the Canadian insurance data. n addition, different judgment criteria on CEIs and h_t in these studies might have caused the differences.

Methodological Comparison

As for retrograde survival function, Brameld et al [15] chose a hazard rate under 0.00001 as the standard when using the retrograde survival method for identifying the optimal LP for diabetes, resulting in a 13-year optimal LP for diabetes among a group of LPs with the longest LP being 15 years, much longer than our study and most other studies [20,23,24]. We think an overly strict standard may have caused an overly long LP. To avoid an overly long estimation of optimal LP, we used $h_t \leq 0.0005$ as the criterion, which is similar to the study by Asghari et al [7], which showed that a 2-year LP was optimal for diabetes. That study defined the optimal LP as the time when S(t) was stable and constant [7]; however, the authors did not provide a detailed definition for stable S(t), that is, $S(t_f)$. In our study, we tried a new approach. We counted the frequency of S(t) and defined $S(t_f)$ by the frequency of S(t) being greatest and increasing significantly.

Regarding CEIs, such as the κ coefficient, PPVs, and overestimation rate, although they are convenient to calculate and used by many researchers, their criteria are not completely consistent between studies. The overestimation rate has been used by a few researchers to evaluate the impact of varying lengths of LP [11,21,25-27], with values such as 10% [11] and 20% [21]. It is the same for PPVs, as some studies have chosen 80% as the evaluation criterion [19], while some have chosen 90% [28]. The criteria of the κ coefficient have generally between consistent (0.8 or 0.9) [7,18], but some researchers have considered that such high agreement may be related to the high number of prevalent cases of diabetes [7]. Therefore, the effectiveness of κ may remain to be further verified.

Because of the inconsistency of criteria, Beaudet et al [18] chose to combine the results of κ and PPV to identify the optimal LP. In our study, we compared the results of the κ coefficient, PPV, the overestimation rate, and the retrograde survival method. We found that a κ coefficient of 0.9, 90% PPV, 10% overestimation, and 0.0005 hazard rate may be the most suitable criteria, returning stable and constant results, with a 2-year LP as the optimal period.

In general, the CEIs were convenient to calculate, while retrograde survival curves showed the probability of "surviving" converging to the plateau, allowing us to obtain the optimal LP visually and quantitively. Moreover, the criteria of these methods are different. Previous studies have mostly used only one method for identifying the optimal LP, whereas 2 different methods, as used in this study, may lead to more robust results, which could then be referred to when analyzing LPs for other diseases in the administrative data.

Number of Incident Diabetes Cases

In our study, there were 109,467 diabetes cases in 2020 before LP adjustment. After using the 2-year LP, the number of incident cases decreased to 21,472, which means this adjustment is important. In addition, our study showed that 84.74% (18,192/21,472) of incident cases were between the ages of 45 to 79 years, indicating that the middle-aged and older population has a high incidence of diabetes. We should make efforts to focus on this population to prevent diabetes.

Innovativeness

Our study is the first to identify 2 years as the optimal LP for diabetes in the Chinese population when using insurance data, which supports efforts to estimate the incidence of diabetes among populations using insurance data. More importantly, we used 2 different methods to identify the optimal LP, a method that could be referred to when analyzing LPs for other diseases in administrative data.

Limitations

Our study has some limitations. In our database, without more detailed records for disease classification, it was not possible to differentiate between type 1 and type 2 diabetes. However, there are far fewer patients with type 1 diabetes than with type 2 diabetes in the overall population. Thus, we considered the study population to be generally homogeneous and that these results may be representative and stable. Furthermore, we only applied up to a 4-year LP. Although the results of the retrograde survival function analysis showed stabilization of risk of being a preceding case after a 2-year LP, we expect to use longer LPs in future studies with more accumulated data.

Conclusion

All CEIs (the κ coefficient, PPV, and overestimation rate) and the retrograde survival function method can effectively identify the optimal LP for diabetes incident cases, with stable and constant results. We found that a 2-year LP was optimal to remove preceding diabetes cases and identify the true incidence of diabetes using medical insurance data in the Chinese population.

Acknowledgments

The authors thank all participants and staff of the Weifang Medical Insurance Center for their contributions to this work. The authors also acknowledge the contribution to this study of the Center for Disease Control and Prevention of Weifang City. The authors appreciate the support of the China Medical Board (CMB), which supported the CMB Collaborating Program in Burden of Diseases in China (15-208).

Abstract

Background: The seroprevalence of SARS-CoV-2 infection in the French population was estimated with a representative, repeated cross-sectional survey based on residual sera from routine blood testing. These data contained no information on infection or vaccination status, thus limiting the ability to detail changes observed in the immunity level of the population over time.

Objective: Our aim is to predict the infected or vaccinated status of individuals in the French serosurveillance survey based only on the results of serological assays. Reference data on longitudinal serological profiles of seronegative, infected, and vaccinated individuals from another French cohort were used to build the predictive model.

Methods: A model of individual vaccination or infection status with respect to SARS-CoV-2 obtained from a machine learning procedure was proposed based on 3 complementary serological assays. This model was applied to the French nationwide serosurveillance survey from March 2020 to March 2022 to estimate the proportions of the population that were negative, infected, vaccinated, or infected and vaccinated.

Results: From February 2021 to March 2022, the estimated percentage of infected and unvaccinated individuals in France increased from 7.5% to 16.8%. During this period, the estimated percentage increased from 3.6% to 45.2% for vaccinated and uninfected individuals and from 2.1% to 29.1% for vaccinated and infected individuals. The decrease in the seronegative population can be largely attributed to vaccination.

Conclusions: Combining results from the serosurveillance survey with more complete data from another longitudinal cohort completes the information retrieved from serosurveillance while keeping its protocol simple and easy to implement.

Introduction

In the ongoing global effort to contain the SARS-CoV-2 pandemic, population-wide serological surveys are recommended for disease surveillance and policymaking [1]. Serological assays directly measure the antibody response to SARS-CoV-2 resulting from viral infection or vaccination. Monitoring seroprevalence is of paramount interest to complement case-based surveillance that does not capture subclinical cases or people using self-tests and to evaluate the effectiveness of the vaccination strategy over time. Therefore, the World Health Organization's UNITY initiative promotes serological surveys by providing guidelines to standardize worldwide serological studies.

Despite the availability of well-known methods as well as guidelines, implementation of serological surveys remains challenging in terms of the resources and logistic means needed to obtain samples [2]. Collecting residual sera from routine clinical blood testing represents an easy and inexpensive solution. This strategy was chosen for the nationwide SARS-CoV-2 serosurvey in France (SERPICO) [3]. This survey, conducted by the national health agency Santé publique France and the National Reference Centre for Respiratory Infections Viruses of the Institut Pasteur, aimed to estimate the seroprevalence of anti–SARS-CoV-2 antibodies in the French population over time according to gender, age, and region. The humoral immune status of individuals was determined by 3 complementary serological assays: 2 luciferase-linked immunosorbent assays (LuLISAs) detecting the nucleocapsid (LN) and the spike (LS) proteins of SARS-CoV-2 and a pseudoneutralization assay (PNT). In total, 8 collection periods between March 2020 and March 2022 monitored the evolution of seroprevalence in the French general population.

Substantial differences were reported in the effectiveness and duration of natural versus vaccine-conferred or hybrid immunity against SARS-CoV-2 reinfection [4,5]. In particular, prior infection after 1 dose of vaccine elicited antispike IgG antibody responses with higher peak levels or longer half-lives than 1 or 2 vaccinations in seronegative individuals [6]. We therefore aimed to reconstruct the proportion of infected versus vaccinated or infected and vaccinated individuals over time as it may carry meaningful lessons and potential applications for future vaccine-preventable disease pandemics.

Although the SERPICO serosurvey lacked data documenting the status of the sampled individuals with respect to previous SARS-CoV-2 infection or vaccination, the detailed serological data presented here could allow novel approaches to monitor the SARS-CoV-2 seroprevalence of the French population with regard to infection or vaccination.

In this study, we propose a model derived from a machine learning procedure to predict individuals' immune status with respect to SARS-CoV-2 infection and vaccination based on results from 3 serological assays. We applied this predictive model to the SERPICO serosurvey to characterize immune status resulting from natural infection and vaccination for the French population between 2020 and 2022.

Methods

Serological Assays

The National Reference Centre for Respiratory Infections Viruses and the Diagnostic Test Innovation and Development core facility of the Institut Pasteur developed 3 serological assays: 2 LuLISAs detecting the LN and LS proteins of SARS-CoV-2 and a PNT [7]. These serological results are considered explanatory variables in the predictive models. They were expressed as $\log_{10}$ of their original value.

Data

This study used 3 data sets (Table 1). The CURIE-O-SA [7] and prepandemic [3,7] data sets were used to build and validate the model, and the SERPICO [3] data set was used for application of the model.

The CURIE-O-SA study is a large cohort of 1917 workers in a hospital and research center specialized in oncology. Of the 4394 individuals included in this data set, 77% (n=3595) were men and 23% (n=899) were women. The median age was 38 (IQR 19-82) years with 94% (n=4130) of participants between 20 and 59 years of age. The CURIE-O-SA serological assay results were available at different sampling times ("individual date") with a mean number of times per participant equal to 2.5 (SD 1.2) and 73% (n=3208) of individuals with 1, 2, or 3 sampling times. Information on SARS-CoV-2 history (symptoms and date of positive reverse transcription polymerase chain reaction [RT-PCR] test, if any) and on SARS-CoV-2 vaccination (number of injections and dates) was collected. The uninfected status (0) was set if the following 3 conditions were met: no positive PCR test, no declaration of ageusia or anosmia, and a $\log_{10}$LN value below 4.60. Individuals with $\log_{10}$LN>4.60 and no positive PCR test were considered potential subclinical cases and were excluded. The infected status (1) was set for individuals with a positive RT-PCR result history only; individuals reporting symptoms for SARS-CoV-2 with no positive RT-PCR result were excluded. The vaccination status (0=unvaccinated, 1=1 injection, 2=2 injections) was defined while taking into account a delay of 15 days after vaccination (immunity onset) and no more than 6 months after the last injection (immunity waning). Of the 4394 results, 80.4% (n=3532) of results were negative (uninfected and unvaccinated), 5.2% (n=231) were infected and unvaccinated, 10.9% (n=477) were vaccinated twice, 1.9% (n=82) were vaccinated once, and 1.6% (n=72) were infected and vaccinated.

The prepandemic results came from healthy donors from a blood bank before 2019 and were expected to be predicted negative (uninfected and unvaccinated) by the model. In this data set, of the 233 individuals, 32.2% (n=75) were men and 67.8% (n=158) were women with a median age of 44 (IQR 18-81) years.

The SERPICO data were considered application data for the model. The SERPICO survey monitored the evolution of seroprevalence of anti–SARS-CoV-2 antibodies in the French population (mainland area) from March 2020 to March 2022 with 8 periods of sampling. Results for the 3 serological assays (LN, LS, and PNT) were available for 23,886 samples.

Table 1. Description of the 3 data sets under study.

Data set	Description	Use	Number of results	Variables
CURIE-O-SA [7] (n=4394)	Cohort study among health workers; April 2020-November 2021	Reference for SARS-CoV-2 status; reference for SARS-CoV-2 vaccination status	4394 individuals × dates	LS[a], LN[b], PNT[c] values; gender; age; SARS-CoV-2 infection status (0=uninfected, 1= infected); SARS-CoV-2 vaccination status (0=unvaccinated, 1=1 injection, 2=2 injections)
Prepandemic [3,7] (n=233)	Blood donors; 2014-2018	Control for uninfected SARS-CoV-2 status; control for unvaccinated SARS-CoV-2 status	233 individuals	LS, LN, PNT values; gender; age
SERPICO [3] (n=23,886)	Transversal nationwide survey, residual sera; March 2020-March 2022	Application	23,886 individuals × dates	LS, LN, PNT values; gender; age; region

[a] LN: nucleocapsid.

[b] LS: spike protein.

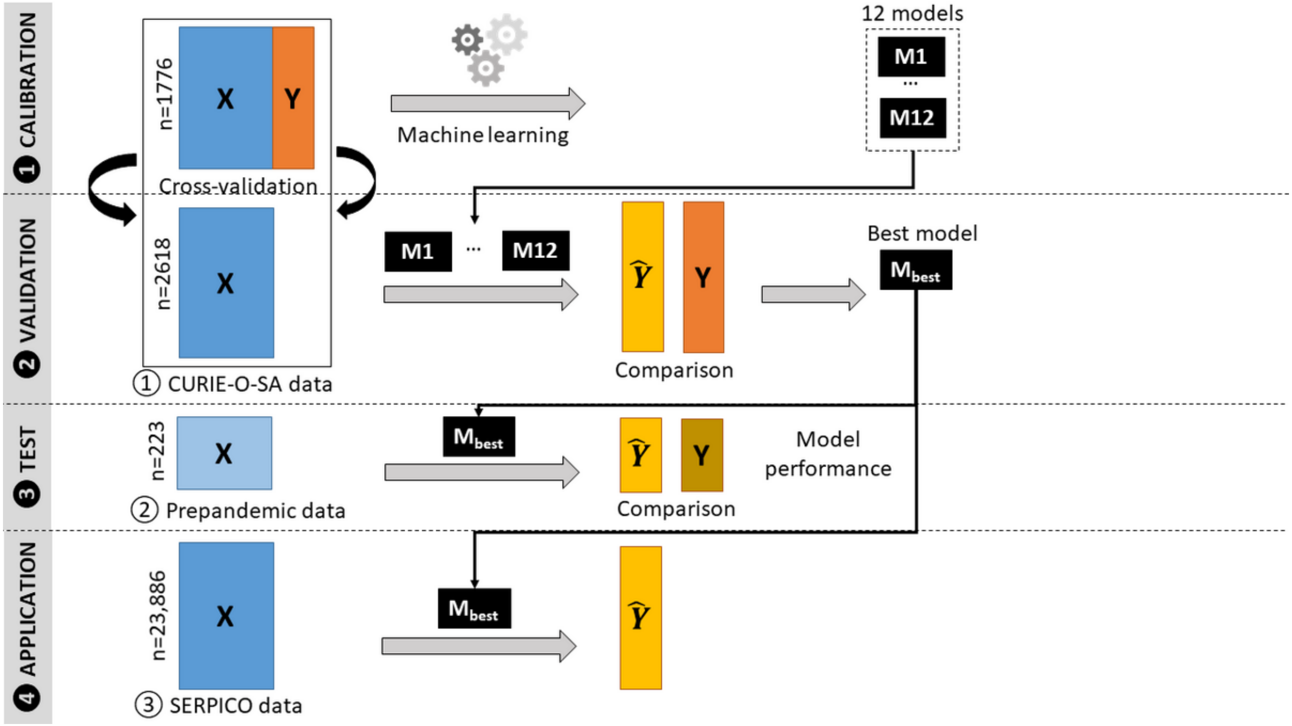
[c] PNT: pseudoneutralization assay.

Machine Learning Procedure

The model was built using a 4-step procedure involving calibration, validation, testing, and application (Figure 1). It aimed to predict the SARS-CoV-2 status at the individual level from 3 serological assays (LS, LN, and PNT) and 2 covariables (age and gender). The SARS-CoV-2 status was defined as a variable with 5 modalities: uninfected-unvaccinated (NEG), vaccinated with 1 dose (VAC1), vaccinated with 2 doses (VAC2), infected-unvaccinated (INF), and infected-vaccinated regardless of the number of doses (INF.VAC). A machine learning procedure was applied to challenge several classification models [8]. The model with the best predictive performance was selected from a cross-validation procedure on the first data set (CURIE-O-SA) then validated on an external data set (prepandemic). Finally, the selected model was applied to the French nationwide serosurveillance survey (SERPICO) to infer the proportions of the 5 SARS-CoV-2 statuses.

More precisely, 12 parametric and nonparametric classification models from 5 main statistical families were assessed within a machine-learning procedure. The models came from the following families: (1) generalized linear models (standard multinomial regression, penalized generalized linear model), (2) Bayesian models (naive Bayesian classification), (3) factor analysis models (discriminant analysis, mixture discriminant analysis, regularized discriminant analysis, kernel partial least squares discriminant analysis), (4) decision tree models (bagged classification and regression tree, Quinlan's C5.0 algorithm), and (5) nonparametric classification models (K nearest neighbors, support vector machine, neural network) [9]. To select the best predictive model and avoid overfitting, a repeated (200 times) 2-fold cross-validation was applied. To ensure the independence of the "individual x date" units, calibration data were randomly selected so that there was only 1 sample per individual involved in the CURIE-O-SA cohort; the remaining data were used for validation. The model parameters were optimized by means of a 10-fold cross-validation procedure on the calibration data. Percentages of well-classified samples for each modality of the status were calculated on the validation data. The best model was the one that best predicted the status modalities on average. Using the mean predictive performance of the 5 statuses to select the best model (rather than the overall prediction) can be considered oversampling of the rare modalities [10]. Repeated bootstrap simulations (50 times) were used to obtain 95% CIs. The overall procedure was implemented in R software (version 4.1.2, R Foundation for Statistical Computing) [11] by means of the "caret" package (version 6.0-90) [12].

Figure 1. Sketch graph of the 3-step model-building procedure (calibration, validation, and testing) and the application step. Regardless of the data set (ie, CURIE-O-SA, prepandemic, or SERPICO), the X explanatory data contained the $\log_{10}$ values of the 3 serological assays ($\log_{10}$LN, $\log_{10}$LS, and $\log_{10}$PNT) and the Y outcome data, with the SARS-CoV-2 status being known (CURIE-O-SA, prepandemic) or unknown (SERPICO).



Ethical Considerations

The study was based on a secondary use of pseudonymized data collected from health professionals and already published [3,7]. According to French law, such studies are not required to receive ethics committee approval.

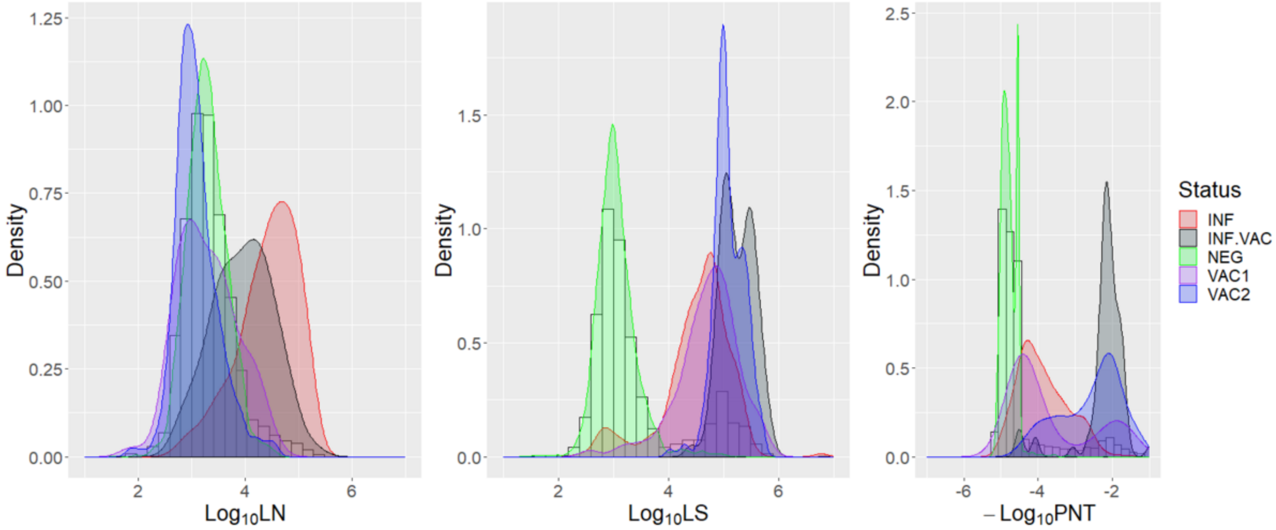
Results

Descriptive Statistics

The CURIE-O-SA data set used to build and validate the predictive model is illustrated in Figure 2. The serological LN results differentiated INF and to a lesser extent INF.VAC individuals from the others. The serological results targeting the SARS-CoV-2 LS separated the NEG individuals from the others. INF individuals developed anti-LS and anti-LN protein immunoglobulins, while VAC1 and VAC2 individuals developed anti-LS immunoglobulins only. This difference in immunization between infected (and unvaccinated) and vaccinated individuals was expected in a cohort where VAC1 and VAC2 individuals were vaccinated by vaccines targeting the LS only. The PNT results separated the INF.VAC individuals from the others as INF.VAC individuals presented a higher response to the PNT assay than did VAC1 and VAC2 individuals.

The prepandemic data set used for model validation consisted of 223 negative sera with the following average values for the serological assays ($\log_{10}$ values): 3.16 (SD 0.30) for LN, 3.16 (SD 0.20) for LS, and 5.07 (SD 0.11) for PNT.

Figure 2. Density estimation of the $\log_{10}$ values of the serological assays (LN, LS, and PNT) according to their known SARS-CoV-2 status in the CURIE-O-SA cohort. INF: infected-unvaccinated; INF.VAC: infected-vaccinated regardless of the number of doses; LN: nucleocapsid; LS: spike protein; NEG: uninfected-unvaccinated; PNT: pseudoneutralization assay; VAC1: vaccinated with 1 dose; VAC2: vaccinated with 2 doses.



Model

The percentages of well-classified results for each status and for all the models under study were calculated (Table 2).

The selected model was the mixture discriminant analysis with the best average prediction performance (mean 69.9%, SD 0.5%). More precisely, 98.4% (SD 0.2%) of the NEG status was well-predicted, as well as 40.6% (SD 6.9%) of the VAC1, 87.5% (SD 3.1%) of the VAC2, 42.6% (SD 11.3%) of the INF.VAC, and 78.9% (SD 3.8%) of the INF statuses. Best performances were obtained for the modalities with the largest numbers of “individual × date” units (NEG, VAC2, and INF). The VAC1 individuals were usually (60%) incorrectly predicted as VAC2; the error in the prediction did not depend on age or gender. The INF.VAC individuals were usually (84.4%) incorrectly predicted as VAC2; the error in the prediction did not depend on age and gender. As expected, this model predicted 99.5% of the negative prepandemic sera (Figure 3).

The model was applied to the prepandemic data (n=223). It predicted 222 results as negative and 1 as VAC1. This confirms the ability of the model to predict infection-free individuals, as 99.5% of the results were correctly predicted as NEG. This performance is in accordance with that calculated by means of cross-validation (98.4%). However, this performance is expected in that the model has many NEG values in the calibration data set (3532/4394; 80.4%) and is tested on expected NEG results. The only result not correctly predicted was predicted to be VAC1 with values $\log_{10}$LN=3.09, $\log_{10}$LS=4.44, and $\log_{10}$PNT=5.04. This individual had higher LS values than expected for NEG individuals ($\log_{10}$LN=3.28, $\log_{10}$LS=3.05, and $\log_{10}$PNT=4.78 for average NEG individuals in the CURIE-O-SA data set).

Table 2. Predictive performances of different models obtained by means of a repeated (200 times) 2-fold cross-validation using the CURIE-O-SA cohort (n=4394 individual × date units from April 2020-November 2021).

Model	Predictive performance (%), mean (SD)					
	NEG[a] (n=3532)	VAC1[b] (n=82)	VAC2[c] (n=477)	INF.VAC[d] (n=72)	INF[e] (n=231)	Average[f]
Multinomial regression	99.1 (0.2)	3.4 (4.7)	95.4 (1.5)	29.1 (9.8)	68.1 (2.9)	59 (41.8)
Penalized generalized linear model	99.1 (0.2)	1.9 (3.6)	95.4 (1.3)	24.8 (12.6)	68 (2.8)	57.8 (43.1)
Naive Bayesian classification	98.5 (0.2)	6.7 (4.7)	91.3 (1.9)	47.8 (8.7)	83.8 (1.8)	65.6 (38.3)
Linear discriminant analysis	98.7 (0.1)	31.1 (5.8)	81.1 (4)	45 (6.1)	77.9 (1.8)	66.8 (27.8)
Regularized discriminant analysis	98.3 (0.2)	22.9 (11.3)	91.5 (3)	46.9 (6.3)	82.5 (2.8)	68.4 (32.2)
Mixture discriminant analysis[g]	98.4 (0.2)	40.6 (6.9)	87.5 (3.1)	42.6 (11.3)	78.9 (3.8)	69.6 (26.5)
Kernel PLS[h] discriminant analysis	99.7 (0.1)	0 (0)	90.3 (1)	0 (0)	41.7 (3.1)	46.3 (47.7)
Bagged CART[i]	98.7 (0.2)	22.7 (7.8)	89.6 (2.6)	31.1 (8.8)	72.3 (4.6)	62.9 (34.3)
Quinlan's C5.0 algorithm	98.8 (0.4)	13.3 (9.6)	91.6 (3.5)	29 (14.5)	72.4 (7.8)	61 (38.1)
K nearest neighbors	98.8 (0.2)	18.9 (7.7)	92 (2.4)	31.4 (9.9)	70.2 (4.3)	62.8 (35.8)
Support vector machine	98.9 (0.2)	1.1 (2.6)	95.6 (1.5)	23.3 (15.8)	76.2 (2.8)	59 (44.3)
Neural network	98.7 (0.3)	14.1 (10.7)	94 (2.4)	30.7 (15.6)	77.1 (5.5)	62.9 (38.3)

[a] NEG: uninfected-unvaccinated.

Prediction for the SERPICO Serosurvey

The model was applied to the French nationwide serosurveillance survey SERPICO (n=23,886). The consistency of the predictions was confirmed by comparing the predicted results to internal and external reference information (Multimedia Appendix 1). It follows that the estimation of the vaccinated proportion of the French population was correctly predicted, especially between March 2020 and June 2021. Predictions were less accurate for the last 2 periods as the proportion of individuals with a complete vaccination scheme

(VAC2 and INF.VAC) tended to be underestimated in the prediction.

The average percentages of the 5 predicted SARS-CoV-2 immune statuses are shown in Figure 4 for the 8 sampling periods. For the first 4 periods, individuals were mostly predicted as NEG (March 2020: mean 99.1%, SD 0.2%; October 2020: mean 94.7%, SD 0.4%). Between February 2021 and March 2022, the number of INF individuals increased from 7.5% (SD 0.4%) to 16.8% (SD 0.7%). From June 2021, the numbers of vaccinated (VAC1 and VAC2) and INF.VAC individuals increased in relation with the rollouts of vaccination for the older population from the end of December 2020, for any person older than 12 years from June 2021, and for children aged 5 to 11 years from December 2021 in France. The prediction performances of the model were usually better for the most common statuses (NEG and INF). The INF.VAC status was better predicted in the 4 later periods during the vaccination rollout.

No difference in SARS-CoV-2 predicted status was observed between genders, except in October 2021 (Figure 5, left panel). At this time, the percentage of predicted NEG men was higher than that of women. No other significant difference was observed due to large CIs associated with the VAC1, VAC2, and INF.VAC predictions.

The percentage of INF individuals was similar in all age groups over the 7 sampling periods (Figure 5, right panel). In June 2021, the proportions of individuals predicted as VAC1 and VAC2 increased first in older age groups (60-69, 70-79, and older than 80 years) as vaccination was rolled out for these age groups first. Conversely, the proportion of individuals predicted to be NEG remained higher for the younger age groups during the same period. The proportion of NEG individuals was still higher in children aged 0 to 9 years in comparison with other age groups in October 2021 because vaccination was open only to children aged 5 to 11 years.

Predictions for the 5 SARS-CoV-2 statuses can be illustrated according to French administrative regions (Figure 6). The epidemic first progressed in the Eastern part of France between March and May 2021 and then spread to the Paris region and to the northern part of France in October 2021. Spatial variability was observed in immune status, with the predicted fraction of vaccinated individuals being higher in the western part of France than in other regions in June and October 2021.

Figure 4. Percentages (95% CI) of SARS-CoV-2 predicted status for the 8 collection periods. INF: infected-unvaccinated; INF.VAC: infected-vaccinated regardless of the number of doses; NEG: uninfected-unvaccinated; VAC1: vaccinated with 1 dose; VAC2: vaccinated with 2 doses.

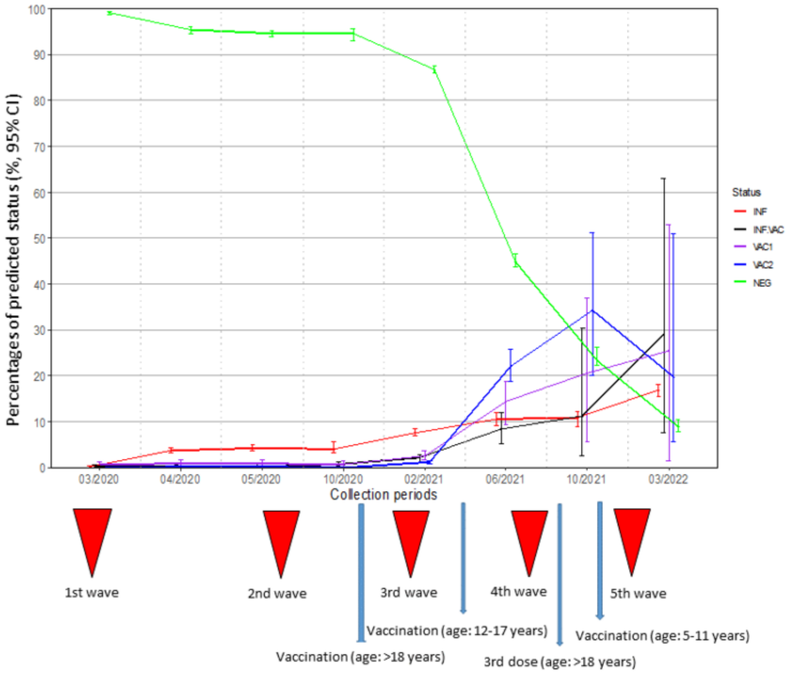

Figure 5. Percentages (95% CI) of SARS-CoV-2 predicted statuses for the 8 collection periods according to gender (left panel) and age group (right panel) in the SERPICO data set. INF: infected-unvaccinated; INF.VAC: infected-vaccinated regardless of the number of doses; NEG: uninfected-unvaccinated; VAC1: vaccinated with 1 dose; VAC2: vaccinated with 2 doses.

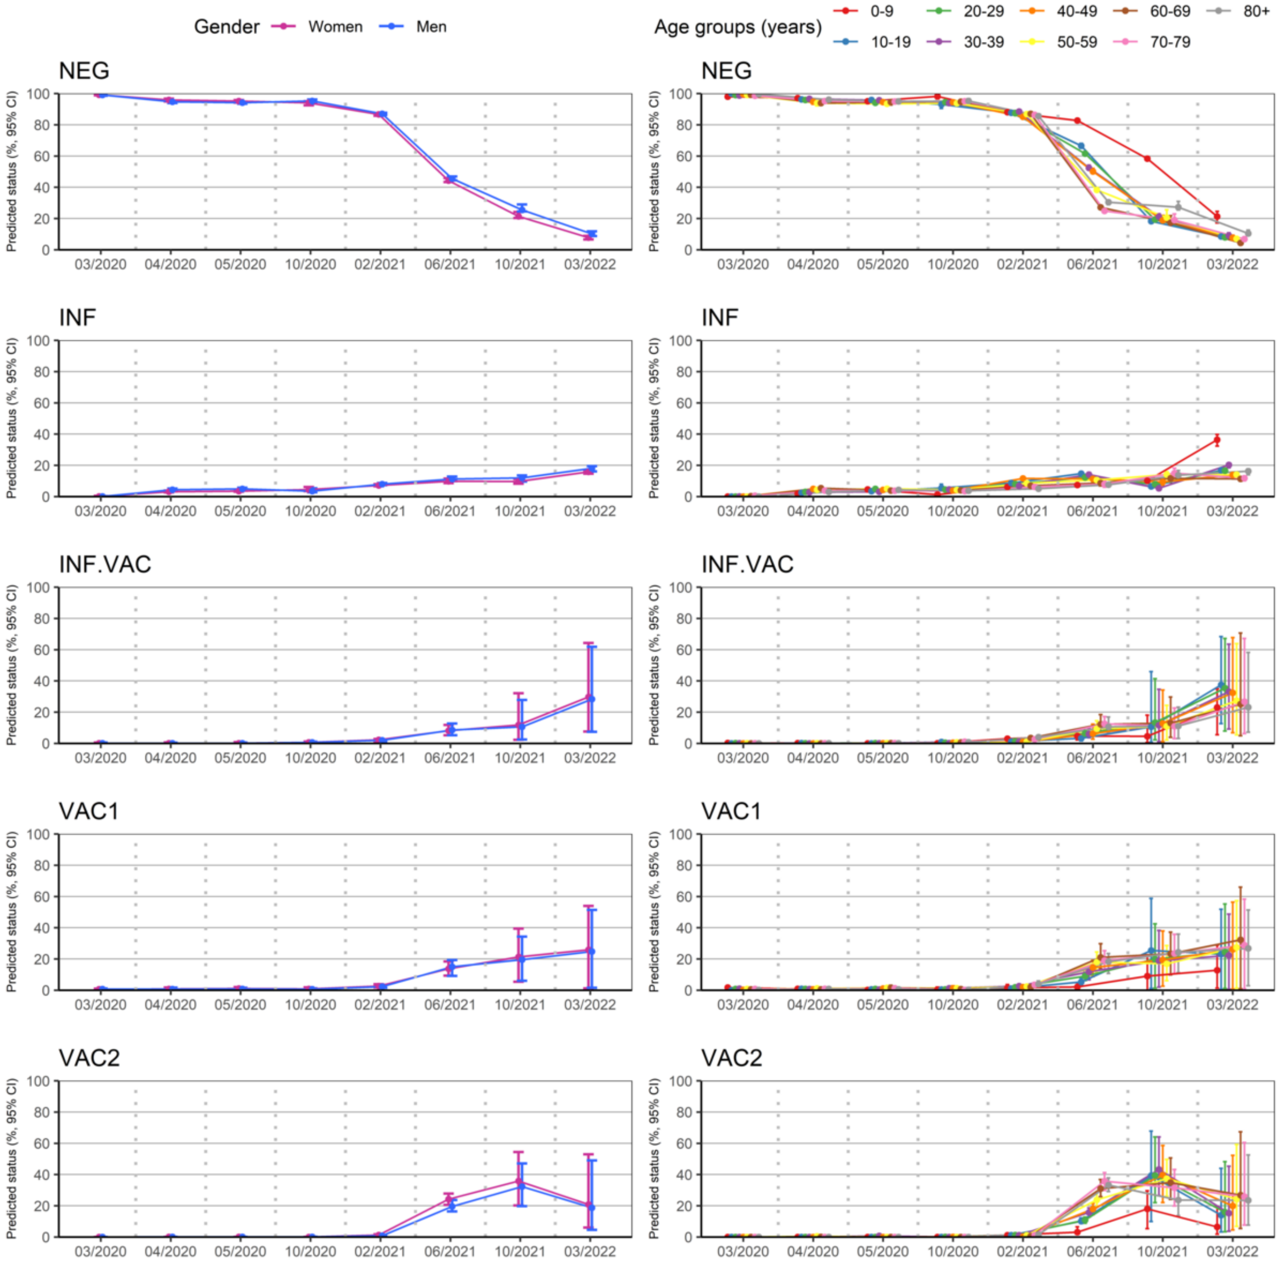

Figure 6. Percentages of SARS-CoV-2 predicted status for the 8 collection periods according to regions in France for the SERPICO data set. INF: infected-unvaccinated; INF.VAC: infected-vaccinated regardless of the number of doses; NEG: uninfected-unvaccinated; VAC1: vaccinated with 1 dose; VAC2: vaccinated with 2 doses. For a higher-resolution version of this figure, see Multimedia Appendix 2.

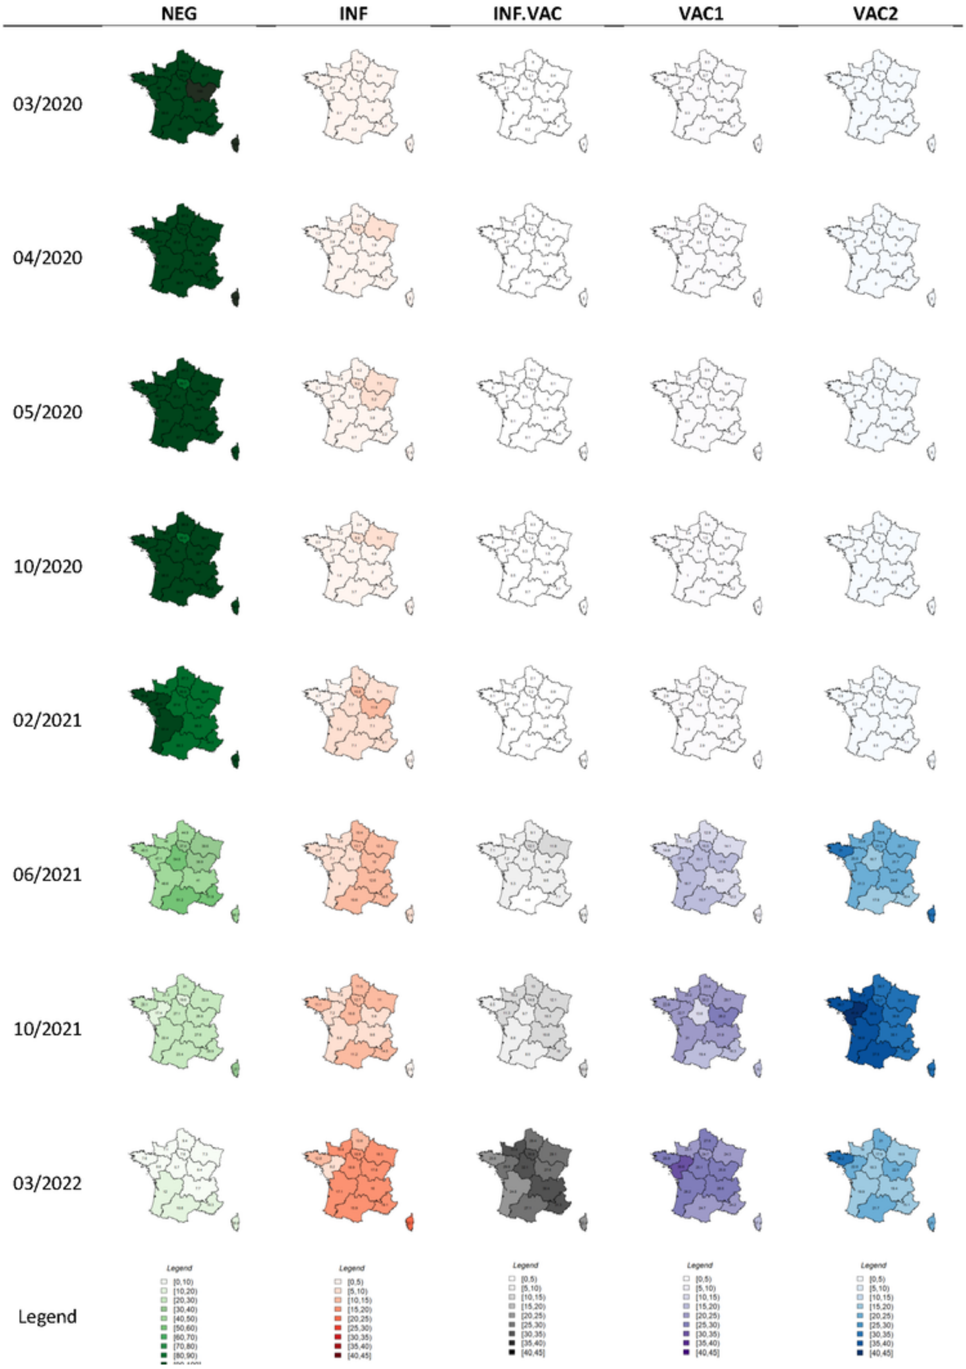

Discussion

Serological Assays

The objective of our study was to predict the infected or vaccinated status of the individuals enrolled in the SARS-CoV-2 serosurveillance survey without prior information on their SARS-CoV-2 infection or vaccination status. For that purpose, reference data on serological profiles of seronegative, infected, and vaccinated individuals from another French cohort were used to build the predictive model. This approach was possible because serological testing was carried out using the same assays developed by the National Reference Centre for Respiratory Diseases of the Institut Pasteur, ensuring the comparability of the serological results between studies.

LuLISA-S is a sensitive assay for identifying individuals exposed to SARS-CoV-2 infection or vaccination. As the vaccines used in France target the SARS-CoV-2 spike protein only, we were confident in the ability of the LuLISA-N assay to distinguish naturally infected individuals from vaccinated ones in the CURIE-O-SA and SERPICO surveys. The LN and LS assays were studied in the context of infection and vaccination [13]. What was less expected was the determinant role of the PNT assay in differentiating INF.VAC individuals from others. The infected status was characterized by a higher pseudoneutralization capacity than that in vaccinated individuals only, confirming previous observations of the higher protection conferred by infection followed by vaccination [4]. Therefore, the 3 serological assays were complementary and essential to obtain a clear distinction between all SARS-CoV-2 statuses in the population, despite the fact that using 3 assays is costly and time-consuming for serosurveillance purposes.

Machine Learning and Data-Driven Analysis

To build models predicting the SARS-CoV-2 status from serological assays, a machine learning procedure was applied. This procedure made it possible to compare a large number of classification models and select the most predictive one. This kind of procedure was previously used for prediction of SARS-CoV-2 status based on serological test results in a population vaccinated with whole virion vaccines [8].

The proposed procedure was based on raw serological results without setting any thresholds, contrary to previous works [3]. The thresholds used in the SERPICO survey were designed to maximize the specificity of the assays in a context of a low prevalence of SARS-CoV-2 infection in France from March 2020 to April 2021. In this study, adopting a data-driven strategy without any assay threshold enabled us to capture the evolution of the SARS-CoV-2 epidemic without modifying the assay interpretations over time [14]. The proposed model exhibited similar performance to the standard method for distinguishing negative versus positive SARS-CoV-2 immune statuses; however, it provided additional information about the positive status (ie, vaccinated, infected, or both; Multimedia Appendix 1).

To ease the use of the model, an R-shiny application was developed for the National Reference Centre and implemented in a user-friendly environment. Input data from the serological assays can be uploaded as a data frame and the most likely SARS-CoV-2 status is given [15].

Vaccination Impact on Seroprevalence

Application of the predictive model to serosurveillance results gave useful insights for interpreting the evolution of SARS-CoV-2 seroprevalence in France. Between June and October 2020, the proportion of individuals who were seronegative to SARS-CoV-2 infection was still higher than 90% despite the first 2 SARS-CoV-2 waves that greatly impacted health services in March and September 2020. The observed quasistability of seroprevalence over this period could be explained by an increase in seroprevalence due to the waves of infections, tempered by the fairly rapid decrease in anti–SARS-CoV-2 antibodies.

Between October 2020 and March 2022, the proportion of seronegative individuals decreased. As the proposed predictions showed that the proportion of INF individuals did not increase over the same period, the decrease of the seronegative population could be mainly attributed to vaccination. Additionally, the decrease of the NEG population occurred earlier in the older age groups (older than 60 years) who were targeted first by the vaccination program. A part of this older population also benefited from a hybrid immunity due to vaccination and infection, although to a lesser degree than the rest of the adult population. On the contrary, two-thirds of children aged 0 to 9 years were still seronegative to SARS-CoV-2 in October 2021 due to a later rollout of vaccination for children aged 5 to 11 years. The expected percentages infected children aged 0 to9 years increased from 1.3% to 36.4% from October 2021 to March 2021. This clearly shows the impact of the Omicron strain on this poorly vaccinated population. All together, these results confirm that population immunity toward SARS-CoV-2 infection would progress very slowly without vaccination in the French population [16]. Moreover, such a strategy—necessarily combined with continued restrictive measures aimed to avoid overwhelming the health care system—would have had a tremendous impact on the economy and mental health.

Consistency of the Predictions

The proposed predictive model produced SARS-CoV-2 immune status predictions in accordance with the observed SARS-CoV-2 epidemiological situation in France from March 2020 to March 2022 as results were only given in terms of infection prevalence (Multimedia Appendix 1). Predictions by region, gender, and age were consistent with the epidemiological weekly observations of the SARS-CoV-2 epidemic [17].

The consistency of the predictions was largely due to the use of 3 complementary serological assays that enabled us to finely distinguish the 5 SARS-CoV-2 statuses through a machine learning procedure. The main limit of the predictive models is associated with the data from the cohort used for calibration and validation of the models. Indeed, women and middle-aged individuals were overrepresented in the CURIE-O-SA cohort. The lack of profile diversity in the calibration and validation data set may explain why including the covariates (gender and age) did not improve model predictions. In addition, the CURIE-O-SA study took place from April 2020 to November 2021; therefore, it did not capture key evolutions in the SARS-CoV-2 epidemic in France, such as the emergence of the Omicron variant (November 2021) that provoked a different response to the PNT assay used in our study. In addition, infected and vaccinated individuals became more frequent in the overall population over time. This profile of individuals and individuals vaccinated with 1 dose were rare in the CURIE-O-SA cohort, leading to poor accuracy in the prediction of those statuses. The high percentages of individuals predicted to be vaccinated with 1 dose in October 2021 and March 2022 may have been due to the waning immunity of individuals vaccinated with 2 doses for a long time [5,18-20]. Lastly, the CURIE-O-SA cohort did not cover the rollout of the third vaccination dose. The validity limits of the predictive models were thus reached in October 2021, as exemplified by the overlapping CIs of the different percentages of vaccination statuses. The collection of new reference results including both results for the 3 serological assays and SARS-CoV-2 infection and vaccination history of the individuals is needed to update the model. Maintaining serosurveillance distinguishing vaccinated or infected populations is of interest to describe the evolution of SARS-CoV-2 immunity in the overall population and to understand immunity waning over time, but additional samples are needed for that purpose.

Conclusion and Perspectives

A predictive model of individual vaccination or infection status with respect to SARS-CoV-2 was proposed based on 3 complementary serological assays and based on a machine learning procedure. This model was applied to the French nationwide serosurveillance survey from 2020 to 2022 to estimate the proportions of the French population that were seronegative, infected, vaccinated (1 or 2 doses), or infected and vaccinated, as this data set included no prior information on the SARS-CoV-2 infection or vaccination status of the individuals. This allowed us to follow the level of SARS-CoV-2 infection and the vaccine response profile of the French population over time.

Combining the results from the serosurveillance survey with previously acquired results from a cohort studied longitudinally improved the information retrieved from serosurveillance while keeping its protocol simple and easy to implement (no need to collect SARS-CoV-2 information on a large sample of individuals). We think that such a combination strategy is of interest to improve serosurveillance of emerging vaccine-preventable diseases. The results of our predictive model make it possible to measure the crucial contribution of SARS-CoV-2 vaccination to rapidly reach a level of collective immunity that has made it possible to relax sanitary measures without overloading the health care system. Indeed, population immunity toward SARS-CoV-2 infection would have progressed very slowly without vaccination.

Acknowledgments

We thank from the Institut Pasteur, the Recombinant Protein Production and Purification core facility for SARS-CoV-2 protein preparation, the Molecular Biophysics core facility for their quality checking, and Yves L. Janin (Unit of Chemistry and Biocatalysis) for providing the Hikarazine luciferase-linked immunosorbent assay substrate. We also thank the whole Integrated Collections for Adaptive Research in Biomedicine (ICAReB) team and COVID-19 support staff at the Institut Pasteur, the team from the Eurofins Biomnis Sample Library, and the team from CerbaHealthcare for serum sample management.

We also thank the personnel of the Institut Curie who volunteered to participate to the CURIE-O-SA study, which was set up and managed by the staff of the clinical and laboratory departments of the Institut Curie.

The blood and clinical study at the Institut Curie was funded by Fondation de France, Agence Nationale de la Recherche (grant ANR-21-COVR-002) and institutional funding from the Institut Curie.

Authors' Contributions

SB, AHS, HN, and SBS wrote the manuscript. OL and HN designed the study. SB and VA analyzed and visualized the data. TR, SVDW, MA, CD, SG and BCC performed laboratory investigations. MA, JBR, CD, JP, VA, SLV, SG, VG, BCC, GJ, NR, SVDW, OL, and TR revised the manuscript.

Abstract

Background: Self-reported questions on blindness and vision problems are collected in many national surveys. Recently released surveillance estimates on the prevalence of vision loss used self-reported data to predict variation in the prevalence of objectively measured acuity loss among population groups for whom examination data are not available. However, the validity of self-reported measures to predict prevalence and disparities in visual acuity has not been established.

Objective: This study aimed to estimate the diagnostic accuracy of self-reported vision loss measures compared to best-corrected visual acuity (BCVA), inform the design and selection of questions for future data collection, and identify the concordance between self-reported vision and measured acuity at the population level to support ongoing surveillance efforts.

Methods: We calculated accuracy and correlation between self-reported visual function versus BCVA at the individual and population level among patients from the University of Washington ophthalmology or optometry clinics with a prior eye examination, randomly oversampled for visual acuity loss or diagnosed eye diseases. Self-reported visual function was collected via telephone survey. BCVA was determined based on retrospective chart review. Diagnostic accuracy of questions at the person level was measured based on the area under the receiver operator curve (AUC), whereas population-level accuracy was determined based on correlation.

Results: The survey question, “Are you blind or do you have serious difficulty seeing, even when wearing glasses?” had the highest accuracy for identifying patients with blindness (BCVA ≤20/200; AUC=0.797). The highest accuracy for detecting any vision loss (BCVA <20/40) was achieved by responses of “fair,” “poor,” or “very poor” to the question, “At the present time, would you say your eyesight, with glasses or contact lenses if you wear them, is excellent, good, fair, poor, or very poor” (AUC=0.716). At the population level, the relative relationship between prevalence based on survey questions and BCVA remained stable for most demographic groups, with the only exceptions being groups with small sample sizes, and these differences were generally not significant.

Conclusions: Although survey questions are not considered to be sufficiently accurate to be used as a diagnostic test at the individual level, we did find relatively high levels of accuracy for some questions. At the population level, we found that the relative prevalence of the 2 most accurate survey questions were highly correlated with the prevalence of measured visual acuity loss among nearly all demographic groups. The results of this study suggest that self-reported vision questions fielded in national surveys are likely to yield an accurate and stable signal of vision loss across different population groups, although the actual measure of prevalence from these questions is not directly analogous to that of BCVA.

Introduction

Vision loss and blindness affect approximately 7.08 million Americans and cost the US economy US $134 billion per year [1,2]. Improving and targeting public health and medical interventions to reduce this burden depend on measuring changes in vision loss and blindness prevalence over time at the national, state, and local level. The 2016 National Academies of Sciences, Engineering, and Medicine report *Making Eye Health a Population Health Imperative* [3] highlighted the role that epidemiological surveillance of vision loss could play in mitigating the burden of vision loss. This report included recommendations for the Centers for Disease Control and Prevention (CDC) to develop case definitions to measure visual health, evaluate the utility of self-reported vision measures, and establish a national surveillance system to track vision and eye health indicators in available data sources [3]. A particular challenge to meeting these recommendations is reconciling the different types of data and case definitions used to identify vision loss and blindness prevalence. Historically, most estimates of the prevalence of vision loss and blindness available in the published literature are derived from either population-based examination studies that objectively measure visual function in a defined geographic area and apply these rates to the national population or from nationally representative surveys that measure self-reported vision loss through responses to a wide variety of survey questions [4-8].

Direct measurement of best-corrected visual acuity (BCVA) in the better-seeing eye as evaluated by a trained eye-care technician is accepted as the gold standard method to determine vision impairment or blindness at the person level. Several high-quality population-based studies have attempted to measure BCVA among all persons or persons of a specific race/ethnicity group residing within specific localities [5,6,9-11]. The National Health and Nutrition Examination Survey (NHANES), which approximated BCVA using autorefractors from 1999-2008, is the only examination study derived from a nationally representative sample [4,12]. However, the high cost of examination studies limits their sample size and collection frequency, and study recruitment logistics result in the exclusions of important populations including younger persons, persons with risk factors, the oldest age groups, and persons living in institutional settings such as nursing homes. As a result, examination studies have limited capacity to measure and monitor prevalence for the entire population, identify trends or disparities over time among sociodemographic and risk factor groups, or identify variation in prevalence at the state or local level.

In contrast, survey-based measures of self-reported vision loss and blindness offer advantages of timeliness and much larger sample sizes and typically include richer covariate information on demographic, socioeconomic, behavioral, access to care, and health risk factors. At least 16 nationally representative surveys include self-reported vision questions, including several at the state level and one at the county level [13,14]. Given their low cost of administration, self-reported vision questions can be extremely useful for population health surveillance if they yield a consistent signal of vision problems at the population level, even if they are less precise at the individual level. However, the large number of different survey questions and differences in how they are administered in different surveys result in a wide range of estimates, and experts have expressed skepticism about their accuracy [15,16]. Currently, the validity and correlation of self-reported vision for determining measured visual function is unknown.

Two recent surveillance estimates of the prevalence of vision loss by the CDC’s Vision and Eye Health Surveillance System (VEHSS) and the World Health Organization’s (WHO) Global Burden of Disease project used statistical modeling approaches to combine information from both examination- and survey-based data sources [17]. The VEHSS composite prevalence estimates of blindness and visual acuity loss used Bayesian meta-analytic methods to combine prevalence information from multiple published examination studies that measured BCVA, benchmarked to the NHANES examination measures. The analysis then used self-reported information from the American Community Survey and the National Survey of Children’s Health to predict visual acuity loss prevalence among populations that were excluded or insufficiently captured by examination-based data, including children, older age groups, and persons living in institutional settings, as well as to allocate prevalence by state and county based on the 2019 US population [2]. The WHO estimates similarly combine examination- and survey-based data to estimate burden in WHO regions for which insufficient data exist.

However, more research on the relationship between self-reported vision problems and measured BCVA is vital to better understand the utility of these questions for public health surveillance. Determining the extent to which variation in self-reported vision problems correlates to variation in underlying visual function will support the ongoing development and interpretability of novel surveillance estimates that leverage multiple types of data. In this paper, we sought to estimate the accuracy of self-reported vision loss measures fielded in national surveys by comparing their results to a gold standard of evaluated BCVA at both the individual and population level.

Methods

We conducted a retrospective chart review and concurrent telephone interview among a sample of patients from the University of Washington (UW) ophthalmology and optometry clinics and calculated statistics to inform the accuracy and validity of telephone survey self-reported visual function compared to examination-measured BCVA. We evaluated findings both at the person level, where we assessed the diagnostic accuracy of the survey questions for identifying BCVA loss, and at the population level, where we compared sample-level prevalence rates derived from survey responses to those based on BCVA.

Participant Sample

We sampled study participants from current or recent patients from the UW ophthalmology and optometry clinics. First, we restricted a patient-level electronic health record file to only include patients with a visit from May 2018 through April 2020. We then sampled 1200 patients for inclusion such that approximately 20% had diagnoses for age-related macular degeneration, 20% had diagnoses for diabetic retinopathy, and 20% had diagnoses for glaucoma. Among these patients, we attempted to oversample patients with severe or vision-threatening stages of disease. We sampled for 2 additional cohorts of 20% each, which excluded any patients with diagnoses of age-related macular degeneration, diabetic retinopathy, or glaucoma: one cohort in which patients had presenting visual acuity loss of 20/40 or worse in the better-seeing eye and another cohort in which patients had no record of visual acuity loss. The diagnosed prevalence of cataract was so high that we did not need to oversample for patients with this condition. The overall sample size was too low to specifically oversample for additional diseases, so the prevalence of these conditions in the sample was based on the background rate of selected patients. Between the summer of 2020 and the spring of 2021, UW ophthalmology students and residents recruited and obtained informed consent from 669 patients, of whom 438 (65.5%) completed the telephone survey interview.

Chart Review

We abstracted chart information for all 669 recruited patients from October 2020 until March 2021. The project team developed a secure, web-based form that allowed chart abstractors to complete their reviews remotely (due to COVID-19) and automatically aggregate and store the review information. The form was reviewed by an external panel of experts in ophthalmology, and recommended revisions were incorporated. The form captured presenting (or habitual) acuity and BCVA in each eye and contained additional free-text fields designed to capture patient vision information from electronic health record assessment and treatment plan information. The abstractions were conducted by 2 UW ophthalmology residents (GLS and RL) under the supervision of a professor (AL). Study authors manually reviewed the acuity fields and assigned a single *logMar* value to each patient based on BCVA in the better-seeing eye. These values were re-reviewed by the original abstractors. For reporting purposes, acuity is shown in Snellen acuity ratios.

Telephone Survey

A telephone survey was administered to consented patients in 2 rounds (November 2020 and May 2021) to minimize the amount of time between the survey and the patients' recruitment and consent. Nonrespondents from the first round were recontacted in the second round. The survey was administered by professional interviewers with experience conducting federally funded national surveys. The survey included sections with questions related to patient sociodemographic characteristics, eye diseases, visual function, and vision-related difficulties with activities of daily living (ADL). The question order within each section was randomized for each respondent.

To select questions to include in the survey, we first identified vision-related survey questions from 16 recent or ongoing national surveys [14]. We reviewed the questions with the CDC's Vision Health Initiative and an expert advisory panel convened under the VEHSS, as well as experts in telephone survey administration and psychometrics at NORC at the University of Chicago. We selected three visual function questions from current or recent national surveys: (Question [Q] 1) "Are you blind, or do you have serious difficulty seeing, even when wearing glasses?" which has been administered by the American Community Survey since 2008 and the Behavioral Risk Factor Surveillance System core module since 2013. (Q2) "At the present time, would you say your eyesight, with glasses or contact lenses if you wear them, is excellent, good, fair, poor, or very poor" which is a scaled response question included in NHANES from 1999-2008. (Q3) "Are you blind or unable to see at all?" was administered by the National Health Interview Survey (NHIS) since 1999. We considered but ultimately did not select other questions, including the NHIS question, "Do you have any trouble seeing, even when wearing glasses or contact lenses?" because the wording was deemed to be too similar to Q1.

We also added 2 additional questions not included in prior surveys: "Have you ever been told by a doctor or other health professional that you..." (Q4) "have visual impairment?" and (Q5) "are blind?" which are similar in structure to self-reported eye disease questions that were also included in the survey. We included 6 questions on vision-related ADL that were fielded in the NHIS from 2016-2018, which all began with, "Even when wearing glasses or contacts lenses, because of your eyesight, how difficult is it for you to..." followed by descriptions of ADL, including reading newsprint and driving during the day. Full details and results for the ADL questions are included in Multimedia Appendix 1.

Analyses

We calculated descriptive statistics for all survey responses and chart abstraction values. To assess diagnostic accuracy of questions at the person level, we calculated the sensitivity, specificity, and area under the receiver operator curve (AUC), comparing survey responses to a gold standard of chart-reviewed BCVA. We did not report positive and negative predictive values because these varied based on the underlying prevalence of vision loss in the sample, and by design, we oversampled for vision loss. For Q1 and Q2, we calculated box-and-whisker plots including the mean, median, and IQR of *logMar* values for each survey response value. To assess the validity of self-reported survey questions for quantifying population-level prevalence rates of BCVA-assessed vision loss and blindness, we compared the sample-level prevalence rate and 95% CI, overall and by subgroup. To test for response bias in the telephone survey, we calculated Kruskal-Wallis or chi-square *P* values for differences in baseline demographic characteristics for respondents compared to nonrespondents (Multimedia Appendix 2).

Ethics Approval

The study protocol was reviewed and approved by the UW Institutional Review Board (STUDY00008957) and conforms to the Declaration of Helsinki. All patients included in the study provided informed consent for inclusion in the study, including consenting to the telephone interview and secondary analysis of their medical records and claims information. Consent was obtained via telephone due to COVID-19 restrictions on in-person research activities. No person-level data from this study are released. Participants received no compensation for participation in the study.

Results

Sample Characteristics

The study sample included 438 patients who completed the telephone survey, which was 65.5% of the 669 patients who consented for participation (Table 1). On average, the interview was conducted 5 months after the most recent acuity measurement. Nearly half (n=215, 49.1%) of the 438 patients were interviewed within 120 days of their last acuity measurement and 86.5% (n=379) were interviewed within a year of their last exam, where the longest time difference was 1 year 3 months. We found no significant differences in AUCs associated with duration of time between the survey and exam. We also found no significant differences in demographic characteristics between patients who did and did not respond to the telephone survey (age: *P*=.53; sex: *P*=.44; and race/ethnicity: *P*=.12; Multimedia Appendix 2). The sample was 54.1% (n=237) female, 70.5% (n=309) non-Hispanic White, 9.6% (n=42) non-Hispanic Black, 4.8% (n=21) Hispanic, and 11.6% (n=51) other races/ethnicities. The majority (n=251, 57.3%) of patients were aged 65-84 years; 25.8% (n=113) were aged 40-64 years, 8% were aged (n=35) 85+ years, 8% were aged (n=35) 18-39 years, and 0.9% were aged (n=4) 0-17 years. Of all the respondents, 38.4% (n=168) reported education beyond a bachelor’s degree, 28.8% (n=126) had an associate’s or bachelor’s degree, and 32.4% (n=142) had less than a college degree. Nearly two-thirds (n=281, 64.2%) of patients had BCVA better than 20/40, equating to normal vision; 17.8% (n=78) had mild impairment of 20/40 to <20/80; 4.8% (n=21) had moderate impairment of 20/80 to <20/200; and 13.2% (n=58) were blind, including 2.1% (n=9) with 20/200 to <20/400 and 11.2% (n=49) with blindness defined as acuity ≤20/400, difficulty counting fingers or seeing hand motions, or having no light perception.

Table 1. Demographic characteristics of the study population.

Characteristic	Patient (n=438), n (%)
Sex	
Male	199 (45.4)
Female	237 (54.1)
Age (years)	
0-17	4 (0.9)
18-39	35 (8)
40-64	113 (25.8)
65-84	251 (57.3)
85+	35 (8)
Race/ethnicity	
Hispanic	21 (4.8)
Non-Hispanic Black	42 (9.6)
Non-Hispanic White	309 (70.5)
Other	51 (11.6)
Unknown	15 (3.4)
Education	
Less than college degree	142 (32.4)
Associate's or bachelor's degree	126 (28.8)
Graduate degree	168 (38.4)
Unknown	2 (0.5)
Best-corrected visual acuity in the better-seeing eye	
>20/40 (normal vision)	281 (64.2)
20/40 to <20/80 (mild vision impairment)	78 (17.8)
20/80 to <20/200 (moderate vision impairment)	21 (4.8)
20/200 to <20/400 (blindness)	9 (2.1)
≤20/400 (blindness based on acuity, CF[a], HM[b], or NLP[c])	49 (11.2)

[a] CF: counting fingers.

[b] HM: hand motion.

[c] NLP: no light perception.

Survey Responses

Of respondents, 19.2% (n=84) self-reported "yes" to the question Q1, "Are you blind or do you have serious difficulty seeing, even when wearing glasses?"; 3.7% (n=16) responded that they are "blind or unable to see at all" (Q3); and 55.5% (n=227) and 7.3% (n=32) of respondents stated they had ever been told by a doctor that they had visual impairment (Q4) and blindness (Q5), respectively (Figure 1).

Figure 1. Sample prevalence, sensitivity, specificity, and area under the receiver operator curve (AUC) of survey questions versus any vision loss or blindness. The sample prevalence of survey response options compared to the gold standard of best-corrected visual acuity (BCVA) thresholds of ≤20/40 (vision loss) and ≤20/200 (blindness) is shown. The diagnostic accuracy of each question is compared to BCVA-assessed vision loss or blindness. Sensitivity (sens.) refers to the rate at which the question accurately identifies vision loss or blindness in comparison to BCVA (true positive), whereas specificity (spec.) refers to the rate at which the question correctly identified BCVA vision, indicating no vision loss or blindness (true negative). AUC measures both sensitivity and specificity and, therefore, is the primary measure of diagnostic accuracy reported in this analysis. Q: question.

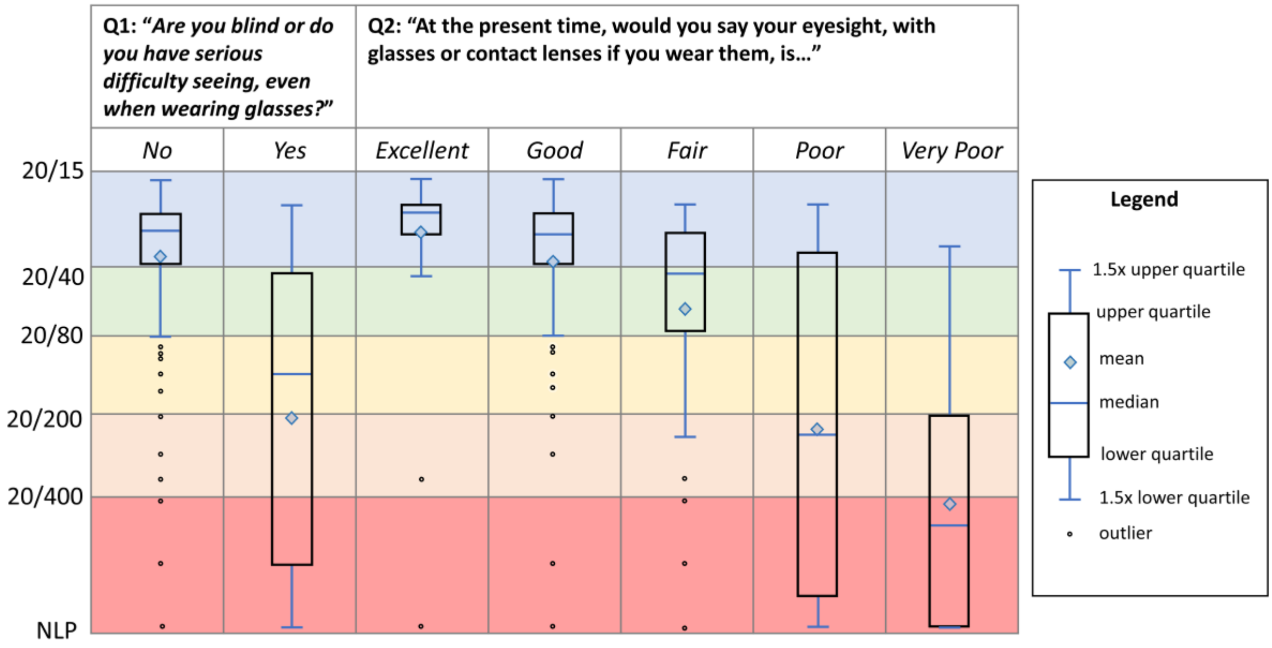
	Question	Response	Prevalence		Accuracy vs BCVA ≤20/40			Accuracy vs BCVA ≤20/200		
			#	Percent	Sensitivity	Specificity	AUC	Sensitivity	Specificity	AUC
Q1	*Are you blind or do you have serious difficulty seeing, even when wearing glasses?*	Yes	84	19.2%	0.43	0.93	0.68	0.70	0.88	0.80
Q2	*At the present time, would you say your eyesight, with glasses or contact lenses if you wear them, is excellent, good, fair, poor, or very poor*	Fair, Poor, or Very Poor	144	32.9%	0.62	0.81	0.72	0.75	0.73	0.74
		Poor or Very Poor	50	11.4%	0.27	0.96	0.61	0.51	0.95	0.73
		Very poor	14	3.2%	0.09	1.00	0.54	0.19	0.99	0.59
Q3	*Are you blind or unable to see at all?*	Yes	16	3.7%	0.11	1.00	0.56	0.23	1.00	0.63
Q4	*Have you EVER been told by a doctor or other health professional that you have visual impairment?*	Yes	227	51.8%	0.79	0.57	0.68	0.91	0.50	0.70
Q5	*Have you ever been told by a doctor or other health professional that you are blind?*	Yes	32	7.3%	0.20	0.99	0.60	0.40	0.98	0.70

Person-Level Accuracy of Survey Responses for Indicating BCVA

Figures 1 and 2 show associations between BCVA and survey responses at the person level. Figure 1 reports the sensitivity, specificity, and AUC of each survey question for predicting either vision loss (≤20/40) or blindness (≤20/200). For any vision loss, Q4 had the highest sensitivity (0.79), whereas Q3 had 100% specificity. Q2 achieved the highest AUC (0.72) and the smallest percentage difference when including any response of “fair,” “poor,” or “very poor” to indicate vision loss (data not shown). Q1 had the second highest AUC of 0.68, but this appears to be achieved through high specificity (0.930) despite relatively low sensitivity (0.43). Q1 also underestimated vision loss by 46%. For blindness, the highest sensitivity and specificity were achieved by Q4 (0.91) and Q3 (0.995), respectively. Q1 had the highest AUC at 0.80 but overestimated blindness by 47% relative to BCVA. The second highest AUC was achieved by Q2 (0.74) when including responses of “fair,” “poor,” or “very poor” to indicate blindness. Q2 responses of “poor” or “very poor” resulted in the closest overall prevalence estimate for blindness, underpredicting blindness by 12% relative to BCVA. Multimedia Appendix 3 shows the receiver operating characteristic curves associated with these results.

Figure 2 includes box plots depicting the distribution of visual acuity values by survey responses to Q1 and Q2 (selected because these questions achieved the highest AUC values for blindness and vision loss, respectively). For responses to Q1, the IQR of “no” responses is almost entirely within the range of normal acuity values of <20/40, whereas the lower threshold of 1.5 × IQR for “no” is almost entirely within the range of mild visual impairment of 20/40 to < 20/80. The IQR of “yes” responses ranges from just over 20/40 to <20/400, but the upper threshold of 1.5 × IQR is nearly 20/20. For Q2, the box plots show that the mean and median acuity values of the 5-response options fall within 5 corresponding levels of acuity loss, although the IQR and outer thresholds span multiple acuity categories.

Figure 2. Distribution of best-corrected visual acuity (BCVA) in the better-seeing eye by survey response value. The box-and-whisker plots show the distribution of BCVA among patients who gave a response to both Q1 and Q2. These questions were selected because they were the 2 questions with the highest diagnostic accuracy for BCVA blindness and vision loss, respectively. The box-and-whisker plots show the mean, median, upper and lower quartiles, 1.5× quartiles, and outliers defined as values outside of the range of 1.5× the lower and upper quartiles. The distribution of BCVA generally corresponds with the survey response. However, for Q2, “Excellent” and “Good” responses are both primarily within the normal vision range, whereas “Poor” responses exhibits a very wide distribution. NLP: no light perception; Q: question.

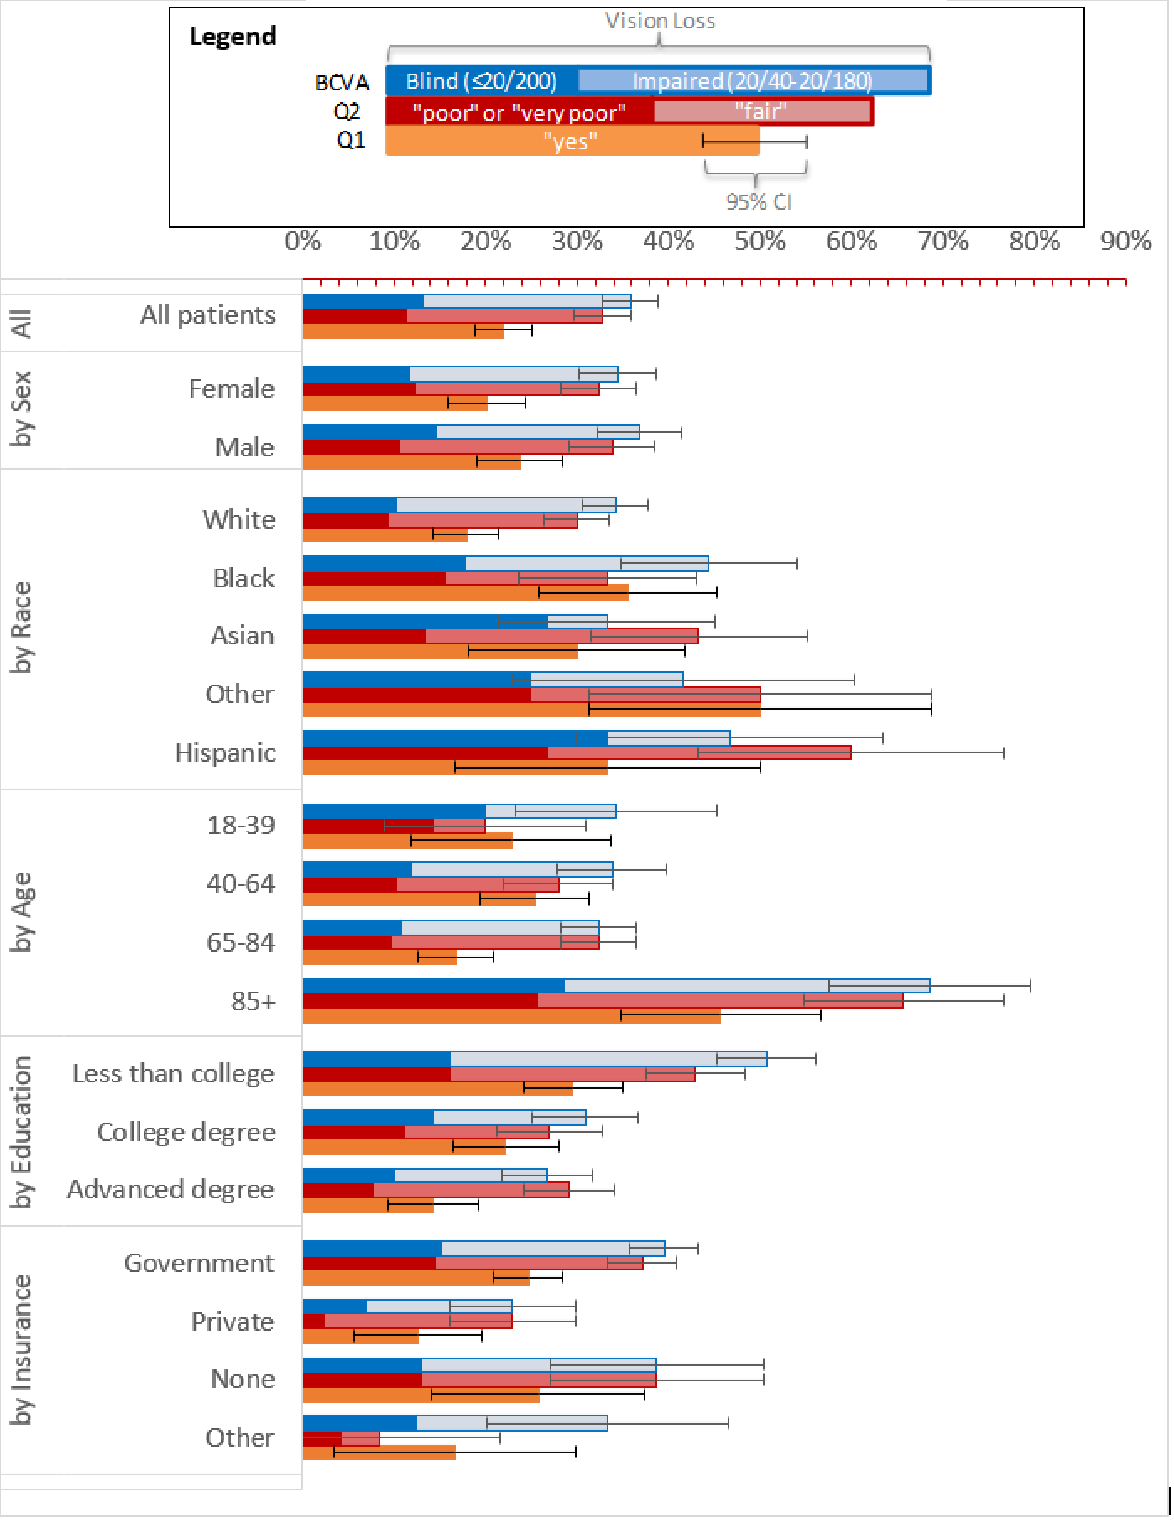


Population-Level Vision Loss and Blindness Prevalence

Figure 3 shows the population-level prevalence rates for BCVA and Q1 and Q2 responses overall and by sex, race/ethnicity, age group, insurer, and education status among the sample. BCVA is shown as a stacked bar with blindness on the left and impairment on the right; the cumulative sum of these bar charts is equivalent to any BCVA loss. The prevalence of vision loss for all patients was 35.8% (157/438). Responses for Q2 are similarly stacked, such that the left bar includes responses of “poor” or “very poor” and the right bar includes “fair”; thus, the stacked cumulative total would equate to the responses of “fair,” “poor,” or “very poor,” which had an overall prevalence of 32.9% (n=144). Q1 “yes” responses had an overall prevalence of 21.9% (96/438).

At the population level, Q1 and Q2 responses exhibit similar trends and disparities in prevalence rates as those of BCVA. The two Q2 response groupings are closely correlated with the 2 BCVA categories. For Q2, the relative difference in prevalence rate of “poor” or “very poor” responses was 14% lower than that of BCVA blindness, whereas the prevalence of Q2 responses of “fair,” “poor,” or “very poor” was 8% lower than BCVA vision loss. Q1 response of “yes” relatively overpredicts BCVA blindness (≤20/200) by 66% and underpredicts BCVA vision loss (≤20/40) by 39%. The relative relationships in prevalence between BCVA, Q1, and Q2 were stable across most sample subgroups. Prevalence based on Q1 falls within the range of BCVA blindness to vision loss for every subgroup except the “Other race” subgroup, although this result is based on a sample of only 12 patients. Similarly, the cumulative responses from Q2 fell within the range of blindness to vision loss for all subgroups except the “Other race,” “Hispanic,” “Advanced degree,” and “Other insurance” subgroups.

Figure 3. Sample-level prevalence rates of best-corrected visual acuity (BCVA)–assessed blindness and visual impairment, Q2 responses of “poor" or "very poor" and “fair,” and Q1 response of “yes.” The relationship between population-level prevalence rates based on BCVA, Q1, and Q2 at the population level is shown. BCVA is based on the better-seeing eye. Q1 is “Are you blind or do you have serious difficulty seeing, even when wearing glasses?” and Q2 is ”At the present time, would you say your eyesight, with glasses or contact lenses if you wear them, is excellent, good, fair, poor, or very poor?” For each population group, there are 3 bars. The top blue bar is BCVA and depicts 2 stacked bars. The darker blue bar on the left is the prevalence of blindness (≤20/200). The lighter blue bar stacked to the right is the prevalence of persons with visual impairment (20/40 to 20/180). Thus, the sum of the upper, blue stacked bars represents any vision loss (≤20/40). The red stacked bar below depicts prevalence results from Q2. The dark red bar on the left includes patients who reported “poor” or “very poor” eyesight. The lighter red bar stacked to the right is the prevalence of “fair” responses. Thus, the value of the dark and light red stacked bars represents patients who reported “very poor,” “poor,” or “fair” eyesight. The lower orange bar is the prevalence of “yes” responses to Q1. Q: question.



Discussion

This study provides evidence on the accuracy and validity of vision and eye health survey questions, including those currently or recently deployed through federally funded national surveys. We measured the concordance between self-reported vision loss or blindness and vision-related ADL limitations versus vision measured with BCVA among a sample of patients from ophthalmology and optometry clinics and reported results both at the person and population level. The highest AUC for predicting blindness (0.80) was achieved by Q1, “Are you blind, or do you have serious difficulty seeing, even when wearing glasses?” The highest AUC (0.72) for predicting any BCVA loss was achieved by Q2, “At the present time, would you say your eyesight, with glasses or contact lenses if you wear them, is…” when the responses of “fair,” “poor,” or “very poor” are used to indicate any vision loss. Prevalence rates based on Q2 or adjusted Q1 responses were highly correlated to population-level prevalence of BCVA blindness and vision loss and suggest that at the population level, variation in self-reported prevalence based on Q1 and Q2 is likely to accurately reflect patterns and variations in the underlying prevalence of visual acuity loss and blindness.

This study has several limitations. Our study sample consisted of current or recent patients from optometry and ophthalmology clinics, which are not representative of the general population and may have higher awareness of their visual health. This sample also exhibited higher levels of education and, due to our intentional oversampling, a much higher prevalence of evaluated BCVA impairment than would be seen in a nationally representative population. Due to COVID-19–related restrictions on in-person research, patient acuity measures were collected through retrospective chart review. Among the 669 recruited patients, 231 (34.5%) did not complete a telephone interview. In addition, we define vision loss based on BCVA only. We did not consider other measures of vision loss such as reduced visual field, contrast sensitivity, or near-distance acuity because this information was not routinely recorded in the medical charts. Due to this limitation, we likely misclassified some patients with better vision. We additionally compared self-reported values to BCVA as opposed to presenting visual acuity because of data quality concerns regarding how consistently presenting or habitual acuity may have been recorded in patient charts and because historically, vision loss and blindness prevalence estimates are reported based on BCVA. Finally, time differences between the patients’ survey interview and the date of their nearest examination may bias results. Presumably, longer time periods would reduce the apparent accuracy of the self-reported responses, although we did not find a significant association between this time difference and AUC.

Identifying and documenting the concordance and relationship between self-reported vision problems and BCVA is important to enhance national surveillance of vision loss and eye problems. Historically, visual health epidemiological estimates were derived from either national surveys or examination studies, each of which have inherent strengths and limitations. Examination studies provide estimates of objectively measured vision loss, but due to their high cost and complexity, they are all based on small, localized samples, many of which are arguably out of date. National self-reported surveys provide large, representative, and ongoing samples that examination studies lack, but self-reported instruments previously lacked evidence of validity as proxy measures of actual vision loss.

The purpose of this study was to evaluate the validity of self-reported vision measures to assess population health. The results of this study imply that self-reported questions should not be used as a substitute for clinical vision evaluation but do support the interpretation of self-reported survey questions as proxy measures of variation in population visual health for use in surveillance. The recent surveillance estimates of the prevalence of visual acuity loss produced by the CDC’s VEHSS and the WHO both leverage the strengths of examination studies (their robust measurement of vision loss) as well as that of national surveys (their large, ongoing representative samples) to provide more complete and detailed epidemiological estimates than can be supported by either type of data alone [2,17]. Our findings lend support to the methodologies and assumptions of these ongoing national and international visual health surveillance efforts by measuring the accuracy of self-reported vision at the individual and population level.

Acknowledgments

Abstract

Background: Rabies is a deadly zoonotic disease with nearly 100% fatality rate. In the United States, rabies virus persists in wildlife reservoirs, with occasional spillover into humans and domestic animals. The distribution of reservoir hosts in US counties plays an important role in public health decision-making, including the recommendation of lifesaving postexposure prophylaxis upon suspected rabies exposures. Furthermore, in surveillance data, it is difficult to discern whether counties have no cases reported because rabies was not present or because counties have an unreported rabies presence. These epizootics are monitored by the National Rabies Surveillance System (NRSS), to which approximately 130 state public health, agriculture, and academic laboratories report animal rabies testing statistics. Historically, the NRSS classifies US counties as free from terrestrial rabies if, over the previous 5 years, they and any adjacent counties did not report any rabies cases and they tested ≥15 reservoir animals or 30 domestic animals.

Objective: This study aimed to describe and evaluate the historical NRSS rabies-free county definition, review possibilities for improving this definition, and develop a model to achieve more precise estimates of the probability of terrestrial rabies freedom and the number of reported county-level terrestrial rabies cases.

Methods: Data submitted to the NRSS by state and territorial public health departments and the US Department of Agriculture Wildlife Services were analyzed to evaluate the historical rabies-free definition. A zero-inflated negative binomial model created county-level predictions of the probability of rabies freedom and the expected number of rabies cases reported. Data analyzed were from all animals submitted for laboratory diagnosis of rabies in the United States from 1995 to 2020 in skunk and raccoon reservoir territories, excluding bats and bat variants.

Results: We analyzed data from 14,642 and 30,120 county-years in the raccoon and skunk reservoir territories, respectively. Only 0.85% (9/1065) raccoon county-years and 0.79% (27/3411) skunk county-years that met the historical rabies-free criteria reported a case in the following year (99.2% negative predictive value for each), of which 2 were attributed to unreported bat variants. County-level model predictions displayed excellent discrimination for detecting zero cases and good estimates of reported cases in the following year. Counties classified as rabies free rarely (36/4476, 0.8%) detected cases in the following year.

Conclusions: This study concludes that the historical rabies freedom definition is a reasonable approach for identifying counties that are truly free from terrestrial raccoon and skunk rabies virus transmission. Gradations of risk can be measured using the rabies prediction model presented in this study. However, even counties with a high probability of rabies freedom should maintain rabies testing capacity, as there are numerous examples of translocations of rabies-infected animals that can cause major changes in the epidemiology of rabies.

Introduction

Background

Rabies is a deadly zoonotic disease caused by an RNA virus (rabies virus) in the *Lyssavirus* genus, which causes acute progressive encephalitis in mammals with nearly 100% fatality rate [1,2]. Globally, an estimated 60,000 people die annually from rabies infection, with the highest fatality rates attributable to the dog-mediated rabies virus variant (DMRVV) in African and Asian countries [3]. However, established dog population management and vaccination methods have successfully eliminated DMRVV in most Western countries [4].

With the elimination of DMRVV in the United States, terrestrial mesocarnivores and bats are the remaining rabies reservoirs in the United States [5]. Reported infections in domestic animals have decreased since the implementation of animal control and vaccination programs in the 1940s and 1950s in the United States; however, contact with wildlife and unvaccinated domestic animals can still pose a threat of infection [6,7]. Human rabies deaths in the United States are rare, and rabies pre-exposure prophylaxis and postexposure prophylaxis (PEP) are effective when administered according to the Advisory Committee on Immunization Practices guidance [6,8,9]. Annually, an estimated 55,000 to 60,000 people in the United States receive rabies PEP for suspected rabies exposures at an estimated cost of >US $150 million [6,10]. The distribution of reservoir hosts in a given US county (ie, local administrative unit) can inform rabies risk assessment algorithms to determine if rabies PEP is required following a human exposure, based on the epizootiology of the area where the exposure occurred [11]. Therefore, understanding the geographic and temporal patterns of animal rabies in the United States through routine surveillance is essential for public health interventions such as the recommendation of costly but lifesaving rabies PEP as well as for developing and evaluating wildlife rabies management actions and responding to unexpected rabies occurrences [7].

Rabies reservoirs in the United States include multiple bat species and 5 terrestrial mesocarnivores, including raccoons (*Procyonlotor*), skunks (family *Mephitidae*), foxes (*Vulpes* spp and *Urocyoncinereoargenteus*), and the small Indian mongoose (*Herpestesauropunctatus*) in Puerto Rico [7]. Substantial geographical variation exists in the risk of rabies exposure in the United States owing to the distinct geographic distribution of the different rabies virus variants (RVVs) associated with these terrestrial reservoirs [12]. The eastern raccoon RVV, for example, was first reported in Florida in the 1950s and later spread throughout the east coast following an apparent translocation event [13,14]. Three distinct skunk RVVs exist: south central, north central, and California skunks, named for their geographical locations within the United States. Other regions of the United States, such as the northwestern states of Washington and Oregon, are believed to be free from terrestrial rabies reservoirs. However, bat rabies is present throughout the continental US as it is uniquely unconstrained by the geographic barriers that define the territories of terrestrial reservoirs [5,7,12].

Animal and human rabies are both nationally notifiable conditions in the United States [15,16]. The US Centers for Disease Control and Prevention (CDC) manages the National Rabies Surveillance System (NRSS), which comprises approximately 130 jurisdictional public health, agriculture, and academic laboratories that conduct passive public health surveillance, as well as the US Department of Agriculture National Wildlife Rabies Management Program, which conducts active case surveillance in areas where wildlife vaccinations are distributed [12]. Jurisdictional laboratories conduct diagnostic testing; some perform viral characterization for positive samples; and the US CDC offers laboratory assistance for diagnostics, viral typing, and exposure tracing and assessment. Animal and human rabies case definitions and data elements reportable to the NRSS are defined by the Council of State and Territorial Epidemiologists Animal Rabies and Human Rabies position statements, respectively [17,18].

Objectives

As the NRSS is largely a passive public health surveillance system, it can be difficult to discern through surveillance data if counties report no animal rabies cases because of the absence of rabies or because of the inability to detect cases. Historically, the NRSS defines counties in the United States as *terrestrial rabies free* if there have been no terrestrial rabies cases reported in that county or any adjacent county for the previous 5 years and if the county has achieved a sufficient level of surveillance testing for rabies over those 5 years [12]. However, no previous attempts have been made to validate or improve this definition since its inception in 2005 [19]. Therefore, the objectives of this analysis were to describe and evaluate the performance of the historical NRSS rabies-free county definition, review the possibilities for improving this definition, and develop a model to achieve more precise estimates of the probability of terrestrial rabies freedom and the number of reported terrestrial rabies cases at the county level.

Methods

Domestic Animal Rabies Testing and Reporting in the United States

The NRSS collects data from state public health, agriculture, and academic laboratories that test animal samples for rabies using the direct fluorescent antibody test or other diagnostic methods recommended by the Council for State and Territorial

Epidemiologist's Animal Rabies position statement [17]. Confirmed animal cases are reportable to the state public health officials and notifiable to the CDC [15,17,20]. Recommended data elements included the species, capture location, test date, and RVV (when available) of each animal tested for rabies virus. The NRSS has been relatively unchanged since 1995 in terms of consistent diagnostic approaches, access to testing, and epidemiological circumstances.

The passive public health surveillance system prioritizes the testing of animals involved in human or domestic animal exposures, although specific testing criteria vary by jurisdiction. Passive public health surveillance accounted for 95% of reported rabid animals. Active surveillance is conducted in selected high-priority areas and informs wildlife rabies management such as management of oral rabies vaccination campaigns. Passive public health data and active surveillance data were both included in this analysis.

Historical Rabies-Free Definition

The historical definition used to classify counties as terrestrial rabies free is as follows [12]:

- No terrestrial rabies cases reported in that county for ≥5 years;
- No terrestrial rabies cases reported in any neighboring counties for ≥5 years; and
- ≥15 surveillance points were tested over the past 5 years, where surveillance points=0.5 × (number of domestic animals) + 1 × (number of reservoir animals tested). Companion animals and livestock (eg, dogs, cats, cattle, and horses) are considered domestic animals. Foxes, raccoons, skunks, and mongooses are considered reservoir animals, regardless of the state or county in which they are found.

Data Set

This analysis used county-level data from the NRSS from 1995 to 2020 regarding the number and species of animals tested, and positive, for rabies each year (excluding bats) as well as accompanying viral characterization results when available. Bats and bat variants were excluded to focus the analysis on rabies from terrestrial reservoirs; the entire continental United States is considered to be at risk for rabies transmitted by bats. First, we evaluated the historical surveillance definition using measures of sensitivity, specificity, positive predictive value, and negative predictive value. Next, we applied a zero-inflated negative binomial model to describe the contributions of each individual variable involved in the historical definition, evaluate alternative definitions of rabies freedom, and predict the presence or absence and the number of rabies cases that would be reported in a given county in the following year.

All bats submitted for testing, as well as rabies virus–positive terrestrial mammals recorded as having bat RVVs, were excluded from the analysis. As data files for some states before 2014 included inconsistent reporting of negative test results, we included data from each state starting from the year after which <3 in 4 consecutive years contained incomplete rabies test results (1995 for most states; 1998 for Delaware; 2002 for Florida, Mississippi, New Mexico, and Vermont; 2006 for California, Georgia, Iowa, and South Carolina; and 2014 for Oklahoma). Eight remaining state-years had missing county information for >50% of negative results. In these data files, to avoid loss of these data in the analysis, the negative results were assigned to counties using the average distribution from the 4 closest years of complete data. Nineteen state-years had ≤10 samples tested or <50% of samples testing negative, suggesting that negative results had not been fully reported. In these data files, we set the number of negatives equal to the average of the 4 closest years of the complete data. Overall, 6.99% (104/1486) of the state-years of data were removed for missing negatives and 2% (27/1350) had negative results imputed.

The total number and species of animals tested and positive were aggregated by county and year. All terrestrial species were included unless they were noted as having bat RVVs. The historical rabies freedom definition requires data on the detection of rabies in the preceding 5 years. We used the first 8 continuous years of data from each county (regardless of whether any samples were submitted) as a baseline and began predicting the presence or absence of rabies from the 9th year of the data. Thus, our predictions began in 2003 for counties in the states with complete data.

Models were fitted separately for counties in states that were historically designated as raccoon and skunk reservoir territory based on past detections of the respective RVVs, as reported by the NRSS [12]. Counties in states with other terrestrial rabies reservoirs (Arctic fox variant, gray fox variant, and dog-mongoose variant) were excluded to focus on the most common RVVs found in the United States. For the raccoon territory, we first selected all counties that had at least 1 recorded positive case in the data set and were located in states where raccoons were the primary terrestrial reservoir. We then added all counties within 100 km of this area (county centroid-to-centroid) unless the new county was located in a state with a different terrestrial reservoir. We followed the same procedure to define the counties as skunk territories.

For modeling analyses, data were separated into "training" and "validation" data sets. Data from 2018 were used to train the models, whereas data from 2019 and 2020 were used as separate validation data sets. The results of nonparametric analyses are presented for both the training and validation data sets.

Modeling Approach

We used a zero-inflated negative binomial regression model to describe the presence or absence of terrestrial rabies and the number of reported terrestrial rabies cases per county-year. A zero-inflated negative binomial model is appropriate for count data when there is a greater than expected number of zeros in the data set, and the process generating these zeros is independent of the count process [21,22]. In this case, excess zeros may occur in counties that are truly rabies free, that is, not enzootic for terrestrial RVVs. The counting process represents rabid animal observations in counties where rabies is enzootic. The first process is encoded as a logistic model for rabies freedom (1a) and the second as a negative binomial count model (1b). We refer to the zero-inflated negative binomial model as the rabies prediction model.

Freedom model 1a: $\text{logit}(P(\textit{rabies free})) = \alpha_0 + \alpha_1 A + \alpha_2 B + \alpha_3 C + \alpha_4 D$ **(1)**

Count model 1b: $\log(E(\textit{cases reported}|\textit{not rabies free})) = \beta_0 + \beta_1 A + \beta_2 B + \beta_3 E$ **(2)**

Where:

A = log(number of rabid animals reported in the county of interest in the past year + 0.5) **(3)**

B = log(number of rabid animals reported in any neighboring county in the past year + 0.5) **(4)**

C = log(years with no rabies reported in the county of interest) [1=case reported in past year, 2=last case reported in the year before last, etc] **(5)**

D = log(years with no rabies reported in any neighboring county) [1=case reported in the past year, 2=last case reported in the year before last, etc] **(6)**

E = log(surveillance points in the past 5 years + 0.5) **(7)**

The count portion of the model estimates the number of cases that will be reported if rabies is enzootic. The freedom portion of the model estimates the probability that there truly are no cases within the county. From these model outputs, we can derive three outcomes: (1) the probability that the county is rabies free, (2) the probability that the county would observe rabies cases (if present) through their surveillance efforts, and (3) the probability that the county would have cases that would go unreported by surveillance efforts.

Predictor variables for each component model were selected based on the historical rabies-free definition and a consideration of possible causal pathways. For example, surveillance may have a causal effect on the number of rabies cases reported (count model) but not on the underlying endemicity of terrestrial rabies RVVs (freedom model).

We natural log transformed all the variables to provide a better fit. We defined the number of years since rabies was last reported as ranging from 1 (last year) to 9 (cutoff for any >8). Variables for surveillance points and cases reported in the prior year were shifted by 0.5 to avoid zero values in log-transformed variables.

Model Validation and Comparison

To evaluate the impacts of different surveillance effort definitions, we applied different definitions of surveillance effort to the rabies prediction model: including only domestic or only reservoir animals, adjusting the relative value of surveillance effort by changing the coefficient applied to domestic animals from 0.1 to 1 times that of reservoir animals, applying specific coefficients to different domestic and wild animal species based on their reported test positivity rates, changing the number of years of surveillance effort considered from 1 to 8, and normalizing surveillance effort by county size or population.

Several criteria were used to evaluate different model formulations. First, we calculated the Spearman correlation between the predicted and reported cases each year. Second, we computed the area under the receiver operating characteristic curves (AUCs), treating the observed data in the prediction year as "true" values. We considered two different options as predicted values for AUCs: (1) the model-predicted probability of rabies freedom and (2) the model-predicted probability of reporting 0 cases. As the number of observed cases in the prediction year is not a perfect measure of rabies freedom, we also considered the detection of any rabies cases in the following 5 years as a marker of true rabies presence in a sensitivity analysis.

$P(\textit{rabies free}) = \textit{expit}(\alpha_0 + \alpha_1 A + \alpha_2 B + \alpha_3 C + \alpha_4 D)$ **(8)**

$P(\textit{0 cases reported}) = P(\textit{rabies free}) + (1 - P(\textit{rabies free})) \times P(\textit{0 cases reported}|\textit{not rabies free})$ **(10)**

Where:

r=the negative binomial dispersion parameter

In surveillance data, it is difficult to discern which counties had zero cases reported because rabies was not present versus which counties had unreported rabies. To approximate how well the model captures observing at least 1 case when a county is enzootic, we calculated the AUC by comparing the predicted probability of rabies observing at least 1 positive case if rabies is present in a county (ie, the probability of >0 cases reported from model 1b) with county-level bat observation data in a sensitivity analysis using bat variant data. Rabid bats are considered to be present everywhere in the continental United States, so we hypothesized that counties with a high probability of observing terrestrial rabies would also be more likely to observe rabid bats. However, counties not observing rabid bats would still not be considered "rabies free," hence their exclusion from model fitting and the main analysis.

Calculations

All analyses were performed using R [23]. The zero-inflated models were run using the package *pscl* [24].

Ethical Considerations

These data were reported to the CDC by the State Public Health Departments under the authority of the Council for State and Territorial Epidemiologists, Position Statement 22-ID-06. As this study is a secondary analysis of data, institutional review board approval was not needed.

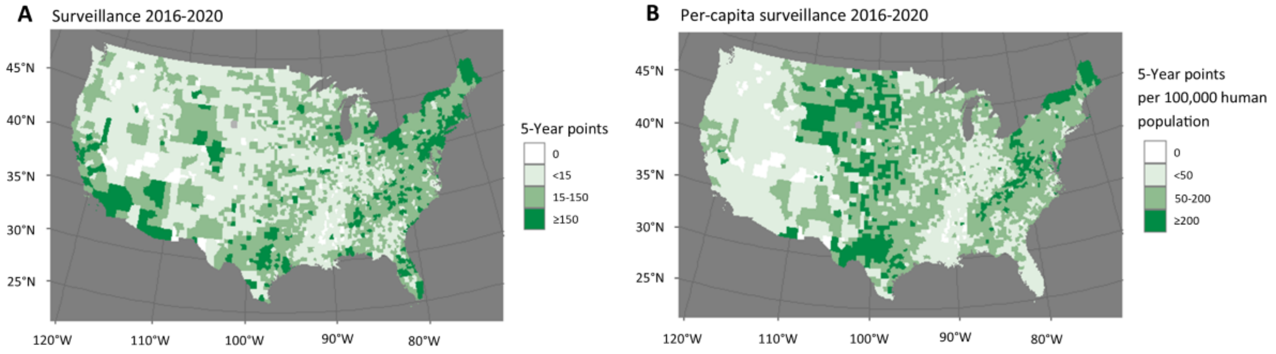
Results

Overview

Our analyses for raccoon territory included data from 1005 counties across 23 states beginning in 2003 for a total of 14,642 county-years. For skunk territory, we included 1799 counties across 25 states beginning in 2003 for a total of 30,120 county-years. Counties from some states were included after 2003, as described in the *Methods* section.

Of the county-years included for raccoon territory analysis, 57% (8346/14,642) had reported a terrestrial rabies case in the past year, 2% (293/14,642) had not reported a case for exactly 5 years, and 23% (3368/14,642) had not reported a case for >8 years. In skunk territory, only 17% (5120/30,120) of county-years had reported a case in the past year, 3% (904/30,120) had not reported a case for exactly 5 years, and 54% (16,265/30,120) had not reported a case for >8 years. The median number of surveillance points, under the existing NRSS definition, over the preceding 5-year period was 63.0 (IQR 22.0-143.9) in raccoon territory counties and 14.5 (IQR 5.5-39.0) in skunk territory counties. This corresponds to a median of 98.2 (IQR 55.7-153.6) surveillance points per 100,000 people in raccoon territory and 72.9 (IQR 36.2-147.2) per 100,000 people in skunk territory. The overall and per capita surveillance points from 2016 to 2020 are shown in Figure 1.

Figure 1. Rabies surveillance points (A) and per-capita rabies surveillance points (B) tested in the contiguous United States during 2016 to 2020 at the county level. Each reservoir animal tested contributes 1 surveillance point, and each domestic animal contributes 0.5 surveillance points.



Nonparametric Evaluation of Historical Definition

Only 0.85% (9/1065) of counties in raccoon territory and 0.79% (27/3411) of counties in skunk territory had rabies reported in a year for which rabies was predicted to be absent using the historical rabies-free definition from 2003 to 2020 (Table 1). According to the historical definition, counties predicted as rabies free for a given year had no cases reported 99.2% of the time in both raccoon and skunk territories (negative predictive value). Counties predicted to be rabies free for a given year also had a high probability of no cases being reported throughout the following 5 years (97.8% in raccoon territory and 94.9% in skunk territory). Only a small proportion of counties with zero rabies cases reported in a given year met the historical rabies-free criteria (16.6% in raccoon territory and 13.5% in skunk territory).

We performed a deeper investigation into the 9 counties in raccoon territory where rabies was reported in a year for which rabies was predicted to be absent. Of these 9 detections, 2 (22%) were attributed to bat variants that had not been reported to the CDC and 1 (11%) was associated with a data entry error in the state submission file. Of the remainder, 3 were associated with a rabies incursion into northeastern Ohio in 2004 and 1 with a translocated rabid cat [25]. No explanation was found for the remaining 2 counties. Therefore, only 56% (5/9) of detections in raccoon territory were falsely predicted to be rabies free.

Table 1. Nonparametric evaluation of historical rabies freedom definition in counties in both skunk and raccoon territories.

Reservoir and county-level rabies prediction (historical rabies-free definition)	Rabies reported in county in the next 1 year			Rabies reported in county in the next 5 years		
	Yes	No	Total	Yes	No	Total

Rabies Prediction Model Fit and Parameters

The Spearman correlation between the predicted and reported number of cases was 0.77 in raccoon territory and 0.44 in skunk territory and was applied to the test data sets using the original model (Table 2). Varying the surveillance definitions as described in the *Methods* section did not substantially improve model fit (Table 2), with AUCs that generally varied only by 0.01 or 0.02 across all models.

Within both the skunk and raccoon reservoir territories, counties predicted to have a higher probability of observing rabid animals (if present) were more likely to report rabid bats (AUC 0.76 in raccoon territory and 0.78 in skunk territory).

Reviewing the rabies prediction model parameters, the probability that a county is free from rabies decreases with the increasing number of rabid animals reported in the previous year in the county of interest. The probability decreases with an increasing number of rabid animals reported in the previous year in any adjacent counties, although the latter effect is less impactful. The probability of rabies freedom increases with increasing years since the last rabies case was reported in the county of interest and also increases with increasing years since the last rabies case was reported in any adjacent counties, although again the latter effect is less impactful on the model prediction (model 1A in Table 3).

If a county is not free from rabies, the number of reported cases in 1 year is positively associated with the number of positive reported cases in the following year. The number of cases reported also increases with an increasing number of rabid animals reported in any adjacent counties, although the effect is less strong. Finally, the number of cases reported the next year increases with surveillance points tested over the past 5 years in the county of interest (model 1B in Table 3).

Table 2. Performance of original model and models using different surveillance point definitions on the training and validation data sets.

	Spearman correlation predicted: reported cases	AUC[a] predicted: reported zero cases	AUC predicted free: reported zero cases
Raccoon model			
Original model, training data set	0.82	0.93	0.93
Different surveillance definitions[b], training data set	0.81-0.83	0.93-0.93	0.93-0.93
Original model predictions compared with rabies presence or absence in the next 5 years, training data set	0.89	0.97	0.97
Original model applied to validation data set (2019)	0.78	0.90	0.90
Original model applied to validation data set (2020)	0.77	0.90	0.90
Skunk model			
Original model, training data set	0.52	0.89	0.89
Different surveillance definitions[b], training data set	0.51-0.52	0.89-0.89	0.89-0.89
Original model predictions compared with rabies presence or absence in the next 5 years, training data set	0.66	0.88	0.88
Original model applied to test data set (2019)	0.44	0.91	0.91
Original model applied to test data set (2020)	0.44	0.91	0.91

[a] AUC: area under the receiver operating characteristic curve.

[b] Explored definition included the following: including only domestic or only reservoir animals, adjusting the relative value of surveillance effort by changing the coefficient applied to domestic animals from 0.1 to 1 times that of reservoir animals, applying specific coefficients to different species based on their observed test positivity rates, changing the number of years of surveillance effort considered from 1 to 8, and normalizing surveillance effort by county size or population.

Table 3. Rabies prediction zero-inflated negative binomial model parameters (fit to county-level data on the number of rabid animals detected from 2003 to 2018). Models were fit separately in raccoon reservoir territory and skunk reservoir territory.

Model-Based Evaluation of Historical Definition

The model predicts an approximately 98% probability of observing zero cases in the next year in both raccoon and skunk territories (Table 4) for a hypothetical county meeting the historical rabies-free definition (ie, 15 surveillance points, 5 years with no cases in the county of interest, and 5 years with no cases in any adjacent counties). This probability is equivalent to the probability of rabies in counties predicted to be rabies free from Table 1, except that Table 1 considers all counties meeting or exceeding the historical rabies-free criteria, whereas Table 4 considers a scenario that exactly meets the criteria.

Table 4. Model predictions for a scenario meeting historical rabies freedom criteria. In contrast to this assumes exactly 5 years with no cases reported in the county of interest or any neighboring counties and exactly 15 surveillance points over the past 5 years.

	Model: raccoon territory	Model: skunk territory
NPV[a]: probability of zero cases reported in the next year, historical criteria are met	0.982	0.979
Probability of being rabies free in the next year, historical criteria are met	0.947	0.920
Probability that a case occurs in the next year but goes unreported, historical criteria are met	0.034	0.059

[a] NPV: negative predictive value.

Separating the probability of zeros derived from the rabies freedom model (ie, county is truly nonendemic for rabies) and those derived from the count model (ie, county is endemic for rabies, but no rabies cases are reported), the probability of being truly rabies free is slightly higher for raccoon territory (0.95) than skunk territory (0.92), and the probability that rabies is present but unrecognized is slightly lower in raccoon territory (0.03) than in skunk territory (0.06).

County-Specific Predictions: Rabies Freedom and Number of Reported Cases

In contrast to the binary yes or no cutoff of the historical rabies freedom definition, the rabies prediction model allows each county to have a predicted probability of being free from rabies and the expected number of terrestrial rabies cases reported in the following year. The median predicted probability of rabies freedom in 2020 was 0.10 (IQR 0.04-0.71) for counties in raccoon territory and 0.91 (IQR 0.55-0.96) for counties in skunk territory. The median expected number of rabies cases reported per county in 2020 was 1.4 (IQR 0.2-3.6) in raccoon territory and 0.03 (IQR 0.01-0.2) in skunk territory. For comparison, the median reported number of rabies cases reported in 2020 was 1.0 (IQR 0.0-3.0) in raccoon territory and 0.0 (IQR 0.0-0.0) in skunk territory. Counties with cases reported in 2020 tended to have a low probability of freedom from rabies (Figure 1).

Discussion

Principal Findings

The results of this study show that the historical definition of rabies freedom in the United States is largely successful in identifying counties with the lowest risk of rabies. Applying this definition, 99.2% of counties predicted as rabies free did not have a case reported in the following year. Modeling analyses showed that all 3 components of this definition (in-county presence, neighboring county presence, and surveillance effort) play an important role in making this prediction. Increased number of years since a case was last reported in the county of interest or any contiguous counties is associated with increased probability of rabies freedom, and increased surveillance over the past 5 years is associated with better rabies observation in the subsequent year in endemic counties.

Although the evaluation method used in these analyses supports the use of the historical definition, it also presents a more nuanced assessment of rabies freedom. Although we did not find an advantage of changing the definition of surveillance points from its historical definition (0.5 points per domestic animal tested and 1 point per reservoir animal tested), the model allowed us to estimate an individualized risk for each county rather than a binary designation of rabies presence or absence (Figures 2 and 3). Predictions of the probability of rabies freedom and the expected number of cases reported in 2019 and 2020 correlated with actual cases reported in the same years.

This analysis only considered variables related to historical rabies surveillance and detection, as in the historical definition. The inclusion of other variables such as county population and the size of land use could be considered in the future. In addition, modifications to these methods that consider the point locations of samples could be considered when subcounty designations are needed. Subcounty location data (eg, Geographic Information Systems coordinates) are not routinely reported to the CDC's NRSS, necessitating an aggregated county-level analysis. Trade-offs between distance and time from the last case reported could also be considered (eg, is it possible to consider an area "rabies free" if a recent case was reported but is very far from the nearest positive?).

Figure 2. Raccoon territory model predictions of the probability of rabies freedom (A) and the number of expected rabies cases (B), compared with the number of actual reported rabies cases per county (C) in 2020. Model estimated probability that a rabies case will occur but go unreported (D).

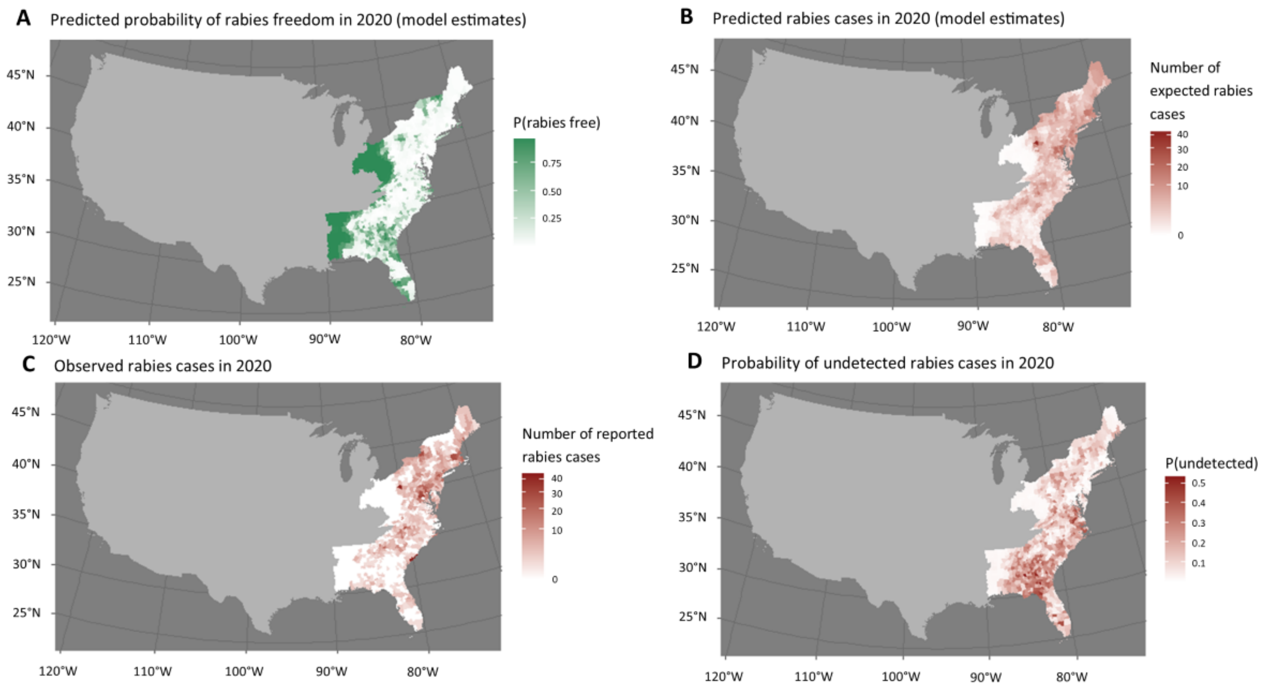

Figure 3. Skunk territory model predictions of the probability of rabies freedom (A) and the number of expected rabies cases (B), compared with the number of actual reported rabies cases per county (C) in 2020. Model estimated probability that a rabies case will occur but go unreported (D).

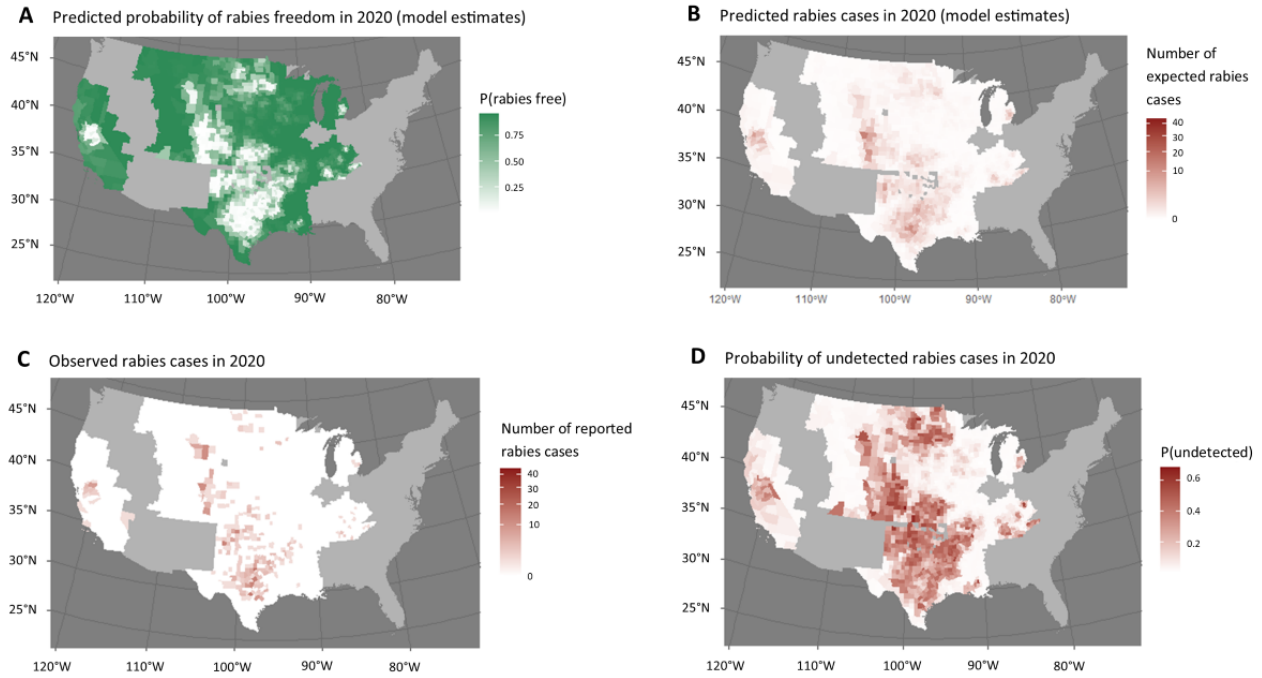

Designations of terrestrial rabies endemicity are important for clinical, public health, and wildlife management decision-making at a local, state, and national scale. The model presented in this study uses data only from the United States, and model parameters may not be generalizable to other countries, particularly those where DMRVVs may be found or where surveillance systems differ substantially from the US NRSS. When considering the application of these methods to locations outside of the United States, several important considerations must be made. First, the models described here differed according to the reservoir species. This suggests that a modeling process is required for each unique rabies reservoir species, of which >30 species have been described globally. Second, administrative divisions may differ substantially from US counties by size or population, making rabies detection more or less likely.

The United States has one of the most robust rabies surveillance systems in the world, with more laboratories and testing per capita than nearly any other country. From 2016 to 2020, nearly all counties in the United States tested at least 1 terrestrial animal for rabies (Figure 1). Therefore, under the US system, the amount of testing conducted in a county-year may not be as important as having access to laboratories and relatively high rabies awareness among the public and health jurisdictions. According to the US surveillance scheme, the cost of testing and access to laboratories are rarely cited as reasons for not testing animals suspected of having rabies. Although access to rabies testing in the United States is robust, 1 sensitivity analysis presented in this study showed that counties predicted to detect more terrestrial rabies cases (ie, those with greater surveillance efforts for terrestrial animals and more terrestrial animal rabies reported in the past year) are more likely to detect rabid bats in the following year. This could indicate that accessing testing is not equivalent in all counties, and future analyses could consider investigating ways to identify locations where a lack of testing could overshadow rabies virus transmission. In countries where access to testing is less secure and awareness of rabies and appropriate postexposure behaviors is lacking, predictive variables (such as number of samples tested) are likely to be more important in predicting the presence or absence of rabies in a defined area.

Limitations

This study had several limitations. Variant typing was not performed on all rabid animals in the United States, and some rabid animals with bat variants may have been inadvertently included in our data set. However, previous studies have found that >99% of terrestrial mammals in an area with a terrestrial RVV have the expected viral variant [26]. Of the 9 county-years for which rabies was reported despite meeting the rabies freedom definition, at least 2 had bat variants that were not reported to the CDC at the time of the analysis. Some states inconsistently reported negative rabies testing results in the early years of our data, leading us to exclude certain years of data from some states; however, <10% of the data were affected. In addition, we included data from the United States only, so counties bordering Mexico or Canada have incomplete data on rabies cases in the surrounding areas. We only explicitly developed models for raccoon and skunk RVV territories, as the number of counties with other terrestrial rabies variants in the United States is small. Counties in states, such as Arizona and New Mexico, with multiple RVVs were not included when fitting the models, as the rabies dynamics may differ in these regions. It is possible that animal location data submitted to the NRSS may not reflect the location where the animal was exposed to rabies but could reflect other locations noted by case investigators such as the location where the animal was found.

Finally, it is possible that even counties in which no rabies is reported over long periods may not truly be free from rabies.

Conclusions

In conclusion, the historical rabies freedom definition is a reasonable approach for identifying counties that are truly free from terrestrial raccoon and skunk rabies virus transmission. Gradations in risk can also be measured using the rabies prediction model presented in this study, with AUCs >0.9. Nevertheless, bat variant rabies in terrestrial mammals remains a possibility throughout the United States, excluding Hawaii, and translocation events can occur, which can lead to unpredictable shifts in rabies epidemiology [16]. Even counties with a high probability of rabies freedom should maintain vigilance and rabies testing capacity, as there are numerous examples of anthropogenic and natural translocations of rabies-infected animals that can cause major changes in the epidemiology of rabies.

Acknowledgments

The findings and conclusions of this study are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention. The authors thank the state and territorial public health and agriculture departments and laboratories for their annual contribution of rabies surveillance data to the National Rabies Surveillance System.

Abstract

Background: Young breast cancer patients are more likely to develop aggressive tumor characteristics and a worse prognosis than older women, and different races and ethnicities have distinct epidemiologies and prognoses. However, few studies have evaluated the clinical biological features and relapse patterns in different age strata of young women in Asia.

Objective: We aimed to explore survival differences and the hazard function in young Chinese patients with breast cancer (BC) by age.

Methods: The patients were enrolled from West China Hospital, Sichuan University. The chi-squared test, a Kaplan-Meier analysis, a log-rank test, a Cox multivariate hazards regression model, and a hazard function were applied for data analysis. Locoregional recurrence–free survival (LRFS), distant metastasis–free survival (DMFS), breast cancer–specific survival (BCSS), and overall survival (OS) were defined as end points.

Results: We included 1928 young BC patients diagnosed between 2008 and 2019. Patients aged 18 to 25, 26 to 30, 31 to 35, and 36 to 40 years accounted for 2.7% (n=53), 11.8% (n=228), 27.7% (n=535), and 57.7% (n=1112) of the patients, respectively. The diagnosis of young BC significantly increased from 2008 to 2019. Five-year LRFS, DMFS, BCSS, and OS for the entire population were 98.3%, 93.4%, 94.4%, and 94%, respectively. Patients aged 18 to 25 years had significantly poorer 5-year LRFS ($P<.001$), 5-year DMFS ($P<.001$), 5-year BCSS ($P=.04$), and 5-year OS ($P=.04$) than those aged 31 to 35, 26 to 30, and 36 to 40 years. The hazard curves for recurrence and metastasis for the whole cohort continuously increased over the years, while the BC mortality risk peaked at 2 to 3 years and then slowly decreased. When stratified by age, the annualized hazard function for recurrence, metastasis, and BC mortality in different age strata showed significantly different trends, especially for BC mortality.

Conclusions: The annual diagnosis of young BC seemed to increase in Chinese patients, and the distinct age strata of young BC patients did not differ in survival outcome or failure pattern. Our results might provide strategies for personalized management of young BC.

Introduction

Breast cancer (BC) is the most frequently diagnosed cancer (approximately 31% of all cancer sites) and is the second cause of mortality among female patients based on a 2022 prediction [1]. Young BC, defined as BC occurring in people aged ≤40 years, has always been a hotly discussed issue due to its lower incidence but poorer prognosis than BC in older patients [2]. The annual number of diagnoses of young BC is approximately 14,000 in the United States, with an estimated incidence of 5% to 7%, while a higher proportion is reported in Asia, up to 20% [3-5]. The diagnosis of young BC has sharply increased in several countries over the last years [3,6].

Young BC patients are more likely to develop aggressive tumor characteristics and have a worse prognosis compared with older patients [7-15]. Previous studies that used population-based data have reported that young BC patients have higher rates of advanced, poorly differentiated tumors, estrogen receptor (ER) negativity, progesterone receptor (PR) negativity, human epidermal growth factor receptor 2 (HER-2) positivity, a higher Ki-67 index, and lymphovascular invasion [7-12]. Young BC patients have also been definitively demonstrated to have a higher proportion of invasive molecular subtypes, including triple-negative and HER-2–positive subtypes; higher rates of distant disease at initial diagnosis; and poor long-term survival outcomes compared with older patients [13-15].

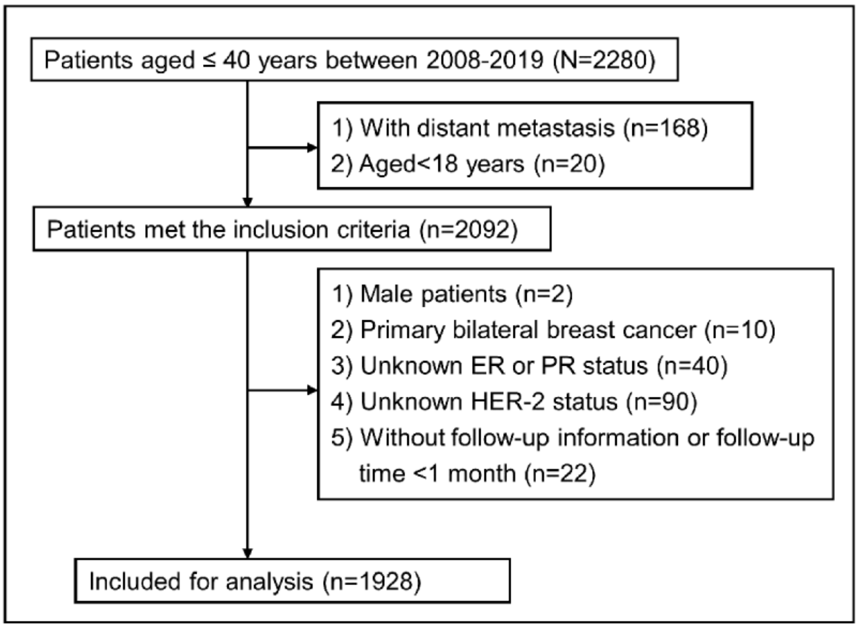
Several studies have reported that the epidemiology and prognosis of young BC also vary in different races and ethnicities [16-18]. The incidence of young BC in the United States is significantly lower than that in Asian countries (approximately 7% vs approximately 20%) [3-6]. Young African-American BC patients have increased risk of BC at a younger age, higher pathological grade, and higher rates of hormone receptor (HR) negativity compared to young White women [16,17]. In addition, young Asian patients have higher proportions of advanced-stage cancers and lower rates of poorly differentiated cancers and invasive BC subtypes (triple-negative and luminal B subtypes) but a better prognosis than young White patients [18]. However, few studies have evaluated the clinical biological features and relapse patterns in different age strata among young women in Asia. Therefore, our study aims to explore the clinicopathological characteristics, survival outcomes, and hazard function of Chinese patients aged ≤40 years by age group (18-25, 26-30, 31-35, and 36-40 years).

Materials

Patients

The patient data were extracted from the database of West China Hospital, Sichuan University. The database, the Breast Cancer Information Management System (BCIMS), prospectively collects patient information from medical records on demographics, tumor characteristics, treatment, and follow-up. We included patients based on the following criteria: (1) diagnosis with BC between 2008 and 2019; (2) age ≤40 years; (3) nonmetastatic disease; and (4) availability of detailed information on age, tumor stage, nodal stage, clinical stage, ER status, PR status, HER-2 status, molecular subtype, surgery, neoadjuvant/adjuvant chemotherapy, radiotherapy, endocrine therapy, anti–HER-2 targeted therapy, and follow-up. We excluded patients with the following characteristics: (1) male, 2) age ≤18 years, and (3) bilateral BC. The inclusion flow sheet of the patients is shown in Figure 1.

Figure 1. Inclusion flow sheet of patients. ER: estrogen receptor; HER-2: human epidermal growth factor receptor 2; PR: progesterone receptor.



Variables

The following patient demographic and clinicopathological variables were included: age (18-25, 26-30, 31-35, and 36-40 years), tumor stage (tumor in situ [TIS], T1, T2, T3, T4), nodal stage (N0, N1, N2, N3), clinical stage (0, I, II, III), pathological grade (well differentiated, moderately differentiated, poorly differentiated/undifferentiated, unknown), ER status, PR status, HER-2 status, molecular subtype (luminal A, luminal B, HER-2 positive, triple-negative), surgery (breast-conserving, mastectomy, unknown), neoadjuvant chemotherapy, adjuvant chemotherapy, radiotherapy, endocrine therapy, and targeted therapy.

Treatment, Follow-Up, and End Points

Surgery, chemotherapy, and radiotherapy regimens were formulated by a cooperative, multidisciplinary group including surgeons, oncologists, radiotherapy physicians, and patients. Neoadjuvant/adjuvant chemotherapy depended on advanced tumor stage, advanced nodal stage, invasive molecular subtype, such as triple-negative BC, and the willingness to undergo breast-conserving surgery. Radiotherapy was administered to patients receiving breast-conserving surgery with a positive margin and positive axillary lymph nodes. Patients who were HR positive received neoadjuvant or adjuvant endocrine therapy, and patients with HER-2 overexpression were treated with an anti–HER-2 targeted therapy, permitting economic conditions. Follow-up information was collected from medical records, office visits, and telephone calls every 3 months in the first 2 years, semiannually during years 2 to 5 years, and once a year after 5 years. The end points in this study were locoregional recurrence–free survival (LRFS), distant metastasis–free survival (DMFS), breast cancer–specific survival (BCSS), and overall survival (OS). The definitions of LRFS, DMFS, BCSS, and OS were stated in our previous study [19].

Statistical Analysis

The chi-squared test was used to compare differences in patient baseline characteristics in different age groups. Excel (2016 version; Microsoft Corp) was used to draw variation trends between 2008 and 2019 in the 4 age groups. A Kaplan-Meier analysis was applied to draw survival curves for LRFS, DMFS, OS, and BCSS. A log-rank test was used to compare differences between the 4 groups. A Cox multivariate hazards regression model was used to identify protective and risk factors for predicting LRFS, DMFS, OS, and BCSS. Annualized hazard rates for the whole group and different age strata, defined as percentage of events occurring within a time interval, were calculated using maximum likelihood estimate of a piece-wise exponential model. SPSS (version 25.0; IBM Corp) and Excel were used to analyze and map data. *P* values less than .05 (2-tailed) were considered statistically significant.

Ethical Considerations

Our study was approved by the Biomedical Ethics Committee of West China Hospital, Sichuan University (2020427). Informed consent was obtained from the participants when they first received treatment in our institution. Patient privacy was well protected due to the deidentification of their information.

Results

Patient Characteristics and Treatment Information

A total of 1928 patients met the inclusion criteria and were included for analysis. Patients aged 18 to 25 years, 26 to 30 years, 31 to 35 years, and 36 to 40 years accounted for 2.7% (n=53), 11.8% (n=228), 27.7% (n=535), and 57.7% (n=1112) of the participants, respectively. The proportions of patients at the TIS, T1, T2, T3, and T4 stages were 1.5% (n=28), 36.2% (n=697), 50.5% (n=976), 6.3% (n=121), and 5.5% (n=106), respectively. In addition, 44.6% (n=860), 32.2% (n=621), 11.8% (n=228), and 11.4% (n=219) of the patients were at the N0, N1, N2, and N3 stages, respectively.

The majority of the patients were at an early clinical stage (n=1405, 72.9%), had moderately or poorly differentiated tumors (n=1342, 69.7%), were ER positive (n=1345, 69.8%), were PR positive (n=1288, 66.8%), and were HER-2 negative (n=1383, 71.7%). Regarding molecular subtype, 17.9% (n=346), 54.9% (n=1059), 10.1% (n=194), and 17.1% (n=329) of the patients had the luminal A, luminal B, HER-2–positive, and triple-negative subtypes, respectively. Detailed patient characteristics are presented in Table 1.

In total, 17.4% (n=335) and 79.5% (n=1534) of the patients received breast-conserving surgery and mastectomy, respectively, while 3.1% (n=59) were not treated with surgery or had no record of surgery. In total, 19.8% (n=382) of the patients received neoadjuvant chemotherapy, 89.8% (n=1731) of the patients received adjuvant chemotherapy, and 45.7% (n=881) of the patients were treated with radiotherapy. In addition, 71% (n=1389) of the patients received endocrine therapy and 17.6% (n=340) were treated with targeted therapy (Table 1).

There were no statistical differences in baseline characteristics between the 4 groups (ages 18-25, 26-30, 31-35, and 36-40 years), including tumor stage (*P*=.53), nodal stage (*P*=.65), clinical stage (*P*=.33), ER status (*P*=.42), PR status (*P*=.16), HER-2 status (*P*=.89), pathological grade (*P*=.07), and molecular subtype (*P*=.43). However, patients aged 18 to 25 years were more likely to receive breast-conserving surgery (*P*<.001), adjuvant chemotherapy (*P*=.006), and radiotherapy (*P*=.02), while patients aged 36 to 40 years were more likely to receive mastectomy (*P*<.001). Patients aged 26 to 30 years were more likely to be treated with neoadjuvant chemotherapy (*P*<.001) and targeted therapy (*P*=.04; Table 1).

Trends in Annual Diagnosis by Age

The trends in the diagnosis of BC in the whole cohort and patients aged 18 to 25, 26 to 30, 31 to 35, and 36 to 40 years from 2008 to 2019 are presented in Table 2. The proportion of young BC patients significantly increased from 4.7% (n=92) in 2008 to 12.8% (n=247) in 2019. When stratified by age, annual diagnosis of patients aged 36 to 40 years significantly decreased from 59.4% (52/92) in 2008 to 44.6% (86/194) in 2018, while the diagnosis of patients aged 26 to 30 showed a significant upward trend, from 5.9% (6/92) in 2008 to 17.5% (34/194) in 2018. However, there were no significant tendencies in the diagnosis of patients aged 18 to 25 years, with 3% (3/92) in 2008 and 5.1% (10/194) in 2018; for patients aged 31 to 35 years, diagnosis was 31.7% (31/92) in 2008 and 32.8% (64/194) in 2018 (Table 2).

Table 2. Trends of annual diagnosis of patients in different age groups (18-25, 26-30, 31-35, and 36-40 years).

Year	Age group (years), n (%)			
	18-25	26-30	31-35	36-40
2008 (n=92)	3 (3)	6 (5.9)	31 (31.7)	52 (59.4)
2009 (n=140)	5 (4.2)	11 (7.7)	36 (25.9)	88 (62.2)
2010 (n=120)	1 (0.8)	15 (12.5)	26 (21.7)	78 (65)
2011 (n=152)	3 (1.9)	10 (6.5)	32 (20.8)	107 (70.8)
2012 (n=160)	4 (2.5)	13 (8)	41 (25.9)	102 (63.6)
2013 (n=146)	3 (2.7)	9 (6.1)	30 (20.3)	104 (70.9)
2014 (n=144)	3 (2.1)	17 (11.8)	33 (22.9)	91 (63.2)
2015 (n=176)	3 (1.7)	26 (15.3)	50 (28.2)	97 (54.8)
2016 (n=149)	7 (4.7)	23 (15.4)	40 (26.8)	79 (53)
2017 (n=208)	5 (2.4)	40 (19.2)	68 (32.7)	95 (45.7)
2018 (n=194)	10 (5.1)	34 (17.5)	64 (32.8)	86 (44.6)
2019 (n=247)	6 (2.4)	24 (9.6)	84 (33.7)	133 (54.2)

Survival and Prognostic Analysis by Age

With a median follow-up time of 75.7 months (range 1.1-173 months), 75 (3.9%) recurrences, 236 (12.2%) cases of distant metastasis, 132 (6.8%) BC-related deaths, and 138 (7.2%) other deaths occurred among the 1928 participants. In the entire group, 5-year LRFS, DMFS, BCSS, and OS were 98.3%, 93.4%, 94.4%, and 94%, respectively. There were better survival outcomes with age in BC patients aged ≤40 years. Patients aged 18 to 25 years had significantly poorer 5-year LRFS (ages 18-25, 26-30, 31-35, and 36-40 years: 88.5%, 96.7%, 98.6%, and 98.9%, respectively; *P*<.001; Figure 2A), 5-year DMFS (ages

18-25, 26-30, 31-35, and 36-40 years: 82.8%, 89.1%, 93.7%, and 94.6%, respectively; *P*<.001; Figure 2B), 5-year BCSS (ages 18-25, 26-30, 31-35, and 36-40 years: 85%, 91.8%, 95.8%, and 94.5%, respectively; *P*=.04; Figure 2C), and 5-year OS (age 18-25, 26-30, 31-35, and 36-40 years: 85%, 91.3%, 95.8%, and 94%, respectively; *P*=.04; Figure 2D) than those aged 31-35, 26-30, and 36-40 years. Cox multivariate regression model showed that age was a significant predictor for LRFS (hazard ratio [HR] 0.645, 95% CI 0.500-0.831; *P*<.001) and DMFS (HR 0.743, 95% CI 0.641-0.861; *P*<.001), while it was not a predictor for BCSS (HR 0.889, 95% CI 0.729-1.805; *P*=.25) or OS (HR 0.867, 95% CI 0.709-1.061; *P*=.17; Table 3).

Figure 2. Survival curves of locoregional recurrence–free survival, distant metastasis–free survival, breast cancer–specific survival, and overall survival for young patients of different ages.

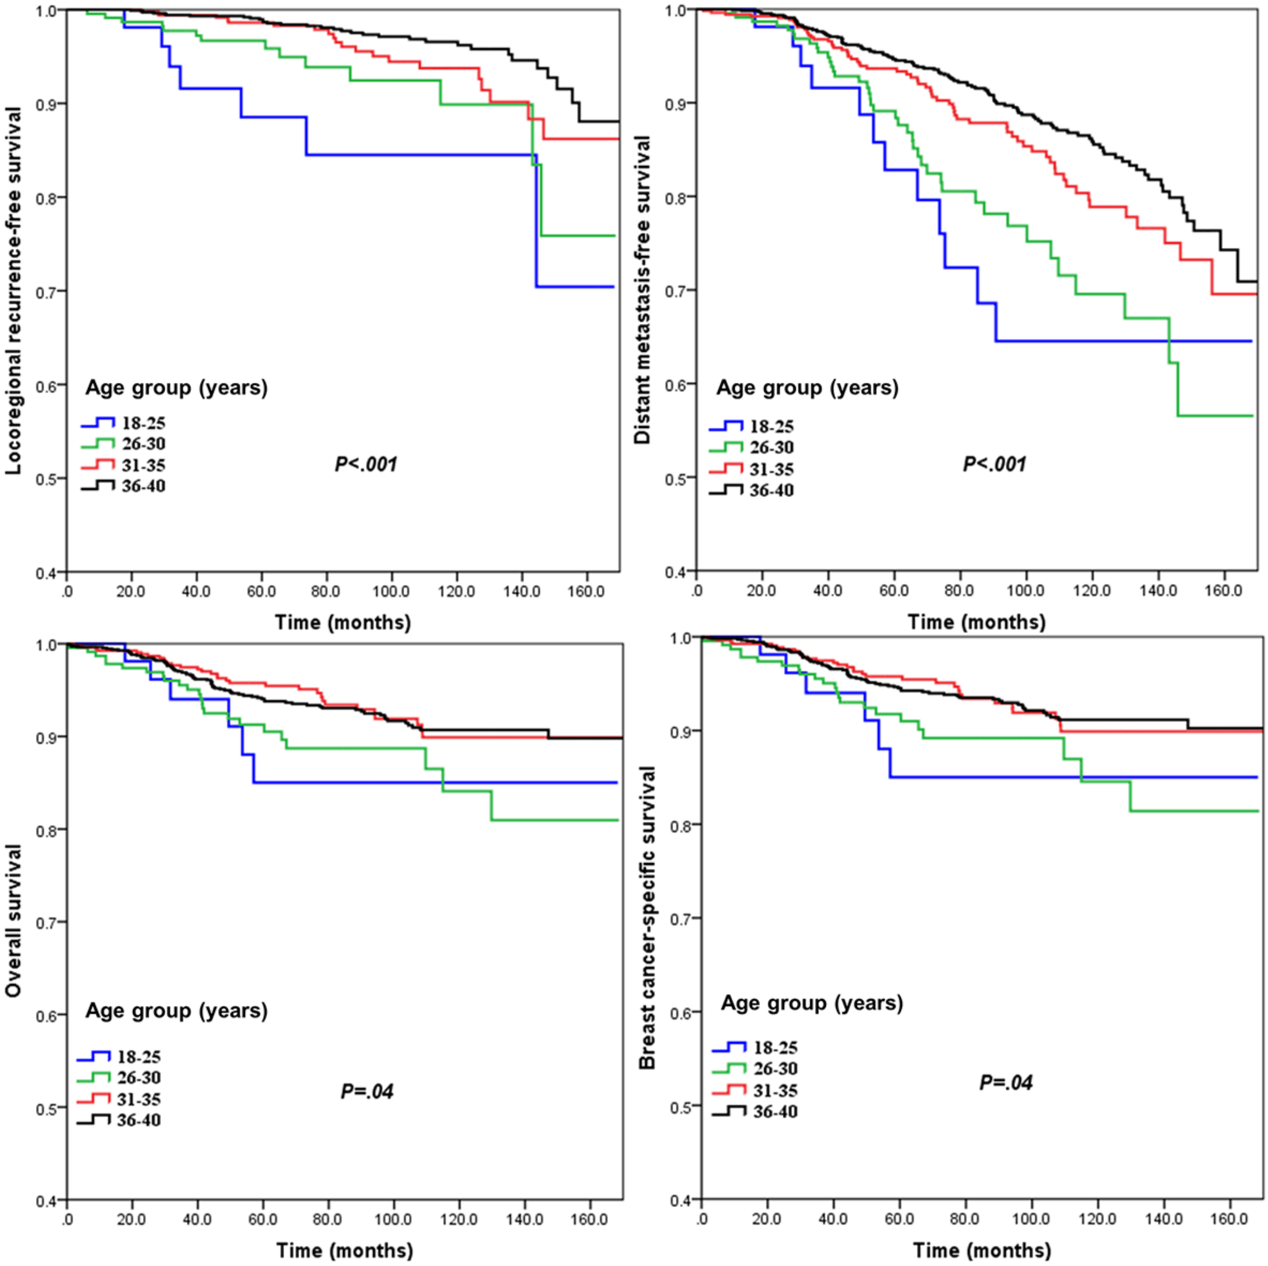

Table 3. Cox multivariate analysis of locoregional recurrence–free survival, distant metastasis–free survival, breast cancer–specific survival, and overall survival in all patients.

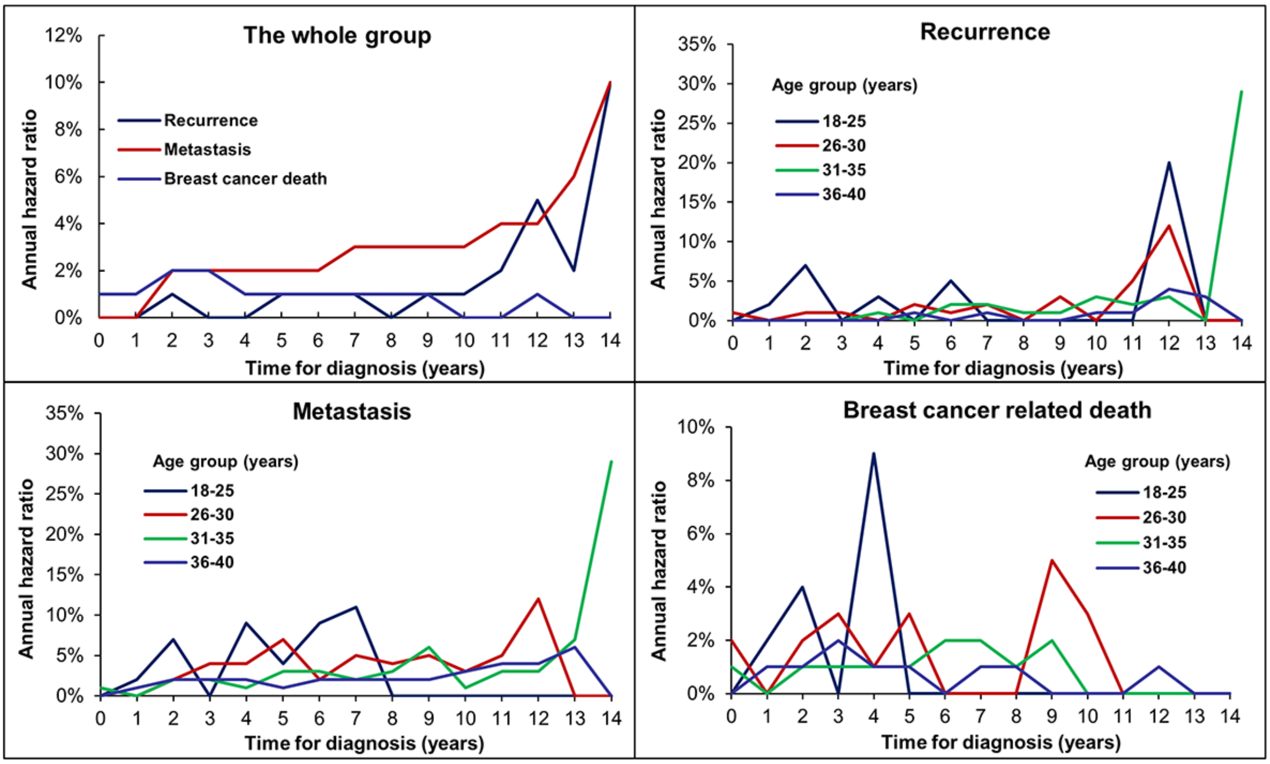
Outcome and age group (years)	Hazard ratio (95% CI)	*P* value
Locoregional recurrence–free survival		
18-25	1	
26-30	0.551 (0.193-1.571)	.27
31-35	0.280 (0.105-0.752)	.01
36-40	0.228 (0.088-0.590)	.002
Distant metastasis–free survival		
18-25	1	
26-30	0.967 (0.489-1.910)	.92
31-35	0.539 (0.280-1.035)	.06
36-40	0.448 (0.238-0.845)	.01
Breast cancer–specific survival		
18-25	1	
26-30	0.959 (0.378-2.432)	.93
31-35	0.518 (0.210-1.227)	.15
36-40	0.596 (0.252-1.410)	.24
Overall survival		
18-25	1	
26-30	0.997 (0.395-2.515)	.99
31-35	0.517 (0.210-1.272)	.15
36-40	0.644 (0.273-1.518)	.32

Annualized Hazard Curve of Recurrence, Metastasis, and BC Death

We also explored the annualized hazard trends of recurrence, metastasis, and BC mortality in this population (Figure 3). The hazard curves for recurrence and metastasis in the whole cohort continuously increased over time and did not reach a peak within the follow-up of 14 years. The BC mortality risk curve peaked at 2 to 3 years (at 2%), maintained a steady lower level after 3 years, then changed to a slowly decreasing plateau (Figure 3). After conducting a stratified analysis by age, we found that patients aged 18 to 25 years had peak BC mortality at 2 and 4 years and still had peak metastasis risk before the first 8 years. Patients aged 26 to 30, 31 to 35, and 36 to 40 years all showed a slow upward trend of recurrence and metastasis risk during follow-up. In addition, patients aged 26 to 30 years had high risk of BC mortality during years 0 to 6 and 8 to 11, while patients aged 31 to 35 years had high risk before the first 10 years. The hazard function for BC mortality in patients aged 36 to 40 years maintained a high plateau before the first 8 years then changed to a low death rate (Figure 3).

Figure 3. Annualized hazard curves for recurrence, metastasis, and breast cancer–related mortality for the whole group and distinct age strata of the patients.



Discussion

Principal Findings

We provide updated data on the clinicopathological characteristics, survival outcomes, and hazard function of different age strata of Chinese BC patients aged younger than 40 years. The main finding was that different age strata of young BC patients had different rates of survival: the younger the patient, the worse the prognosis. In addition, we found the risk of recurrence and metastasis continuously increased over time, and the failure patterns of different age strata were significantly different. Our result demonstrating different survival outcomes and failure patterns in different age strata could be used to tailor personalized management of young BC patients.

Previous studies have demonstrated that young BC patients have worse prognoses than older patients; 5-year BCSS in patients aged ≤35 years was approximately 80%, while it was 90% in patients ≥60 years [7,20]. The reasons for this biological difference between young and old patients have not been well elaborated. Several possible reasons might explain the phenomenon. First, younger patients are more likely to develop tumors with aggressive characteristics, such as higher Ki-67 and a triple-negative subtype [7-12]. Second, younger patients have higher expression of RANK-ligand, c-kit, mammary stem cell, and BRCA1 mutation signatures and the deregulation of PI3K and Myc pathways, which are associated with a poor prognosis [21-23]. Third, young BC patients have increased risk of psychosocial stress, and their treatment strategies are more likely to be affected by considerations of sexual function, fertility, beauty, body image, and their careers [24,25]. In this study, the 5-year BCSS and OS in young patients were 94.3% and 93.9%, respectively. These survival rates were higher than those of older Chinese patients in a previous study; the reason might be that more patients had early-stage tumors (6279/7553, 83.1%), as well as nodal-stage (6821/7553, 90.3%) and luminal-subtype (5937/7553, 78.6%) tumors in this study [26]. In addition, survival outcomes among younger patients in our study were also higher than those in younger women in the United States, which might be attributable to racial, dietary, climate, and living differences leading to Asian BC patients having better survival than White patients [7,26,27].

It has not been fully delineated whether survival and prognoses are the same in different age strata among young women. A study conducted by Fredholm et al [28] included 1120 women with stage I to III cancer; their results showed that patients aged <30 years had significantly poorer 5-year BCSS than those aged 35 to 40 years (80% vs 86%; *P*<.001). However, the opposite result was found in another population-based report in Italy: there was no survival difference among patients aged <25, 25 to 29, and 30 to 34 years in locoregional relapse (*P*=.87), distant metastasis (*P*=.40), BCSS (*P*=.58), and OS (*P*=.99) [27]. In our study, there were significant differences in LRFS (*P*<.001), DMFS (*P*<.001), BCSS (*P*=.035), and OS (*P*=.037) in younger patients by age, and patients aged <25 years old had the worst survival rate. The reasons for the difference might be that the sample size in the previous study was small (n=497) and that the included patients were White; these are important differences from our study [27]. Therefore, it is important to establish policies for better managing and improving the survival of very young Chinese BC patients.

There is limited evidence available evaluating the risk of relapse and death in young BC patients. A recent analysis from the

International Breast Cancer Study Group clinical trials included 4105 BC patients and explored the patterns of late BC recurrence. The authors demonstrated that the annualized hazard of recurrence peaked at 2 years and then decreased slowly; however, the study did not stratify the analysis for young BC patients [29]. Another study by de la Rochefordiere and his colleagues [30] assessed failure patterns in young age groups. They included 3371 women aged ≤55 years and divided them into 3 groups (≤33 years, 34-40 years, and ≥40 years). The results showed that the annual hazard rate of relapse peaked at 2 years and patients aged ≤33 years had a higher relapse risk than those aged 34 to 40 years for about 5 years, but a lower risk after 5 years [30]. A similar result was found in our study: BC death risk peaked at 2 and 3 years after diagnosis; however, totally different trends were observed for the annual hazard of recurrence and metastasis, which both showed a slow upward trend in our study that did not reach a peak during follow-up, possibly attributable to differences in race and sample size between the studies (1950 patients in this study vs 456 patients in the past study) [29]. The reasons for the different failure patterns might include differences in the expression of RANK-ligand, c-kit, mammary stem cell, and BRCA1 mutation signatures, as well as in the PI3K and Myc pathways [21-23]. Therefore, it is essential to further explore the optimal management of young BC patients to reduce the risk of recurrence and metastasis.

Limitations

Our study has several limitations that might affect the results. First, the patient data were extracted from a database that was built beforehand; selection bias in retrospective studies is inevitable. Second, our data were collected at a single center, and the result thus cannot represent all patients in China. Third, this study only included hospitalized patients, which probably does not represent all patients with cancer (ie, there may be patients that have cancer but are not hospitalized). Finally, the sample size in our study was relatively small, especially for patients aged 18 to 25 years. Therefore, a multicenter prospective study with a larger sample size should be conducted to further explore the characteristics of young BC patients and their management. Despite the limitations of our study, we have expanded the understanding of young BC in different races and ethnicities.

Conclusions

Our study demonstrates that the annual diagnosis of young BC increased in Chinese patients. The diagnostic rate of patients aged 36 to 40 years decreased, while it remained stable in those aged 18 to 25 and 31 to 35 years. Young BC patients of different age groups did not differ in survival outcomes, but the younger the patient, the worse were the 5-year LRFS, DMFS, BCSS, and OS. In addition, there were significantly different failure patterns in different age strata among the young BC patients, especially for BC mortality. Our results demonstrating different survival outcomes and failure patterns in different age strata may allow tailored, personalized management for young BC patients.

Acknowledgments

We thank all the patients who participated in this study.

Data Availability

The data sets generated during and/or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

JW and ZZX drafted the manuscript. TL and LL conceived the study. YYZ, TY, XYW, SY, NYX, ZLD, and CFT acquired and organized the data sets. JW, YYZ, TY, and XYW conducted the statistical analyses. MMH assisted in revising the manuscript. JW, ZZX, TL, and LL participated in the study design. All authors read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The extent of tick-borne disease (TBD) risk in the United States is generally unknown. Active surveillance using entomological measures, such as presence and density of infected nymphal *Ixodes scapularis* ticks, have served as indicators for assessing human risk, but results have been inconsistent and passive surveillance via public health systems suggests TBDs are underreported.

Objective: Research using various data sources and collection methods (eg, Google Trends, apps, and tick bite encounters [TBEs] reports) has shown promise for assessing human TBD risk. In that vein, and engaging a One Health perspective, this study used multimodal databases, geographically overlaying patient survey data on TBEs and concomitant reports of TBDs with data drawn from other sources, such as canine serological reports, to glean insights and to determine and assess the use of various indicators as proxies for human TBD risk.

Methods: This study used a mixed methods research strategy, relying on triangulation techniques and drawing on multiple data sources to provide insights into various aspects of human disease risk from TBEs and TBDs in the United States. A web-based survey was conducted over a 15-month period beginning in December 2020 to collect data on TBEs. To maximize the value of the covariate data, related analyses included TBE reports that occurred in the United States between January 1, 2000, and March 31, 2021. TBEs among patients diagnosed with Lyme disease were analyzed at the county level and compared to *I scapularis* and *I pacificus* tick presence, human cases identified by the Centers for Disease Control and Prevention (CDC), and canine serological data. Spatial analyses employed multilayer thematic mapping and other techniques.

Results: After cleaning, survey results showed a total of 249 (75.7%) TBEs spread across 148 respondents (61.9% of all respondents, 81.7% of TBE-positive respondents); 144 (4.7%) counties in 30 states (60%) remained eligible for analysis, with an average of 1.68 (SD 1.00) and median of 1 (IQR 1) TBEs per respondent. Analysis revealed significant spatial matching at the county level among patient survey reports of TBEs and disease risk indicators from the CDC and other official sources. Thematic mapping results included one-for-one county-level matching of reported TBEs with at least 1 designated source of human disease risk (ie, positive canine serological tests, CDC-reported Lyme disease, or known tick presence).

Conclusions: Use of triangulation methods to integrate patient data on TBE recall with established canine serological reports, tick presence, and official human TBD information offers more granular, county-level information regarding TBD risk to inform clinicians and public health officials. Such data may supplement public health sources to offer improved surveillance and provide bases for developing robust proxies for TBD risk among humans.

Introduction

Tick-borne illness is steadily increasing across the United States. Lyme disease (LD), in particular, is the fastest growing vector-borne disease in the United States and accounts for the majority of all tick-borne diseases (TBDs) in the country [1,2]. Research using various data sources and collection methods (eg, Google trends, apps, and tick bite encounters' [TBEs'] reports) has shown promise for assessing human TBD risk [3-9]. However, the extent of TBD risk is relatively unknown. Entomological measures, such as presence and density of infected nymphal *Ixodes scapularis* ticks, have served as indicators for assessing human LD risk [10-13], but results have been inconsistent [11,14]. These measures do not consider human behavior [11]. Creating models that incorporate human behavior and adverse events—for example, TBE recall—can produce improved and more nuanced approaches for assessing human TBD risk. Internet and database searches on LD have demonstrated that information-seeking behaviors share similar temporal and spatial trends with known epidemiological reports [8,9]. Similar information seeking behaviors among health care providers also follow similar regional and temporal patterns to know human disease trends [10].

LD is transmitted by ticks in the *Ixodes* genus. *I scapularis*, the blacklegged tick, and *I pacificus*, the western blacklegged tick, are the primary vectors of the spirochete (*Borrelia burgdorferi*) that cause LD [10,15]. The blacklegged tick transmits other pathogens, including *Anaplasma phagocytophilum*, *Borrelia miyamotoi*, *Babesia microti*, *Powassan virus*, and ehrlichiosis associated with *Ehrlichia muris* eauclairensis [10,16]. *I pacificus* is known to transmit *Borrelia burgdorferi* sensu stricto, *Borrelia mayonii*, *Anaplasma phagocytophilum*, and *Borrelia miyamotoi* [16]. In addition, transmission of TBD pathogens to humans can result in related coinfections, such as Babesia, ehrlichiosis, or granulocytic anaplasmosis [16,17]. Recent modeling suggests the expansion of both *I scapularis* and *I pacificus* in areas where surveillance previously did not indicate reported or established tick populations [18]. The spread of *I scapularis* and *I pacificus* ticks with accompanying pathogens points to LD and other TBDs as a major public health risk [10], but, again, the actual prevalence of multiple TBDs or coinfections from related tick encounters is largely unknown, posing a problem for public health planning. Public health systems face significant challenges in identifying the spread of tick populations, as well as the associated risk and burden of TBDs among humans [19]. TBDs in this regard—accounting for 95% of all vector-borne diseases in the United States—are an especially serious and growing public health threat, with LD accounting for more than 70% of cases [20].

Veterinary studies that capture TBDs are shown to be useful in identifying possible coinfections and providing an important basis for human risk comparison [11], especially in areas where the Centers for Disease Control and Prevention (CDC) indicates TBD existence but where the actual number of cases may be unknown [12]. This study incorporates multimodal data triangulation using TBE, canine serological reports, public health data, and tick presence indicators to assess human disease risk among survey respondents reporting a TBE and concomitant diagnosis of a TBD.

Methods

Study Design

Various studies have introduced the use of web-based and other survey data along with other sources of patient information, on matters such as TBEs to demonstrate promising approaches and indicators for investigating human disease risk [3,4]. This study builds upon and extends recent research to include data on human TBEs at the county level and associated self-reports of TBDs in not only officially designated endemic regions but, importantly, also regions perceived as nonendemic in the United States relative to known tick and human and canine disease case reports.

The analytical objective in this study was to assess human TBD risk by employing a mixed methods approach using triangulation techniques and multimodal databases, geographically overlaying TBE reports to official data sources. Specifically, a web-based survey was conducted over a 15-month period beginning in December 2020 to collect data on TBEs. To maximize the value of the covariate data, related analyses included only TBE reports that occurred in the United States between January 1, 2000, and March 31, 2021. Adopting a One Health perspective, TBEs among patients diagnosed with LD were analyzed at the county level and compared to *I scapularis* and *I pacificus* tick presence, human cases identified by the CDC, and canine serological data. Spatial analyses included multilayer thematic mapping and statistical analyses, involving the amalgamated use of county-level patient TBEs, canine serological cases, tick presence, official CDC-reported human cases as an indicator for human TBD risk, and US Census data. Mapping and analyses of data conducted at the county level across the resultant data sets were supplemented by Fisher's exact tests of independence.

Ethical Considerations

The study protocol was approved by the institutional review board at the University of Texas at Dallas (IRB-21-149). Institutional review board approval was obtained prior to the survey, under formal adoption of the Declaration of Helsinki. All answers were completely anonymous and patients consented to voluntarily take the survey. All survey respondents provided informed consent. No personally associated identification data were collected or reported as such. Human subjects were not compensated. Data are available upon request.

Tick Bite Encounters and Respondent Data

The Tick Bite Encounter Survey (henceforth referred to as the "survey") was conducted on the internet via social media and shared through selected national TBD-related nonprofit organizational websites. The survey was available beginning in December 2020 for 15 months via an anonymous link (administered by Qualtrics). Designed to engage individuals diagnosed with a TBD, participation was voluntary, with respondents constituting a convenience sample for the study. Survey respondents were asked to report their diagnoses, tick-bite recall by month and year, and by county or zip code and state where tick bites occurred. Respondents listed county or zip code where and when they recalled receiving up to 4 tick bites or TBEs, and data were assessed to ensure entries matched corresponding states as reported. To maximize the value of the covariate data (eg, CDC-positive LD diagnoses), only TBEs that occurred in the United States between January 1, 2000, and March 31, 2021, were included in the analysis. In addition, TBEs were only analyzed if the location provided by the respondent could be unambiguously localized to a single zip code or county. Selected demographic information was also collected, including those who did not recall a TBE.

Additional study end points derived from official national databases were obtained from two main sources: (1) official by-county databases maintained by the CDC and US Census Bureau: (A) total number of human LD cases that met CDC diagnostic criteria and were recorded by state health officials to the CDC between 2000 and 2019; (B) counties officially established and reported by the CDC to contain *I scapularis* or *I pacificus* ticks as of 2020). The CDC notes that “counties classified as ‘no records’ should not be interpreted as the tick being absent. No records could be a result of a lack of sampling efforts, tick collections, or a lack of reporting or publishing the results of sampling efforts” [21]. Accordingly, for each county, tick presence was coded as present, absent, or unknown (no data); and (C) county populations as reported by the US Census Bureau’s Intercensal Estimates for 2000 to 2010 and 2010 to 2020. (2) Companion Animal Parasite Council county-level databases: total number of serological tests conducted on canines in 2020 (specifically: number of tests positive for ehrlichiosis; number of tests positive for anaplasmosis; number of tests positive for LD). The maps were presented as demonstrating county-level overlap of TBEs by each human disease risk indicator (ie, canine serological reports, CDC LD cases, and tick presence). In addition to thematic and multilevel mapping analyses using the ESRI’s ArcGIS (version 10.7), cross tabulations are provided across all data sources for all counties containing 1 or more survey TBEs, aligning with the thematic maps.

Results

Overview

Statistical analyses were conducted at the county level for all counties which had at least 1 TBE reported on the survey. Of the 239 respondents who completed the web-based survey, 182 (76.2%) reported at least 1 TBE, as shown in Table 1. A combined total of 329 TBEs were reported, with an average of 1.82 (SD 1.11) and a median of 1 (IQR 1) TBE per TBE-positive respondent. TBEs were filtered to restrict the sample to respondents who met the following criteria: the TBE could be definitively localized to a single county or zip code in a US state, and the TBE could be definitively localized to a single year between 2000 and 2021, inclusive. Note that some respondents indicated the location of TBEs using zip codes that occasionally encompassed areas crossing and belonging to different counties; in those cases, the TBE was considered to have occurred in the zip code’s “primary county” [22] and was considered “definitively localized” for analytical purposes. After applying these criteria, a total of 249 (75.7%) TBEs were apparent across 148 respondents (61.9% of all respondents, 81.8% of “TBE-positive” respondents), 144 (4.8%) counties in 30 states (60%) remained eligible for analysis, with an average of 1.68 (SD 1.00) and median of 1 (IQR 1) TBEs per respondent. County-level statistics appear in Table 2, with 144 eligible counties and their county-level data in the final data set. Unless otherwise noted, all further county-level proportions and percentages described herein were derived from this set of 144 counties; likewise, all state-level statistics were derived from the set of 30 states. None of the 144 counties or 30 states analyzed was missing survey TBE data, as only counties with one or more reported TBEs were included in the analysis. Of these, 14 (9.72%) counties across 7 (23.33%) states reported no CDC LD cases. These data include official LD reports from the CDC; patient reports of TBEs via web-based survey; established tick presence, indicating counties with habitats suitable for ticks; and canine serological data for Lyme, ehrlichiosis, and anaplasmosis.

Table 1. Survey respondents and tick bite recall (December 2020 to March 2021).

	Recall tick bite, n (%)	Do not recall tick bite, n (%)	All respondents, n (%)
Age			
9 to 45 years old	65 (66.3)	33 (33.7)	98 (41)
46 or more years old	116 (82.9)	24 (17.1)	140 (58.6)
Age not reported	1 (100)	0 (0)	1 (0.4)
Total	182 (76.2)	57 (23.9)	239 (100)
Number of years sick			
0 to 5 years	113 (77.4)	33 (22.6)	146 (61.1)
6 or more years	67 (75.3)	22 (24.7)	89 (37.2)
Not reported	2 (50)	2 (50)	4 (1.7)
Total	182 (76.2)	57 (23.6)	239 (100)

Table 2. Number of US counties with reported TBDs[a] by frequency of primary end points.

	Counties with disease indicator present, n (%)	Counties with no disease indicator present, n (%)	Data unavailable, n (%)	Total, n (%)
Human cases				
CDC[b] LD[c]	130 (90.3)	14 (9.7)	0 (0)	144 (100)
Survey TBE[d]	144 (100)	0 (0)	0 (0)	144 (100)
Tick presence				
Ixodes scapularis	110 (76.4)	34 (23.6)	0 (0)	144 (100)
I pacificus	2 (1.4)	142 (98.6)	0 (0)	144 (100)

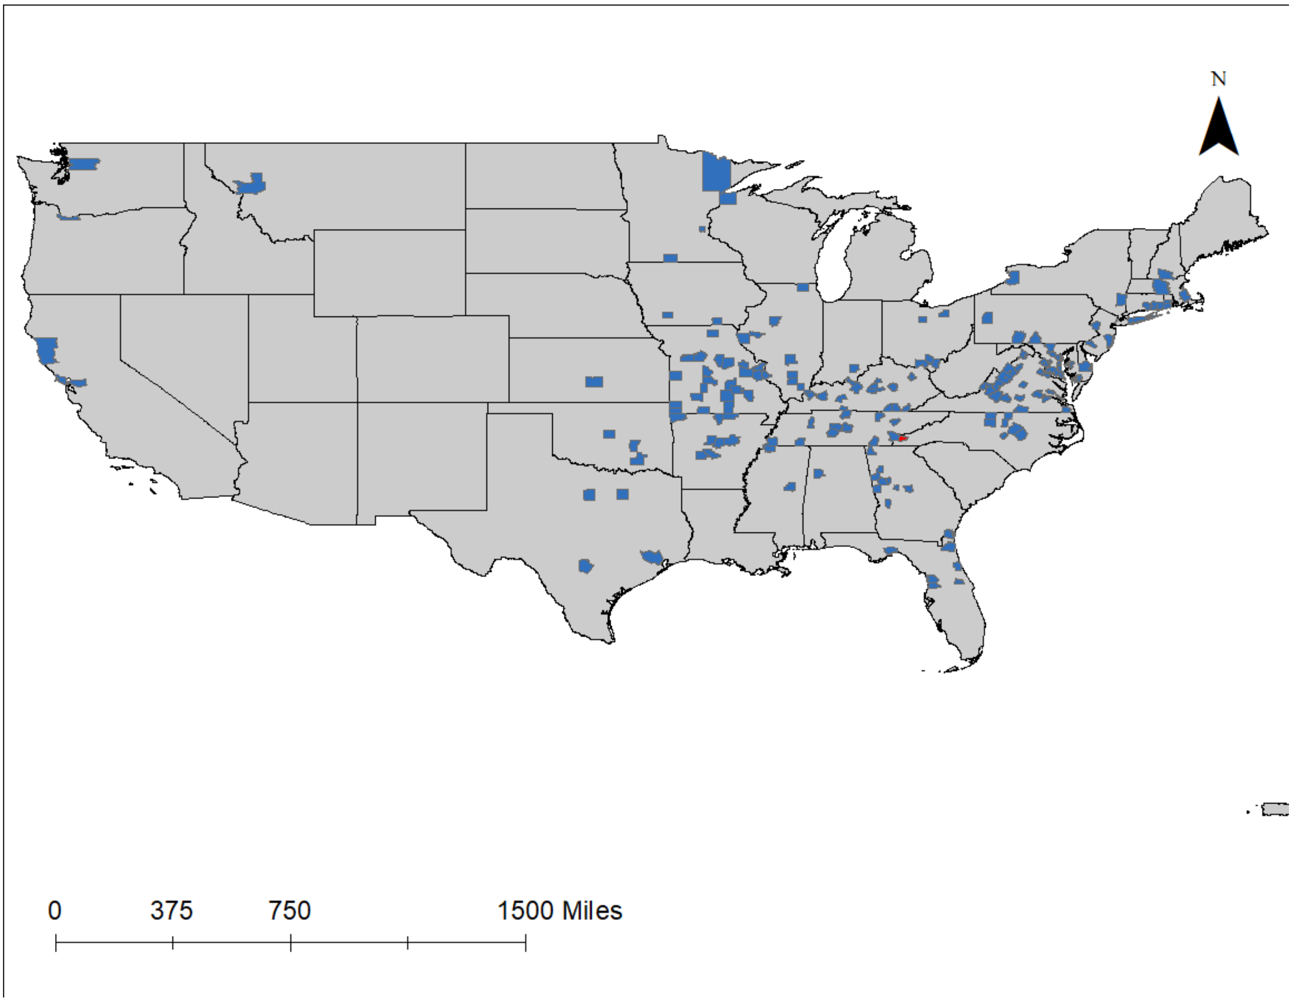
Self-Reported TBEs

Using triangulation methods, Figures 1-5 show tick presence and the existence of human and canine disease by county in the United States. Multilayered thematic maps of self-reported TBEs among patients diagnosed with LD and coinfections, in addition to statistical alignments and comparisons of data regarding TBE reports and recall, was developed and performed.

Taken together, the maps offer a representation of human TBD risk, based on the more nuanced approach engaging triangulation of human and canine reports in addition to tick presence. Survey-reported TBEs in 144 counties, as shown in Figure 1, are then compared to official disease and tick data. Official CDC data are also compared separately to demonstrate county level overlap via human and canine laboratory testing and tick presence.

Figure 1. Survey respondents with LD and reported tick bite encounters by county. LD: Lyme disease.



Mapping and analyses of subsequent county-level data also included Fisher's Exact tests of independence, as reported in Tables 3-6, to evaluate the likelihood that the co-occurrence or "county overlap" of given pairs of variables was random. A significant outcome ($P<.05$ level of significance) provides evidence that the 2 variables may be used as proxies for one other.

Table 3. Association across US counties by tick presence (significance set at $P<.05$).

Fisher exact test	*Ixodes pacificus* − Counties	*I pacificus* + Counties	Total
I scapularis – Counties	32	2	34
I scapularis + Counties	110	0	110
Total	142	2	144

Table 4. Association of US counties with survey respondent TBEs[a] by canine LD[b] and CDC[c] LD cases (significance set at $P<.05$).

Fisher exact test	County has reports of CDC LD	County has no reports of CDC LD	Total
County has reports of canine LD	5	11	16
County has no reports of canine LD	5	108	113
Data unavailable	4	11	15
Total	14	130	144

[a] TBE: tick bite encounter.

[b] LD: Lyme disease.

[c] LD: Lyme disease.

Human LD, Survey TBEs, and Canine LD

Figures 2-5 present integrated, multilayer thematic maps that show overlap of survey respondent TBEs with canine cases of LD, ehrlichiosis, and anaplasmosis, and human cases of LD (the only available county-level TBD data from the CDC). Figure 2 presents a thematic overlap of CDC and canine cases of LD within counties with at least 1 survey-reported TBE. Yellow counties indicate containing canine LD, CDC-reported LD cases, and where TBE survey respondents reported a TBE and concomitant disease. Red counties represent overlap among canine LD and TBE survey respondents, but without CDC reports of human LD. Green graduated shaded counties are all LD counties in the United States as reported by the CDC. Table 4 provides statistical data representing LD by county for respondent TBE, canine LD, and CDC LD. Some counties do not have canine data, so disease presence among dogs in those counties is unknown.

Figure 2. Respondent TBEs with canine and CDC LD cases by county (CDC LD cases 2000-2019). CDC: Centers for Disease Control and Prevention; LD: Lyme disease; TBE: tick bite encounter.

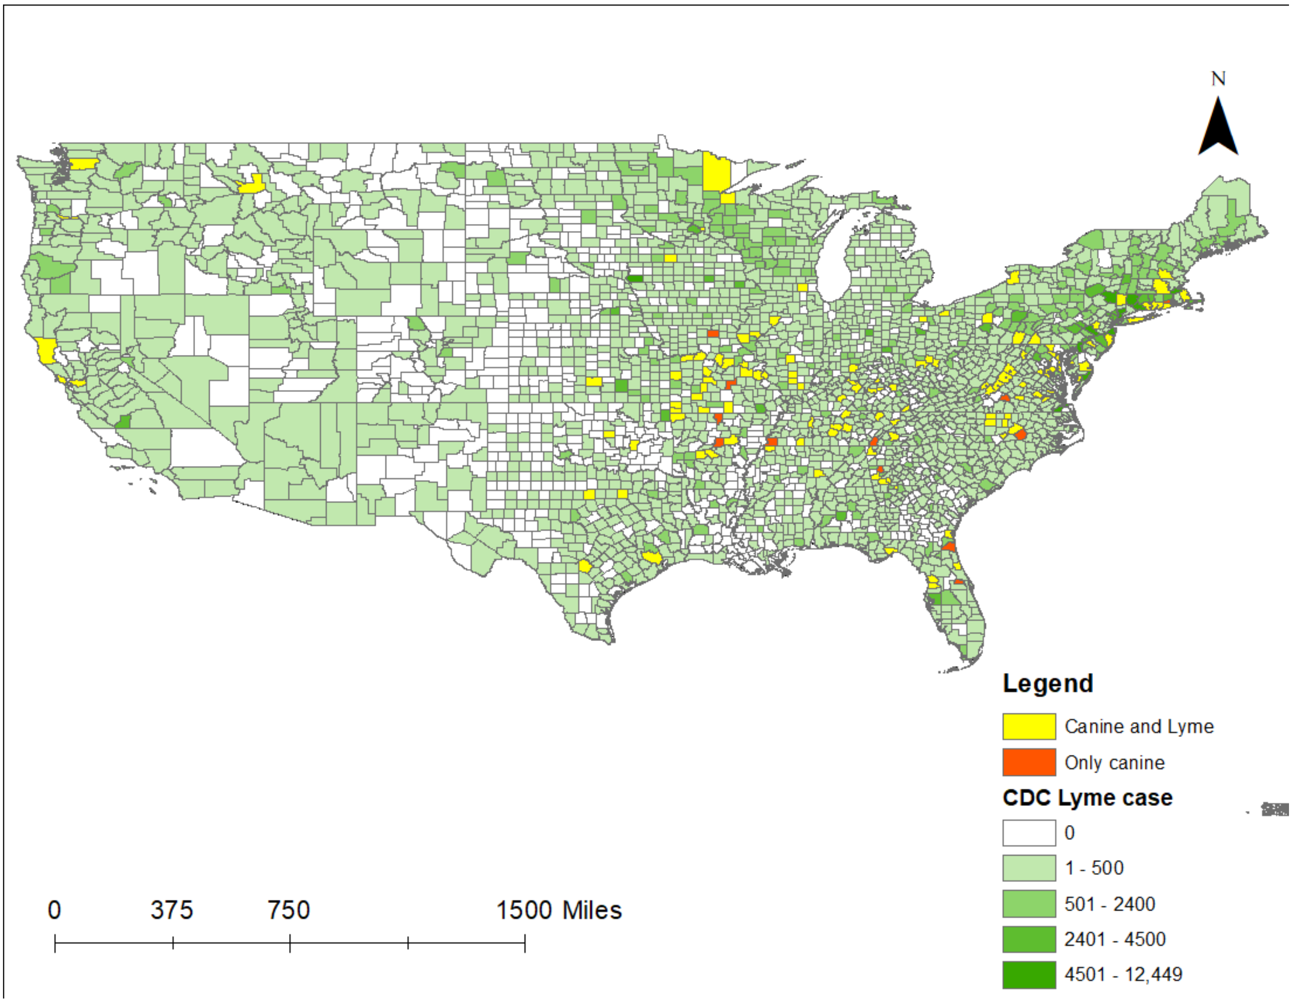

Figure 3 offers a map of CDC data and canine cases of anaplasmosis within TBE survey respondent counties. Blue counties indicate where canine cases overlap with CDC LD cases and survey-reported TBEs. Light blue counties represent overlap among canine LD and TBE survey respondents, but without CDC reports of human LD. Green counties are all LD counties with TBE survey respondent overlap. Table 5 highlights the thematic mapping overlaying, indicating significant association between canine anaplasmosis and CDC cases of LD within counties that had reports of a human TBE.

Figure 3. Respondent TBEs with canine anaplasmosis and CDC LD cases by county (CDC LD cases 2000-2019). CDC: Centers for Disease Control and Prevention; LD: Lyme disease; TBE: tick bite encounter.

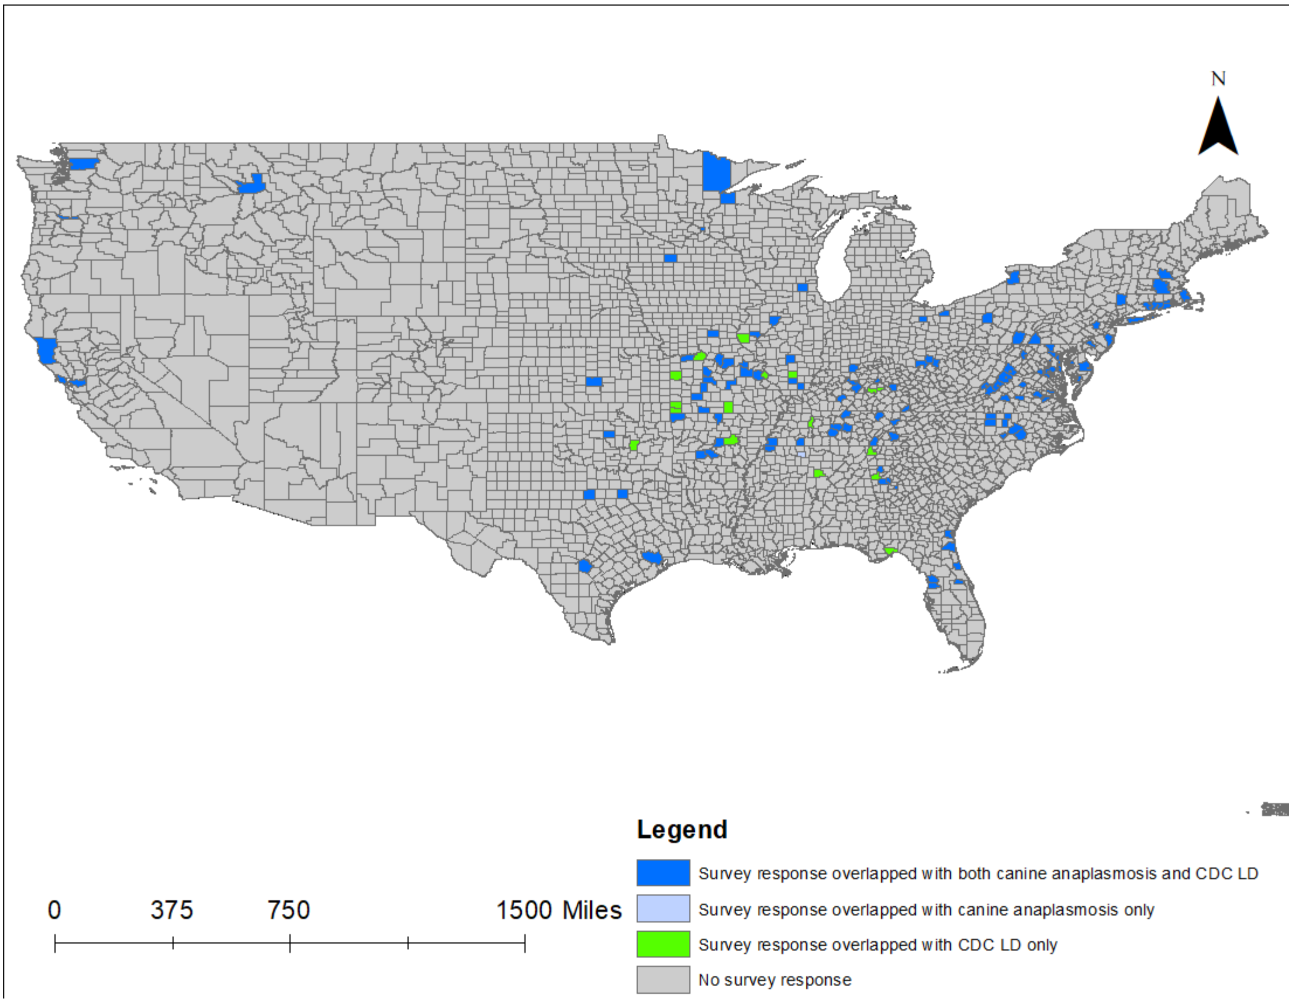

Figure 4 presents a thematic overlay of CDC and canine ehrlichiosis cases within TBE survey respondent counties. Yellow counties indicate where canine LD cases overlap with CDC LD cases and survey reported TBEs. Light yellow shading represents overlap between canine LD and TBE survey respondents, but without CDC reports of human LD. Green shading likewise represents counties with overlap between CDC LD and TBE survey data, but with no canine LD cases. Table 6 highlights the thematic mapping indicating significant associations between canine ehrlichiosis and CDC reported cases of LD within counties with human TBE reports.

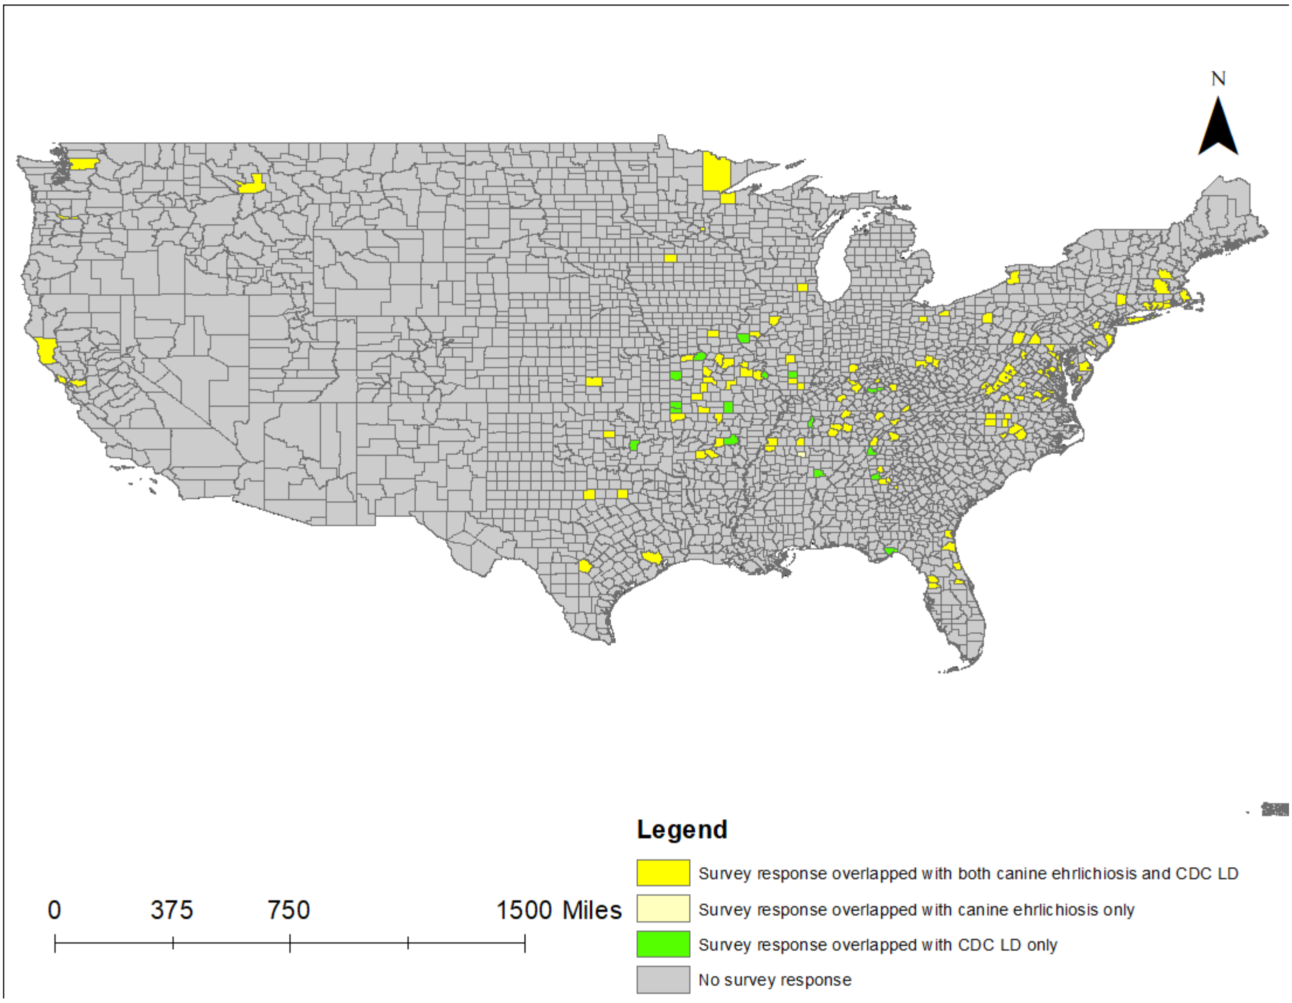
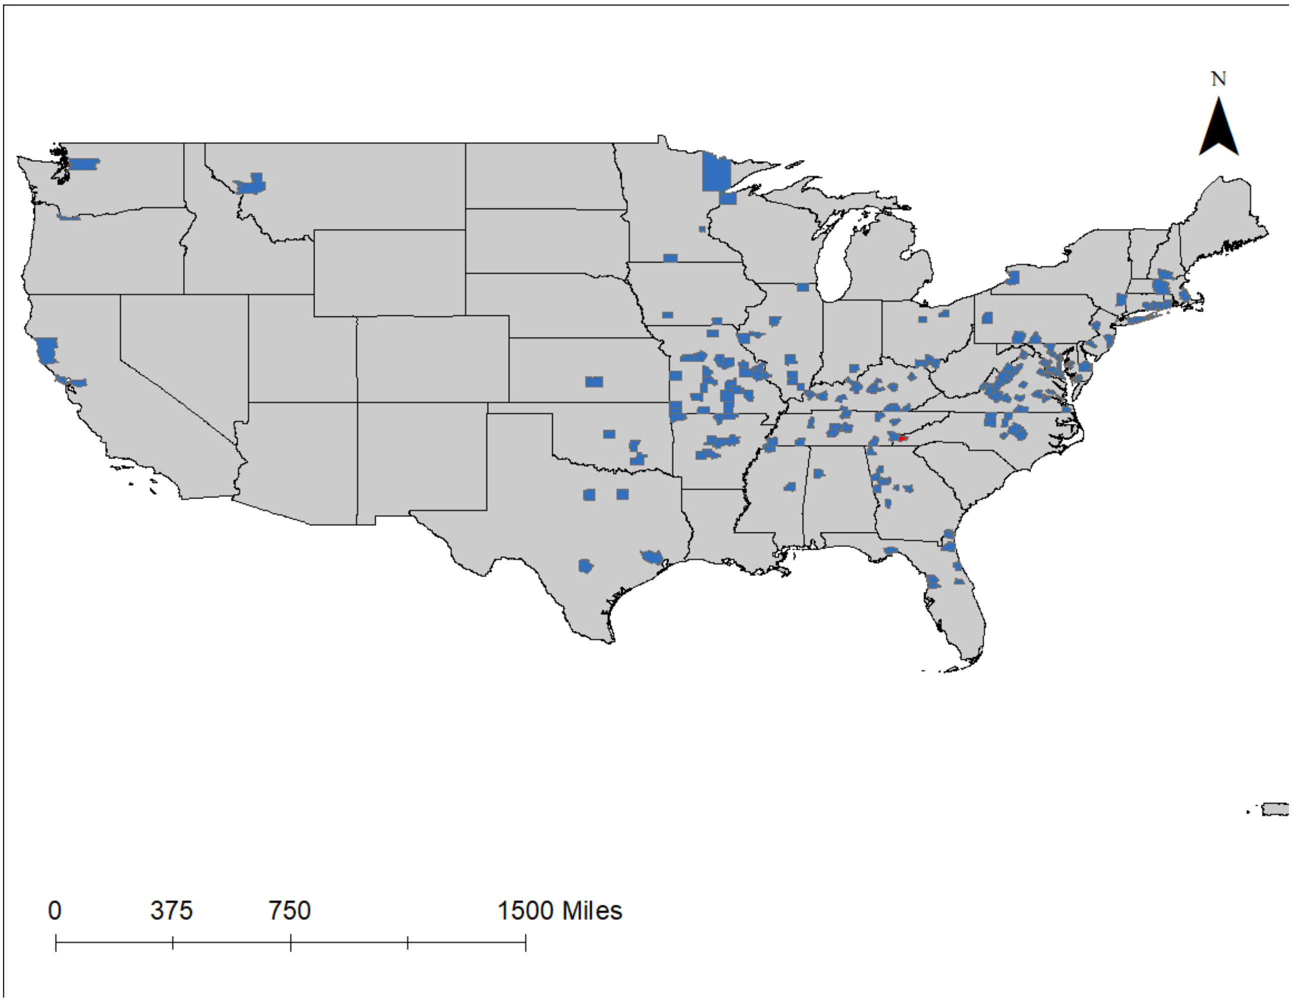
Figure 4. Respondent TBEs with canine ehrlichiosis and CDC LD cases by county (CDC LD cases 2000-2019). CDC: Centers for Disease Control and Prevention; LD: Lyme disease; TBE: tick bite encounter.



In sum, the maps offer visual representation of TBE overlap with official data from 3 primary sources: tick presence, CDC-reported LD cases, and positive canine tests for LD, ehrlichiosis, and anaplasmosis. Using thematic overlays to triangulate matching human disease risk, every county overwhelmingly matched TBE survey reports and at least 1 disease risk indicator from official sources. Figure 5 is a summary map, depicting all counties where a survey respondent reported a TBE and a LD diagnosis and where the TBE matched at least one of the triangulated data points of tick presence or human or canine disease. The scope of influence is substantial in this respect; out of a total of 144 counties included in the final analytical data set, only 1 did not overlap with an official source of disease risk—Graham County, North Carolina—which appears as the only county in red on the summary map in Figure 5. In other words, the respondent TBEs and subsequent self-reported LD offer a one-to-one match with human or canine official serological reports. The lack of overlap in Graham County does not mean that disease risk does not exist but, rather, was the result of missing canine data. In fact, neighboring counties showed positive serological tests for LD, ehrlichiosis, and anaplasmosis in canines, and ticks do not adhere to county lines.

Figure 5. US counties with survey respondent reported TBEs and LD diagnoses, with TBEs matched to triangulated data points of tick presence or human or canine disease. LD: Lyme disease; TBE: tick bite encounter.



Discussion

Implications of the Relative Proportions of CDC LD Cases and Survey TBEs

To date, surveillance of TBDs typically is presented in aggregate national and state level databases, hindering analyses at levels that may be more revealing and provide more detailed depictions of relevant indications of TBD risk. The current public health system in the United States does not recognize as endemic areas that may cluster in various states outside of the Northeast. Data for most TBDs are provided by the CDC, aggregated from state public health departments following positive laboratory results. Although county-level data on TBDs are collected by some states, the CDC reports such data for LD only. In addition, while LD reports are available by county, no distinctions are drawn between locally as opposed to travel-acquired disease. Accordingly, TBE likelihood—which is geographically dependent—could not be confidently determined from such data alone.

However, multilayer thematic mapping has demonstrated clear overlapping among TBEs and concomitant human disease reports with canine and CDC LD reports and tick presence data by county. As noted, previous studies have demonstrated the utility of multilayer thematic mapping using canine and self-reported TBEs, particularly as it pertains to ecologically distinct regions [23]. Specifically, the survey sample, although relatively small, was national in scope. However, respondents reported TBEs only in western, mid-Atlantic, and eastern regions where LD and ticks are either established or considered endemic. Note that this could be an artifact and limitation of the data with the use of respondents as a convenience sample. In any case, a one-to-one match was found for TBE and human disease self-reports with at least one of the human disease risk indicators. The critical point here, as revealed through the mapping and the statistical analyses, is the substantial overlap in the TBE counties among canine (especially canine ehrlichiosis), CDC reported LD cases, and presence of ticks carrying associated pathogens.

Triangulating TBD Risk via Proxy Data

Developing robust proxies for human TBD risk to address data and testing limitations is an important analytical undertaking, especially until objective, standardized, and centralized diagnostic monitoring can be implemented for a more detailed picture below the state level as needed. Research has pointed to similar spatial distributions and county-level findings among canines and humans using official public health data, in addition to self-reports of TBEs and subsequent diagnoses (both clinical and CDC+) and tick infectivity [23-26]. The use of other data sources, including patient surveys, also points to other surveillance data and techniques that have the potential to inform public health practitioners when local data are scarce or clinical evaluations are made in geographic areas not generally considered endemic [27,28].

This study has explored paths for improving disease surveillance by triangulating TBD risk via proxy data. Proxies were considered to help establish risk, relying on “indirect data” such as surveys and veterinary assessments to supplement and extend official data when available. The use of canine TBDs as proxies was supported by research indicating, for example, links between companion pets and human disease. In fact, owners of dogs and cats are at increased risk of encountering ticks and of developing TBDs [29], which also reflects the One Health perspective given connections among humans and their pets. In other words, canine TBD data are not fully divested from human TBD data and, so, with proper consideration of their differences and precise characterization of their common factors, they can usefully serve as proxies, as demonstrated in this study.

Limitations and Recommendations for Future Work

The survey was intentionally aimed at individuals likely to have experienced TBEs and to have a high probability of participation and response (eg, web-based support groups focused on TBDs). This approach naturally sat the survey respondent sample apart from the general population and could lead to underestimation of TBEs. In addition to survey limitations and possible bias and simple recollection errors by respondents, some statistical issues can also be noted. In particular, the canine data represented cases only from 2020, rather than across the 2000-2021 study period. Future work will incorporate more nuanced multilevel models that can account for unequal variances, mixed and fixed effects, nesting, and other confounding issues. Additional data too will address broader contextual concerns and data set gaps. For example, other tick species (eg, the Lone Star Tick) can act as vectors for TBDs and are extant in different geographical locations. Inclusion of such entomological data can improve analytical coverage. In addition, expanded historical data will help elucidate long-term trends that may not be detectable over shorter periods and will aid in outcome interpretation.

Conclusions

Controversy arises as a burgeoning population reports TBD diagnoses that do not match official reports. LD and other TBDs can be difficult to diagnose and physicians and health care professionals may be unaware of growing risks and public health threats in locally clustered areas, particularly in areas generally considered nonendemic [23]. Diagnostic ambiguity is exacerbated by symptomatic overlap in TBD presentation, as well as insufficient tracking and characterization of the various vectors and TBEs that cause them.

To date, surveillance of TBDs in the United States is a patchwork of activities that are unable to provide a satisfactory picture of risk or infection rates across TBDs, not to mention overlapping comorbidities in infected humans. Resulting controversies plague the patient-physician-public health relationship and discourse, with LD and other TBD sufferers turning to advocacy in demand for diagnosis and treatment. The importance of identifying opportunities to improve surveillance and data for determining TBD risk cannot be overstated for informing the public and the medical community.

Acknowledgments

The authors wish to thank the hundreds of respondents who completed the web-based survey and whose reporting made this work possible.

Data Availability

Abstract

Background: While the End Tuberculosis (TB) Strategy has been implemented worldwide, the cause of the TB epidemic is multifactorial and not fully understood.

Objective: This study aims to investigate the risk factors of TB and incorporate these factors to forecast the incidence of TB infection across different age groups in Sichuan, China.

Methods: Correlation and linear regression analyses were conducted to assess the relationships between TB cases and ecological factors, including environmental, economic, and social factors, in Sichuan Province from 2006 to 2017. The transfer function-noise model was used to forecast trends, considering both time and multifactor effects.

Results: From 2006 to 2017, Sichuan Province had a reported cumulative incidence rate of 1321.08 cases per 100,000 individuals in male patients and 583.04 cases per 100,000 individuals in female patients. There were significant sex differences in the distribution of cases among age groups (trend χ^2_{25}=12,544.4; *P*<.001). Ganzi Tibetan Autonomous Prefecture had the highest incidence rates of TB in both male and female patients in Sichuan. Correlation and regression analyses showed that the total illiteracy rate and average pressure at each measuring station (for individuals aged 15-24 years) were risk factors for TB. The protective factors were as follows: the number of families with the minimum living standard guarantee in urban areas, the average wind speed, the number of discharged patients with invasive TB, the number of people with the minimum living standard guarantee in rural areas, the total health expenditure as a percentage of regional gross domestic product, and being a single male individual (for those aged 0-14 years); the number of hospitals and number of health workers in infectious disease hospitals (for individuals aged 25-64 years); and the amount of daily morning and evening exercise, the number of people with the urban minimum living standard guarantee, and being married (for female individuals aged ≥65 years). The transfer function-noise model indicated that the incidence of TB in male patients aged 0-14 and 15-24 years will continue to increase, and the incidence of TB in female patients aged 0-14 and ≥65 years will continue to increase rapidly in Sichuan by 2035.

Conclusions: The End TB Strategy in Sichuan should consider environmental, educational, medical, social, personal, and other conditions, and further substantial efforts are needed especially for male patients aged 0-24 years, female patients aged 0-14 years, and female patients older than 64 years.

tuberculosis; risk factors; age; sex; prediction; TB control; tuberculosis control

Introduction

Tuberculosis (TB) has been the leading cause of the global disease burden. Approximately 25% of the population worldwide are infected with *M tuberculosis* [1]. In 2019, according to the World Health Organization, there were approximately 10 million new cases of TB globally and 1.2 million deaths [2]. Of note, almost 90% of individuals who are infected with TB each year originate from low-income countries [2]. Poor health services, malnutrition, and crowded working and living conditions in these countries leads to the increased risk of TB across populations. Fighting poverty has become a major theme for the World Health Organization, which aims to end the global TB epidemic using “the End TB Strategy” [2]. According to the End TB Strategy, the targeted percentage reduction in the absolute number of TB deaths and incidence rate for 2035 are 95% and 90% of the 2015 baseline, respectively [1]. However, the cause of the TB epidemic is multifactorial and not fully understood.

Most people (approximately 90%) develop the disease in adulthood, with men being more susceptible than women [1-4]. Previous ecological studies have demonstrated a significant association between TB cases and ecological factors, including environmental, economic, health, and social conditions [3-11]. Although ecological risk factors for TB at the population and individual levels have raised great concerns, these results are not consistent [1,2,11-16]. The cause of TB varies in different populations and countries, especially in different groups (eg, of different ages and sexes) or in areas with a high TB burden [1], which is a major barrier for the End TB Strategy. China had the third-largest TB burden in the world in 2019, while Sichuan Province, known for its geographical and ethnic diversity, has a top-ranked TB burden, thus providing the opportunity to comprehensively identify specific risk factors in a complex background.

Furthermore, elucidating the trend of TB incidence with identified TB factors helps to assess the effectiveness of containing measurements that may aid policy maker decisions and public health practice. Therefore, our research aimed to identify these potential risk factors for TB in Southwest China using multiple regression and to predict the trend of TB incidence using a transfer function-noise (TFN) model [17-21]. The overarching goal of our study was to gain insight into the secular TB trend, providing implications for advancing TB prevention and control strategies to achieve the targets of the End TB Strategy.

Methods

Data Sources and Objects

Geographic Information

We obtained data from China’s Geographic Information Center on Sichuan Province in 2009. The map of county-level administrative divisions included prefectures, counties, cities, and districts. In total, Sichuan Province has 21 cities or prefectures and 181 districts, counties, and cities, with a total of 1.4 million inhabitants.

Social, Economic, Environmental, Education, and Health Information

Data were extracted from the 2006-2017 Statistical Yearbook of Sichuan Provincial Bureau of Statistics. All TB cases were grouped by sex and age. The age groups were as follows: children (aged 0-14 years), youths (aged 15-24 years), adults (aged 25-64 years), and older individuals (aged >64 years).

From the age-stratified population of the “Epidemic Information Network Direct Reporting System” from 2006 to 2017, we enrolled the subpopulation in Sichuan Province. All population data were for permanent residents, specific to county administrative divisions, and included population data by age and sex. Information on TB and HIV/AIDS was obtained from the TB Information Management System of the Chinese Disease Prevention and Control Information System and the Statistical Yearbook published by the Sichuan Provincial Bureau of Statistics. The incidence of TB was analyzed in different age groups.

Statistical Analysis

The ecological analysis used data such as case reports, registered case data, and ecological information to explore the risk factors related to the prevalence of TB. Data on TB cases and the incidence rate of TB were collected per administrative division, sex, and age group. The variables for each model were chosen by auto-modeling.

The 128 ecological factors were all obtained from 12 years (2006-2017) of data. The transfer function model was fitted by the autoregressive integrated moving average (ARIMA) model by time series [17-21], using expert modeling and adding independent variables for the model fitted to choose the variables through the fitted data and prediction data; we used 3 different models (the Grey model, the ARIMA model, the TFN model) to identify the model that most closely aligned with the real TB data of 2018.

TFN Model

The expert modeler selected the optimal model from multiple fitted models, when the R^2 value reached the ideal state. The linear regression analysis adopts the stepwise regression analysis method and uses multiple models to fit and to achieve a better R^2 value in four different age groups. Finally, only the best model was used for display. Multiple stepwise regression was carried out for multivariate analysis (stepwise regression rules: F-to-enter≥3.840, F-to-remove≤2.710). The models were established by each factor, stepwise in and out of the models. Multimedia Appendix 1 shows the stepwise regression summary; when the R^2 and standard estimated error reached the best value, the model concluded.

Univariate analyses (Pearson correlation analysis) and multivariate analyses (regression analysis) were used to analyze the protective factors and risk factors for TB in Sichuan Province according to sex and age group (trend χ^2_{25}=12,544.4; $P<.001$). Statistical analysis (descriptive analysis and cluster analysis of spatiotemporal scans) and prediction of TB incidence in 2035 were performed according to sex and age.

The autocorrelation test of the residuals uses the Durbin-Watson (DW) test, with the following test statistic:

DW values occur in a range from 0 to 4 as follows: a DW value of 0 indicates complete positive autocorrelation, values between 0 and 1.5 indicate positive autocorrelation, values between 1.5 and 2.5 indicate no autocorrelation, values between 2.5 and 4 indicate negative autocorrelation, and a value of 4 indicates complete negative autocorrelation. In addition, the autocorrelation function and partial autocorrelation function show whether the data sequence reached a stable state. At the same time, the R^2 and Bayesian information criterion values of the TFN model were used before and after data unit standardization to find the best model. The closer the DW value is to 2, the more independent the observations of multiple linear regression are.

Considering the effect of time and multiple factors, we used Panel regression, Poisson regression, and Lasso regression for the analysis; however, the data were not suitable for these regressions; for example, our study has a large number of factors to explore the relationship, so the Panel regression could not include all 128 factors and ID and time to fit. The pilot analyses revealed that the random effect model was better than the pool model and fixed effect model. For these reasons, we did not use other regression methods.

We included all reported cases of TB during 2006-2017; these data possibly contain information and selection bias. The TFN model is a multivariate time series analysis method that can be seen as a combination of the ARIMA model and a multiple regression model. We used SPSS 23.0 (IBM Corp) and ArcGis Map 10.6 (ESRI Inc) to create spatiotemporal scans and to conduct the analyses that predicted TB trends by sex and age. The three main steps were as follows: model identification, parameter estimation, and model testing. For the calculation of the *P* value, the analysis was applied under the assumptions of unequal variances and a statistical significance of $P<.05$.

Ethics Approval

Data collection of TB was required by the Law of the People's Republic of China on Prevention and Treatment of Infectious Diseases. The ethics approval in this study was granted by the Ethics Committee of Sichuan Center for Disease Control and Prevention (SCCDCIRB2022-001).

Results

Annual TB Cases and Incidence Rate

From 2006 to 2017, Sichuan Province reported 548,584 cases of pulmonary TB in male patients, with a reported cumulative incidence rate of 1321.08 cases per 100,000 individuals (average 110.09 cases/100,000 individuals), and 235,149 cases of pulmonary TB in female patients, with a reported cumulative incidence rate of 583.04 cases per 100,000 individuals (average 48.59 cases/100,000 individuals). Thus, there were approximately 2.33 times more cases in male patients than in female patients. The reported cumulative incidence of TB in Sichuan Province from 2006 to 2017 was 961.71 cases per 100,000 individuals (average 80.14 cases/100,000 individuals). These TB cases mainly occurred in individuals aged 15-64 years, which accounted for 82.02% (n=642,808) of the total cases.

As shown in Figure 1, there were sex differences in the distribution of cases among age groups, and these differences were significant (trend χ^2_{25}=12,544.4; $P<.001$). The number of TB cases in Sichuan Province peaked in individuals aged 20-24 years and gradually decreased in individuals older than 64 years (Figure 1). During these 12 years (2006-2017), the incidence rate in those aged 80-85 years was lower than in those aged 60-79 years, while individuals older than 70 years had the highest TB incidence peak (Figure 2).

Figure 1. TB cases in Sichuan Province of China during 2006-2017. TB: tuberculosis.

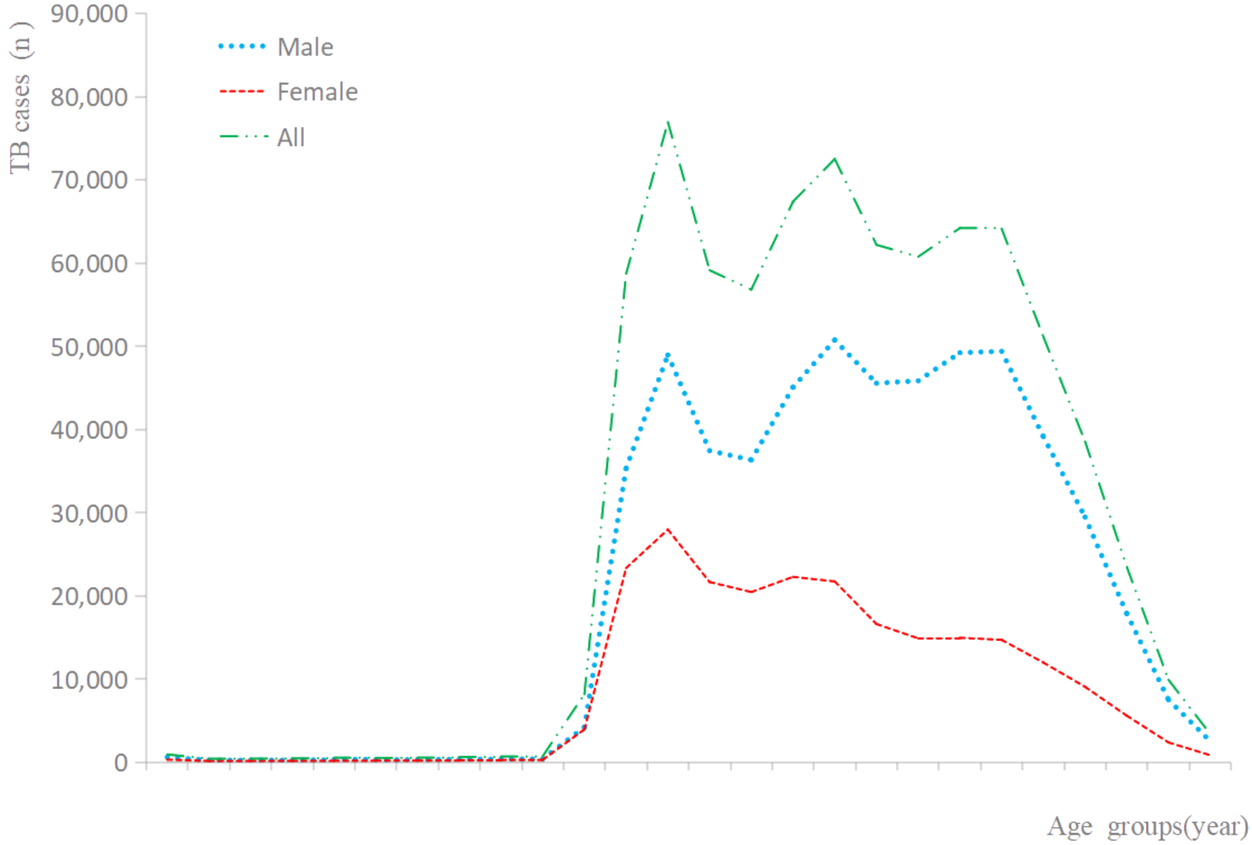

Figure 2. TB incidence rate in Sichuan Province of China during 2006-2017. TB: tuberculosis.

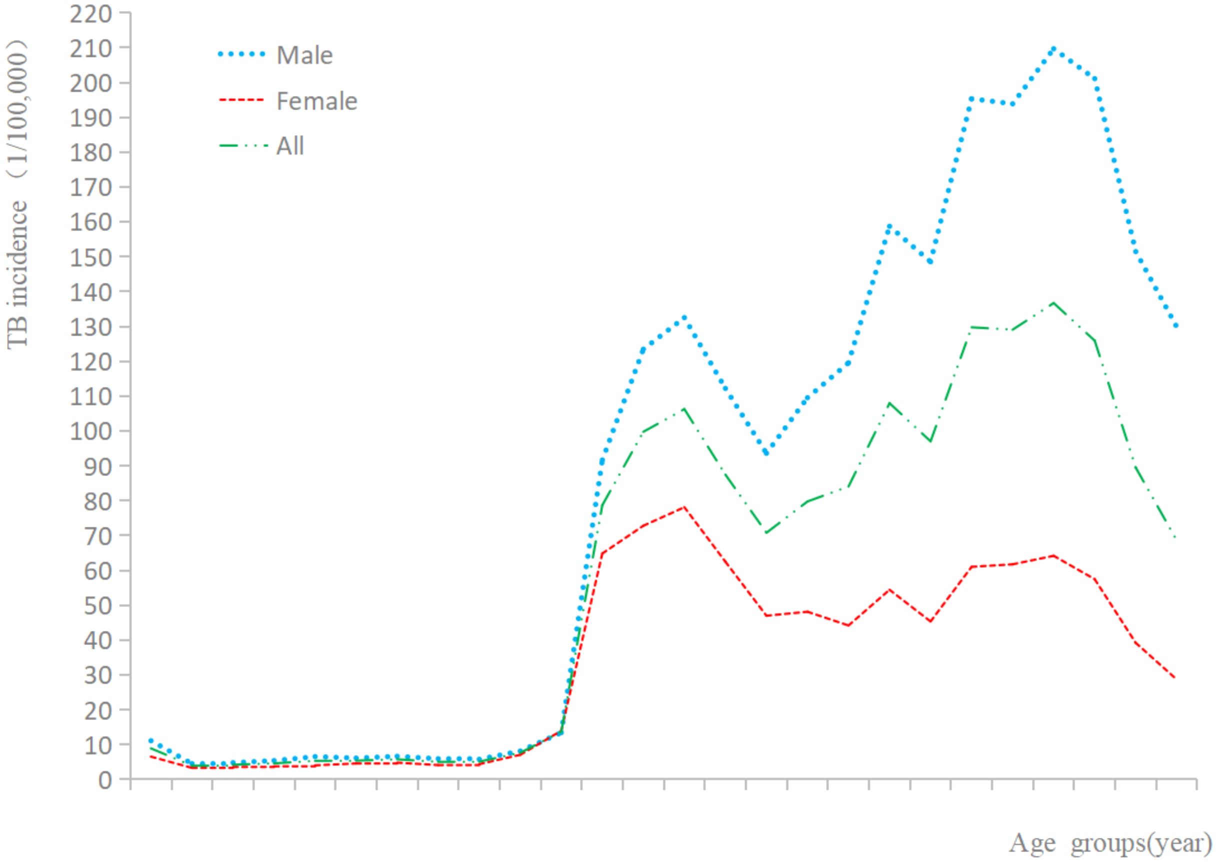
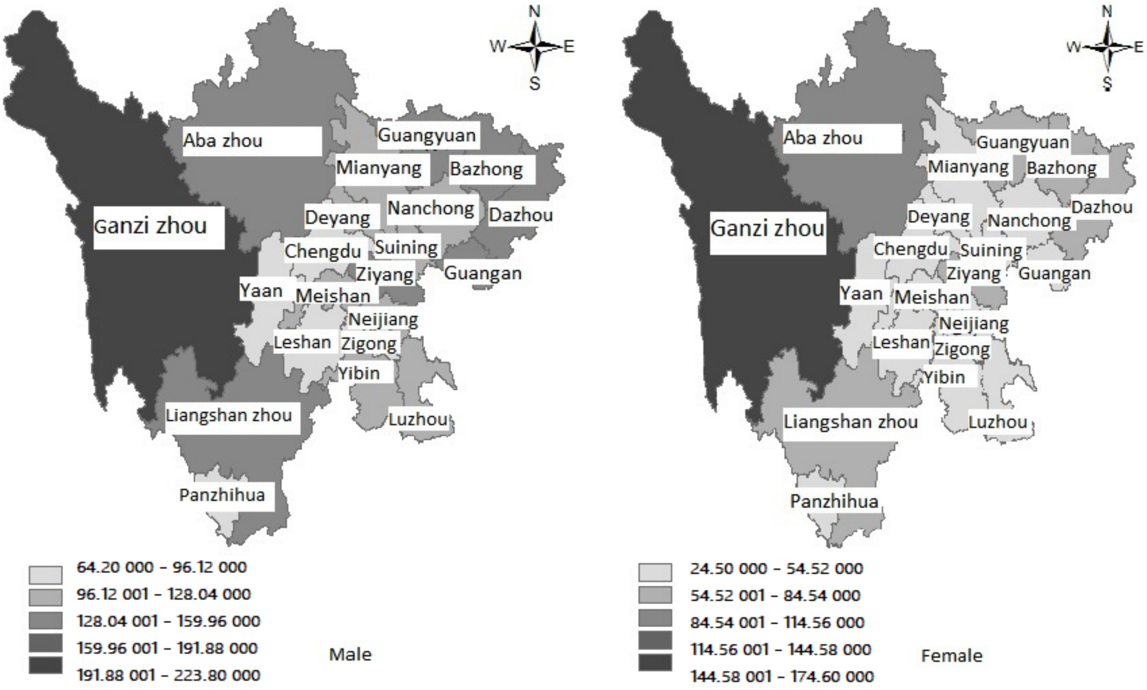


Geographic Distribution

Figure 3 displays the TB cumulative incidence in 21 cities/prefectures during this time period. The 5 cities/prefectures with the highest incidence rates of TB in male patients were Ganzi Tibetan Autonomous Prefecture, Aba Tibetan and Qiang Autonomous Prefecture, Guangyuan City, Liangshan Yi Autonomous Prefecture, and Dazhou. The five cities/prefectures with the lowest incidence rates of TB in male patients were Chengdu, Panzhihua, Ya’an, Leshan, and Zigong. In female patients, the top five cities/prefectures according to TB incidence rates were Ganzi Tibetan Autonomous Prefecture, Aba Tibetan and Qiang Autonomous Prefecture, Liangshan Yi Autonomous Prefecture, Guangyuan City, and Dazhou; the bottom five were Chengdu, Zigong, Ya’an, Leshan, and Panzhihua.

Figure 3. The incidence of male and female TB in Sichuan Province of China during 2006-2017(1/100,000). TB: tuberculosis.



Relationships Among the Variables

Across the four age groups, there were significant associations between TB incidence and the environmental and socioeconomic effects in five aspects, including other diseases as well as health resources; economic and social factors; pollutant, forestry, and meteorology variables; population structure, marriage, and habit variables; and educational investment and education level (all *P*<.05; Multimedia Appendix 1, Tables S1-S5).

Multivariate Analysis

As shown in Table 1, a linear regression analysis was performed on the incidence of TB and the various factors, and a multivariate analysis was performed on the four age groups in the whole population, the male population, and the female population. The regression model exhibited multivariate multicollinearity; the DW values for the four age groups (individuals aged 0-14, 15-24, 25-64, or ≥65 years) were 2.433, 1.340, 2.491, and 3.114, respectively.

In addition, in those aged 0-14 years, the factors affecting the risk of TB were as follows: the number of families with the urban minimum living standard guarantee, average wind speed, number of patients with invasive pulmonary TB discharged, number of people with the rural minimum living standard guarantee, total health expenditure as a percentage of regional gross domestic product (GDP), and being a single man. These factors reduced the risk of TB. The incidence of TB in those aged 15-24 years, sex ratio, number of forest fires, and regular exercise rate of adults increased the risk of TB in children (Table 1).

In those aged 15-24 years, the incidence of TB in those aged 0-14 years, total illiteracy rate, number of infectious disease hospitals, enrollment number (secondary school and above), exposure to secondhand smoke among nonsmokers (%), fraction of married men (%), number of forest fires, and number of junior high school boys (%) increased the risk of TB (Table 1).

In those aged 25-64 years, the number of hospitals, number of health workers in infectious disease hospitals, TB rate in those aged ≥65 years, daylight duration, and male life expectancy decreased the risk of TB (Table 1).

Finally, in the group of people older than 64 years, the risk of TB was increased by the following factors: the rate of TB cases in female patients, cumulative precipitation over 24 hours (8 PM to 8 PM), rate of TB in those aged 25-64 years, total health expenditure as a percentage of regional GDP, number of families with the rural minimum living standard guarantee, rate of TB in patients aged 15-24 years, and civil medical assistance. The risk of TB decreased with the amount of daily morning and evening exercise and the number of people with the urban minimum living standard guarantee and in women who were married (Table 1).

Table 1. Multivariate analysis of tuberculosis (TB) incidence by age group (individuals aged 0-14, 15-24, 25-64, or ≥65 years) in Sichuan Province.

Model and variables	B (95% CI)	*T* test (*df*)	*P* value
Model 1 (dependent variable: TB incidence in those aged 0-14 years; Durbin-Watson value: 2.433)

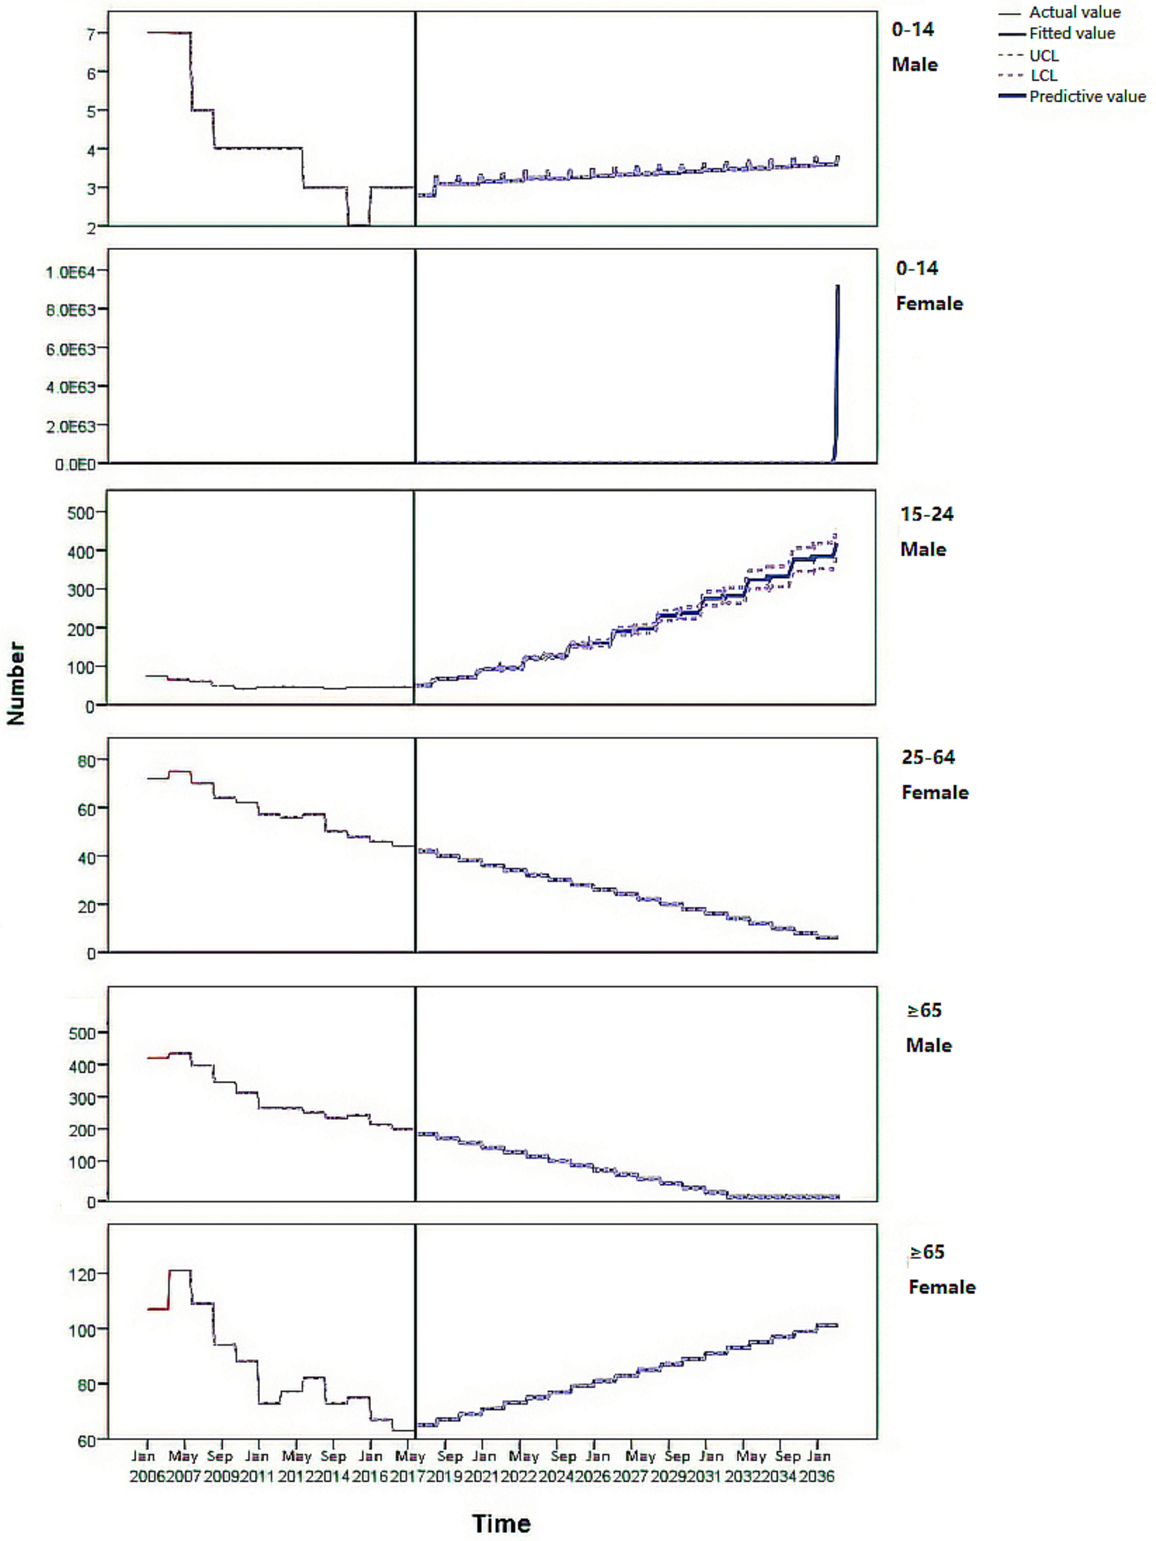
[a] GDP: gross domestic product.

Forecast Trend

In addition, the TFN model predicted that in 2035, the incidence of TB in male patients aged 0-14, 15-24, 25-64, and ≥65 years per 100,000 individuals would be 4.00, 377.08, 0.00, and –54.00, respectively (Figure 4). Our model predicted that the incidence of TB in males aged 0-14, 15-24, 25-64, and ≥65 years would not fall to 0 by 2035 and that the incidence rate of TB in male patients aged 0-14 and 15-24 years would increase.

Moreover, the TFN results showed that the incidence of TB among female patients aged 0-14, 15-24, 25-64, and ≥65 years per 100,000 individuals in 2018 was 3.00, unpredictable, 42.00, and 65.00, respectively. However, in 2035, these rates were predicted to increase, and TB incidence among female patients aged 0-14 years was predicted to be higher than among women aged ≥65 years, which might also exhibit an upward trend (Figure 4).

Figure 4. The transfer function-noise model predicts the trend of age-specific incidence rates (male/female: aged 0-14, 15-24, 25-64, and ≥65 years). LCL: lower confidence limit; UCL: upper confidence limit.



Model Selection

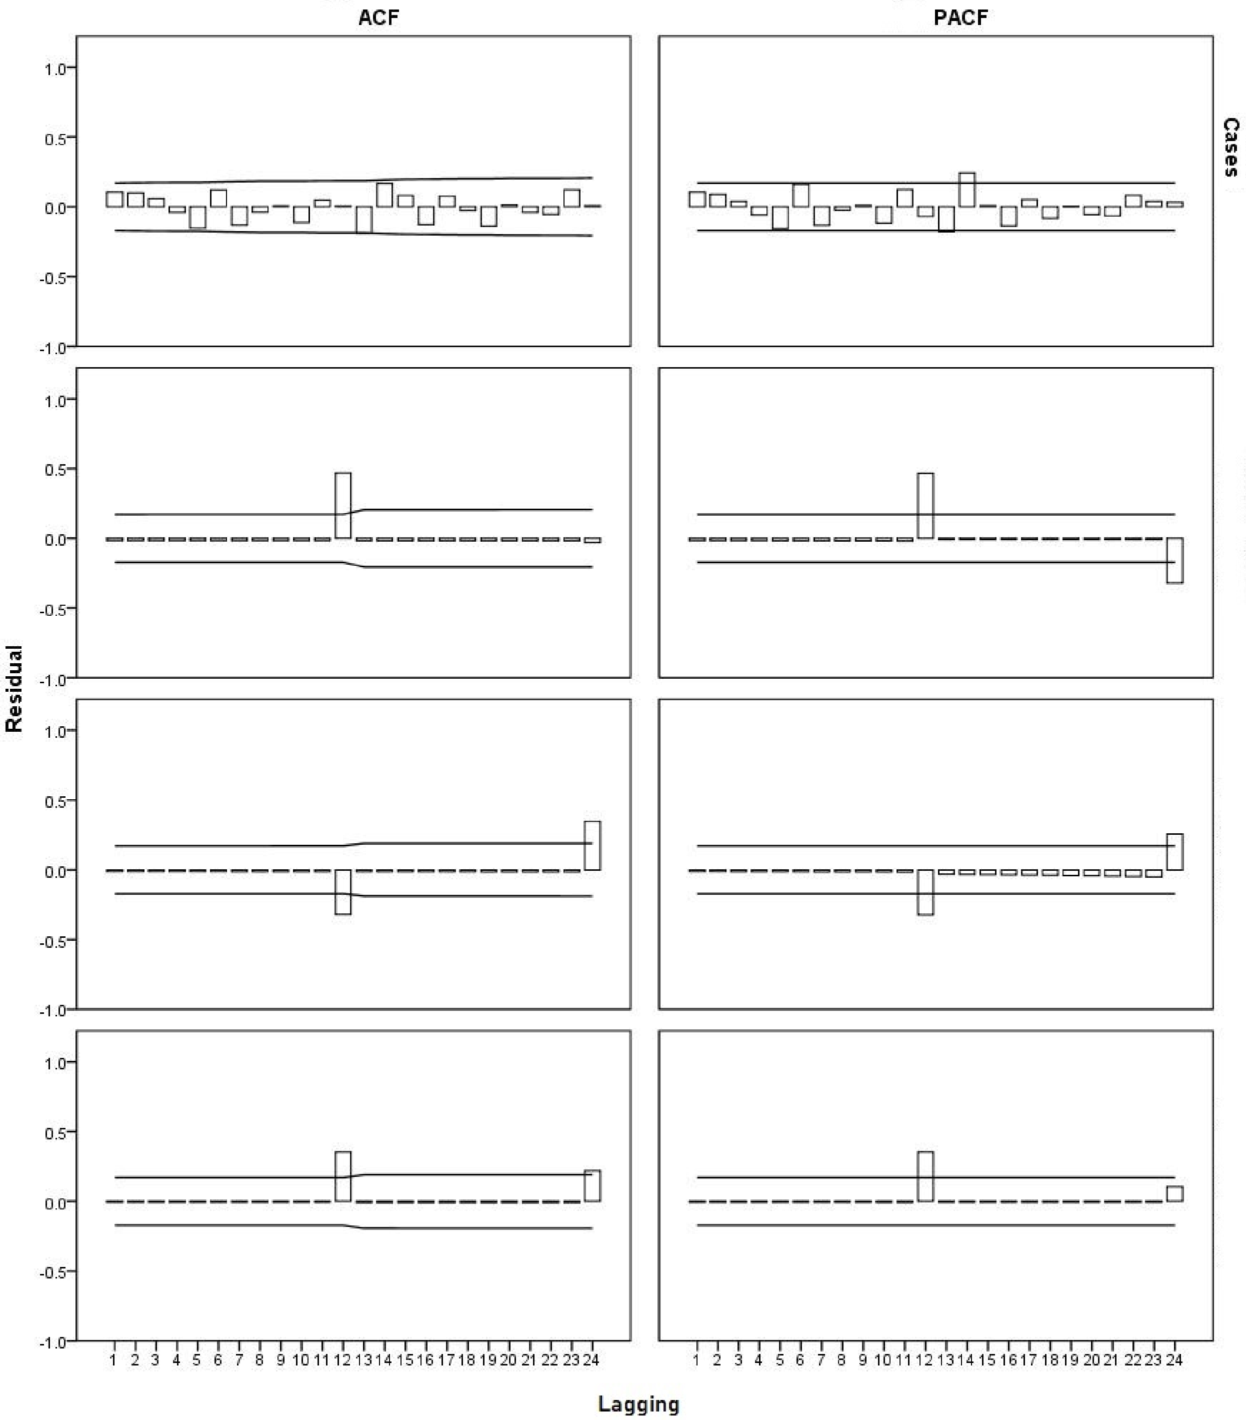
The TFN model was used to fit the number and incidence rate of TB cases reported in Sichuan Province during 2006-2017, establish and judge the models, and predict TB incidence in Sichuan Province during 2018-2035. The TFN model was fitted for different groups to determine the TB incidence. The R^2 and Bayesian information criterion of the models and evaluations were all ideal, as shown in Table S6 in Multimedia Appendix 1.

The TFN models used female and male data separately in the multivariate models, and the total of all cases was 783,735. From 2006 to 2017, Sichuan Province reported 548,585 cases of pulmonary TB in male patients, with a reported incidence rate of 11 cases per 100,000 individuals, and 235,150 cases of pulmonary TB in female patients, with a reported cumulative incidence rate of 4.85 cases per 100,000 individuals. There were 12-year observations per model at the population level. For each model, using stepwise regression methods, 10 well-fitting models were established (a better R^2 value), and the rule was carried out for multivariate analysis (stepwise regression rules: F-to-enter≥3.840, F-to-remove≤2.710).

Additionally, we adjusted the variables of the data to be standardizing variables, and the result did not change. The findings also show that the data trend is relatively stable after multiple data processing, such as splitting or logarithmic processing. Both the destandardized and standardized results and indicators showed that the models were the same.

The TFN model, number and incidence rate of TB cases, autocorrelation function, and partial autocorrelation function showed that the data sequence reached a stable state, and the effect of white noise was eliminated (Figure 5).

Figure 5. Transfer function-noise model: tuberculosis and incidence rate of ACF and PACF in the whole population. ACF: autocorrelation function; PACF: partial autocorrelation function.



We found that the total illiteracy rate and average pressure at each measuring station (in individuals aged 15-24 years) were risk factors for TB incidence overall. Factors that protected against TB incidence were the number of families with the minimum living standard guarantee in urban areas, average wind speed, number of patients with invasive TB discharged, number of people with the minimum living standard guarantee in rural areas, total health expenditure as a percentage of regional GDP, being a single man (aged 0-14), number of hospitals, number of health workers in infectious disease hospitals (for those aged 25-64 years), amount of daily morning and evening exercises, number of people with the urban minimum living standard guarantee, and being a married woman (aged ≥65 years). The noise transfer-function model predicts that until 2035, the incidence of TB in male patients aged 0-14 and 15-24 years will increase, while in female patients aged 0-14 and ≥65 years, the incidence will increase rapidly.

Discussion

Principal Findings

To our knowledge, this is the most comprehensive ecological correlation and time series trend forecast analyses to investigate the associations of ecological factors with TB epidemic and the secular trend of TB incidence. The ecological correlation analyses demonstrated an overall limited influence of the environmental and socioeconomic effects and prediction on the TB epidemic. Incorporating these environmental and socioeconomic conditions into time series trend forecast models found that the TB incidence rate will continue to increase among male patients aged 0-24 years, female patients aged 0-14 years, and female patients older than 64 years, which should be considered as targeted populations to end the TB epidemic before 2035.

Compared with the worldwide rate and those for high-income countries, TB incidence in rural areas of Sichuan Province was very high, which was supported by a significant increase risk of TB infection among farmers compared with individuals with other occupations and in clustering areas of ethnic minorities in western and northeastern Sichuan [12]. Given that most people reside in rural areas worldwide, more effective strategies are needed to contain the TB epidemic.

Additionally, in China, the highest TB burden was found in those aged >70 years, the same as our findings that they had the peak TB incidence [22]; nevertheless, their incidence of this disease will not grow fast. Meanwhile, male patients aged 0-24 years, female patients aged 0-14 years, and female patients older than 64 years will have substantial growth by 2035 and take a heavy TB burden. Because of health problems and risk factors of chronic disease such as hypoimmunity, high systolic blood pressure, and high total cholesterol, with greater longevity, may predispose older adults to TB [22,23]. Apart from social aging and the above reasons, further national surveys to estimate the latent reasons for the increasing incidence of TB in female patients are required.

Of note, the risk factors for TB incidence varied across different ages. For children aged 0-14 years, we found that the proportion reflected by the total health expenditure divided by the regional GDP was associated with a decrease in the incidence of TB, while an inverse association was observed in the population older than 64 years. In-depth investigations need to reveal its role in TB incidence. In addition, a decrease in the number of forest fires led to a decrease in TB incidence. This finding was in line with those of Chen et al [11], who reported an association between decreased per capita living space and TB incidence. Forest fires may lead to air pollution, causing more patients with TB to seek diagnosis and treatment. Chen et al [11] suggested that future studies should consider social factors such as income and education. Furthermore, we found that in individuals aged 15-24 years, the total illiteracy rate can predict the incidence of TB.

For female individuals older than 64 years, daily morning and evening exercise, the number of people with the urban minimum living standard guarantee, and marriage (for women) may reduce the incidence of TB. Married women who do not require assistance for extreme poverty may have better nutrition and better health well-being [1,2], while the urban minimum living standard guarantees and the aid of a spouse provides support to seek TB treatment, especially for older persons (aged ≥65 years). Collectively, social and environmental supports also help control TB incidence in Sichuan.

Moreover, our findings did not support the protective role of neonatal BCG vaccination in TB incidence across all age groups. Notably, delivering the neonatal BCG vaccination displayed a negative correlation with TB incidence across all age groups, principally in line with previous findings [1,2]. Given that BCG vaccines offer the best chance to contain the accelerating spread of multidrug-resistant TB, more data are required to draw definitive conclusions on its role in TB incidence.

Limitations

This study also has several limitations. First, we did not take into account determinations of genetic predisposition, treatments, treatment efficacy, and other ecological factors due to limited data availability. Second, all data in this study was obtained from Sichuan Province, and the results were subject to the inherent limitations of an ecological study; thus, principal findings may not be generalizable. Prospectively, further long-term cohort studies with large sample sizes as well as randomized controlled experimental studies are needed to determine the causal relationships.

Conclusion

In conclusion, our study identifies a series of environmental and socioeconomic conditions associated with TB incidence through the most comprehensive ecological analyses. Incorporating these TB factors into the TFN model clarifies that male individuals aged 0-24 years, female individuals aged 0-14 years, and female individuals older than 64 years are barriers to the End TB Strategy in Sichuan, and provides new insights into TB prevention and control strategies.

Acknowledgments

We appreciated Professor Jianwei Zhao and Professor Chuang Chen for help with the study design and writing, and Professor Shujuan Yang, Professor Fangfang Zeng, and Dr Sui Zhu for revising the manuscript.

Data Availability

All data used in the analysis of this manuscript are freely available by contacting the corresponding author. Data are available in a public open access repository, available on reasonable request.

Authors' Contributions

RL and WW designed the study and searched the publications. WW and LX analyzed the data and wrote the Methods section. JW wrote the Results section and checked all the data. Abstract

Background: Seasonal respiratory viruses had lower incidence during their 2019-2020 and 2020-2021 seasons, which overlapped with the COVID-19 pandemic. The widespread implementation of precautionary measures to prevent transmission of SARS-CoV-2 has been seen to also mitigate transmission of seasonal influenza. The COVID-19 pandemic also led to changes in care seeking and access. Participatory surveillance systems have historically captured mild illnesses that are often missed by surveillance systems that rely on encounters with a health care provider for detection.

Objective: This study aimed to assess if a crowdsourced syndromic surveillance system capable of detecting mild influenza-like illness (ILI) also captured the globally observed decrease in ILI in the 2019-2020 and 2020-2021 influenza seasons, concurrent with the COVID-19 pandemic.

Methods: Flu Near You (FNY) is a web-based participatory syndromic surveillance system that allows participants in the United States to report their health information using a brief weekly survey. Reminder emails are sent to registered FNY participants to report on their symptoms and the symptoms of household members. Guest participants may also report. ILI was defined as fever and sore throat or fever and cough. ILI rates were determined as the number of ILI reports over the total number of reports and assessed for the 2016-2017, 2017-2018, 2018-2019, 2019-2020, and 2020-2021 influenza seasons. Baseline season (2016-2017, 2017-2018, and 2018-2019) rates were compared to the 2019-2020 and 2020-2021 influenza seasons. Self-reported influenza diagnosis and vaccination status were captured and assessed as the total number of reported events over the total number of reports submitted. CIs for all proportions were calculated via a 1-sample test of proportions.

Results: ILI was detected in 3.8% (32,239/848,878) of participants in the baseline seasons (2016-2019), 2.58% (7418/287,909) in the 2019-2020 season, and 0.27% (546/201,079) in the 2020-2021 season. Both influenza seasons that overlapped with the COVID-19 pandemic had lower ILI rates than the baseline seasons. ILI decline was observed during the months with widespread implementation of COVID-19 precautions, starting in February 2020. Self-reported influenza diagnoses decreased from early 2020 through the influenza season. Self-reported influenza positivity among ILI cases varied over the observed time period. Self-reported influenza vaccination rates in FNY were high across all observed seasons.

Conclusions: A decrease in ILI was detected in the crowdsourced FNY surveillance system during the 2019-2020 and 2020-2021 influenza seasons, mirroring trends observed in other influenza surveillance systems. Specifically, the months within seasons that overlapped with widespread pandemic precautions showed decreases in ILI and confirmed influenza. Concerns persist regarding respiratory pathogens re-emerging with changes to COVID-19 guidelines. Traditional surveillance is subject to changes in health care behaviors. Systems like FNY are uniquely situated to detect disease across disease severity and care seeking, providing key insights during public health emergencies.

Introduction

Globally, seasonal respiratory viruses had lower incidence during the 2019-2020 season, which overlapped with the emergence of COVID-19 [1-4]. In the United States, decreases in influenza activity were also observed in 2019-2021 [2,5-8]. A national influenza-like illness (ILI) reference configured using an average of the previous few seasons was established at 2.6%; however, no week within the 2020-2021 season reached an ILI rate above 1.7% [8]. While influenza burden varies seasonally [9], COVID-19 contributed to this widespread decrease [5-7,10].

Many nonpharmaceutical interventions (NPIs) enacted for COVID-19 are also recommended for pandemic influenza [11-13]; therefore, their extensive uptake impacted the cocirculation of influenza. For example, those with mild symptoms for both illnesses are advised to remain home [13]. Traditional disease surveillance may omit these mild illnesses and not capture health care–related changes [14,15]. Crowdsourced estimates can be less susceptible to fluctuations in care seeking resulting from the pandemic [15,16]. Here, we use Flu Near You (FNY), a previously validated crowdsourced influenza surveillance system, to measure seasonal influenza incidence during the COVID-19 pandemic [17].

FNY is uniquely situated to further assess changes in seasonal ILI during the pandemic [14,17,18]. Historically, FNY has provided ILI trend insights that complement traditional surveillance and display compatibility with data from systems like the US Centers for Disease Control and Prevention's Influenza-like Illness Surveillance Network [17,18]. This study aims to assess whether crowdsourced syndromic surveillance capable of capturing mild influenza also revealed the global decrease in ILI during influenza seasons concurrent with the COVID-19 pandemic.

Methods

FNY Participatory Syndromic Surveillance System

Flu Near You (FNY) is a web-based participatory syndromic surveillance system where participants in the United States report their health using a weekly survey. Guest participants may also submit ad hoc reports. Participants are asked if they or household members feel healthy or sick. If sick, participants are prompted with a populated list of symptoms to select (Multimedia Appendix 1). Seasonal influenza vaccination status is also collected. Self-reported influenza diagnosis data were captured starting February 2020.

Population Sample

Data from 2016-2021 were included, with influenza seasons defined as *Morbidity and Mortality Weekly Report* weeks 40 through 20 (Multimedia Appendix 2, Table S1). Data were included for the entire FNY week that captured the influenza season start and end dates. Weekly reports by both registered and guest participants were included. Registered participants had a single identifier, while guest participants were assigned one per report. FNY used token validation between the front and back ends of the website to reduce the risk of spam reporting. Reports by registered participants were deduplicated by week if multiple reports were captured, with the most recent report included. For demographic analysis, each user was counted once per flu season, and those with missing data were excluded. No further restrictions were applied [17].

Ethical Considerations

This study of FNY data received approval from the Boston Children's Hospital Institutional Review Board (IRB-P00023700) and received a waiver of informed consent. FNY participants may report anonymously. Those who opted to provide contact information were deidentified. No compensation was provided to participants.

Analysis

ILI was defined as fever in addition to sore throat, cough, or both [19]. Influenza diagnosis was classified as self-reported influenza diagnosis (hereafter called self-reported diagnosis). Influenza vaccination rate was defined as the proportion of unique reporters who indicated being vaccinated any time during the influenza season. ILI rates were determined as the number of reports meeting the ILI definition over the total reports during that time. Season and monthly ILI rates were assessed with October and May rates truncated to align with the defined season. CIs were calculated via a 1-sample test of proportions.

Total ILI cases and unique reports from the 2016-2017, 2017-2018, and 2018-2019 influenza seasons were averaged by month and are presented as "baseline seasons." Demographics across the baseline seasons were aggregated to retain their specific proportions, accounting for participants reporting across seasons. Analyses were conducted with R (version 4.0.4; R Foundation for Statistical Computing).

Results

Population

During the baseline influenza seasons, 237,309 unique individuals reported on FNY, while 68,800 individuals reported for the 2019-2020 season and 25,996 in 2020-2021. There were more female respondents to FNY across seasons (Table 1). Higher proportions of older individuals reported across seasons (Table 1). In 2019-2020 and 2020-2021, respondents aged 65 years and older comprised the largest proportions (n=9812, 32.6% and n=8236, 39.9%, respectively) among those who reported age (n=30,139, 43.8% and n=20,650, 79.4%). Those younger than 18 years were the smallest proportion across influenza seasons (Table 1).

Table 1. Characteristics of respondents for age and sex.

	Respondents, n (%)		
	Baseline flu seasons (N=274,235[a])	2019-2020 flu season (n=68,800)	2020-2021 flu season (n=25,996)
Respondents who reported age	85,745 (31.3)	30,139 (43.8)	20,650 (79.4)
Age group (years)[b]			
13-17	6625 (7.7)	2419 (8.0)	1448 (7.0)
18-34	10,409 (12.1)	3445 (11.4)	2035 (9.9)
35-44	10,356 (12.1)	3269 (10.9)	1733 (8.4)
45-54	14,291 (16.7)	4638 (15.4)	2697 (13.0)
55-64	19,874 (23.2)	6556 (21.8)	4501 (21.8)
≥65	24,190 (28.2)	9812 (32.6)	8236 (39.9)
Respondents who reported sex	85,741 (31.3)	29,897 (43.5)	20,561 (79.1)
Sex[c]			
Female	52,221 (60.9)	17,980 (56.6)	12,110 (58.9)
Male	33,520 (39.1)	11,917 (43.4)	8451 (41.1)

[a] Combined demographics from the 2016-2017, 2017-2018, and 2018-2019 influenza seasons.

[b] Percentages reflect the proportion among those who reported age.

[c] Percentages reflect the proportion among those who reported sex.

ILI Trends

ILI variability was observed across the baseline seasons (Table 2). The characteristics of ILI captured on FNY in the described seasons followed patterns observed in traditional surveillance [9]. The 2016-2017, 2018-2019, and 2019-2020 influenza seasons were classified as moderate, and the 2017-2018 season was severe [9]. On FNY, the observed rate of ILI was 1.51% in 2016-2017, 4.98% in 2017-2018, and 4% in 2018-2019. Across the baseline seasons, the rate of ILI was 3.8%. Both the 2019-2020 and 2020-2021 seasons had lower ILI rates compared to the baseline seasons (Table 2). An ILI rate of 2.55% was observed in 2019-2020 and a rate of only 0.27% was captured in 2020-2021.

Monthly ILI rates displayed expected fluctuations within influenza seasons. The baseline seasons had ILI rates between 2.1% (95% CI 1.89%-2.34%) and 5.79% (95% CI 5.56%-6.02%), with peak activity seen from December to February (Figure 1). ILI activity peaked in January 2020 (4.5%) before moderately declining in February (3.29%) and further declining over the remainder of the season (Figure 1). For the 2020-2021 season, there was no evident peak in ILI (Figure 1).

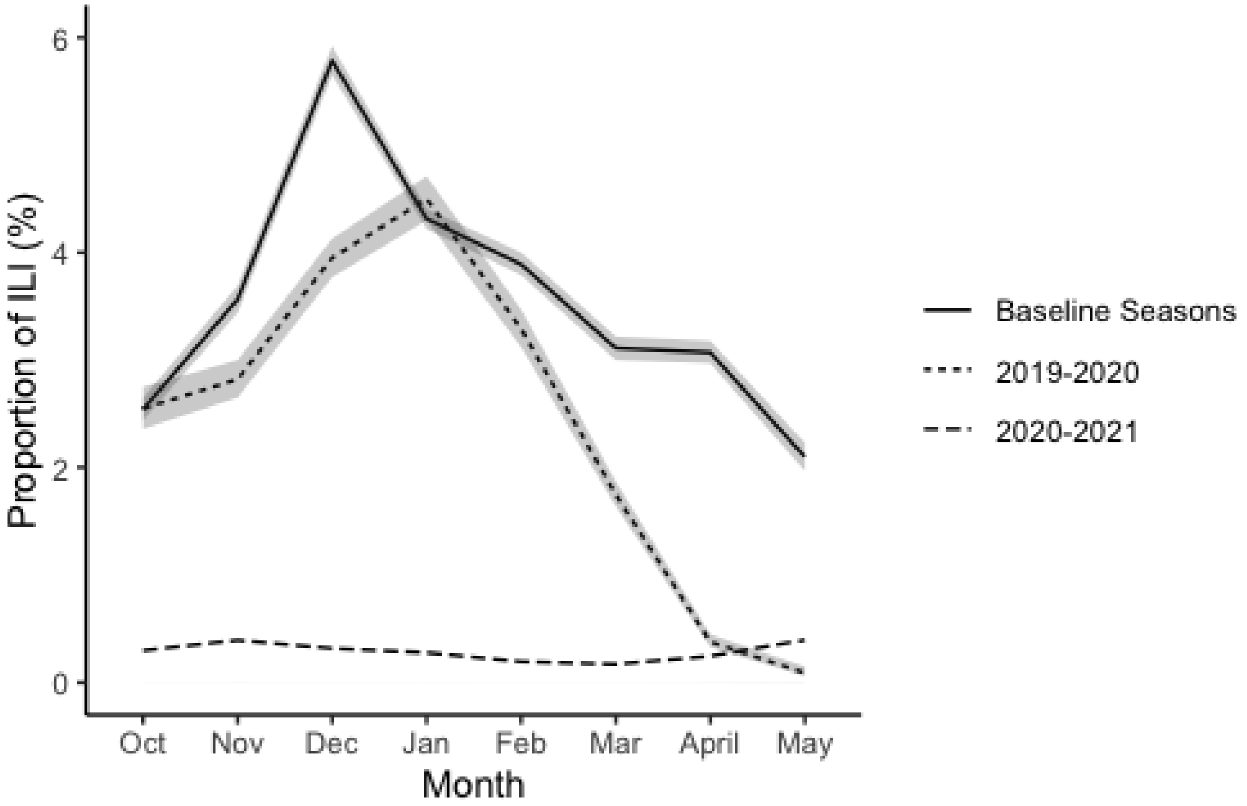
Table 2. Influenza-like-illness (ILI; defined as fever with cough, sore throat, or both) across influenza seasons on Flu Near You.

Influenza season	ILI cases, n	Total reports[a], n	ILI rate, % (95% CI)	Peak month(s)	Rate during peak month(s), %
2016-2017	3146	207,901	1.51 (1.46-1.57)	Feb	3.82
2017-2018	17,616	353,758	4.98 (4.91-5.05)	Dec	10.17
2018-2019	11,477	287,219	4 (3.92-4.07)	Feb	4.94
2019-2020	7418	287,909	2.55 (2.52-2.64)	Jan	4.5
2020-2021	546	201,079	0.27 (0.25-0.3)	Nov, May	0.4
Baseline seasons[b]	32,239	848,878	3.8 (3.76-3.83)	Dec	5.79

[a] Number of unique weekly reports submitted to Flu Near You.

[b] Combined ILI rate from the 2016-2017, 2017-2018, and 2018-2019 influenza seasons.

Figure 1. Monthly rates of influenza-like illness (ILI) detected in Flu Near You by influenza season. The 95% CIs are presented with the rates.



Self-Reported Influenza Diagnosis

Reductions in self-reported influenza diagnosis were detected in FNY (Table 3). Starting at the point of collection (February 2020), the rates of self-reported influenza diagnosis continually decreased (Table 3). February 2020 saw the highest rate of self-reported diagnosed influenza (0.97%) and the highest positivity rate (11.72%) among those tested. The lowest rates of influenza (0.01%) were detected in May 2020 and February and March 2021. From February to May of the 2019-2020 influenza season, the overall influenza rate was 0.21%, and the positivity rate was 7.04%. For the entire 2020-2021 influenza season, there was a lower rate of influenza (0.03%) and a lower positivity rate (1.1%). Reduced reports of influenza-positive ILI were also observed (Table 3).

Table 3. Self-reported influenza diagnoses in Flu Near You population.

Time period	Confirmed diagnoses of influenza[a]/total reports, n/N (%)	Positivity[b] (confirmed diagnoses/total tested for influenza), n/N (%)	Confirmed cases of ILI[c,d]/ILI cases, n/N (%)
2019-2020			
February	389/40,169 (0.97)	389/3318 (11.72)	109/1321 (8.25)
March	243/52,499 (0.46)	243/4135 (5.88)	87/919 (9.47)
April	18/38,096 (0.05)	18/1197 (1.5)	14/146 (9.59)
May	1/16,962 (0.01)	1/517 (0.19)	0/16 (0)
2020-2021			
October	7/24,812 (0.03)	7/606 (1.16)	5/74 (6.76)
November	5/25,023 (0.02)	5/824 (0.61)	3/99 (3.03)
December	10/31,181 (0.03)	10/798 (1.25)	0/99 (0)
January	13/30,157 (0.04)	13/751 (1.73)	7/84 (8.33)
February	4/30,097 (0.01)	4/534 (0.75)	1/59 (1.69)
March	4/36,149 (0.01)	4/610 (0.66)	3/62 (4.84)
April	4/16,629 (0.02)	4/359 (1.11)	1/41 (2.44)
May	6/7031 (0.09)	6/301 (1.99)	2/28 (7.14)

[a] Self-reported influenza diagnoses among entire reporting population by month.

[b] Self-reported influenza diagnoses among those who reported influenza testing by month.

[c] ILI: influenza-like-illness.

[d] Self-reported influenza diagnoses among those who met the definition of ILI by month.

Influenza Vaccination

Influenza vaccination rates varied seasonally, with 58.6% (160,610/274,235) of participants being vaccinated in the baseline seasons. Both the 2016-2017 and 2018-2019 seasons had over 80% vaccinated participants (23,632/27,024, 87.4% and 68,588/84,185, 81.5%, respectively). In the 2017-2018 season, which had more guest participants, 42% (68,390/163,026) of participants reported influenza vaccination. The 2019-2020 season had a high vaccination rate of 84% (57,823/68,800). The 2020-2021 season had a lower vaccination rate (66.5%) (17,299/25,996) compared to the previous season.

Discussion

FNY observed unseasonably low rates of ILI during 2019-2021. Late 2019 had higher rates of ILI than early 2020, mirroring a globally observed reduction in ILI [2,3,5-7,10]. FNY observed ILI decreasing in February 2020, slightly ahead of the nationwide implementation of COVID-19 precautions. This early decrease is likely attributed to high health literacy among FNY participants, as they are probable early adopters of NPIs [17]. For the entirety of the 2020-2021 influenza season, FNY ILI rates were comparable to those outside of the viral season [3,8]. Influenza diagnoses on FNY also decreased from February to May 2020, mirroring ILI trends. This alignment of trends displays the importance of complementing traditional surveillance with participatory systems [20,21], and further suggests that prevention measures for COVID-19 may have secondarily reduced transmission of seasonal influenza.

FNY participants have historically reported influenza vaccination rates around 80% [22], compared to under 50% in the US population [23-25]. Both 2019-2020 and 2020-2021 had higher vaccination rates than the baseline seasons, potentially contributing to low rates of ILI. However, this correlation was impractical to assess due to the high influenza vaccination rates among FNY participants.

This study has limitations worth noting. First, the FNY population is not representative of the US population, limiting the scope of the results [14,15,18]. However, as the FNY data are longitudinal, we are able to compare influenza seasons within this specific population. Second, self-reported data are subject to bias, which can lead to misclassification. Furthermore, ILI is a coarse measurement that may detect other circulating respiratory infections. Therefore, ILI rates may include other seasonal viruses and have inflated baseline levels [1]. Contrarily, COVID-19 may have been captured as ILI. In April and May 2021, there was a delivery issue with FNY reminders, resulting in fewer reports than expected. The minimal increase in detected ILI is likely attributable to less reporting of being healthy, as sick individuals are more likely to report unprompted. Lastly, Outbreaks Near Me [26] was launched in March 2020, contributing to lower reporting on FNY. The low rates of ILI during the 2020-2021 season suggest prevention measures for COVID-19 may have secondarily mitigated transmission of seasonal influenza. However, interpretation of ILI during periods of low circulation should be approached cautiously and may be best studied with the use of zero-inflation models that can appropriately account for zeros in the syndromic surveillance data.

Concerns persist regarding respiratory pathogens re-emerging with COVID-19 guideline changes and declined NPI use [5-7]. The fall 2022 “triple-demic” exemplifies the legitimacy of this concern. Traditional surveillance provides valuable insights but can be subject to delays and changes to the health care system [27]. For example, at-home diagnostics data revealed additional populations traditional surveillance is prone to omit [28]. Crowdsourced surveillance systems like FNY are uniquely situated to detect disease among populations who may be missed by traditional surveillance, thereby providing key insights early in public health emergencies.

Acknowledgments

The authors thank the Flu Near You team, as well as the platform participants. JSB and MS conceptualized the survey and platform. JSB, MS, KS, and AG facilitated project administration. AG and KS conceptualized the study; AG, BR, KS, and JSB designed the analysis; AG conducted the analyses; BR and TJV provided analytic supervision. AG drafted the initial manuscript; all authors contributed to the revised draft and approved the final manuscript. This study and analysis were not funded.

Abstract

Background: COVID-19 hospitalizations and deaths disproportionately affect underserved and minority populations, emphasizing that vaccine hesitancy can be an especially important public health risk factor in these populations.

Objective: This study aims to characterize COVID-19 vaccine hesitancy in underserved diverse populations.

Methods: The Minority and Rural Coronavirus Insights Study (MRCIS) recruited a convenience sample of adults (age≥18, N=3735) from federally qualified health centers (FQHCs) in California, the Midwest (Illinois/Ohio), Florida, and Louisiana and collected baseline data in November 2020-April 2021. Vaccine hesitancy status was defined as a response of “no” or “undecided” to the question “Would you get a coronavirus vaccine if it was available?” (“yes” categorized as not hesitant). Cross-sectional descriptive analyses and logistic regression models examined vaccine hesitancy prevalence by age, gender, race/ethnicity, and geography. The expected vaccine hesitancy estimates for the general population were calculated for the study counties using published county-level data. Crude associations with demographic characteristics within each region were assessed using the chi-square test. The main effect model included age, gender, race/ethnicity, and geographical region to estimate adjusted odds ratios (ORs) and 95% CIs. Interactions between geography and each demographic characteristic were evaluated in separate models.

Results: The strongest vaccine hesitancy variability was by geographic region: California, 27.8% (range 25.0%-30.6%); the Midwest, 31.4% (range 27.3%-35.4%); Louisiana, 59.1% (range 56.1%-62.1%); and Florida, 67.3% (range 64.3%-70.2%). The expected estimates for the general population were lower: 9.7% (California), 15.3% (Midwest), 18.2% (Florida), and 27.0% (Louisiana). The demographic patterns also varied by geography. An inverted U-shaped age pattern was found, with the highest prevalence among ages 25-34 years in Florida (n=88, 80.0%,) and Louisiana (n=54, 79.4%; *P*<.05). Females were more hesitant than males in the Midwest (n= 110, 36.4% vs n= 48, 23.5%), Florida (n=458, 71.6% vs n=195, 59.3%), and Louisiana (n= 425, 66.5% vs. n=172, 46.5%; *P*<.05). Racial/ethnic differences were found in California, with the highest prevalence among non-Hispanic Black participants (n=86, 45.5%), and in Florida, with the highest among Hispanic (n=567, 69.3%) participants (*P*<.05), but not in the Midwest and Louisiana. The main effect model confirmed the U-shaped association with age: strongest association with age 25-34 years (OR 2.29, 95% CI 1.74-3.01). Statistical interactions of gender and race/ethnicity with the region were significant, following the pattern found by the crude analysis. Compared to males in California, the associations with the female gender were strongest in Florida (OR=7.88, 95% CI 5.96-10.41) and Louisiana (OR=6.09, 95% CI 4.55-8.14). Compared to non-Hispanic White participants in California, the strongest associations were found with being Hispanic in Florida (OR=11.18, 95% CI 7.01-17.85) and Black in Louisiana (OR=8.94, 95% CI 5.53-14.47). However, the strongest race/ethnicity variability was observed within California and Florida: the ORs varied 4.6- and 2-fold between racial/ethnic groups in these regions, respectively.

Conclusions: These findings highlight the role of local contextual factors in driving vaccine hesitancy and its demographic patterns.

(JMIR Public Health Surveill 2023;9:e34163) doi:10.2196/34163

KEYWORDS

COVID-19 vaccine; vaccine hesitancy; underrepresented in research; minority populations; federally qualified health center (FQHC); public health; COVID-19

Introduction

Vaccine hesitancy has been defined as a “delay in acceptance or refusal of vaccination despite the availability of vaccination services” and is recognized among the 10 major public health threats by the World Health Organization (WHO) [1]. A recent review of the literature showed that vaccine hesitancy has become 1 of the key research topics [2]. The Centers for Disease Control and Prevention (CDC) published a map with the estimates of COVID-19 vaccine hesitancy, demonstrating its wide geographical variability [3]. Such variability emphasizes the importance of cultural, social, and economic contexts in driving COVID-19 vaccine hesitancy. It has been documented that COVID-19 vaccine hesitancy and vaccination rates have been low among racial/ethnic minority populations [4], even though these populations have been disproportionately affected by the pandemic, as shown by the rates of hospitalizations and deaths [5-8]. However, in contrast to the United States, a greater prevalence of COVID-19 vaccine hesitancy was not found among Black participants in the United Kingdom [9], emphasizing the importance of contextual cultural and socioeconomic factors.

The focus of our research is underserved communities in different geographical regions of the United States with vastly different racial/ethnic, cultural, and socioeconomic contexts. People in historically underserved communities have a higher proportion of racial/ethnic minorities, groups that are disproportionally affected by COVID-19 [5-8]. Moreover, people in underserved communities are at higher risk of more severe COVID-19 outcomes because of a greater prevalence of comorbidities associated with severe COVID-19 [10]. Understanding the variability in vaccination interest within and between minority and underserved communities is essential as effective vaccine administration policies and interventions require a nuanced understanding of the obstacles [11]. To date, few studies of COVID-19 vaccine hesitancy have reported estimates from underserved communities; this includes studies conducted in Delaware, North Carolina, and Monterey County, California [12-14]. Two studies were conducted in the year 2020, one study in North Carolina and one in California. The study in North Carolina classified overall 69% of respondents as vaccine hesitant, with the highest prevalence among White (74%), followed by Black (62.7%) and Hispanic (59.5%) participants. The study in Monterey County, California, included Hispanic farmworkers and reported 48.4% “not extremely likely to get vaccinated.” The study in Delaware was conducted in March-May 2021 and reported an overall 42% vaccine hesitancy prevalence, with 45% of Black participants expressing vaccine hesitancy. These previous studies also demonstrate that vaccine hesitancy is likely to be driven by contextual factors specific to geographic regions.

Here, we present the results from a large Minority and Rural Coronavirus Insights Study (MRCIS; N=3462) conducted in November 2020-March 2021 among underserved racially/ethnically diverse communities across 4 geographical US regions. The MRCIS is a multisite, community-based, epidemiologic investigation of the social and structural determinants of health, clinical, environmental, and genetic factors associated with the COVID-19 pandemic in minority and rural communities in the United States. Our objectives are to describe the demographic determinants of COVID-19 vaccine hesitancy within each geographical region and compare the estimates of vaccine hesitancy in these underserved communities with those expected for the general population in their respective local regions.

Methods

Study Design

This cross-sectional analysis of COVID-19 vaccine hesitancy prevalence was conducted using the baseline data collected by the MRCIS. A total of 3735 participants were enrolled, 155 (4.1%) participants were not qualified to participate (under the age of 18 years), and 29 (0.8%) participants were removed from the study due to missing informed consent, resulting in a study population of 3551 (95.1%) participants. The analytical sample included 3491 (98.3%) participants after the exclusion of 60 (1.7%) participants, who responded to the vaccine hesitancy question as “N/A” or left that question blank. As the last step of the analysis, we excluded 29 participants who were erroneously enrolled twice with a separate ID; this exclusion yielded a final analytical sample of 3462.

Study Participants

In November 2020, the National Minority Quality Forum (NMQF) launched the MRCIS, a prospective longitudinal investigation of risk and socioeconomic factors associated with the disproportionate impact of COVID-19 on minority and rural communities. Federally qualified health centers (FQHCs), funded through the Health Resources & Services Administration (HRSA), were invited to partner with the MRCIS as community-based health care providers. The FQHCs were established to operate in communities that are underserved and therefore have been underrepresented in research. Research sites were selected based on the high proportion of deaths in minority populations that they serve compared to the proportion of minorities in the state population. In total, 5 community health centers in 4 geographically diverse HRSA regions (regions 6, 4, 5, and 9) were selected to participate in the MRCIS. In the Southeast region, participants were recruited from FQHCs located in HRSA regions 4 and 6. Participants in HRSA region 4 were recruited from Osceola Community Health Services (OCHS), located in Kissimmee, Florida, and participants in HRSA region 6 were recruited from the Teche Action Clinic (TAC), located in Franklin, Louisiana. In the Southwest region, HRSA region 9, participants were recruited from the John Wesley County Hospital (JWCH), an FQHC located in Los Angeles, California. In HRSA region 5, recruitment occurred at 2 FQHCs: Aunt Martha (AM) in Olympia Fields, Illinois, and Primary One (PO) in Columbus Ohio.

Volunteers were recruited from a convenience sample of adults (age≥18 years). Recruitment strategies varied by site and included 1 or more of the following methods: (1) in-person recruitment at the site; (2) in-person recruitment at study centers set up in the communities, including the recreational center, a low-income housing complex, the fire department, and homeless shelters; and (3) advertising through flyers distributed to the community. Participants did not receive any compensation for participation in this study.

Ethical Considerations

At enrollment, participants completed an informed consent form and a baseline survey. The protocol was reviewed and approved by the WIRB-Copernicus Group Institutional Review Board (WCG IRB; #1292174). Each participant received a unique study ID, and the identifying information was removed from the data set for analysis to maintain patient privacy and confidentiality.

Data Collection and Outcome Definition

The data used in this analysis were collected in the MRCIS using a baseline survey, including self-reported age, gender, race, and ethnicity. The question for reporting race was the following: “Select all that apply for race: American Indian/Alaskan Native, Asian, Black/African American/Native Hawaiian/Other Pacific Islander, White, Other, and Prefer Not to Answer.” The options for the ethnicity question were the following: “Hispanic or Latino,” “Not Hispanic or Latino,” and “Prefer not to answer.” We used the race and ethnicity questions to develop combined race/ethnicity categories. Although participants were allowed to select more than 1 category for the race, no one in our sample reported multiple races. All individuals who self-reported Hispanic/Latino as their ethnicity were characterized as Hispanic/Latino regardless of what they indicated as their race. We developed 4 mutually exclusive racial/ethnic categories as follows: Hispanic/Latino, non-Hispanic Black, non-Hispanic White, and non-Hispanic other.

Participants were asked, “Would you get a coronavirus vaccine if it was available,” with the option to answer “yes,” “no,” or “undecided.” According to the WHO definition [1], vaccine hesitancy was defined as a response of “no” or “undecided.” The responses were recorded from November 2020 to March 2021.

Statistical Analysis

Vaccine Hesitancy Prevalence by Demographic Characteristics and Geographical Region

Self-reported age was categorized into the following age groups: 18-24, 25-34, 35-44, 45-54, 55-64, and ≥65 years. Race and ethnic information were categorized as noted before (Hispanic/Latino, non-Hispanic Black/African American, non-Hispanic White, and non-Hispanic other). Gender was characterized as female, male, and other (n=3). Due to a small sample size, the “Other” gender category was excluded from the regression analysis that adjusted for gender as a confounder. Descriptive statistics, including counts and proportions comparing individual-level factors in the overall study population and by vaccine hesitancy (not hesitant vs hesitant), were calculated. The strength of the adjusted associations of vaccine hesitancy prevalence with the demographic characteristics and geographical regions was assessed in logistic regression models by calculating odds ratios (ORs) and their 95% CIs. The main effect model included age (6 categories), gender (females vs males), race/ethnicity (4 categories), and HRSA site (4 sites). The reference groups for age, gender, race/ethnicity, and HRSA site were individuals aged 65 years and above, males, non-Hispanic White, and California, respectively.

Observed and Expected Vaccine Hesitancy Prevalence

The observed vaccine hesitancy prevalence and corresponding 95% CIs were calculated for each of the study sites. The expected vaccine hesitancy was calculated based on the county-level estimates reported by the CDC [3].

Each MRCIS participant was assigned to a residential county based on the reported residential zip code and the US Department of Housing and Urban Development (HUD) crosswalk files [15]. These crosswalk files are derived directly from the United States Postal Service (USPS) and are updated quarterly reflecting changes in zip code configurations. Converting the MRCIS participant zip code to residential counties enabled us to compare the MRCIS prevalence of vaccine hesitancy to the national estimates reported by the CDC [3]. National COVID-19 vaccine hesitancy data were downloaded directly from the CDC website. The CDC's outcome definition for vaccine hesitancy was derived from the US Census Bureau's Household Pulse Survey (HPS), which asked the following survey question: "Once a vaccine to prevent COVID-19 is available to you, would you…get a vaccine?" Participants were given the following response options: (1) "definitely get a vaccine," (2) "probably get a vaccine," (3) "unsure," (4) "probably not get a vaccine," and (5) "definitely not get a vaccine." The estimate of vaccine hesitancy we used was "hesitant or unsure," which directly compares with our definition of vaccine hesitancy [3].

For each region, the expected number of hesitant subjects was calculated by multiplying the number of MRCIS participants per county by the CDC's reported vaccine hesitancy prevalence. For example, 930 participants resided in Los Angeles County, California, where the vaccine hesitancy was estimated by the CDC as 9.6%, so the expected number of vaccine-hesitant participants was 89.2. With 27.1% vaccine hesitancy estimates for St Mary Parish, Louisiana, among 882 participants, 239 were expected to be hesitant. The expected number of participants was summed across each study site, and their percentage (ie, percentage of the participants at the site) was calculated. In addition to the expected vaccine hesitancy prevalence, we provided a county-based range for estimated vaccine hesitancy in each MRCIS site.

The assessment of COVID-19 vaccine hesitancy was conducted by the CDC and our study in different periods (mid-2021 vs November 2020-March 2021). Based on the previously published time trends of COVID-19 vaccine hesitancy, it is likely that our expected estimates are approximately 1/3 greater compared to the CDC's reported ones [16]. Therefore, we presented time-adjusted expected prevalence in the general population in the counties of our participants' residences.

Demographic Patterns of Vaccine Hesitancy Prevalence by Geographical Region

Age, gender, and the race/ethnicity patterns of vaccine hesitancy were explored in descriptive analyses (Figures 1-3). The Pearson chi-square test was performed to determine the statistical significance of each demographic pattern within each study site. As this crude analysis strongly suggested the modification of the demographic patterns by geographical region, multivariable logistic regression models were performed to evaluate the interactions between each of the demographic covariates and the study site in separate logistic regression models. In the model exploring the interaction between age and geographical region, individuals in California aged 55 years and above served as the common reference group. In this model, we collapsed the 2 oldest categories (55-64 and ≥65 years) because the main effects model detected similar adjusted associations of these age categories with vaccine hesitancy prevalence. In the model exploring the interaction between gender and geographical region, males in California served as the common reference group. Lastly, non-Hispanic White participants in California served as the common reference group in the model exploring the interaction between race/ethnicity and geographical region. A type 1 error rate of 5% was used in the entire analysis.

Akaike information criterion (AIC) statistics were used to assess model fitness, in which lower AIC estimates indicated improved model fitness. We reported the following AIC statistics:

- Main effects multivariable logistic regression model AIC=4218.985
- Multivariable logistic regression model with the interaction between age and region AIC=4227.904
- Multivariable logistic regression with the interaction of gender and region AIC=4213.966
- Multivariable logistic regression with the interaction of race/ethnicity and region AIC=4200.983

As demonstrated by the AIC, the interaction terms between age and region did not improve the model, with the interaction term *P* value of .32.

All analyses were conducted in SAS version 9.4 (SAS Institute) and R version 4.2.1 (Comprehensive R Archive Network).

Results

Participant Details

Our study population was diverse, including females (n=2076, 60.0%) and males (n=1379, 39.8%) aged 18-94 years. The 3 major racial/ethnic groups were well represented, with the largest group presented by Hispanic participants (n=1684, 48.6%), followed by non-Hispanic Black/African American (n=896, 25.9%) and non-Hispanic White (n=740, 21.4%) participants. Other non-Hispanic racial/ethnic groups were presented by 107 (3.1%) participants; due to the small sample size, this demographic group was not further stratified (Table 1). Among females, 781/2076 (37.6%) were considered as being of reproductive age (18-44 years).

In this study population, vaccine hesitancy exceeded 50% among the following demographic groups: females, participants 25-44 years of age, and non-Hispanic Black/African American participants (Table 1). Overall, no linear trend was apparent in vaccine hesitancy with the increase in age. In relation to geography, a striking variability of hesitancy prevalence was observed: the highest prevalence was found in Florida (653/1680, 38.9%) and Louisiana (597/1680, 35.5%); see Table 1. The differences between the highest (Florida) and the lowest (California) hesitancy prevalence were greater than 2-fold (Table 1). Because of this strong geographic variability, we explored whether the observed geographic differences were similar to what would be expected in the general population within the same geographic areas.

The range of vaccine hesitancy in the general population is presented for the counties where our participants resided (Table 2). The expected vaccine hesitancy in the general population overall resembled the geographical pattern that we observed in the underserved communities, that is, lower in California and the Midwest (Illinois/Ohio) compared to Florida and Louisiana. Considering the expected time trend, that is, approximately 1/3-fold reduction in hesitancy by mid-2021 (period of estimates from the CDC) as opposed to 2020-early 2021, when our study was conducted, we adjusted the expected vaccine hesitancy prevalence as presented in Table 2. Even after such an adjustment, the observed vaccine hesitancy prevalence in the underserved population tended to be greater than expected in the general population (Table 2). These results further emphasized the importance of assessing vaccine hesitancy in the underserved population.

Examination of the crude (unadjusted) prevalence estimates for vaccine hesitancy showed that their demographic patterns vary between geographical regions. There was no clear age pattern among the California and Midwest participants (Figure 1). In other regions, a trend for greater hesitancy among participants aged 25-44 years was evident (*P*<.05); see Figure 1. Greater vaccine hesitancy among females was noticeable in all regions but was more pronounced (*P*<.05) in Florida, Louisiana, and the Midwest (Figure 2). Racial/ethnic differences were detected in California and Florida (*P*<.05) but not in Louisiana and the Midwest (Figure 3).

The adjusted estimates of the associations between vaccine hesitancy prevalence and both demographic and geographical characteristics (main effect model, Table 3) followed a pattern similar to the observations presented in Table 1. An inverted U-shaped correlation was found between vaccine hesitancy and age. Specifically, vaccine hesitancy was less associated with the younger and older age groups, whereas the association with age was 1.4-2.3-fold greater among adults aged 25-54 years compared to older adults aged ≥65 years (Table 3). Within the 25-54-year age group, there was a clear trend of the inverse association with age, with vaccine hesitancy declining among participants older than 25-34 years (Table 3). Females were approximately 1.7-fold more likely to express vaccine hesitancy compared to males. We hypothesized that vaccine hesitancy would be even more strongly associated with the female gender among females of reproductive age and tested the interaction between gender and age categorized as reproductive (18-44 years) and older (≥45 years); this model with age-gender interaction did not reveal differences in the association with gender by age. Non-Hispanic Black/African American and Hispanic participants had 1.8- and 1.2-fold greater odds of vaccine hesitancy compared to non-Hispanic White participants, respectively (Table 3). Overall, the magnitude of the strongest associations between demographic characteristics and vaccine hesitancy clustered around ORs of 2. Much stronger associations were found with geographical regions. Compared to California, even after adjustment for age, gender, and race/ethnicity, the odds of vaccine hesitancy were almost 6-fold greater in Florida and 4-fold greater in Louisiana (Table 3). Thus, the main effect analysis demonstrated that the geographical region has the strongest association with vaccine hesitancy.

[b] OR: odds ratio.

[c] HRSA: Health Resources & Services Administration.

We further explored the adjusted associations between each demographic characteristic and vaccine hesitancy, considering the geographical differences (models with interaction terms, Tables 4 and 5). These models showed significant interactions (*P*<.05 for the interaction term) between the geographical region and 2 demographic characteristics, namely gender and race/ethnicity, not with age. The adjusted association with gender followed the same tendencies revealed by the crude analysis (Figure 2 and Table 4). Within each gender group, the association between the female gender and vaccine hesitancy was strongest in Florida, followed by Louisiana and the Midwest (Table 4). Within each region, the tendency of a stronger association with the female gender was obvious; however, only in Louisiana, the 95% CIs for the gender-specific estimates did not overlap, indicating sufficient precision to detect gender differences in this region.

The racial/ethnic differences in the adjusted estimates of vaccine hesitancy also followed the pattern found in the crude analysis (Figure 3). As compared to non-Hispanic White participants in California, all racial/ethnic groups in Florida and Louisiana had a greater association with vaccine hesitancy (Table 5). In California, non-Hispanic Black/African American participants clearly had greater odds of vaccine hesitancy compared to non-Hispanic White participants. However, in other regions, the likelihood that non-Hispanic Black participants would express vaccine hesitancy was similar to other racial/ethnic groups. The strongest association of vaccine hesitancy with being non-Hispanic White was observed in Louisiana, whereas the strongest association with being Hispanic was observed in Florida. Thus, in this study, the demographic patterns of vaccine hesitancy, especially racial/ethnic differences, strongly depended on local contextual factors defined by geographical region.

Table 4. Association between vaccine hesitancy and gender modified by geographical location, as observed by the MRCIS[a] (2020-2021).

Gender	California, OR[b] (95% CI)[c]	Midwest (Illinois/Ohio), OR (95% CI)[c]	Florida, OR (95% CI)[c]	Louisiana, OR (95% CI)[c]
Female	1.14 (0.86-1.52)	1.58 (1.14-2.17)	7.88 (5.96-10.41)	6.09 (4.55-8.14)

Discussion

Principal Findings

Our study of COVID-19 vaccine hesitancy in underserved populations revealed several important findings. We found profound differences in vaccine hesitancy between geographical regions (Table 1). These observed differences might be expected based on the estimates published by the CDC (Table 2). However, our estimates for the MRCIS population showed a clear tendency of greater vaccine hesitancy than expected in the general population. This finding is important because the underserved population is at a greater risk of worse outcomes of this infection [5-8]. Thus, our study highlights the need to clearly communicate the benefits and risks of the vaccine to this high-risk population.

Another important finding is the difference in demographic patterns of vaccine hesitancy by geographical region. Although in California, the greatest vaccine hesitancy was among non-Hispanic Black/African American participants, this finding cannot be extrapolated to Louisiana and Florida. Similarly, the highest hesitancy prevalence among Hispanic participants in Florida cannot be extrapolated to other regions. These findings suggest that local contextual factors are major contributors to vaccine hesitancy in contrast to demographic characteristics. Future studies of vaccine hesitancy and other health behaviors should consider the local specifics. Additionally, these findings could prove important to developing effective local public health initiatives as streamlined, catch-all approaches may lack the nuance and specificity needed to impact vulnerable communities.

Results of prior studies support our findings, emphasizing the importance of local contextual factors in driving racial/ethnic patterns of vaccine hesitancy. A prior study conducted in the underserved population of North Carolina found the highest prevalence among White (74%), followed by Black (62.7%) and Hispanic (59.5%) participants, whereas a study in the Delaware underserved community found the greatest hesitancy among Black participants (45%). The online study conducted by the market research firm YouGov [17] found a similar prevalence of vaccine hesitancy among Black and White participants in 2020, once again confirming that racial/ethnic patterns strongly depend on the study population examined and cannot be extrapolated from one population to another.

We found that vaccine hesitancy tended to be lower among participants younger than 25 years and older than 55 years in the Midwest, Florida, and Louisiana (Figure 1 and Table 3). Evaluating the interaction between age and geographical region strongly suggests that in this study, the age patterns adjusted for gender and race/ethnicity did not differ by geography. The highest vaccine prevalence and the strongest association with age were found among ages 25-34 years. Similarly, among US Facebook respondents in January-May 2021, this age group had the highest vaccine hesitancy prevalence [18]. Another study conducted for the New York City Transport Workers Union found that adults aged 50 years and above were less likely to be COVID-19 vaccine hesitant than their younger counterparts [19]. These investigations examined study populations different from this report both socially and geographically. Thus, the age pattern with the high prevalence of vaccine hesitancy among ages 25-34 years appears to be consistent and less sensitive to the local contextual factors as opposed to racial/ethnic patterns.

The tendency of females to be more likely vaccine hesitant was apparent in all geographical regions but especially pronounced in Louisiana (Figure 2 and Table 4). Similar results were found by the US Facebook study, with females being more likely hesitant compared to men [18]. In addition, the analysis of a nationally representative sample from the 2021 Household Pulse Survey, administered by the US Census Bureau, showed greater vaccine hesitancy among US women [20]. Similar to the age patterns, gender differences in vaccine hesitancy may not be as sensitive to the local contextual factors and, therefore, are more generalizable to different population segments in the United States compared to racial/ethnic differences.

Limitations

There are several limitations to our study. Because the participants were drawn from volunteers and represented a convenience sample, the results may be liable to self-selection bias. To discuss whether such a bias potentially increased or decreased participation among the vaccine-hesitant individuals, we considered the major incentive for participation (ie, the availability of COVID-19 testing). Such an incentive suggests that volunteers were concerned about their infection status. However, neither the COVID-19 incidence rate nor mortality correlated with vaccine hesitancy worldwide [21]. Thus, it is unclear whether a potential self-selection bias was likely to increase or decrease participation among the hesitant subgroup, given the interest in the COVID-19 test. Because similar geographical patterns were found by the CDC data (Table 2), likely, self-selection did not distort the observed differences by geographical region. Similar age and gender patterns found in our and other studies suggest that either self-selection bias may have influenced all these studies or a potential self-selection bias did not distort these associations. Finally, self-selection bias could influence racial/ethnic patterns. However, the direction of the bias should have been specific to contextual local factors governing the observed geographical differences. Overall, even considering the likelihood of self-selection bias, our study clearly demonstrates the importance of local contextual factors in driving COVID-19 vaccine hesitancy. Another limitation of our study is the lack of additional data to further investigate the reasons for the revealed differences in vaccine hesitancy. Which local contextual factors are important remains unknown. We will focus our future investigations on answering this question.

Conclusion

In summary, our findings strongly suggest that local contextual factors drive the overall level of vaccine hesitancy in different regions, as demonstrated by the low prevalence in all demographic groups in California compared to Florida and Louisiana. Importantly, in all geographical regions, our estimates of vaccine hesitancy in the underserved population tended to be greater than what was expected in the general population in those same regions. Future investigations on this topic should include recording reasons for vaccine hesitancy to gain further insight into this subject. The same vaccine hesitancy factors will likely play a significant role in curbing future epidemics through vaccinations.

Acknowledgments

The National Minority Quality Forum was responsible for the design and conduct of the study; collection, management, analysis, and interpretation of the data; and preparation, review, approval, and the decision to submit the manuscript for publication. Quest Diagnostics provided in-kind and staffing support for the diagnostic tests during the enrollment process. The Centene Corporation provided startup support for the study.

Abstract

Background: Mass shootings result in widespread psychological trauma for survivors and members of the affected community. However, less is known about the broader effects of indirect exposure (eg, media) to mass shootings. Crisis lines offer a unique opportunity to examine real-time data on the widespread psychological effects of mass shootings.

Objective: Crisis Text Line is a not-for-profit company that provides 24/7 confidential SMS text message–based mental health support and crisis intervention service. This study examines changes in the volume and composition of firearm-related conversations at Crisis Text Line before and after the mass school shooting at Robb Elementary School on May 24, 2022, in Uvalde, Texas.

Methods: A quasi-experimental event study design was used to compare the actual volume of firearm-related conversations received by Crisis Text Line post shooting to forecasted firearm conversation volume under the counterfactual scenario that a shooting had not occurred. Conversations related to firearms were identified among all conversations using keyword searches. Firearm conversation volume was predicted using a seasonal autoregressive integrated moving average model trained on the 3 months of data leading up to the shooting. Additionally, proportions of issue tags (topics coded post conversation by volunteer crisis counselors at Crisis Text Line after the exchange) were compared in the 4 days before (n=251) and after (n=417) the shooting to assess changes in conversation characteristics. The 4-day window was chosen to reflect the number of days conversation volume remained above forecasted levels.

Results: There was a significant increase in the number of conversations mentioning firearms following the shooting, with the largest spike (compared to forecasted numbers) occurring the day after the shooting (n=159) on May 25, 2022. By May 28, the volume reverted to within the 95% CI of the forecasted volume (n=77). Within firearm conversations, “grief” issue tags showed a significant increase in proportion in the week following the shooting, while “isolation/loneliness,” “relationships,” and “suicide” issue tags showed a significant decrease in proportions the week following the shooting.

Conclusions: The results suggest that the Uvalde school shooting may have contributed to an increase in demand for crisis services, above what would be expected given historical trends. Additionally, we found that these firearm-related crises conversations immediately post event are more likely to be related to grief and less likely to be related to suicide, loneliness, and relationships. Our findings provide some of the first data showing the real-time repercussions for the broader population exposed to school shooting events. This work adds to a growing evidence base documenting and measuring the rippling effects of mass shootings outside of those directly impacted.

Introduction

Mass shootings result in widespread psychological distress and trauma symptoms for survivors and members of the impacted community [1]. Research demonstrates that following a mass shooting, higher rates of psychological symptoms (eg, depressive symptoms, increased feelings of fear, and decreased perceptions of safety) are found in the immediately affected community [2]. While there is emerging evidence suggesting that mass shootings may have negative mental health consequences that reach beyond local communities to broader populations through indirect exposure (eg, conversations, media exposure) [2], information about immediate effects of mass shootings on broader public well-being is nearly absent in the literature. One study showed that teachers who had increased exposure to school shooting–related media had increased experiences of secondary trauma [3]. Advancing understanding of indirect exposure and resulting mental health–related issues will inform future public health response.

There are several challenges associated with studying the effects of indirect exposure to mass shootings using traditional survey methods. Mass shooting events are unpredictable low-base rate events. Scheduled data collection of longitudinal or repeated cross-sectional studies may not align with when mass shootings occur, leading to excessively inefficient and costly survey operations. Furthermore, prolonged periods between exposure and data collection may lead to recall bias [4], reducing the quality of responses and the ability to make strong inferences. Recently, alternative study designs have been used to address these methodological challenges. For example, studies have analyzed the content of social media posts before and after mass shooting events to show increases in expression of emotions in the general population [5,6].

Data from crisis lines provide a unique opportunity to examine real-time data on the widespread psychological effects of mass shootings. Crisis Text Line (CTL) is a not-for-profit company that provides 24/7 confidential crisis counseling via SMS text messaging and WhatsApp. The majority of texters served by CTL in the United States are younger than 25 years (76% aged <25 years) [7]. CTL provides rich data specifically focused on mental health–related crises in the moments that they occur. Previous studies have used time series research designs with deidentified CTL data to analyze changes in the number and types of crises due to exposure to *13 Reasons Why* on Netflix [8], celebrity suicide deaths [9], and Hurricane Florence [10]. These prior investigations collectively demonstrate that poignant events that have widespread coverage on various media outlets (including social media) have measurable impact on the larger corpus of individuals texting CTL.

In this study, we investigated CTL's anonymized conversations related to firearm violence, including mass shootings, suicide, and other firearm-related issues. To our knowledge, no existing study has examined firearm-related crises in CTL conversations or other crisis lines. We examined changes in the volume and composition of CTL firearm-related texts before and after the Robb Elementary School mass school shooting on May 24, 2022, in Uvalde, Texas. Based on previous investigations with deidentified CTL data and national events [8-10], we hypothesized that conversations mentioning firearms would increase in the days following the mass shooting. Because work has not examined the broader effects of indirect exposure to mass shootings on mental health, we did not have a specific hypothesis about how social and mental health–related stressors may change before and after a mass shooting event. The objective of this study was to provide direct evidence of the effects of mass shootings on the broader public's mental health.

Methods

Overview

Anonymized and deidentified full crisis conversation transcripts and postconversation survey data completed by volunteer crisis counselors (vCCs) was obtained from CTL for the dates surrounding the Robb Elementary School shooting (March 1 to May 30, 2022). We filtered the anonymized and deidentified individual CTL conversations by 123 firearm-related keywords (eg, "gun," "shooting") to create a corpus of firearm-related crisis conversations. The keyword list started with common terms for firearms and was expanded using a word embedding similarity search [11] to discover firearm terms in the conversation text that were not present in the initial list (eg, "gsw," "9 mm"), expanding the number of keyword terms from 23 to 37. Word embeddings were generated using the Word2Vec algorithm [12] trained on all CTL conversations from September 2018 to August 2021 (N=2,539,460 conversations), which is the date range of focus for additional ongoing projects with the CTL data. Keywords were expanded to 123 words by examining conversations where vCCs' postconversation survey notes had a firearm keyword listed as the potential means of suicide but that were not already identified based on the conversation text using our existing keyword list. A full list of keywords is available in Multimedia Appendix 1.

A quasi-experimental event study design [13] was used to compare the actual firearm conversation volume post event to forecasted firearm conversation volume under the counterfactual scenario that a shooting had not occurred. Expected volumes were estimated using a seasonal autoregressive integrated moving average time series model with an order of (0, 1, 1) and seasonal order of (1, 1, 1, 7) on daily counts for a pre-event period (March 1 to May 23, 2022) to forecast the firearm conversation volume post event (May 4 to May 30, 2022). Other mass shooting events in the pre-event period were incorporated into the model using an exogenous dummy variable (1=mass shooting, 0=no shooting). Other mass shooting events were identified using the Gun Violence Archive [14] and the US Congress definition of mass public shooting [15]. A start date of March 1, 2022, was chosen to focus on recent months, though a start date of January 1, 2022, was also tested with similar results. An end date of May 30, 2022, was chosen to exclude the June 1, 2022, mass shooting in Tulsa, OK.

Lastly, we compared proportions of conversation issue tags (characteristics of the text conversation coded by CTL vCCs during/after the exchange) 4 days before (n=251) and after (n=417) the shooting to assess changes in conversation characteristics. The duration of the time before and after the event was chosen empirically to represent days in which the actual volume of firearm-related conversations exceeded the expected. Chi-square tests were used to test the hypothesis that issue tag proportions differed in the pre- and postevent periods.

Data Management

Data from CTL was accessed on a secure remote server hosted by CTL. All data used in this study will be deleted upon completion of the broader Centers for Disease Control and Prevention–funded research project.

Ethical Considerations

This project was reviewed by the RTI Office of Research Protection Institutional Review Board (IRB; STUDY00021510) and deemed to fall under the category of Not Human Subjects Research (public health practices and surveillance activities). Data used within this study are collected by existing infrastructure at CTL as part of the crisis services they provide. All data gathered from texters including text conversations and postconversation survey data provided by CTL are anonymized and deidentified before transfer to the research team for analysis. Texters agree to the use of their anonymized information for research purposes as part of the CTL's terms of service automatically shared before being connected with a vCC [16]. Anonymized texter information is shared for public good in aggregate at CrisisTrends.org and with select researchers following a rigorous screening process and IRB approval, and texters can request that their conversations be removed from CTL's systems at any time following their conversations.

Results

We observed a significant increase in the number of conversations mentioning firearms following the shooting at Robb Elementary School (Figure 1). The largest spike in conversations mentioning firearms occurred the day after the shooting (n=159), May 25, 2022, with volume reverting to within the 95% CI of forecasted volume 4 days after the shooting on May 28 (n=77).

Table 1 reports the frequency and proportions of issue tags for conversations in the immediate 4-day pre- and postevent period. For firearm conversations during the postevent period, the count of all issue tags increased, except for the "COVID-19" issue tag. To control for increases in tags post event, we examined the percentage of total firearm conversations in the pre- and postevent period that each unique tag was used. Comparing pre-event to postevent, the "grief" issue tag increased significantly in the days following the shooting (*d*=0.06; *P*=.03), while the proportions for the "isolation/loneliness" (*d*=–0.07; *P*=.04), "relationships" (*d*=–0.11; *P*<.001), and "suicide" (*d*=–0.14; *P*<.001) issue tags decreased in the days following the shooting.

Figure 1. Count of Crisis Text Line firearm-related conversations following the Robb Elementary School shooting.

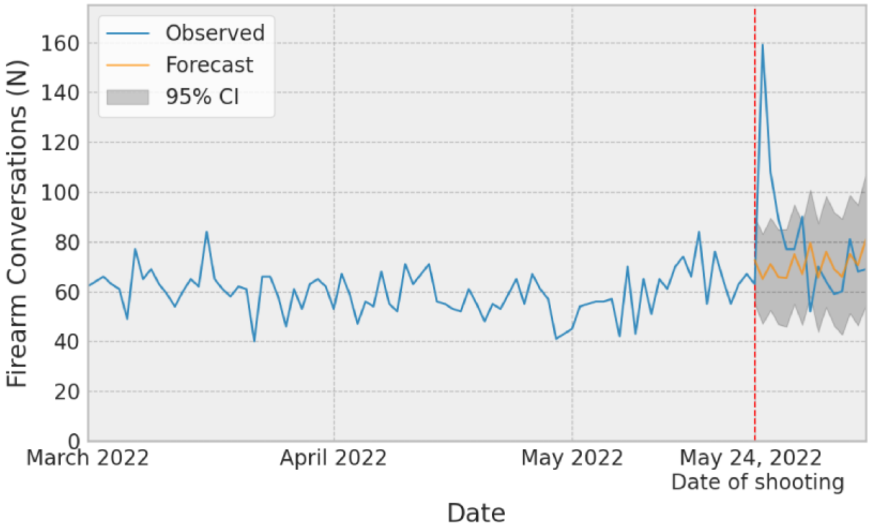

Table 1. Issue tag proportions for conversations prior and in the week following the shooting sorted by pre-post difference in proportions.

Issue tag	Count before, n	Count after, n	Pre-event proportion (n=251)	Postevent proportion (n=417)	Difference	*P* value
Grief	19	55	0.08	0.13	0.06	*.03* [a]

Discussion

The objective of this investigation was to examine the effect of a mass shooting event on the broader public's mental health. To do so, we examined the immediate effects of a widely publicized mass shooting in the United States on volume of mental health crisis text conversations that mentioned firearms. We also examined the psychosocial context of those text conversations by investigating changes in issue tags associated with firearm conversations as coded by the vCCs. Consistent with our hypothesis, we found that firearm-related crisis conversations following the Uvalde school shooting significantly increased. In addition to this main finding, we observed an increase in the proportion of grief-related conversations that mentioned firearms and a decrease in suicide-related conversations that mentioned firearms. We also observed a decrease in firearm conversations associated with relationships or feelings of isolation/loneliness following the Uvalde school shooting. Overall, we saw evidence that a widely publicized mass shooting influenced the broader public's mental health beyond the specific location of the mass shooting event.

Our innovative methodological approach of analyzing real-time mental health crises through CTL conversations allowed us to address a critical gap in knowledge of the psychological effects of mass shootings on remote populations of individuals who are not directly exposed to the mass shooting event. Only a couple of prior studies have investigated the effects of mass shooting events on youth populations beyond the communities directly involved in these events, and these studies have mainly focused on youth expressions of emotion such as fear. However, our study findings may have the potential to have a significant impact on mental health crises (beyond general expressions of negative emotions) among the public. Interestingly, the increase in crisis conversation volume existed even when accounting for other mass shootings in the study period. It is possible that the Uvalde shooting has a particularly strong impact on users of CTL because school shootings (relative to other forms of mass shootings) appear to significantly affect youth mental health [17], and the CTL population is largely composed of youth [7]. Of course, other confounding factors such as the amount of media coverage or social media mentions may also be influential.

The increase in proportion of grief-related conversations, along with the decrease in suicide-related conversations, further suggest that firearm crisis conversations post event may be focused more on loss rather than suicide as is typically more common in firearm-related mental health crisis conversations. These findings are consistent with prior research showing that grief is a common reaction immediately following school shootings [18]. We also observed a decrease in firearm conversations associated with isolation and relationship issues. Although the data does not illustrate why this shift occurred, we speculate that an increase in social solidarity after the mass shooting event leads to fewer crises due to isolation and relationship factors. This possibility is consistent with prior studies suggesting that community members often reach out to provide more emotional support to one another after traumatic events [19]. Together, our results demonstrate that firearm-related mental health crisis conversations immediately following a mass shooting differ from typical firearm conversations in that they are more likely to be associated with grief issues and less likely to be associated with suicide, isolation, and relationship issues.

Several limitations of the study should be noted. First, we assume that the firearm conversations represent users that were not directly impacted by the Uvalde shooting (survivors, direct family members, etc) due to the relatively smaller number of people expected to incur direct versus indirect effects. Future studies should use geographic indicators to increase the chance of examining those directly related to a mass shooting event. Second, our study design does not address why the text volume associated with the Uvalde school shooting is greater than other mass shootings observed in the study period. Future research studying the magnitude of indirect impacts of mass shootings across different types of events could greatly enhance the literature, for example, the impact of school shootings compared to nonschool shootings. Additionally, this study does not attempt to quantify the impact of increased awareness of or referrals to CTL due to the Uvalde shooting. Lastly, issue tags were designated by the vCCs and thus relatively subjective. Future work could study the reliability of vCCs' tagging to help better understand how mass shootings may be related to increases in firearm-related mental health crises. Overall, our findings support two main conclusions. First, the Uvalde, TX mass school shooting increased firearm-related text conversations at a national mental health crisis line even after factoring in the effects of other mass shootings that occurred proximally in time. Our findings provide some of the first data showing the real-time repercussions for the broader population exposed to school shooting events. Public health officials must recognize that the reverberations of school shootings on mental health extend beyond just the immediate community where the event takes place. Second, these firearm-related crises conversations may be most frequently related to grief. Thus, findings suggest that public health interventions that target feelings of grief may have the potential to reduce mental health crises immediately following a school mass shooting. Overall, the findings lay the foundation for future research on effective public mental health interventions that may be implemented after school mass shootings.

Acknowledgments

This work was funded by grant R01CE003295 from the Centers for Disease Control and Prevention. We thank Crisis Text Line for making anonymized and deidentified data available to our team for research purposes.

Data Availability

Data from Crisis Text Line used in this research is not available publicly due to concerns of privacy and anonymity of texters who use Crisis Text Line's service. Aggregated anonymized data from more than 7 million conversations with people in crisis supported by Crisis Text Line is available at CrisisTrends.org.

Conflicts of Interest

None declared.

Abstract

Background: *Sexual violence* against women is prevalent worldwide. Prevention programs that treat men as allies and integrate a bystander framework are emerging in lower income settings, but evidence of their effectiveness is conflicting.

Objective: This study aimed to test the impact of GlobalConsent on sexually violent behavior and prosocial bystander behavior among university men in Vietnam.

Methods: We used a double-blind, parallel intervention versus control group design with 1:1 randomization at 2 universities. A total of 793 consenting heterosexual or bisexual men aged 18-24 years who matriculated in September 2019 were enrolled and assigned randomly to GlobalConsent or an attention-control adolescent health education (AHEAD) program. GlobalConsent is an adapted, theory-based, 6-module web-based intervention with diverse behavior change techniques and a locally produced serial drama. AHEAD is a customized, 6-module attention-control program on adolescent health. Both the programs were delivered to computers and smartphones over 12 weeks. Self-reported sexually violent behaviors toward women in the prior 6 months and prosocial bystander behaviors in the prior year were measured at 0, 6, and 12 months.

Results: More than 92.7% (735/793) of men in both study arms completed at least 1 program module, and >90.2% (715/793) of men completed all 6 modules. At baseline, a notable percentage of men reported any sexually violent behavior (GlobalConsent: 123/396, 31.1%; AHEAD: 103/397, 25.9%) in the prior 6 months. Among men receiving GlobalConsent, the odds of reporting a high level (at least 2 acts) of sexually violent behavior at the endline were 1.3 times the odds at baseline. Among men receiving AHEAD, the corresponding odds ratio was higher at 2.7. The odds of reporting any bystander behavior at endline were 0.7 times the odds at baseline for GlobalConsent, and the corresponding odds ratio for AHEAD was lower at 0.5.

Conclusions: Compared with a health attention-control condition, GlobalConsent has sustained favorable impacts on sexually violent behavior and prosocial bystander behavior among matriculating university men in Vietnam, who would otherwise face increasing risks of sexually violent behavior. GlobalConsent shows promise for national scale-up and regional adaptations.

Introduction

Background

Sexual violence is defined as a sexual act committed against a person when consent is not freely given. Sexual violence ranges from unwanted noncontact sexual experiences to completed forced penetration [1]. Among sexually experienced women aged 15-19 years, forced sexual debut is common worldwide (15%), including in the Asia and Pacific (14%) [2], and women comprise 91% of the victims [3]. The physical, psychological, and economic aftermath of sexual violence often is severe for victims [4,5] and is costly for societies [6].

In Vietnam, sexual violence persists [7,8] despite the legal reforms to address it. Men may discount, excuse, or deny acts of sexual violence [9], and their reported rates of sexually violent behavior (0.2%) are lower than women's reported rates of victimization (12%) [10]. Thus, prevention with men is crucial to create environments where women's freedom from violence is possible [11]. However, young men are often difficult to reach [12] and may resist participation in prevention programs [13]. The behavior of bystanders, or witnesses of sexual violence, may also be gender specific [14]. Thus, prevention with men that integrates a bystander framework and treats men as "allies" [15] may address attitudes and behaviors while decreasing resistance to participation [16,17].

However, evidence of programmatic impacts from rigorous evaluations is limited [18]. In an Ovid database search for "sexual violence," "intervention," and "review," we identified 4 reviews published since 2016 that focused on interventions to prevent sexual violence in adolescents and young adults [19-22]. A 2017 review of reviews identified a few interventions focused on boys [19]. A subsequent review of 44 bystander intervention programs in North America found that, on average, programs involved a single session (75%) of <2 hours (mean 116 minutes; range 10-480 minutes) in college populations (75%) as well as in-person presentations (68%) and discussions (54%) with mixed-gender groups (56%). Relatively few interventions were tailored to men (27%) and involved web-based delivery (11%; [20]). Moreover, study designs had important limitations: the majority were not randomized controlled trials (RCTs; 62%) and had small sample sizes (mean 536, range 1-4311) in White populations (73%), high attrition (36%) [20], and short follow-up periods of ≤6 months (89%) focused on nonbehavioral outcomes (66%). A third systematic review focused on interventions to prevent intimate partner, dating, and sexual violence in men and boys and found heterogeneity across the 9 included studies in program content and delivery strategies, study designs, sample sizes, and outcome measurement [21]. Most studies used cluster-randomized designs, recruited undergraduate college students, and evaluated a multisession program delivered via group sessions; however, only 1 program reduced men's self-reported sexually violent behavior, and most studies were based in the United States. A fourth review that focused on intervention studies to change "hegemonic masculinities" found that 8 of the 10 included quantitative studies were conducted in the United States or Africa, only 1 was web-based, and impacts on sexually violent behavior were mixed [22]. Thus, especially in lower- and middle-income countries (LMICs), gender-specific interventions with men to prevent sexually violent behavior are rare, and theoretically grounded, web-based sexual violence prevention interventions engaging men and involving a bystander framework have not been evaluated in such settings.

This study tested the impact of GlobalConsent on sexually violent behavior and prosocial bystander behavior in university men in Vietnam. The team adapted GlobalConsent from RealConsent, an evidence-based web-delivered intervention tested among university men in the United States [23]. RealConsent is based on formative research [24], social cognitive theory [25], social norms theory [26], and the bystander education model [27]. Sexually violent behavior is theorized to arise from the interplay of sociocontextual factors, personal factors, and behavior. To operationalize this theory of change, programmatic features of RealConsent include gender-specific content [28-31] that resonates with the viewer [32] and diverse behavior change techniques [33], such as providing information and instruction on obtaining effective consent for sex and intervening safely, modeling communication and intervening behaviors, showing positive outcomes for obtaining consent and intervening plus negative outcomes for perpetrating and not intervening, and reinforcing with positive feedback [34]. RealConsent uses didactic presentation of material via integrated audio, video, and infographics; problem-based learning with interactivity and reinforced practice; short videos or animations to model behavior; and educational entertainment, starting and ending each module with a brief episode of a serial drama [23,35].

RealConsent aimed to change 2 primary behaviors by changing 7 cognitive, attitudinal, and affective mediators. The 2 primary behaviors were prosocial intervening behaviors, such as trying to stop a peer from being sexually coercive and sexually violent behavior toward women. The 7 mediators included knowledge of the elements of sexual consent, knowledge and skills to intervene safely, misperceptions of norms about sexual violence and rape, negative attitudes about date rape, positive masculinity, skills in sexual communication, and empathy for the victims of sexual violence. Results from a randomized controlled trial supported the efficacy of RealConsent. A random probability sample of 743 undergraduate men aged 18-24 years attending a large, public, urban university in the Southeastern United States was randomized to RealConsent (376/743, 51%) or a web-based health education attention-control program (367/743, 49%) [23]. Participants were surveyed on the web at baseline, after intervention, and 6 months after intervention. Six 30-minute modules were delivered via a password-protected web portal. At 6 months after intervention, compared with the control group, the RealConsent group intervened more often and engaged in less sexual violence. They reported greater knowledge about legal definitions of sexual assault and elements of effective consent; lower adherence to rape myths, negative date-rape attitudes, hypergender ideology, and hostility to women; greater empathy for rape victims; greater intentions to intervene; less positive outcome expectancies for nonconsensual sex; more positive outcome expectancies for intervening; and less comfort with other men's inappropriate behavior. The trial experienced high loss to follow-up in the intervention (67%) and control (75%) arms; therefore, results in the retained sample should be interpreted with caution.

Objectives

To adapt RealConsent for delivery to a new context, we followed the Centers for Disease Control and Prevention's 5-step process [36]. Step 1, *assess*, involved assessing the target population, the evidence-based intervention (EBI) being considered for implementation, and the implementing agency's capacity to use the intervention. Step 2, *select*, entailed determining whether to adopt the EBI without adaptations, with adaptations, or to choose another EBI for adaptation. Step 3, *prepare*, involved making the necessary adaptations to the EBI while retaining the core elements. Step 4, *pilot*, entailed piloting the adapted intervention and developing a plan for implementation. We conducted qualitative research to implement steps 1 to 4 [37], and those findings are presented elsewhere [38-40].

To complete step 5, *implement*, we undertook an RCT to test, among men attending 2 universities in Vietnam, the impact of GlobalConsent versus a customized adolescent health education (AHEAD) attention-control condition on changes in 2 primary behavioral outcomes—sexually violent behavior and prosocial bystander behavior. The aim of this paper was to present findings from the RCT with regard to 3 a priori hypotheses. First, we expected that GlobalConsent would *mitigate increases in sexually violent behavior* that may occur when men matriculate into university and interact with women with less parental supervision [41-43]. Second, we expected that GlobalConsent would *increase prosocial bystander behavior* relative to attention-control conditions. Third, we expected that GlobalConsent would influence these behavioral outcomes directly and indirectly through changes in knowledge, attitudinal, and affective secondary outcomes. The results presented here focused on the primary, unmediated behavioral outcomes.

Methods

Setting

Universities in Vietnam were suitable contexts for adapting RealConsent, given their similarities to universities in the United States. In Vietnam, undergraduate study is 4-6 years, with 2 foundational years and 2-4 years for specialization. Except for political education and national defense, universities design their curricular and extracurricular activities and maintain networks through the Ministry of Education and Training, professional associations, and the Youth Union, all pathways for the national scale-up of educational programs. The study sites were 2 universities located in Hanoi. One is a 120-year-old state school that trains 1000 students yearly in health professions. The other is a 34-year-old private university that trains 7000 students annually across diverse disciplines. Both universities provided letters of support for this study.

Trial Design

The study design, detailed elsewhere [37], applied a double-blind, parallel intervention versus attention-control group design with balanced (1:1) randomization (Multimedia Appendix 1).

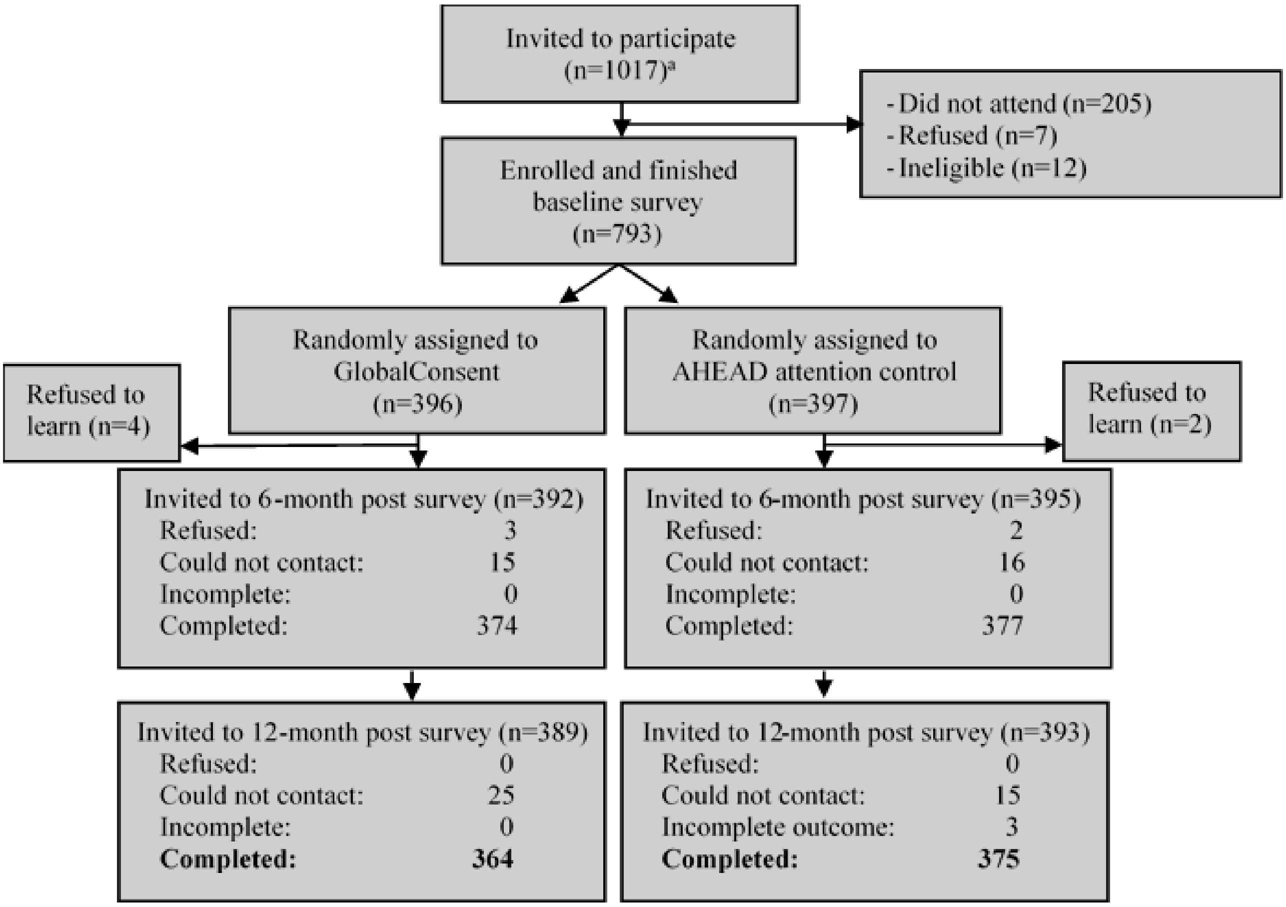
Ethics Approval

Data were collected following established ethical guidelines for research on gender-based violence [37]. The institutional review boards of Emory University (IRB00099860) and Hanoi University of Public Health (017–384/DD-YTCC) reviewed and approved the study protocol, including the web-based consent forms used in the study.

Sample Eligibility, Participation, and Retention

Eligible men for the study were heterosexual or bisexual, aged 18-24 years, and matriculating in September 2019 at either of the 2 study sites. To identify eligible men at university 1, overall, 56% (5/9) of the departments were included in the sample because all departments had an agreed threshold of ≥15 cismale students. For university 2, a total of 59% (13/22) of the departments having at least 20 cismale students were included. All first-year cismale students of the included departments were invited to participate (n=1017; Figure 1; power calculations are presented in the protocol paper by Yount et al [37]). Of these 1017 men, 205 (20.1%) did not attend the orientation, 7 (0.7%) declined, and 12 (1.2%) did not meet the inclusion criteria. Eligible, consenting men who completed an in-person, computer-assisted self-administered baseline survey at their home university in September 2019 (793/1017, 78%) were assigned a random number generated in Microsoft Excel (Microsoft Corp), sorted in ascending order. Of the 793 eligible men, the first 397 (50.1%) were assigned to the AHEAD attention-control group, and the remaining 396 (49.9%) men were assigned to the GlobalConsent group. The participants were blinded to these assignments because of the use of an attention-control condition, and the analysis team was blinded to these assignments throughout the analysis. Furthermore, 6 assigned participants (4 GlobalConsent and 2 AHEAD) declined to login to their assigned learning program. The participants were able to access their assigned programs from November 2019 to January 2020. Owing to the COVID-19 pandemic, posttest 1 (completed in April-May 2020, 3 months after intervention, and 6 months after baseline) and posttest 2 for trial endline (completed in October-November 2020, 9 months after intervention, and 12 months after baseline) were self-administered remotely via the web to ensure completion, regardless of students' location of residence. Some internet disruptions were apparent, as the mean number of survey attempts was >1 in both groups and posttest rounds. However, the agreement across survey attempts between outcome-related responses exceeded 95%. In the GlobalConsent group, 94.4% (374/396) and 91.9% (364/396) students completed posttest 1 and 2, respectively. In the AHEAD group, 95% (377/397) and 94.5% (375/397) of students completed posttest 1 and 2, respectively. Reasons for high retention may have included a cultural tendency to adherence in Vietnam, a progressive compensation schedule for survey and program module completion, and text messages and emails to remind students to complete their studies [37].

Figure 1. Flow diagram of sample enrollment, allocation, and follow-up randomized controlled trial of GlobalConsent. [a] Of the 1017 eligible men, 362 were from University 1 and 655 were from University 2. AHEAD: adolescent health education.



GlobalConsent Program

The adapted GlobalConsent program took into account qualitative findings [38,40] and feedback from focus group discussions with cismale students and university stakeholders on the RealConsent program and the adapted GlobalConsent storyboards before production (Multimedia Appendices 2 and 3). In total, 7 major adaptations have been observed. First, the local cismale characters were grounded in findings from the formative qualitative study, including the family and social contexts in which young men live in Vietnam. The male characters were adapted to evolve in contextualized ways, showing how their gender attitudes and awareness of sexual violence and response were changing. Thus, 5 cismale characters were created to reflect different initial masculinity typologies and different speeds and degrees of "masculinity development" over the program. These characters reflected (1) *positive masculinity* throughout; (2) *somewhat positive masculinity* throughout; (3) *somewhat more traditional masculinity* initially and becoming more aware earlier in the program (modules 2-3), as reflected in verbal tone, language, and marked behavior change; (4) *more traditional masculinity* initially and struggling but becoming more aware, as reflected in a scene in a karaoke bar when he returns to a hotel with drunk young woman and decides not to have sex; and (5) *very traditional masculinity* initially using inappropriate behavior, sanctioned by friends, and becoming more aware of modules 4-5, again as reflected in tone, language, and behavior.

Second, the cisfemale partners of these cismale characters were added because sexual coercion and violence in dating relationships emerged as salient in the formative qualitative findings. Third, "coach-talk" segments for reinforced learning were removed, as they relied on English vernacular, were misunderstood by Vietnamese stakeholders, and caused confusion about key messages. Fourth, "key questions" and "takeaways" were added to specific segments and scenarios, as these forms of reinforced learning were more familiar in Vietnam and helped to reduce misinterpretation of key messages. Fifth, content related to knowledge, attitudinal, and affective pathways in the theory of change was adapted to be relevant for Vietnam, and definitions of sexual violence were expanded to include the full spectrum of sexually violent behaviors. Sixth, anonymized narratives from the qualitative interviews were incorporated into the serial drama script to ensure comprehension and cultural suitability. Finally, all scenarios were refilmed or reanimated to resonate with the learning style of the cismale students in Vietnam.

The final GlobalConsent program included six 30-minute modules, each ranging in the number of segments and types of activities, with diverse actors and languages suitable for students who self-identify as heterosexual or bisexual men in Vietnam. Modules—grounded in social cognitive theory, social norms theory, and a bystander framework [37]—covered 6 topics to address hypothesized knowledge, normative or attitudinal, and affective mediators of the program and behavioral outcomes. These topics included consent for sex, rape-myth beliefs and norms regarding gender roles, effective communication, alcohol and rape, victim empathy, and bystander intervention. Each module included didactic activities, interactivity, and episodes of an adapted serial drama that modeled positive behaviors with cismale peers and cisfemale sex partners. The program was formatted for delivery to the computers and smartphones. Participants were provided with unique login information to access the platform and could work at their own pace, could not skip segments, and were encouraged by email and text messages to complete all modules in 12 weeks. The learning app captured the number of times a student logged in to each module and the total minutes a student spent on each module.

AHEAD Attention-Control Program

The team developed AHEAD, the attention-control program, from open-access content suitable for young people in Vietnam [37]. To approximate the format, intensity, and duration of GlobalConsent, AHEAD was developed as a web-delivered, multimedia program audio-narrated in Vietnamese with 6 learning modules that were 35-45 minutes long on brain development, nutrition, physical activity, substance use, sleep, and agency. Similar to GlobalConsent, participants could work at their own pace, could not skip segments, and were encouraged by email and text messages to complete all modules in 12 weeks. The use of an attention-control condition was justified because the original trial of RealConsent also used an attention-control condition and the team wanted the trial of GlobalConsent to include a similar comparator. In addition, the use of an attention-control condition accounted for the web-based mode of delivery in both study arms, so any effects of the content of GlobalConsent could be compared with those of a general *adolescent health education* program that did not focus on the theoretical knowledge, attitudinal, and affective pathways by which GlobalConsent was theorized to reduce men’s sexually violent behavior and increase their prosocial bystander behavior.

Data

Primary Outcomes

The primary outcomes for this analysis were sexually violent behavior, measured using the Sexual Experiences Survey [44], and prosocial bystander behavior, measured using 4 items from an adapted Bystander Behavior Scale [45] (Table 1). The Sexual Experiences Survey asks about the perpetration of 7 acts of contact sexual violence, ranging from unwanted touching to forced penetration, using any of 7 physical or nonphysical tactics, such as holding someone down or threatening to end the relationship (35 items total). The Sexual Experiences Survey also asked about the perpetration of 10 acts of noncontact sexual violence, such as masturbating in front of someone when they did not agree. We captured *sexually violent behavior* based on the reported frequency (never, once, twice, and ≥3 times) of all 45 items in the prior 6 months. We captured *prosocial bystander behavior* based on the reported frequency (never, once, and ≥2 times) in the prior 12 months of 4 acts, such as “I have talked with someone about sexual or dating violence as an issue for our university.” The frequency of missingness was 0.1%-0.7% across all items, and these responses were recoded as 0, “not reported.” We created kernel density plots of the summative scores for each primary outcome (Multimedia Appendix 4). On the basis of their distributions, we captured 3 measurement scales for each behavioral outcome to assess whether the GlobalConsent program had linear or threshold effects. These measurement scales were any reported act (1 or more vs 0 or none reported), many reported acts (3 or more vs 0-2 or none reported), and the number of reported acts (Table 1).

Table 1. Primary reported behavioral outcomes in the randomized controlled trial of GlobalConsent.

Outcomes	Instrument	Response options	Sample size, n	Example item	“Any act”	“Many acts”	Sum
Sexually violent behavior, past 6 months	Sexual Experiences Survey [44]	- 0, Never - 1, Once - 2, Twice - 3, ≥3 times	45	I took photos or videotapes of someone while they were undressing, were nude, or were having sex, when they did not agree to it.	- 1, Any act - 0, No act[a]	- 1, 3 or more acts - 0, 0-2 acts[a]	0-135
Prosocial bystander behavior, past 12 months	Bystander Behavior Scale [45]	- 0, Never - 1, Once - 2, ≥2 times	4	I have encouraged others to learn more and get involved in preventing sexual or dating violence.	- 1, Any act - 0, No act[a]	- 1, 3 or more acts - 0, 0-2 acts[a]	0-8

[a] Missing responses for the number of acts were coded 0.

Exposures

Participants were assigned randomly to either the GlobalConsent treatment (=1) or the AHEAD attention-control program (=0). Time was coded 0 for baseline and 1 for subsequent time points. A time-by-treatment arm interaction term was created to assess the difference-in-difference (DID) for GlobalConsent versus AHEAD at “endline” (posttest 1 and 2 combined) versus baseline.

Covariates

Covariates included age in years, program of study (health sciences, others), relationship history (ever, never), living situation (parents, other relatives, dormitory, off campus, and other), ethnicity (majority, minority), sexual orientation (heterosexual, bisexual), religion (any, none), and residence in Hanoi for at least 1 year before baseline (yes, no). In addition, past sexual history (ever, never), sexual preference (women only, others), gender identity, and expression (very feminine=1 to very masculine=7) were collected at the posttest 1. At posttest 2, an adapted Vietnam Prevalence Study on Child Maltreatment [46] scale measured maltreatment before the age of 18 years with 28 items capturing any exposure to behaviors by adults in 5 domains: physical, sexual, and emotional abuse as well as physical and emotional neglect. Dichotomous (any, none) variables were created for each domain of child maltreatment. Any exposure (yes, no) to web-based sexually explicit material in the past 6 months was measured for 5 domains (textual, partial nudity, full nudity, nonviolent sexual acts, and violent sexual acts) [47].

Statistical Analysis

First, we conducted descriptive analyses of the sample overall and by study arm to assess qualitative balance across groups. Second, we assessed levels of sexually violent behavior and prosocial intervening behavior at each study wave by study arm. Finally, we conducted DID modeling to estimate the odds ratios (ORs), incidence rate ratios, and 95% CIs for sexually violent behavior and prosocial bystander behavior at endline (posttest 1 and 2 combined) versus baseline. For binary outcomes, we performed logistic regression with the assigned treatment arm, time, and treatment-by-time interaction (DID variable) as predictors. For count outcomes, we performed a negative binomial regression, which accounted for overdispersion in the outcome. To probe significant treatment-by-time interaction or DID effects, we computed and compared the OR and incidence rate ratio of the occurrence of the behavior separately for each group. All analyses were performed using Stata (version 16; StataCorp [48]).

Role of the Funding Source

The funder of the study had no role in study design, data collection, analysis, interpretation, or writing of the report. All authors had full access to all study data and were responsible for the decision to submit this paper for publication.

Results

Sample Characteristics

The characteristics of men across the groups were similar at baseline and follow-up waves (Tables 2-4). At baseline, men were aged 18 years, on average, and a majority were attending university 2, majoring in nonhealth fields, of Kinh ethnicity, heterosexual, nonreligious, and had never been in a dating or sexual relationship. The living arrangements and residential location of men were similarly distributed across the groups (Table 2). After baseline, high percentages of men in both the GlobalConsent and AHEAD groups, respectively, logged into the program (372/396, 93.9% vs 386/397, 97.2%), completed at least 1 module (361/396, 91.2% vs 374/397, 94.2%), and completed all modules (355/396, 89.6% vs 362/397, 91.2%).

At posttest 1, most men in both groups had never had sex and sexually preferred only women (Table 3). In addition, reported gender identities and gender presentations were predominantly masculine, with average scores ≥6.0. About three-fourths (569/751, 75.8%) of men had ever been exposed to textual sexually explicit material or “top nudity.” Almost two-thirds (490/751, 65.2%) had ever been exposed to “full nudity” or nonviolent sexual acts. Approximately 40.9% (302/739; ie, about 4 in 10) had ever been exposed to sexually explicit material showing violent sexual acts against women.

Reported experiences of child maltreatment, by type, were similar in the GlobalConsent and AHEAD groups (Table 4). More than half (401/735, 54.6%) of the men reported experiencing emotional abuse in childhood, and about 1 in 5 reported experiencing emotional neglect in childhood. Almost half (346/736, 47%) of the men reported experiencing physical abuse in childhood and ≤5% reported experiencing physical neglect in childhood. More than 1 in 10 men reported experiencing sexual abuse during childhood. High levels of childhood maltreatment are consistent with 2014 population-based national data from secondary school students. Except for emotional neglect, which is higher, the prevalence estimates for childhood maltreatment in our sample are lower than the national average [46].

Sexually Violent Behavior and Prosocial Intervening Behavior

Reported rates of any sexually violent behavior were 31.1% (123/396), 21.4% (80/374), and 31.9% (116/364) across survey waves in the GlobalConsent group and 25.9% (103/397), 26.3% (99/377), and 31.5% (118/375) across waves in the AHEAD group (Table 5). Rates of "high" sexually violent behavior (>2 acts) were 21% (83/396), 13.6% (51/374), and 24.7% (90/364) across waves in the GlobalConsent group and 17.1% (68/397), 18% (68/377), and 23.2% (87/375) across waves in the AHEAD group. The mean count of sexually violent acts was 3.2, 2.2, and 3.1 across waves in the GlobalConsent group and 2.4, 3.6, and 3.2 across waves in the AHEAD group.

Table 5. Sexually violent behavior and prosocial bystander behavior at baseline, posttest 1 (6 months after baseline), and posttest 2 (12 months after baseline) of men matriculating at 2 universities in Vietnam in September 2019 and randomized to receive the GlobalConsent program or the adolescent health education (AHEAD) attention-control program.

Outcomes	Baseline		Posttest 1		Posttest 2	
	AHEAD (n=397)	GlobalConsent (n=396)	AHEAD (n=377)	GlobalConsent (n=374)	AHEAD (n=375)	GlobalConsent (n=364)
Sexually violent behavior						
Yes any, n (%)	103 (25.9)	123 (31.1)	99 (26.3)	80 (21.4)	118 (31.5)	116 (31.9)
Yes, high (>2 acts), n (%)	68 (17.1)	83 (21)	68 (18)	51 (13.6)	87 (23.2)	90 (24.7)
Count, mean (SE); range	2.4 (9.7); 0-111	3.2 (11.6); 0-96	3.55 (12.1); 0-112	2.24 (8.1); 0-70	3.2 (9.9); 0-79	3.1 (11.7); 0-135
Prosocial bystander behavior						
Yes any, n (%)	258 (65)	258 (65.2)	N/A[a]	N/A	170 (45.3)	203 (55.8)
Yes high (>2 acts), n (%)	141 (35.5)	163 (41.2)	N/A	N/A	108 (28.8)	138 (37.9)
Count, mean (SE); range	2.2 (0.1); 0-8	2.4 (0.1); 0-8	N/A	N/A	1.7 (0.1); 0-8	2.3 (0.1); 0-8

[a] N/A: not applicable (as the 12-month window of observation at posttest 1 overlaps with the 12-month window of observation at baseline).

Reported rates of any prosocial bystander behavior were 65.2% (258/396) and 55.8% (203/364) across survey waves in the GlobalConsent group and 65% (258/397) and 45.3% (170/375) across waves in the AHEAD group (Table 5). Rates of "high" prosocial bystander behavior (>2 acts) were 41.2% (163/396) and 37.9% (138/364) across waves in the GlobalConsent group and were 35.5% (141/397) and 28.8% (108/375) across waves in the AHEAD group. The mean counts of prosocial bystander acts were 2.4 and 2.3 across waves in the GlobalConsent group and were 2.2 and 1.7 across waves in the AHEAD group.

Effects of GlobalConsent on Behavioral Outcomes

Significant interaction effects in the DID models suggested favorable impacts of GlobalConsent relative to AHEAD on sexually violent behavior (>2 acts; OR 0.5, 95% CI 0.3-0.7; *P*=.001) and prosocial bystander behavior (any act; OR 1.5, 95% CI 1.0-2.3; *P*=.05; Table 6). Marginally significant interaction effects in DID models for any sexually violent behavior and the count for prosocial bystander acts suggested a consistent, favorable impact of GlobalConsent relative to AHEAD across the measurement scales of these 2 behavioral outcomes.

Table 6. Difference-in-difference odds ratios (ORs) for the logistic model or incidence rate ratios (IRRs) for the negative binomial model, comparing endline (posttest 1 and 2 combined) versus baseline for 730 university men in the GlobalConsent versus adolescent health education groups.

Outcomes	OR IRR (95% CI)	*P* value
Sexually violent behavior		
Yes, any act	0.71 (0.50-1.00)	.05
Yes, >2 acts	0.47 (0.31-0.72)	.001
Count	0.65 (0.37-1.14)	.13
Prosocial bystander behavior		
Yes, any act	1.51 (1.00-2.27)	.05
Yes, >2 acts	1.19 (0.78-1.81)	.42
Count	1.27 (1.00-1.60)	.05

To probe the interaction effects further, we computed the ORs of sexually violent behavior (>2 acts) and prosocial bystander behavior (any act) at endline (posttest 1 and 2 combined) versus baseline separately for the GlobalConsent and AHEAD groups. Among the GlobalConsent participants, the odds of perpetrating >2 acts of sexual violence at the endline were 1.3 times the odds at baseline. For the AHEAD group, the odds of perpetrating >2 acts of sexual violence at the endline were 2.7 times the odds at baseline. Among the GlobalConsent participants, the odds of any prosocial behavior at endline were 0.7 times the odds at baseline. For the AHEAD group, the odds of any prosocial behavior at posttest were 0.5 times the odds at baseline.

Discussion

Principal Findings

This randomized controlled trial recruited 793 university men in Vietnam to test the efficacy of GlobalConsent, a culturally tailored adaptation of an efficacious, theoretically grounded web-based sexual violence prevention program originally designed for US college men [23]. In this study, compared with men in the attention-control group, men in the GlobalConsent group had lower odds of engaging in sexually violent behavior at the endline than at the baseline. In addition, compared with men in the AHEAD group, men in the GlobalConsent group had higher odds of any prosocial bystander behavior at the endline than at baseline. The favorable impacts of GlobalConsent versus AHEAD were consistent across the measurement scales of these 2 behavioral outcomes. Such behavior changes are notable, as this is the first web-delivered sexual violence prevention program for cismale college students implemented in a middle-income setting. Most sexual violence prevention programs globally have measured changes in reported behavioral *intentions* rather than in reported *behavior* [49].

Study Limitations and Strengths

This study had some limitations. First, the study sites were limited to 2 urban universities to accommodate program adaptation, production, and testing. Therefore, the findings cannot be generalized to all university men in Vietnam. However, the 2 study universities represented public and private institutions of higher education, diverse faculties of study, and diverse student bodies from urban and provincial Vietnam. Second, behavioral outcomes were self-reported and may have been subject to social desirability bias. To mitigate this limitation, the team relied on a validated instrument to measure sexual violence and self-administration, which enhances privacy and may enhance honest disclosures. Third, we did not interview women on campus about changes in behavior, as reported by men, owing to resource constraints and the ethical and logistical challenges of linking women’s reports of men’s behavior at the individual level. Fourth, some nonsignificant differences in behavior and attenuation of behavior change at 12 months suggest the need for booster training after the 3-hour program period. Fifth, the 12-month follow-up period allowed for a short-term impact assessment of GlobalConsent. However, the follow-up period in this study exceeded that in most similar studies. Long-term follow-up of participants would be beneficial to assess the impact of GlobalConsent on behavioral outcomes throughout men’s time at university and beyond. Sixth, similar to other web-based interventions, the content of GlobalConsent may become outdated, and updating or future adaptations to GlobalConsent may incur new costs. To mitigate this limitation, the team adapted a program script and content to ensure maximum durability. Seventh, participants in the GlobalConsent group may have become unblinded to their treatment assignment. Although a possibility, having an attention-control condition in which adolescent-focused health content is provided should reduce the likelihood of unblinding because health-related content is provided in both arms, and participants were not informed about the specific theoretical knowledge-, attitudinal-, and empathy-related pathways by which the GlobalConsent programing was expected to operate. Finally, some loss to follow-up was observed in both study arms. However, in absolute terms and relative to similar intervention studies [20-23], attrition from our study was very low and similarly low for the treatment and control arms. In addition, the baseline characteristics of those who were lost to follow-up were similar across the treatment and control arms. These findings reduce concerns that men who were sexually violent after baseline attrited more often from the treatment group than the control group; however, this possibility cannot be ruled out. Finally, as the DID method focused on changes, it accommodated the baseline differences in both main outcomes between the 2 arms.

Recognizing these potential limitations, the strengths of this study were many. They included a randomized controlled design, customized attention-control condition, web-based delivery of GlobalConsent and attention-control programs to computers and smartphones, a large sample of participating university men, outstanding participation and retention, and refined measurement of primary behavioral outcomes and secondary (mediating) outcomes at 3 months and 9 months after intervention. Ours is among the few RCTs in the field, especially in LMICs, to assess impacts on 2 behaviors and to assess the impact on behavior at 2 time points after intervention.

Implications for Research and Public Health Practice

This study fills critical knowledge gaps on preventing sexual violence globally. In LMICs, interventions to prevent sexual violence in young men are rare [19]. This project adds to the limited evidence from LMICs on efficacious strategies to prevent sexual violence and promote prosocial bystander behaviors in university men. As GlobalConsent is an adaptation of RealConsent, this study adds to the limited evidence on the replication of efficacious sexual violence prevention interventions [50]. The review of bystander interventions by Mujal et al [20] identified 2 programs with evidence of replication; both were group-delivered and relied on presentations and discussions—techniques that can be resource- and cost-intensive. This study provides empirical support for the efficacy of a web-based edutainment approach for sexual violence prevention delivered to the computers and smartphones of students on college campuses, which may be more appealing and feasible in resource-constrained LMICs [51,52]. Finally, globally, most sexual violence prevention interventions have used in-person, small-group formats, with limited reach, standardization, and impact [50,53]. The web-based platform and GlobalConsent delivered to computers and smartphones make wide-scale implementation with higher fidelity more feasible than in-person programs. A large-scale implementation study of GlobalConsent in universities across Vietnam would be a robust next step to assess its effectiveness, and information about barriers and facilitators to university delivery of this intervention would be critical for moving GlobalConsent from research to practice.

This study reveals the value of using a systematic process to adapt evidence-based programs before they are delivered in new settings and populations. The process [36] used here allowed for the preservation of core content responsible for the efficacy of RealConsent and flexibility to add and to tailor other elements for university populations in Vietnam. Although the results here cannot confirm that GlobalConsent was an optimal adaptation to RealConsent, findings from the trial still suggest that following a systematic process to adapt an EBI may yield an adapted program that is efficacious cross culturally. This study demonstrates that GlobalConsent was able to reduce the risk of sexual violence and to promote prosocial bystander behavior in this LMIC. The potentially smaller effects of a web-based intervention are counterbalanced by GlobalConsent's highly standardized delivery relative to in-person, small-group formats; therefore, the consistent delivery and scalability of GlobalConsent to the national level is likely to be high. Research to adapt and test GlobalConsent in other LMICs is warranted.

Conclusions

Given the high rates of sexual violence against women, growing numbers of young men and women attaining postsecondary education, and rapid increases in access to the internet and smartphones globally, universities are ideal settings to provide novel sexual violence prevention programs during this critical developmental window, when young men are leaving home and are at increasing risk of sexually violent behavior. Evidence-based sexual violence prevention programs such as GlobalConsent, which are cost-effective, easily implemented by universities, and appealing to a diverse student population, are needed globally. Reviews of sexual violence prevention programs have described the importance of bystander approaches and engaging men as women's allies in preventing sexual violence. Equally important is the ability of such efficacious programs to reach large populations to expand their impact. This study demonstrates that theoretically grounded, web-based edutainment with gender-specific content, customized didactic and interactive behavior change techniques, and an adapted serial drama make GlobalConsent potentially scalable in Vietnam and adaptable to other LMICs, where efficacious sexual violence prevention programs are needed.

Acknowledgments

This study was supported by a grant from an anonymous charitable foundation. The authors would like to thank Dr Laura Salazar for consultation during proposal development and Ms Emma Jackson in the Hubert Department of Global Health, Rollins School of Public Health for assistance with the project implementation. The authors would also like to thank Dang Hong Linh, Nguyen Phuong Thao, and Le Thu Giang for their assistance to the Center for Creative Initiatives in Health and Population in project implementation. Finally, the authors would like to thank anonymous reviewers of prior versions of this paper and all study participants and volunteers without whom this project would not have been possible.

Abstract

Background: Three years since the onset of COVID-19, pandemic-related trends in child sexual abuse (CSA) remain poorly understood. Common administrative surveillance metrics may have underestimated abuse during the pandemic, given youths' limited access to mandatory reporters. Research using anonymous service-use data showed increased violence-related online help-seeking but overlooked youth-specific help-seeking for CSA during COVID-19. Understanding pandemic-related trends in CSA can inform abuse detection practices and mental health service provision for youth victims.

Objective: The purpose of this study was to harness anonymous help-seeking data from the National Sexual Assault Online Hotline (NSAOH) to glean insights about CSA occurrence in the United States during the COVID-19 pandemic.

Methods: We used an archival sample of victims who contacted NSAOH from 2016 to 2021 (n=41,561). We examined differences in the proportion of youth and adult victims contacting NSAOH during the first COVID-19 year (March 2020 to February 2021) compared to the prior year (March 2019 to February 2020; n=11,719). Further, we compared key characteristics of hotline interactions among youth victims during the first COVID-19 year to the prior year (n=5913). Using joinpoint regression analysis, we examined linear trends in the number of monthly sampled youth and adult victims (excluding victims of unknown age) from 2016 to 2021 who discussed any victimization event (n=26,904) and who discussed recent events (ie, events occurring during the pandemic; n=9932).

Results: Most youth victims were abused by family members prior to (1013/1677, 60.4%) and after (2658/3661, 72.6%) the onset of COVID-19. The number of youth victims contacting NSAOH spiked in March 2020 and peaked in November 2020 for all youth (slope=28.2, 95% CI 18.7-37.7) and those discussing recent events (slope=17.4, 95% CI 11.1-23.6). We observed a decline in youth victims into spring 2021 for all youth (slope=–56.9, 95% CI –91.4 to –22.3) and those discussing recent events (slope=–33.7, 95% 47.3 to -20.0). The number of adult victims discussing any victimization event increased steadily from January 2018 through May 2021 (slope=3.6; 95% CI 2.9-4.2) and then declined (slope=–13.8, 95% CI –22.8 to –4.7). Trends were stable for adults discussing recent events.

Conclusions: This study extends the use of hotline data to understand the implications of the pandemic on CSA. We observed increased youth help-seeking through the NSAOH coinciding with the onset of COVID-19. Trends persisted when limiting analyses to recent victimization events, suggesting increased help-seeking reflected increased CSA during COVID-19. These findings underscore the utility of anonymous online services for youth currently experiencing abuse. Further, the findings support calls for increased youth mental health services and efforts to incorporate online chat into youth-targeted services.

Introduction

As we approach a postpandemic world, understanding trends in child maltreatment during COVID-19 remains vital for informing practices to detect abuse and ameliorate the effects of trauma. Evidence of pandemic-related trends in child maltreatment is conflicting, resulting in part from limitations of traditional surveillance strategies. Apparent declines in child maltreatment reflected in emergency room visits [1] and official reports [2] may be attributed to avoidance of emergency rooms [3] and decreased access to mandatory reporters [4] during the pandemic. These shortcomings underscore the importance of examining child maltreatment during COVID-19 with consideration of youths' context and perspectives [5,6].

While youths' perspectives are often assessed through self-report survey methodologies, indicators of online help-seeking are potentially valuable. Prior to the pandemic, youth actively sought help for experiences of abuse via online and text-based hotlines [7,8], which they prefer over and perceive as more private than telephone-based hotlines [8,9]. Online services offer enhanced privacy, autonomy over disclosure, and easy and immediate support, which make them acceptable and accessible for youth experiencing crisis [10], especially during a pandemic.

Recent work has explored trends in violence-related online help-seeking during the pandemic. Google searches related to child maltreatment increased during the pandemic [11,12] but may not represent help-seeking by victims. Similarly, unsupervised learning of tweets revealed how family violence was discussed during the pandemic but could not delineate whether the source was victims, perpetrators, or organizations [13]. Online help-seeking via victim-centered resources, such as online hotlines (or helplines), offer an important complementary metric.

A study of multinational child helplines [14] lacked consensus as to the presence and direction of trends in violence-related contacts early in the pandemic but did not delineate phone-based from online- or text-based hotlines. Notably, outreach to ChildHelp increased for text-based but not phone-based contacts early in the pandemic [15]. While these studies demonstrated the promise of hotline data for understanding child maltreatment during the pandemic, their limited focus on overall hotline utilization conflated victim and nonvictim contacts. Research examining hotline use specific to youth victims during the pandemic is needed.

Amid these challenges, research on pandemic-related child maltreatment has largely overlooked child sexual abuse (CSA). However, concerns about victims' physical and social isolation and accessibility to perpetrators during stay-at-home orders [16] are particularly applicable to CSA [17]. To address this gap in understanding of pandemic-related trends in CSA, we examine archival data from the National Sexual Assault Online Hotline (NSAOH).

We advance knowledge by addressing limitations of previous work on 3 fronts. First, we examine online help-seeking for sexual violence among youth victims specifically. Second, we incorporate 5 years of observations (2016-2021), providing a broader picture of help-seeking patterns across the pre- and postpandemic onset time periods. Third, we delineate recent events to distinguish violence that occurred during the pandemic.

Methods

Data Collection

The NSAOH is a US-based online hotline providing 24/7 anonymous crisis intervention services via desktop and mobile internet chat. RAINN (Rape, Abuse & Incest National Network), an anti–sexual violence organization in the United States, created and has operated NSAOH since 2006 to serve victims of sexual violence.

Data collection via an in-depth online assessment (called the "session assessment") serves an integral role in hotline operations to identify areas for service improvement and staff training. Directly following the first chat session of their shift, staff record session information, such as event characteristics and topics discussed. Because information is not requested for the purpose of completing the assessment, data are often considered unknown (ie, missing). Staff receive instructions for assessment completion both within the assessment and through supplemental training.

Data in this study represent a sample of all hotline chats in which the visitor discussed an experience of sexual or other interpersonal violence (ie, victims) between January 2016 and December 2021 (N=41,561). Additional information about hotline procedures, the organizational context, and sample inclusion criteria are available in Multimedia Appendix 1.

Ethical Considerations

Data used in this study were originally collected as part of ongoing internal program evaluation; thus, informed consent was not required. Analysis of this archival data for the purposes of generating generalizable knowledge of online hotline users and sexual violence experiences was deemed exempt by the Advarra institutional review board under category 4 of the Revised Common Rule.

Statistical Analysis

We examined differences in the proportion of youth (ie, those younger than 18 years) and adult (aged 18 years and older) victims during the first COVID-19 year (March 2020 through February 2021) compared to the year prior (March 2019 through February 2020; n=11,719), with victims of unknown age excluded (5178/16,897, 31%). Among youth (n=5913), we compared perpetrator type (family vs nonfamily), perpetrator living status (currently living with vs not currently living with the victim), event timeframe (whether the event occurred within the last month, 1 month to 1 year ago, or over 1 year ago), and event frequency (repeated abuse vs single occurrence) during the first COVID-19 year compared to the year prior. These analyses used the chi-squared test with pairwise exclusion of missing data; analyses used SPSS (version 28.0; IBM Corp).

To contextualize trends in youth help-seeking, we used Joinpoint (version 4.9.1.0; National Cancer Institute) to examine linear trends in the number of monthly sampled victims by age group from 2016 to 2021 among all youth and adult victims (n=26,904; Multimedia Appendix 1 provides additional information about joinpoint analyses). Cases of unknown age were excluded (n=14,657; 22.7%-50.3% missingness per month). We repeated this analysis among youth and adult victims known to have discussed recent events that occurred within a month of contacting the hotline (n=9932). We also graphed the proportion of monthly sampled youth victims by year among all victims and those discussing recent events. Data were analyzed in spring 2022.

Results

Sample Characteristics

We observed a significant increase in the proportion of youth victims during the first COVID-19 year relative to the year prior (1871/4560, 41% vs 4042/7159, 56.5%). Among youth, we noted statistically significant but small shifts in the proportion of chats that involved family-perpetrated assaults (1013/1677, 60.4% vs 2658/3661, 72.6%), perpetrators currently living with the victim (1028/1733, 59.3% vs 2815/3841, 73.3%), recent assaults (ie, within the last month; 1017/1313, 77.5% vs 2381/2774, 85.8%), and repeated assaults (1397/1764, 79.2% vs 3250/3773, 86.1%). Table 1 shows full sample characteristics and missingness, as well as characteristics and comparisons using pairwise deletion.

Table 1. Comparison of victim and event characteristics in the pre-COVID year (March 1, 2019-February 29, 2020) and the COVID year (March 1, 2020-February 28, 2021). Information about response option coding for table categories is available in Multimedia Appendix 1.

[a] Chi-square comparisons; unknown (“missing”) data were excluded in these comparisons.

[b] N/A: not applicable.

[b] “Currently” means at the time of contacting the hotline.

Joinpoint Regression Analysis

Inflection points reveal variability in the strength or direction (or both) of trends in the number of victims by age in our sample (Figure 1). Prior to 2019, the number of youth victims fluctuated. In the year prior to COVID onset, the number of all youth victims and those discussing recent events increased by an average of 11.2 (95% CI 7.9-14.5) and 6.6 (95% CI 4.8, 8.3) per month, respectively. The most striking trend commenced in March 2020 at the onset of the pandemic: there were average monthly increases of 28.2 (95% CI 18.7-37.7) and 17.4 (95% CI 11.1-23.6) for all youth victims and youth discussing recent events, respectively. Both the number and proportion of youth victims peaked in November 2020. Subsequently, youth victims declined into early spring 2021, both overall (slope=–56.9; 95% CI –91.4 to –22.3) and for recent events (slope=–33.7; 95% CI –47.3 to –20.0). We observed an increase in all adult victims starting in January 2018 (slope=3.6; 95% CI 2.9-4.2), but this trend was consistent through May 2021, after which adult victims declined into December 2021 (slope=–13.8, 95% CI –22.8 to –4.7). The number of adult victims discussing recent events was largely consistent from 2016 to 2021.

Figure 1. Linear trends in National Sexual Assault Online Hotline use among youth. Analyses were limited to hotline visitors who identified as victims, with the sample reflecting the first chat of a staff member's shift. Panels A and C display all events, whereas panels B and D reflect chats discussing recent events (ie, occurring within the last month). Data are from January 2016 to December 2021 and were analyzed using Joinpoint (version 4.9.1.0; National Cancer Institute). WHO: World Health Organization.

Discussion

Principal Findings

This study is the first, to our knowledge, to reveal increases in youth help-seeking for sexual violence coinciding with the onset of COVID-19. These increases peaked in November 2020 and were present for all youth victims and for youth victims discussing recent events. Although the number of adult victims increased, this trend was more gradual, preceded the onset of COVID-19, and was not present for those discussing recent events. Our finding that trends were sustained for recent events suggests an increase in youth affected by sexual violence during the pandemic rather than increased help-seeking among all victims for current and past events due to limited alternative support options.

While our findings seemingly conflict with declines in abuse-related hospital visits and official reports [1,2], evidence of pandemic-related trends in child maltreatment must be interpreted in light of the pandemic context [6]. Stay-at-home orders limited youths' access to formal services and mandated reporters, but online hotlines remained accessible to youth victims seeking help. Other studies used overall hotline utilization data to estimate pandemic-related child maltreatment [14,15] but conflated help-seeking among youth victims with that of adult victims and other hotline users (eg, supporters, general information seekers, or prank visitors) whose hotline use may have been differentially impacted by COVID-19. We also examined help-seeking for recent victimization, strengthening inferences that increased hotline contacts reflected help-seeking for violence experienced during the pandemic rather than past victimization. These procedures provide a model for how anonymous online hotline data can be used as a surveillance indicator for child maltreatment.

Most youth who contacted the NSAOH—both prior to and during the pandemic—discussed repeated experiences of violence perpetrated by family members or someone else living with them. During the pandemic, we observed small proportional increases in youths' chats that featured these characteristics, consistent with elevated violence driven by victims' increased accessibility to perpetrators in the home amid limited contact with trusted adults (eg, teachers). Future work should examine to what extent increased youth help-seeking reflected increased frequency and severity of ongoing violence predating the pandemic or cases of violence that began during the pandemic.

The number of chats from youth began to decrease after November 2020. This decline could relate to youth having a greater ability to avoid perpetrators or opportunities to disclose to alternative sources of support as schools reopened in the summer and fall of 2020. However, because reopening policies were variable across the United States, driven by state and local government, this trend should be interpreted with caution.

While reported trends were transitory, the effects of sexual abuse are not. Our findings reflect increased help-seeking by youth during the pandemic, an indication of rising demand for mental health services to treat trauma and its sequelae among youth. Given the national shortage of child mental health providers that predates COVID-19 [18], there is a pressing need to expand youth services to address the complex trauma resulting from CSA and other effects of COVID-19 [4].

Limitations

Joinpoint regression analysis allowed us to identify changes in the linear trend of victims' hotline use from 2016 to 2021. While we interpreted the reason for some of these changes, their causes cannot be definitively ascertained from our analysis. We could not differentiate repeat hotline users from new users, which would help delineate new cases of abuse. Our data collection protocol prioritized the delivery of victim-centered services. We did not solicit information from visitors for assessment purposes, resulting in some missing data and limited demographic information. Future work could incorporate anonymous collection of demographics prior to service provision to enhance the utility of hotline data as a surveillance indicator of child maltreatment. Understanding the interplay of hotline supply and demand will also be useful because changes in staff availability (ie, supply) could affect the accessibility and use of services.

Conclusions

Our study demonstrates the utility of anonymous online hotline data as a complementary surveillance indicator for child maltreatment that is transferrable to other public health priority areas (eg, mental health). Increased help-seeking amid decreased safety at home also speaks to the utility of online support options for youth experiencing abuse. Preparing for future public health emergencies necessitates consideration of additional online communication options that allow youth to privately disclose abuse to trusted adults. Future work should explore how to safely incorporate these communication options into existing services, such as online schooling or telemedicine platforms.

Abstract

Background: Suicide by firearms is a serious public health issue in the United States. However, little research has been conducted on the relationship between cultural backgrounds and suicide by firearms, specifically in those born and raised in the United States compared to those who have immigrated to the United States.

Objective: To better understand the relationship between cultural backgrounds and suicide, this study aimed to examine firearm suicide rates among US- and foreign-born suicide decedents based on the firearm possession rate in the decedent’s home country.

Methods: Multivariate logistic regression was performed to analyze data of 28,895 suicide decedents from 37 states obtained from the 2017 National Violent Death Reporting System data set. The firearm possession rate in the home countries of foreign-born suicide decedents was obtained from the 2017 Small Arms Survey.

Results: The firearm suicide rate was about twice as high among US-born suicide decedents compared to their foreign-born counterparts. Meanwhile, suicide by hanging was about 75% higher among foreign-born compared to US-born suicide decedents. Those from countries with a low-to-medium firearm possession rate were significantly less likely to use firearms compared to US-born suicide decedents (adjusted odds ratio [AOR]=0.45, 95% CI 0.31-0.65, and AOR=0.46, 95% CI 0.39-0.53, respectively). Meanwhile, firearm suicide rates were not different between US- and foreign-born suicide decedents from countries with a similarly high firearm possession rate.

Conclusions: The results suggest that there is an association between using firearms as a means of suicide and the firearm possession rate in the decedent’s home country. Suicide by firearms in the United States needs to be understood in the sociocultural context related to firearm possession.

KEYWORDS

firearm suicide; US born; foreign born; means of suicide; firearm possession rate; suicide decedents

Introduction

Currently, suicide by firearms is a serious public health issue in the United States. According to the annual mortality statistics of the Centers for Disease Control and Prevention (CDC) [1], about 100 people die by suicide every day in the United States, with around 50% of them using firearms, 28.6% using poison, and 12.9% using hanging as a means of suicide. Firearm suicide rates in the United States have steadily increased over the past few years [2,3]. The firearm possession rate is defined as an estimate of civilian firearms per 100 individuals in a country [4]. States, regions, and countries with higher firearm possession rates are associated with higher firearm suicide rates [5]. According to Miller et al [6] and Stack [7], firearm possession rates are positively correlated with firearm suicide rates in the United States. In fact, the most common means of suicide in the United States is death by firearms. Other countries with high firearm possession rates, such as Uruguay and Montenegro, have also reported high of suicide by firearms [4,8]. Meanwhile, in countries that do not have high firearm possession rates, such as Asian or Nordic countries, poisoning by pesticides is the most common means of suicide. Similarly, suicide by hanging is the most common means of suicide in Eastern Europe [9]. One evidence-based suicide prevention strategy is to reduce the social acceptance and availability of lethal means for those at risk of suicide [10,11]. Investigating the context around suicide, such as accessibility to specific means, can provide important information when devising suicide prevention interventions [12]. This is because restricting the means of suicide is known to be effective in preventing suicides [13,14].

According to Wong et al [15], the social acceptance and availability of the means of suicide are associated with which means of suicide are more likely to be chosen. In this study, *social acceptance* refers to the cultural beliefs surrounding firearms, familiarity with firearms, the normality of firearm possession, and the role that firearms play in daily life. These factors may influence an individual’s own perceptions about firearms and increase or decrease the likelihood of their owning their own personal firearm [16]. Meanwhile, *availability* in this study is defined as the widespread availability of and accessibility to firearms. Using firearms as the most common means of suicide is associated with the high household firearm possession rate in the United States [17]. However, compared to the volume of research on the availability of firearms and firearm suicide rates, little research has been conducted to understand the relationship between the social acceptance of firearms and firearm suicide rates. The United States is a nation made up of immigrants from many diverse countries. Because of this, it is important to be cognizant of different demographics and their relationships and associations with firearms and, as a result, the likelihood to die by firearm suicide. According to Liu et al [18], US-born individuals have a significantly higher firearm suicide rate, while foreign-born individuals have a significantly higher rate of suicide by hanging, suffocation, jumping from heights, and sharp instruments. Moreover, it is suggested that immigrants are influenced by the culture surrounding firearms in their home countries [19]. Assuming that there is an association between the cultural familiarity with and social acceptance of firearms and the probability of an individual using a firearm as a means of suicide, this cultural distinction may be important in analyzing the difference between US- and foreign-born suicide decedents. Therefore, in this research, we compiled information about firearm possession rates in the home countries of immigrant populations in order to analyze the relationship between firearm familiarity and suicide behaviors of choosing a means of suicide. Despite the critical importance of identifying factors that may impact suicidal behaviors, to the best of our knowledge, little research has been conducted on the firearm possession rate by home country to understand the relationship between cultural/ethnic backgrounds and the means of suicide. Thus, our study aimed to better understand the cultural differences around firearms and how these may impact the likelihood of an individual dying by firearm suicide.

With the goal to determine the relationship between cultural familiarity and the means of suicide, we compared the means of suicide between US- and foreign-born suicide decedents. Focusing on suicides by firearms, in particular, we divided foreign-born individuals by the firearm possession rate in their home countries and compared them with US-born suicide decedents in order to understand the connection between the gun culture of the home country and the familiarity with firearms as a means of suicide. Our findings can serve as baseline data for devising suicide prevention strategies that focus on the restriction of access to various means of suicide, consider sociocultural backgrounds related to specific means, and customize the strategies to the sociocultural backgrounds of target groups.

Methods

Study Design

The National Violent Death Reporting System (NVDRS) is a state-based active surveillance system that provides a detailed account of violent deaths that occur in participating states. The NVDRS provides abundant data on the details of violent deaths in the United States, and it is the first national system to collect comprehensive information about suicides [20]. Moreover, the NVDRS is the nation’s only reporting system for complex events, such as homicide-suicide and mass killings, and offers far richer information about all other violent deaths compared to other data sources [21]. With support from the CDC, the system collects data from multiple sources, including death certificates, police reports, medical examiner/coroner reports, and, sometimes, crime lab information [22].

This study used restricted data of decedents provided by the 2017 NVDRS and examined only deaths resulting from suicide. In 2017, 37 states (Alaska, Arizona, California, Colorado, Connecticut, Delaware, District of Columbia, Georgia, Illinois, Indiana, Iowa, Kansas, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, Nevada, New Hampshire, New Jersey, New Mexico, New York, North Carolina, Ohio, Oklahoma, Oregon, Pennsylvania, Puerto Rico, Rhode Island, South Carolina, Utah, Vermont, Virginia, Washington, West Virginia, and Wisconsin) contributed data to the NVDRS. The 2017 NVDRS data include decedents who died from violent deaths in 2017. Specifically, the data include 33,257 individuals who died by suicide; data on the means of suicide and the home country are missing for 4362 (13.1%) decedents. Our final sample consisted of 28,895 decedents after removing individuals with missing data. So, this study used complete case analysis (CCA) to deal with missing values.

Measurements

The means of suicide were used as the outcome variable in this study. In the NVDRS data, the means of suicide include firearms, hanging or suffocation, poisoning, jumping from a height, sharp instruments, drowning, and other. However, this study used firearms, hanging or suffocation, and poisoning as the main outcome variables. Nativity, the independent variable, was divided into US- and foreign-born suicide decedents. People born in the United States, Puerto Rico, and a US Island Area (Guam, the Commonwealth of the Northern Mariana Islands, or the US Virgin Islands) were defined as US born, and those born outside the United States were defined as foreign born [23].

The firearm possession rate by home country was obtained from the estimate of civilian firearms per 100 individuals per country provided by the 2017 Small Arms Survey (SAS) [4]. The SAS is an independent research project located at the Graduate Institute of International and Development Studies in Geneva, Switzerland. The SAS uses data from various sources, such as official documents, studies, questionnaires, public opinion surveys, news reports, and expert correspondence, to estimate civilian firearm ownership. It systematically integrates these data to generate total estimates for each country, while excluding extreme high and low numbers as outliers, when feasible. This data set is used because it provides information about firearm possession rates for most countries. We matched the information about firearm possession rates to the home countries of the foreign-born individuals. A country with a firearm possession rate of <1 SD from the mean value was coded as "low," of >1 SD from the mean value was coded as "high," and of 1 SD from the mean value was coded as "medium." Sociodemographic variables included race, age, gender, region, education, and marital status.

Ethical Considerations

This study was exempt from human subject research ethics by the Institutional Review Board of Yonsei University (7001988-202010-HR-1013-01E) due to secondary analysis of research data. The data were derived from routine injury mortality surveillance. The NVDRS is incident based and links all victims and alleged perpetrators (suspects) associated with a given incident in 1 record. To fully characterize incidents, states collect information about deaths from numerous data sources. These sources include death certificates, coroner/medical examiner reports, and law enforcement reports [22].

Statistical Analysis

A descriptive analysis was conducted on the general characteristics of suicide decedents. Rates per 100,000 people (by nativity, race, sex, and age group) were calculated using the census data of the 2017 American Community Survey. Logistic regression was performed to analyze the association between nativity and the means of suicide. The independent variables of this study were nativity (US born/foreign born) and the firearm possession rate in the home country. The dependent variable was the choice of a means of suicide (firearm, hanging, and poisoning). Other means of suicide were excluded from the logistic analysis in order to explain the 3 major means of suicide.

First, logistic regression was performed to compare the correlation between sociodemographic variables and the means of suicide. Second, we analyzed the association between nativity and the means of suicide after adjusting for gender, age, place of residence, education, and marital status. Next, we analyzed the association between the firearm possession rate in the home country and the means of suicide. We used the US-born suicide decedents as a reference group for the 2 independent variables and examined how the choice of a means of suicide for the 2 independent variables is different compared to the US-born suicide decedents. The adjusted odds ratio (AOR) and 95% CI were presented, and statistical significance at the α level of .05 was indicated by 95% CIs that did not include 1. All analyses were performed using STATA, version 13.

Results

Demographic Characteristics of Suicide Decedents

Tables 1 and 2 show the demographic characteristics of suicide decedents in 37 states presented by the 2017 NVDRS. Of the total 28,895 deaths by suicide, the firearm suicide rate was 5.9 per 100,000 people, the hanging suicide rate was 3.7 per 100,000 people, the poisoning suicide rate was 1.6 per 100,000 people, and the rate of suicide by other means was 1.0 per 100,000 people. Firearm suicide rates were higher than hanging and poisoning suicide rates among US-born, White, Black, male, and 18-year-old or older decedents. The hanging suicide rates were higher compared to firearm and poisoning suicide rates among were foreign born; belonged to Hispanic, Asian/Pacific Islander, or other ethnic groups; and were less than 18 years old. The poisoning suicide rates were slightly higher than firearm and hanging suicide rates among women.

Table 1. Demographics of suicide decedents by means of suicide: 2017 NVDRS[a].

Characteristics	Decedents (N=28,895), n (%)	Firearms (n=14,041, 48.6%), n (%)	Hanging (n=8679, 30.0%), n (%)	Poisoning (n=3900, 13.5%), n (%)	Other[b] (n=2275, 7.9%), n (%)

[a] NVDRS: National Violent Death Reporting System.

[b] "Other" includes jumping from heights, sharp instruments, drowning, and other means.

First, we examined the correlation between demographic variables and the choice of a means of suicide. The results are presented in Tables 3-5. Compared to Whites, Blacks were more likely to use firearms but less likely to use hanging or poisoning as a means of suicide. Compared to Whites, Hispanic, Asian/Pacific Islander, and other ethnic minorities were more likely to use hanging or poisoning and less likely to select firearms as a means of suicide. Older people were more likely to select firearms or poisoning and less likely to choose hanging as a means of suicide. Compared to men, women selected poisoning more than firearms. Urban dwellers were less likely to choose firearms and more likely to use hanging or poisoning. The higher the education level, the fewer the number of suicides by hanging and the more the number of suicides by poisoning. Those with spouses used firearms but not as much as poisoning as a means of suicide.

Next, we tested the association between nativity and the means of suicide after adjusting for demographic variables. The results are shown in Tables 3-5 and Figure 1. We compared the choice of a means of suicide between US- and foreign-born suicide decedents. Compared to US-born suicide decedents, their foreign-born counterparts were less likely to use firearms and more likely to select hanging as a means of suicide. Next, we compared the means of suicide between US- and foreign-born suicide decedents based on the firearm possession rate in the home countries of the latter. People who immigrated from countries with a low firearm possession rate selected firearms more than they did hanging as a means of suicide compared to US-born suicide decedents. People who were from countries with a medium firearm possession rate chose firearms less than they did hanging as a means of suicide compared to US-born suicide decedents. However, the difference between foreign-born suicide decedents from countries with a high firearm possession rate and their US-born counterparts was not statistically significant.

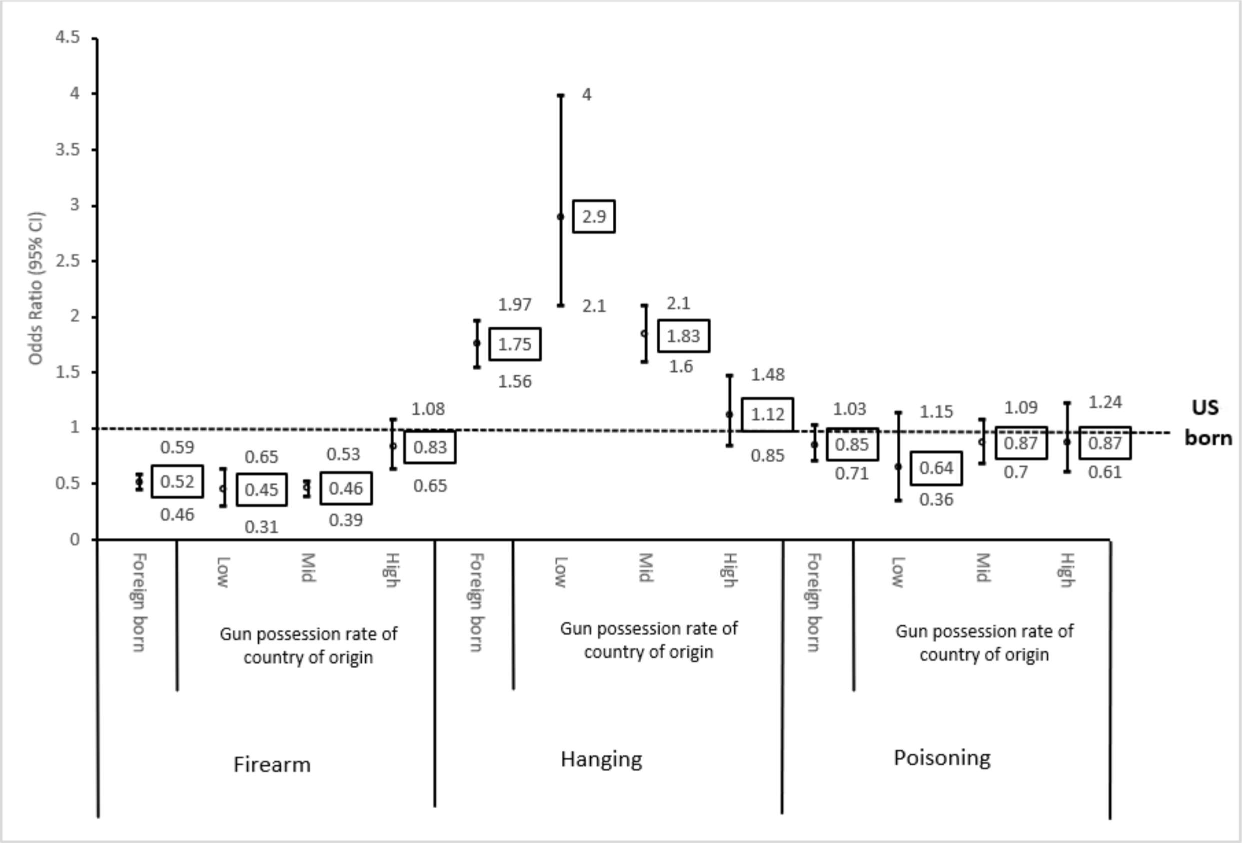
Figure 1. Means of suicide among suicide decedents from the United States and other countries with different levels of the firearm possession rate: 2017 National Violent Death Reporting System.



Discussion

Principal Findings

This research examined the data of 28,895 suicide decedents from 37 states included in the 2017 NVDRS with the goal of comparing the means of suicide between US- and foreign-born American suicide decedents and analyzing whether these differences could be explained by the culture surrounding firearms in their home countries, specifically firearm possession rates that illustrate a cultural familiarity with firearms. We found statistically significant differences in the means of suicide between US- and foreign-born individuals. The firearm suicide rate was about twice as high among US-born suicide decedents compared to their foreign-born counterparts in 2017, while the hanging suicide rate was about 75% higher among foreign-born suicide decedents compared to their US-born counterparts. We divided the home countries of the foreign-born suicide decedents into 3 groups by their firearm possession rate (low, medium, and high) and compared their means of suicide with those of the US-born suicide decedents. Those from countries with low and medium firearm possession rates were significantly less likely to use firearms compared to the US-born suicide decedents (AOR=0.45, 95% CI 0.31-0.65, and AOR=0.46, 95% CI 0.39-0.53, respectively). However, there was no statistical difference in the use of firearms between foreign-born suicide decedents from countries with a high firearm possession rate and their US-born counterparts. Foreign-born individuals from countries with a low or medium firearm possession rate were significantly more likely to use hanging compared to a firearm (AOR=2.90, 95% CI2.10-4.00, and AOR=1.83, 95% CI 1.60-2.10, respectively). In the case of suicide by poisoning, there was no statistical difference between US-born and all foreign-born suicide decedents. Compared to US-born individuals, immigrants from countries with a high firearm possession rate had no significant difference in firearm suicide rates and immigrants from countries with a low firearm possession rate had a significantly lower firearm suicide rate.

The findings of this research are in line with those of Liu et al [18], who found that US-born suicide decedents have a greater firearm suicide rate and a lower hanging suicide rate compared to their foreign-born counterparts and that there is no significant difference in the poisoning suicide rate between US- and foreign-born Americans. Furthermore, our results were confirmed by Wong et al [15], who found that US-born individuals have a significantly greater firearm suicide rate, a lower hanging suicide rate, and no significant difference in the poisoning suicide rate compared to foreign-born Asian/Pacific Islander Americans. In addition, this research compared cultural differences regarding firearms for the various home countries of immigrants residing in the United States who died by suicide. This confirms that there is an association between the firearm possession rate in the home country and the prevalence of various means of suicide. Furthermore, sociocultural familiarity with firearms is associated with a greater likelihood to die by firearm suicide [15]. Those born in a country with a high firearm possession rate are more likely to be exposed to and familiar with firearms, becoming more accepting of guns as a means of suicide, compared to those born in a country with a low firearm possession rate. This argument is supported by a number of studies: Conner et al [24] concluded that the means of suicide is influenced by the culture and gun policy of the home country, Kaplan and Geling [25] described the cultural origin of firearm suicide, Price et al [26] argued that firearm suicide is related to the gun laws of the country where an individual lives, Miller et al [27] supported that both firearm suicide and total suicide rates are associated with state and regional gun prevalence, and Saunders et al [19] suggested that immigrants are influenced by the firearm possession culture of their home country.

Considering that cultural perceptions of firearms can make certain means of suicide appear more manageable [28], it is understood that firearms are most commonly used for suicide in the United States because of their availability [29]. In contrast, hanging is the most common means of suicide in several Asian countries, including Japan, South Korea, and the Philippines [17]. In addition, this research found that the rate of suicide by hanging is high among immigrants from countries with a low firearm possession rate compared to US firearm possession rates.

It is necessary to devise suicide prevention strategies that focus on restricting access to dangerous items for at-risk individuals and that also consider the sociocultural implications of this topic. This is important as certain cultural backgrounds may be more sensitive to the exposure of the means of suicide. Suicide prevention efforts targeting war veterans include the establishment of suicide prevention campaigns and laws, such as the Joshua Omvig Veterans Suicide Prevention Act. In addition, the Veterans Agency and the Department of Defense provide free gun-safe storage to veterans at risk of dying by firearm suicide [30]. This measure is expected to be beneficial, given prior research that has proven the efficacy of proper gun safety and storage in reducing suicides among veterans [31]. Furthermore, it is imperative that suicide prevention campaigns be customized to best fit the needs of various sociocultural backgrounds. The World Health Organization’s National Strategy of Suicide Prevention notes the importance of restricting access to the means of suicide but fails to consider the way in which gun violence disproportionately affects certain sociocultural and ethnic backgrounds. There should be further research on this intersection between suicide rates and various sociocultural and ethnic groups in order to develop more effective suicide prevention campaigns. Wong et al [15] suggest that given the prevalence of suicide by firearms among the US-born population and suicide by hanging among immigrants, public health professionals should advise individuals with suicidal thoughts to remove potentially dangerous items from their environments. Based on our results, there seems to be an association between the culture surrounding firearms that an individual grew up in and the likelihood of them choosing suicide by firearms as opposed to other means. Therefore, public health professionals may need to follow culturally sensitive approaches to establish suicide prevention policies and strategies by reflecting on the cultural backgrounds of the population. In addition, when devising gun safety campaigns, states with high proportions of foreign-born individuals should consider their cultural backgrounds. Foreign-born individuals from countries with high firearm possession rates and US-born individuals are priority populations. In the case of both US- and foreign-born individuals from cultures highly familiar with firearms at risk of suicide, reducing access to lethal means is an evidence-based suicide prevention initiative [10,11]. Ideally, firearm accessibility should be limited in the United States to suppress the innate and widespread culture of firearm possession that has arisen in the country and has led to increased gun violence throughout the country. To alleviate this, federal gun policies must be enforced to reduce gun violence in the United States, including suicide by firearms. Such policies could include banning guns in public spaces, requiring a stricter process prior to buying a gun, banning high-capacity magazines and assault rifles, enforcing that all gun owners must store their guns in an approved gun storage unit, and requiring gun safety courses for everyone who wishes to own a gun. These measures will evidently reduce gun violence and particularly suicide by firearms [22]. The study is meaningful because it shows empirical results that the cultural background is related to suicide by firearms. Although the causal relationship is limited, the significant correlation means that cultural perspectives must be considered in planning firearm suicide prevention policies and interventions in a multicultural society, such as the United States.

Limitations

There are several limitations of this research. First, the NVDRS data used in this study had 13% missing values due to difficulties in obtaining some sensitive information about suicide decedents. To deal with the missing values, this study used CCA. This is because compared to multiple imputation, CCA has been reported to provide unbiased estimates in cases where the missing percentage is less than 20%, and this missing percentage refers to missing completed at random (MCAR) or missing completed random (MAR) [32]. Second, this research was premised around the cultural attitudes of firearms of the home countries of various immigrant suicide decedents. However, when analyzing these decedents, other crucial demographic factors were not considered regarding their culture. Because of this, other exogenous factors, such as the length of exposure to the original culture, the maintenance of the original culture after immigration to the United States, and the length of exposure to US culture, will need to be considered in future research. Third, we were unable to examine the physical availability of or accessibility to firearms at the regional level in the United States due to a lack of relevant data, such as the firearm possession rate at the state level. Fourth, the findings of this research cannot be generalized to the entire country, because the 2017 NVDRS, which contains the most recent scientific data that include detailed information about suicide, obtained data from only 37 states. Fifth, the foreign-born suicide decedents in this research include immigrants with diverse citizenship/residency statuses, including permanent residents, temporary workers, students, visitors, and illegal immigrants. This indicates that their use of a means of suicide may have been impacted by other extenuating factors, such as practical barriers to purchasing guns, rather than cultural familiarity. Sixth, this cross-national comparative study did not consider state-specific differences in the United States, because national-level data were analyzed. Further studies on suicide by firearms in the United States will benefit from considering state-specific gun policies or contexts. Lastly, there was a lack of data on statistics that internationally compare suicide trends by country with regard to US- and foreign-born residents of the country and their suicide rates. This study used the firearm possession rates in the home countries of suicide decedents to indirectly identify potential associations. If such statistics exist and are used in future studies, more direct and robust implications can be drawn.

Conclusion

Despite limitations, this research has contributed to expanding our understanding of how cultural influences affect higher firearm suicide rates in the United States. Our research shows that nativity is related to firearm suicide rates. Those from countries with high firearm possession rates show a similar propensity for firearm suicide as US-born Americans. The firearm suicide rate is significantly lower among immigrants from countries with a low firearm possession rate. Based on these findings, it is arguable that the high prevalence of firearm possession in the United States contributes to the country's high firearm suicide rate by promoting public familiarity toward firearms. Consequentially, US-born individuals are desensitized to gun violence, including suicide by firearms. This is based on the finding that foreign-born individuals from countries with low firearm possession rates have a lower tendency to use firearms to die by suicide compared to US-born individuals. However, immigrants from countries with high firearm possession rates are more likely to die by firearm suicide, which supports the association between cultural norms surrounding firearms and the likelihood of dying by firearm suicide [24]. This study has furthered our understanding of the cultural background that contributes to the process by which individuals choose their means of suicide. We hope that this research will contribute to an effective reduction in firearm suicide in the United States as well as improve suicide prevention efforts throughout the country.

Abstract

Background: Monitoring workplace violence (WPV) against health care workers (HCWs) through incident reporting is crucial to drive prevention, but the actual implementation is spotty and experiences underreporting.

Objective: This study aims to introduce a systematic WPV surveillance in 2 public referral hospitals in Italy and assess underreporting, WPV annual rates, and attributes “before” (2016-2020) and “after” its implementation (November 2021 to 2022).

Methods: During 2016-2020, incident reporting was based on procedures and data collection forms that were neither standardized between hospitals nor specific for aggressions. We planned and implemented a standardized WPV surveillance based on (1) an incident report form for immediate and systematic event notification, adopting international standards for violence definitions; (2) second-level root cause analysis with a dedicated psychologist, assessing violence determinants and impacts and offering psychological counseling; (3) a web-based platform for centralized data collection; and (4) periodic training for workforce coordinators and newly hired workers. We used data from incident reports to estimate underreporting, defined as an observed-to-expected (from literature and the “before” period) WPV ratio less than 1, and the 12-month WPV rates (per 100 HCWs) in the “before” and “after” periods. During the latter period, we separately estimated WPV rates for first and recurrent events.

Results: In the “before” period, the yearly observed-to-expected ratios were consistently below 1 and as low as 0.27, suggesting substantial violence underreporting of up to 73%. WPV annual rates declined in 1 hospital (from 1.92 in 2016 to 0.57 in 2020) and rose in the other (from 0.52 to 1.0), with the divergence being attributable to trends in underreporting. Available data were poorly informative to identify at-risk HCW subgroups. In the “after” period, the observed-to-expected ratio rose to 1.14 compared to literature and 1.91 compared to the “before” period, consistently in both hospitals. The 12-month WPV rate was 2.08 (95% CI 1.79-2.42; 1.52 and 2.35 in the 2 hospitals); one-fifth (0.41/2.08, 19.7%) was due to recurrences. Among HCWs, the youngest group (3.79; *P*<.001), nurses (3.19; *P*<.001), and male HCWs (2.62; *P*=.008) reported the highest rates. Emergency departments and psychiatric wards were the 2 areas at increased risk. Physical assaults were more likely in male than female HWCs (45/67, 67.2% vs 62/130, 47.7%; *P*=.01), but the latter experienced more mental health consequences (46/130, 35.4% vs 13/67, 19.4%; *P*=.02). Overall, 40.8% (53/130) of female HWCs recognized sociocultural (eg, linguistic or cultural) barriers as contributing factors for the aggression, and 30.8% (40/130) of WPV against female HCWs involved visitors as perpetrators.

Conclusions: A systematic WPV surveillance reduced underreporting. The identification of high-risk workers and characterization of violence patterns and attributes can better inform priorities and contents of preventive policies. Our evaluation provides useful information for the large-scale implementation of standardized WPV-monitoring programs.

Introduction

In 2019, the International Labour Organization (ILO) adopted the Violence and Harassment Convention to “promote and realize the right of everyone to a world of work free from violence and harassment” ([1], art 4). The European Foundation for the Improvement of Living and Working Conditions identifies the health and social work sector as the one with the highest prevalence of adverse social behaviors at work in Europe [2]. The official statistics from the Italian Workers Compensations Authority (INAIL) reported a mean of 2500 workplace violence (WPV) cases per year determining a work injury among health care workers (HCWs) over the 2016-2020 period; of these, 75% were directed toward women [3]. Due to the high prevalence and the consequences on the affected HCWs, WPV against HCW is a public health concern [4,5]. A meta-analysis of the studies published up to 2018—including mostly cross-sectional surveys—estimated for Europe a 12-month prevalence of exposure to nonphysical and physical WPV at 36.6% and 20.1%, respectively [4], with a high degree of heterogeneity across studies. These figures did not decline after the SARS-CoV-2 outbreak [5], exacerbating the impact of the pandemic on the mental health of HCWs [6]. In a more recent systematic review of Italian surveys, the 12-month prevalence of WPV ranged between 11.9% and 93.3% and between 27.5% and 50.3% for verbal and physical violence, respectively [7]. Such a large amount of heterogeneity reflects several methodological concerns, and it challenges the interpretation of results and their usability to guide preventive strategies [8]. First, most studies have been conducted on selected, high-risk wards and thus are poorly representative of the entire population. Second, the negative correlation between survey participation rate and reported violence prevalence [7] suggests the presence of self-selection bias. Finally, the retrospective evaluation of violence and the lack of a clear standardized definition of violence increase the risk of recall bias and measurement error [4,5,7,8].

Complementary to retrospective survey data, active monitoring and surveillance based upon systematic incident reporting is important not only to provide estimates of violence rates but also to investigate the circumstances in which WPV occurs, to identify violence determinants and attributes, and to quantify violence consequences on the assaulted workers [8-10]. Of note, these may also vary according to the assaulted HCW: for instance, evidence from Italy suggests the presence of sex-specific patterns in violence [11]. All this information is crucial to better inform prevention and mitigation strategies by health care organizations [8-11]. However, the implementation of such systems is still scanty and spotty [10]: to the best of our knowledge, standardized and regulatory-based violence monitoring programs implemented at a comprehensive regional- or state-level are present only in Australia [9] and in California [12,13]. The Lombardia Region—the most populated region in Italy with about 10 million inhabitants, located in the north of the country—published in 2019 new guidelines for WPV reporting, risk assessment, and management for regional public and private hospitals, to overcome the recognized WPV underreporting in ongoing registration systems [14]. Stemming from such document, our research group designed the study “Determinants of Violence against the Health care Workers” (*Determinanti Violenze Operatori Sanitari* [DeVOS]) to develop and implement a guideline-based incident report protocol for systematic WPV risk monitoring and management. With this paper, we aim to assess data completeness, WPV underreporting, and rates “before-and-after” the implementation of the new standard in 2 public hospitals (about 9000 employees) in the region. In addition, we report on violence attributes, contributing factors, and consequences and assess the presence of sex-specific patterns in these violence characteristics.

Methods

The DeVOS Study

The DeVOS study started in June 2020 in the only 2 publicly funded, referral hospitals (Azienda Socio-Sanitaria Territoriale [ASST]) serving the provinces of Varese (ASST Sette Laghi, hospital 1) and Como (ASST Lariana, hospital 2). Located in the Lombardia Region, the 2 provinces include about 1.5 million inhabitants, corresponding to 15% of the regional population.

Each ASST includes hub-and-spoke hospitals, hospitals dedicated to mothers and children and rehabilitations, and outpatient clinics. To address the feasibility of our protocol in structures at different underlying WPV risks, we included all the hospitals comprising the ASSTs. The study had 4 main objectives: (1) to quantify WPV before the implementation of the new protocol (2016-2020) and to document the extent by which the available information on WPV episodes was compliant with the guidelines [14] across different hospitals; (2) to design and implement a new protocol for WPV reporting and management (Figure S1 in Multimedia Appendix 1), comprising of a standardized and easy-to-access incident report procedure gathering first information on violence attributes, consequences and contributing factors; of a root cause analysis for more in-depth assessment of violence determinants and impacts; and of a web-based platform for comprehensive event management and data collection; (3) to estimate WPV prevalence in the entire HCW population and in different subpopulations and wards after the implementation of the new standard; and (4) to assess the role of work organizational factors by estimating the association between turn-over, downsizing, sickness leaves, night shift working (defined according to a published method [15]), and WPV occurrence. The specific aims of this paper are related to objectives 1 to 3, whereas the role of organizational factors, as well as the psychological impact of violence, will be addressed in dedicated works. In accordance with regional guidelines [14] and international standards [16], WPV was defined as any form of verbal abuse, threats, physical assaults (to persons or things) and sexual harassment occurring at the workplace and perpetrated by hospital patients or visitors or hospital employees.

WPV Reporting Before the Implementation of the Study Protocol (2016-2020)

During 2016-2020, incident reporting was based upon procedures and data collection forms that were neither standardized between hospitals nor specific for aggressions. The affected HCW notified the violence episode to the risk manager in 1 ASST and to the safety personnel in the other. The incident report data collection forms differed across hospitals and were also used for incidents other than WPV (eg, treatments adverse events, “near miss”), and several versions were adopted during the 5 years following changes in hospital’s organizations and managements. A root cause analysis was not implemented in either hospital.

Development and Implementation of the Project’s WPV Reporting Protocol

Figure S1 in Multimedia Appendix 1 depicts the flow chart for the WPV reporting and management protocol of the DeVOS project. Assaulted HCWs were required to notify the WPV to the risk management office (hospital 1) or to the safety personnel (hospital 2) within 72 hours of occurrence by using a standardized, WPV-specific incident report data collection form, available on the hospitals’ intranet. The form was developed taking into account previous experience by the risk managers of the participating hospitals, regional guidelines [14], and existing literature on the topic [9,10,17,18], and it collected information on violence attributes (form, hospital ward, involved HCW, perpetrator, violence date and time, and environmental factors), consequences (physical, psychological, reactions, feelings during the aggression, and work injury), and contributing factors (sociocultural, structural, organizational, relational, and clinical). More details are in Table S1 in Multimedia Appendix 1. Most fields were not mutually exclusive, and the HCW could fulfill more than 1 choice. In the case of WPV involving multiple HCWs, the risk management office was required to check that each assaulted HCW filled in 1 incident report. HCWs signing the specific consent were further contacted by the psychologist for the root cause analysis, comprising of a structured interview including the Modified Overt Aggression Scale [19] and the Broset Violence Checklist [20]. Then, the HCW received to an email address of his or her choice a 1-time access link to the project web platform for a safe and easy completion of the questionnaires assessing the impact of the WPV event (presence of cognitive, emotional, and somatic symptoms [21]; the Maslach Burnout Inventory [22]; and the General Health Questionnaire-12 [23]) and psychosocial work conditions (the Italian version of the Health and Safety Executive’s Management Standards Indicator Tool [24]). These questionnaires were validated for use with Italian HCWs [21,24,25]. Furthermore, the psychologist contacted the HCW supervisor for a guided interview using a checklist on work content and context factors. During periodic training meetings with workforce coordinators, the risk management officers explained the new protocol and provided information on violence notification, field definitions on the incident report form to standardize data collection (including contributing factors), and the rationale and motivation for participation in the root cause analysis. The coordinators were then asked to instruct the HCW of their ward or unit. Additionally, in hospital 1, all newly hired HCWs were targeted by the same training. In both ASSTs, the new protocol became effective on November 1, 2021. One ASST (hospital 2) gradually introduced the protocol to the outpatient departments during the year 2022. Therefore, for that ASST, we included only the hub and the main spoke hospitals in the current analyses, corresponding to 71% of the workforce.

Web-Based Platform for Data Collection and Risk Management

As part of the study, we developed a new web-based platform for centralized data collection, with customized access to data visualization or modification for risk management office personnel, the psychologist, and the data analyst. Due to ethical and confidentiality issues, we collected minimal sensitive information on the HCW and the aggressor. Furthermore, the easy visualization of questionnaire results by the psychologist allowed an immediate identification of high-risk workers for referral to supportive or mitigation resources.

Ethical Considerations

The study received approval by the Ethical Committee of Insubria (IDs 82/2021 and 90/2021). Participants signed an informed consent on data confidentiality and protection and a separate informed consent to participate in the interview with the psychologist. The web-based platform for centralized data collection complied with the European Union legislation on data protection. The platform applied a complete anonymization of personal data, allowing the tracing of repeated events on the same worker. HCWs received no compensation for their participation in the study.

Statistical Analysis

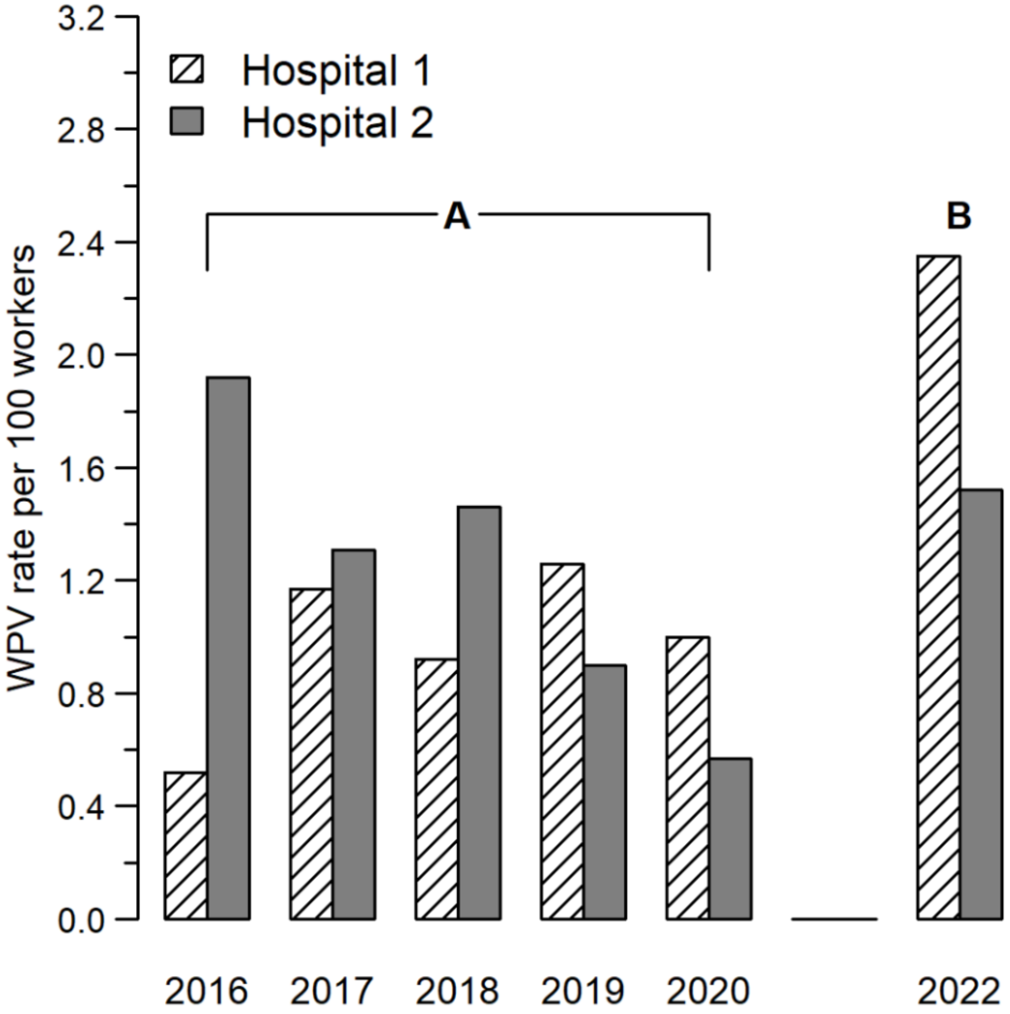
To be consistent with the literature mostly reporting WPV prevalence for a 12-month interval, for each year in the "before" study period (2016-2020) and by hospital, we estimated the 12-month WPV rate (per 100 workers) as the ratio between the number of reported WPV in the year and the number of HCWs in the payroll administrative records at the beginning of each year. The 95% CI for the yearly rate was estimated using the exact binomial distribution [26]. We estimated underreporting as the ratio between the observed and expected number of violent incidents. For the latter, we used the WPV rate estimated in 2015-2017 in a large public University hospital in Northern Italy by Viottini and colleagues [27] as 210 observed incidents each year over a population of 10,970 HCWs, along with the number of HCWs, again from payroll administrative records. The 95% CI for the ratio was estimated from the Poisson exact method [26]. To date, we completed the first 14 months since the implementation of the new reporting standard (November 1, 2021 to December 31, 2022). For the entire period, we reported on data completeness as missing data prevalence on the incident report data collection forms. To describe the violence attributes, we first assessed the co-occurrence of different types of violence in the same episode, by reporting percentages and mean number of violence types by episode. Then, we reported the distribution of major violence characteristics, consequences, and contributing factors, in the overall sample and by sex of the assaulted HCWs, to identify the presence of sex-related patterns. The association between violence characteristics and sex was formally tested through chi-square tests. The analyses of WPV underreporting and rate were restricted to a 12-month period (year 2022, n=166 WPV) adopting the same methods described above for the "before" period and using the number of HCWs in the payroll records at the beginning of the implementation of the new standard. The overall rate was then broken down as the sum of 2 mutually exclusive components: 1 being the rate of the first violent episode and the second being the rate of recurrent violent episodes on the same worker. Statistical analyses were performed using SAS software (version 9.4; SAS Institute Inc).

Results

Data Completeness and WPV Rate in the "Before" Period

Between 2016 and 2020, a total of 400 WPV reports were notified in the 2 study hospitals. Data completeness was scanty: in 160 (40%) of the reports, the affected HCW was not identified (eg, replaced by a "generic" description of job title or by expressions such as "everyone present"), and when identifiable, in 70.8% (170/240) of reports, there was at least 1 missing information on age, sex, or job title. This prevented us from providing specific prevalence estimates by subgroups. Similarly, environmental details, consequences, and contributing factors were not available in 59% (236/400), 18% (72/400), and 50% (200/400) of reports. Yearly WPV rates were diverging between the 2 study hospitals, increasing from 0.52 (95% CI 0.34-0.77) per 100 HCWs to 1.0 (95% CI 0.75-1.31) in 1 hospital and declining from 1.92 (95% CI 1.42-2.54) to 0.57 (95% CI 0.32-0.93) in the other (Figure 1A). The yearly observed to expected ratio was significantly below 1 for most years, suggesting substantial (up to 73%) underreporting. In particular, the ratio from 2016 to 2020 changed from 0.27 to 0.52 (eg, reduction in underreporting) in the hospital with an increasing WPV rate and from 1.0 to 0.30 (eg, increase in underreporting) in the other.

Figure 1. Twelve-month WPV rate observed in the study hospitals, before (period A) and after (period B) the implementation of the study protocol on incident report. The study protocol on incident report was effective since November 1, 2021. The WPV rate (per 100 health care workers) is the number of observed WPV incidents divided by the number of health care workers at the beginning of each year. WPV: workplace violence.



Data Completeness and WPV Rate in the "After" Period

During the first 14 months of implementation of the study standard, a total number of 205 WPV were reported, half (50%) of them on the same day of occurrence, and 75% within the first 72 hours. Data completeness was optimal: only in 2% (4/205) of reports the affected HCW was not identified, and when identifiable, only in another 2% (4/201) there was at least 1 missing information on demographics or job title information (Table S1 in Multimedia Appendix 1). The observed to expected ratio was 1.91 (95% CI 1.63-2.21) as compared to the "before" period in the same hospitals, which was consistent in the 2 hospitals (1.96 and 1.77). When using the reference rate from literature to estimate the expected number of WPVs, the observed to expected ratio was 1.14 (95% CI 0.98-1.32), being slightly lower in hospital 2 where the first notification was to safety personnel (0.83, 95% CI 0.60-1.13) rather than to the risk management office (1.28, 95% CI 1.07-1.52) as in hospital 1. The 12-month WPV rate was 2.08 (95% CI 1.79-2.42) per 100 HCWs (Table 1), being slightly lower in hospital 2 than in hospital 1 (1.52 vs 2.35; *P*=.02; Figure 1B). WPV rate (Table 1) declined with age, with the youngest group being at the highest risk (*P*<.001); it was higher in male than female HCWs (2.82 vs 1.83; *P*=.008); and it was more than doubled in nurses (3.49; 95% CI 2.93-4.15), as compared to nurse assistants (1.74) and physicians (1.08; *P*<.001). Finally, psychiatric wards (14.3) and emergency departments (13.3) were at higher WPV rates than the remaining wards; about one-fifth (0.41/2.08, 19.7%) of the rates are due to recurrences. Analyses by hospital (Table S2 in Multimedia Appendix 1) suggested higher rates in the youngest group in hospital 1 and in psychiatric wards in hospital 2, whereas associations by sex and job title were homogeneous across the hospitals.

Table 1. Twelve-month WPV[a] rate (with 95% CI) for the year 2022 by affected HCW[b] demographic and work characteristics[c].

Characteristics	HCWs (n=7982), n (%)	WPV (n=166), n (%)[d]	12-month WPV rate, (95% CI)			
			First WPV[e]	Recurrent WPV[f]	Overall WPV[g]	*P* value[h]
All WPV	7982 (100)	166 (100)	1.67 (1.41-1.97)	0.41 (0.29-0.58)	2.08 (1.79-2.42)	—[i]
Age group (years)						<.001
<30	829 (10.4)	33 (19.9)	2.90 (1.95-4.28)	1.09 (0.57-2.07)	3.98 (2.85-5.54)	
30-50	3652 (45.8)	88 (53)	1.86 (1.47-2.36)	0.55 (0.35-0.85)	2.41 (1.96-2.96)

[a] WPV: workplace violence.

[b] HCW: health care worker.

[c] Twelve-month rate is the ratio between the number of WPV and the number of HCWs, per 100 HCWs.

[d] Excluding 8 WPVs without data on age, sex, and job title of the affected HCW.

[e] First WPV: number of first WPVs in the 12-month period.

[f] Recurrent WPV: number of WPVs from the second case onward, in the 12-month period.

[g] The overall violence rate is the sum of first and recurrent violence rates.

[h] Wald chi-square test on the overall violence reporting rate, with a number of degrees of freedom equal to the number of classes in the independent variable – 1.

[i] Not applicable (no groups to be compared).

Violence Attributes and Patterns in the “After” Period

Table 2 reports the co-occurrence of violence forms in the incident reports. Verbal abuse was the largest majority (186/205, 90.7%) Of these, verbal abuse was the only form of violence in 26 (14%) out of 186 incidents, whereas 134 (72%) also reported threats, 98 (52.7%) reported physical assaults, and 15 (8%) reported sexual harassment. The mean number of reported violence forms was 2.33. We report similar figures for the other violence forms. Table 3 reports the distribution of major violence characteristics and risk factors, by sex of the assaulted HCW. Male HCWs were more likely than female HCWs to be subject to physical assault (45/67, 67.2% vs 62/130, 47.7%; *P*=.01). Either alone or with a patient, visitors were more likely to assault female than male HCWs (40/130, 30.7% vs 8/67, 12%; *P*=.02). No sex-related differences were observed on violence time or location. Female HCWs were less likely than male HCWs to report a work injury to the insurance authority (4/130, 3.1% vs 15/67, 22.4%; *P*<.001) and were more likely than men to report psychological consequences (46/130, 35.4% vs 13/67, 19.4%; *P*=.02) and life-threatening feelings during the aggression (23/130, 17.7% vs 5/67, 7.5%; *P*=.05). Finally, 47.8% (32/67) of WPV in male HCWs was related to the clinical conditions of the perpetrator, which is greater than that in female HCWs (40/130, 30.8%; *P*=.02). In female HCWs, the single most frequently reported factor was the sociocultural one (eg, related to linguistic or cultural barriers or behaviors; 53/130, 40.8%). Of note, structural factors including safety (the lack of barriers, alarm systems, or escape or poor lightning) were among the least prevalent identified contributing factors, both in men and in women.

Table 2. Co-occurrence of different types of violence observed in the "after" period.

Type of violence (number of reports)	Co-occurrence, n (%)[a]				No co-occurrence, n (%)[b]	Number of violence types in incident reports, mean
	VA[c]	T[d]	PA[e]	SH[f]		
VA (n=186)	—[g]	134 (72)	98 (52.7)	15 (8)	26 (14)	2.33
T (n=139)	134 (96.4)	—	77 (55.4)	12 (8.6)	2 (1.4)	2.60
PA (n=115)	98 (85.3)	77(67)	—	10 (8.7)	14 (12.2)	2.61
SH (n=15)	15 (100)	12 (80)	10 (66.7)	—	0 (0)	3.46

[a] Percent of incident reports with the row type of violence that also reports the column type.

[b] Percent of incident reports with only the row type of violence.

[c] VA: verbal abuse.

[d] T: threat.

[e] PA: physical assault.

[f] SH sexual harassment.

[g] Not relevant.

Table 3. Distribution of major violence attributes, consequences, and contributing factors, by sex of the assaulted HCW[a], in the "after" period.

Attributes	All WPV[b] (n=197), n (%)	WPV against female HCWs (n=130), n (%)	WPV against male HCWs (n=67), n (%)	*P* values
Type of violence[c]				
Verbal abuse	179 (90.7)	120 (92.3)	59 (88.1)	.33

Not identified	28 (14.2)	18 (13.9)	10 (14.9)	.84

[a] HCW: health care worker.

[b] WPV: workplace violence.

[c] More than 1 answer was possible, so the total does not sum up to 100%.

[d] For example, corridors, stairs, and elevators.

[e] Including web-based violence via email or telephone.

[f] Violence determining a work injury must be reported to the Italian Workers Compensations Authority.

[g] Sociocultural (eg, linguistic barriers, behavior conditioned by cultural elements such as education or country of origin, the inadequacy of social

behaviors); structural (eg, lack of barriers/alarm systems/escape, poor lightning); organizational (eg, related to work organization); relational (eg, related to HCW experience and communication abilities); and clinical (eg, related to the conditions of the perpetrator, including psychiatric disorders and substance abuse).

Discussion

The implementation of the ILO convention [1] and its subsequent ratification in state members, including Italy (Law n. 4 of January 15, 2021), calls for a systematic and standardized registration of WPV in HCWs implemented on a large scale to inform prevention, protection, and enforcement actions [7]. In Italy so far, national statistics cover only more severe cases, such as those exiting in a work injury [3], whereas academic data obtained from convenient samples and retrospective investigations exhibit significant heterogeneity, rendering them uninformative for guiding prevention efforts effectively [7]. This study documents underreporting and WPV prevalence estimates in 2 large public referral hospitals before and after the implementation of a standardized, guidelines-based program for systematic violence monitoring. Similar experiences [9,12,13] have not yet documented such temporal changes. WPV data in HCWs are affected by a substantial amount of underreporting [28,29], up to 80% to 90% according to 1 US study [29]. In line with this previous knowledge, in the 2016-2020 period, we estimated a yearly observed to expected ratio mostly below 1 in the 2 study hospitals and as low as 0.27, corresponding to 73% underreporting toward expected prevalence from the literature [27]. Such a large amount of underreporting hampers a meaningful interpretation and comparison of time trends in violence prevalence between the structures. After the implementation of the new standard, the 12-month observed to expected ratio increased to be larger than 1 as compared to the same benchmark and almost 2 as compared to the "before" period in the same hospitals. In addition, only 9.8% (20/205) of the reported WPV determined a work injury, suggesting that we were fairly able to detect less serious incidents in which "no one was hurt," which are generally overlooked [30]. Finally, although verbal abuse was present in 90.7% (186/205) of reports, the affected HCWs were able to describe and report the complex co-occurrence of violence forms in the same episode. However, in the study hospital in which the first notification was to safety personnel, rather than to the risk management office, we found a lower observed to expected ratio, a lower 12-month overall WPV rate but with a higher peak in psychiatric wards, where episodes are more likely to be related to the psychiatric conditions of the perpetrator. Based on these findings, notification to dedicated personnel is recommended in future applications to enhance violence reporting.

Several reasons have been advocated for WPV underreporting, including the feeling that violence is "part of the job" [31], the lack of supervisor or coworker support, the fear of blame, and the belief that reporting would not lead to positive changes [29]. We may speculate that our protocol could have contrasted some of these barriers, through the introduction of a new reporting standard specifically dedicated to WPV; the periodic training of the new procedure with the workforce and newly hired workers; the easiness of reporting by the HCW along with a close support contact with the risk management office during the first 72 hours since the episode; the availability of a dedicated psychologist for counseling, also outside the HCW working hours; and the periodic sharing of reporting with workers' safety representatives for health. These aspects, specifically related to our protocol, might have reinforced the positive impact on violence reporting related to increased awareness of the issue due to the perception that the institution was "giving attention to it." Taken together, these put into light the crucial role of a participative approach to the management of WPV that, starting from standardized and systematic data collection, requires the inclusion and active involvement of the organization, workers, and occupational health figures (risk management, occupational physicians, psychologist, and workers' safety representatives).

The 12-month violence rates we estimated should be compared with caution with those from survey studies, since ours are referring to the entire HCW population and are based on incident reporting rather than on recollection. We add important pieces of information that can help to identify high-risk workers. First, while confirming the highest violence rates for psychiatric wards, emergency departments, and nurses, we add the notion that about 25% of their rate is due to the reoccurrence of aggressions on the same workers, as previously observed in Italy [27,32], Norway [33], and Denmark [34]. As current knowledge on the factors related to multiple aggressions is so far limited [33,34], future analyses are required to elucidate the role of personal and work-related characteristics on multiple aggressions. Second, in identifying high-risk subpopulations, it is important to consider that age, sex, and job title might have an unbalanced distribution in the specific health care workforce. Although in our data the large majority (66%, 130/167) of incident reports involved female HCWs, confirming institutional data [3], these do not appear to be at higher WPV risk as compared to male HCWs once their disproportional number in the workforce has been considered, as in other prospective studies [33,35]. Finally, our data can be used to well-characterize patterns in WPV attributes and consequences related to HCW's characteristics, of which the sex-related one is an exemplification. To this extent, we confirmed the highest prevalence of physical violence in male HCWs recently observed in Italy [11], at the same time expanding knowledge by reporting sex-specific patterns in consequences, contributing factors, and conditions of the perpetrator. Taken together, this information can both guide priorities of interventions and a better design of the contents of primary, secondary, and tertiary prevention policies [36,37]. Systematic incident reporting is important to provide a "time zero" to evaluate the efficacy of future interventions.

Study limitations include the short time period of implementation of the new standard; since it is still in use by the 2 hospitals, we will be able to monitor in future reports its sustainability over time. Our study cannot document changes in WPV prevalence before and after the SARS-CoV-2 pandemic outbreak, given that the change in the reporting system became effective only at the end of 2021. Our underreporting metric is based upon a violence rate derived from literature, but assuming it remained constant during the study periods (2016-2020 and 2022). On the other hand, due to the substantial heterogeneity documented in the introduction, the validity of the metric depends upon the choice of a comparable benchmark for study design, period, and setting, since violence prevalence in Italy is also heterogeneous across public versus private hospitals [32] and country area [38]. The study we chose [27] satisfies most of these requirements. In addition, we used the annual count of HCWs to mitigate the impact on the expected number of incidents due to changes in the workforce. Then, our WPV rates can provide an updated benchmark for assessing underreporting in Italy, using a similar observed-to-expected metric. Our study protocol was implemented and tested in 2 large public general hospitals, each with a complex organizational structure including hub-and-spoke hospitals, as well as rehabilitation and outpatient clinics. We adopted recognized standards for violence definition, attributes, consequences, and determinants [10], to enhance the comparison of our findings with other studies.

In conclusion, a guidelines-based protocol can mitigate the underreporting of violence episodes against HCWs and provide accurate information to identify high-risk workers and describe violence attributes and patterns. The standardization across hospitals can better inform priorities and contents of preventive policies, at both a local and a large scale. To this extent, our evaluation can provide useful information for large-scale implementation of guidelines-based monitoring programs, as well as in other contexts.

Acknowledgments

The authors wish to thank all the health care workers who have participated in the study. The authors are grateful to Davide Trevisan, for the development of the web-based data platform for data collection; to Giacomo Radici and Patrick Tayoun, who helped with bibliographic research; to Eleonora Lusito, for her contribution to data handling and analysis; and to Simona Boneschi, who contributed to the selection of interview or questionnaires to be included in the root cause analysis. The authors also thank the management of the participating organizations, as well as people contributing with their work in the quality and safety and the occupational medicine units, namely Giovanna Martinelli, Roberto Guarnaschelli, Alessandra Tropia, Angela Trentin, Sara Colombo, Roberta Somaschini, Gloria Simonelli, Francesca Cereda, Francesca Ricci, Mariavalentina Giordano, Cristina Curioni, and Andrea Frontini. Preliminary results were presented at the EPICOH 2023 conference, and the abstract was published in a dedicated supplementary issue of Occupational and Environmental Medicine. This study was supported by a grant provided by the Italian Workers Compensations Authority (INAIL; Bando BRIC 2019 - ID29A).

Data Availability

The data sets generated and analyzed during this study are not publicly available due to restrictions imposed by the informed consent obtained for this study and by the legislation of the European Union, but they can be made available from the corresponding author on reasonable request. Approval by each management of the Azienda Socio-Sanitaria Territoriale that participated in the study will be required for the release of the data.

Authors' Contributions

GV and MMF contributed to the conceptualization and design of the study, drafted the original paper, and are the principal investigators of the *Determinanti Violenze Operatori Sanitari* (DeVOS) Project. GV is the study guarantor. GV and EMG were responsible for statistical analyses. RB, LC, AB, and AL contributed to data acquisition and paper editing. EMG, FG, and SDM critically contributed to the interpretation of results, and to review and editing of the paper. MG, BP, CDT, MR, GC, and LI critically reviewed the paper.

Abstract

Background: The Region 1 Disaster Health Response System project is developing new telehealth capabilities to provide rapid, temporary access to clinical experts across US jurisdictions to support regional disaster health response.

Objective: To guide future implementation, we identified hospital-level barriers, facilitators, and willingness to use a novel regional peer-to-peer disaster teleconsultation system for disaster health response.

Methods: We used the National Emergency Department Inventory-USA database to identify all 189 hospital-based and freestanding emergency departments (EDs) in New England states. We digitally or telephonically surveyed emergency managers regarding notification systems used for large-scale no-notice emergency events, access to consultants in 6 disaster-relevant specialties, disaster credentialing requirements before system use, reliability and redundancy of internet or cellular service, and willingness to use a disaster teleconsultation system. We examined state-wise hospital and ED disaster response capability.

Results: Overall, 164 (87%) hospitals and EDs responded—126 (77%) completed telephone surveys. Most (n=148, 90%) receive emergency notifications from state-based systems. Forty (24%) hospitals and EDs lacked access to burn specialists; toxicologists, 30 (18%); radiation specialists, 25 (15%); and trauma specialists, 20 (12%). Among critical access hospitals (CAHs) or EDs with <10,000 annual visits (n=36), 92% received routine nondisaster telehealth services but lacked toxicologist (25%), burn (22%), and radiation (17%) specialist access. Most hospitals and EDs (n=115, 70%) require disaster credentialing of teleconsultants before system use. Among 113 hospitals and EDs with written disaster credentialing procedures, 28% expected completing disaster credentialing within 24 hours, and 55% within 25-72 hours, which varied by state. Most (n=154, 94%) reported adequate internet or cellular service for video-streaming; 81% maintained cellular service despite internet disruption. Fewer rural hospitals and EDs reported reliable internet or cellular service (19/22, 86% vs 135/142, 95%) and ability to maintain cellular service with internet disruption (11/19, 58% vs 113/135, 84%) than urban hospitals and EDs. Overall, 133 (81%) were somewhat or very likely to use a regional disaster teleconsultation system. Large-volume EDs (annual visits ≥40,000) were less likely to use the service than smaller ones; all CAHs and nearly all rural hospitals or freestanding EDs were likely to use disaster consultation services. Among hospitals and EDs somewhat or very unlikely to use the system (n=26), sufficient consultant access (69%) and reluctance to use new technology or systems (27%) were common barriers. Potential delays (19%), liability (19%), privacy (15%), and hospital information system security restrictions (15%) were infrequent concerns.

Conclusions: Most New England hospitals and EDs have access to state emergency notification systems, telecommunication infrastructure, and willingness to use a new regional disaster teleconsultation system. System developers should focus on ways to improve telecommunication redundancy in rural areas and use low-bandwidth technology to maintain service availability to CAHs and rural hospitals and EDs. Policies and procedures to accelerate and standardize disaster credentialing are needed for implementation across jurisdictions.

Introduction

Background

Recent large-scale, no-notice disasters such as mass shootings and tornadoes, and public health emergencies like the COVID-19 pandemic, have exposed how even the most prepared health care systems can be challenged to function effectively in a crisis [1]. To address this problem, the Administration for Strategic Preparedness and Response in the US Department of Health and Human Services launched a new program to develop regional disaster health response systems (RDHRS) as part of the national strategic response plan to support catastrophic disaster medical care [2]. The goal of an RDHRS is to create partnerships among hospitals and health care facilities that support regional (ie, multistate) health care delivery when existing local and state capacity and capability are exceeded by catastrophic events. RDHRS efforts include novel adaptations of telehealth tools and systems to rapidly expand access to highly specialized, disaster-relevant clinical subspecialists on a regional or national level to support medical response in the immediate aftermath of unusual hazards or catastrophic events.

Importance

Regionalization of routine specialty care, like trauma and pediatric emergency care, has concentrated the available expert workforce in urban settings and academic medical centers [3], exacerbating access disparities in underserved areas [4-6]. Telehealth services have been used to bridge access to specialty care in underserved, often rural, communities, and in low-resource settings [7-10]. Despite technological advancements, legal, regulatory, and administrative barriers and variability in access to reliable high-speed telecommunications infrastructure have continued to limit the development and use of regional telehealth care delivery models in the United States [11-13]. Variability in medical licensing and credentialing procedures has also hindered the ability to leverage clinical expertise across state lines and jurisdictions [12]. Telehealth services have demonstrated use in military disaster settings [14]. However, civilian telehealth systems to support trauma, burn, pediatric, and other highly regionalized specialty care remain generally underdeveloped and inaccessible to many community hospitals that may be overwhelmed in disaster events [15,16].

Goals of This Investigation

The Region 1 RDHRS, which covers 6 New England states, is developing a new peer-to-peer disaster teleconsultation system to support disaster health response across state lines [17]. This system is designed to rapidly expand regional access to disaster-relevant medical experts (eg, burn surgeons), who may be in limited supply immediately following a large-scale, no-notice emergency event, such as a mass casualty incident. The goal is not to replace existing telehealth services but to supplement overwhelmed services or provide new ones where they are otherwise unavailable when needed in a crisis. The RDHRS disaster teleconsultation system aims to provide local bedside providers access to electronic consultation services with remote clinical specialists via telephone, video, or other platforms compliant with regulatory standards governing protected health information within hours of an event [18]. This would allow disaster-relevant clinical experts to participate early in the acute response phase before in-person disaster teams can be mobilized and deployed to the field. To guide development and future implementation, the objectives of this study were to identify barriers and facilitators to implementation and to determine willingness (primary outcome) to use a new regional disaster teleconsultation system at a hospital level in New England.

Methods

Study Design and Setting

We conducted a cross-sectional survey study of all hospital-based and freestanding emergency departments (EDs; hospitals and EDs) open in March 2021 in the 6 New England states (Connecticut, Maine, Massachusetts, New Hampshire, Rhode Island, and Vermont).

Ethical Considerations

For this study, we collected only facility-level information about hospitals and EDs. No compensation was provided for the completion of the study. All data are securely stored on a password-protected server accessible to the study staff. The Mass General Brigham Human Research Committee reviewed this project and classified it as exempt.

Survey Administration

Staff from the Emergency Medicine Network (Boston, Massachusetts) used the National Emergency Department

Inventory (NEDI)-USA database to identify all 189 New England hospitals and EDs open during the study period. Briefly, NEDI-USA contains information about all nonfederal, nonspecialty US EDs [19]. Between March 1 and June 30, 2021, we called the main telephone number for each hospital or ED and requested to speak to the emergency manager for survey completion by structured interview. We selected emergency managers as key respondents, as these individuals are responsible for and most knowledgeable about the disaster preparedness and response capabilities of their facilities.

Three staff members with formal training and prior experience with contacting hospitals and EDs for other surveys about facility characteristics conducted the surveys. All used a standardized protocol and interview guide with scripted explanations in case respondents requested clarification of terms and definitions. Telephone survey responses were directly entered into a secure database by the interviewer, using Research Electronic Data Capture (REDCap; Vanderbilt University) tools hosted at Massachusetts General Hospital [20]. REDCap is a secure, web-based software platform designed to support data capture for research studies. We also created a web-based version of the survey administered via REDCap as an alternate means of participation. The web-based survey link was active throughout the entire course of data collection.

Participants were given the option to either complete the interview during the first call, schedule a time for callback, or receive the survey by email. All respondents were able to ask clarifying questions by telephone or via email before completing the survey regardless of the mode of survey administration. Survey respondents also had the option to leave questions unanswered or consult other hospital staff (eg, compliance officers) to confirm answers if needed.

Measurements

The survey questions were developed by the multidisciplinary region 1 RDHRS Telehealth Working Group, which includes experts in adult and pediatric emergency medicine, disaster medicine, public health, hospital emergency system management, and telehealth implementation. Survey questions were reviewed by a hospital credentialing and compliance officer, 2 directors of emergency preparedness, and 2 emergency management specialists to ensure face validity.

The survey collected information about (1) how each hospital and ED receives notification of large-scale or state-wide no-notice emergency events, (2) the availability of 6 disaster-relevant clinical specialist types (toxicology, radiation or nuclear medicine, trauma, burn, high-consequence infectious disease, and critical care) for consultation in-person, via telephone, or via telehealth within 4 hours of an event, (3) disaster credentialing requirements of remote specialists before system use, (4) availability of internet or cellular service to support video streaming in clinical spaces, and (5) whether each hospital and ED has a contingency plan if internet or cellular service is disrupted. To assess hospital-level willingness (primary outcome), we asked respondents how likely it would be for their hospital and ED to use a new disaster teleconsultation system to access specialists (very likely, somewhat likely, somewhat unlikely, or very unlikely). Among those who were "somewhat unlikely" or "very unlikely" to use this system, we asked about potential barriers to use (Multimedia Appendix 1).

Additionally, using the NEDI-USA data set, we identified each ED's total annual visit volume (<10,000; 10,000-19,000; 20,000-39,000; ≥40,000), whether or not each ED was a designated critical access hospital (CAH) [21] or freestanding ED [22], whether each hospital and ED was in an urban or rural location based on location within or outside of a core based statistical area, and whether the ED received routine (nondisaster) telehealth services [23].

Primary Data Analysis

We used descriptive and bivariate statistics to describe and compare the disaster response characteristics of New England hospitals and EDs by state. Data are presented as frequencies with percentages. A chi-square test and the Fisher exact test were used to examine interstate variation in ED disaster response capability. Fisher exact test was used alternatively for low counts. P values of <.05 were considered statistically significant. We also created maps to demonstrate the geographic differences in the hospital or ED disaster response infrastructure. Data analysis and mapping were performed using SAS (version 9.4; SAS Institute).

Results

Of the 189 hospitals and EDs open in New England in 2021, a total of 164 (87%) responded to the survey. Among these, 126 (77%) completed the survey by phone interview, and 38 (23%) completed it digitally. The response rate in each of the 6 New England states was ≥83%. There were no differences in ED characteristics between responders and nonresponders.

Table 1 summarizes the emergency notification mechanisms, whereas Table 2 summarizes gaps in access to disaster-relevant specialists for consultation in New England hospitals and EDs. While the percentage of hospitals and EDs notified by state-level systems or emergency medical services (EMS) and public safety systems was similar across all states, notification by regional- or county-level systems or via media mechanisms was more varied (Table 1). Most New England hospitals and EDs (97%) could access at least 1 type of disaster-relevant specialist for consultation in-person, via telephone, or via telehealth within the first 4 hours of a large-scale, no-notice emergency event (Table 2). There was no significant difference in access to specialists by state.

ED characteristics are summarized in Table 3. Because small volume EDs (<10,000 annual visits), CAHs, and rural hospitals may lack access to specialists, we further examined this subset (Table S1 in Multimedia Appendix 1). Eighteen of the 22 EDs with <10,000 annual visits were also designated CAHs. Among CAHs or EDs with <10,000 annual visits (n=36), 92% received routine nondisaster telehealth services, and most reported access to specialists in trauma (92%), high-consequence infectious disease (92%), and critical care (97%). However, 25% lacked access to toxicologists, 22% to burn specialists, and 17% to radiation or nuclear medicine specialists.

Next, we asked if hospitals and EDs would require disaster credentialing of teleconsultants before permitting system use. Overall, 70% (115/164) of New England hospitals and EDs reported that they would require disaster credentialing and 113 of these had written procedures in their medical staff bylaws. Among those with written procedures (n=113), disaster credentialing (n=105, 93%) was used more frequently than credentialing-by-proxy (n=16, 14%) or other procedures (n=5, 4%). Over half (n=62, 55%) expected disaster credentialing to take 25 to 72 hours to complete and varied by state. Only 32 (28%) expected to complete these procedures within 24 hours and 17 (15%) within 4 hours. Figure 1 depicts the variability in expected time to complete disaster credentialing procedures in hospitals and EDs within and between states in New England. Notably, 43 (38%) had used disaster credentialing procedures during a major event in the past 20 years, of which 53% had successfully completed it within 4 hours. Approximately two-thirds of hospitals and EDs requiring disaster credentialing of teleconsultants were willing to use a third-party verification system to complete this procedure. More hospitals and EDs in Rhode Island (100%), Maine (94%), and New Hampshire (86%) were willing to use a third-party verification system than in Vermont (57%), Connecticut (52%), and Massachusetts (47%).

We then examined the reliability and redundancy of hospital telecommunication infrastructure as this could affect adoption and use of a disaster teleconsultation system. Overall, 154 (94%) hospitals and EDs reported reliable internet or cellular service connectivity for video streaming in clinical areas, and 142 (87%) had a contingency plan for loss of telecommunication services. Of the 154 hospitals and EDs with reliable connectivity, 124 (81%) could maintain cellular service if there was an internet disruption. Hospitals and EDs in Maine, New Hampshire, and Vermont had less reliable telecommunication and lower capability of maintaining services during disruption (Figure 2). Fewer rural hospitals and EDs reported reliable internet or cellular service (19/22, 86% vs 135/142, 95%) and ability to maintain cellular service with internet disruption (11/19, 58% vs 113/135, 84%) than urban hospitals and EDs.

Most (n=133, 81%) New England hospitals and EDs were very or somewhat likely to use RDHRS disaster telehealth services to access specialists if a large-scale no-notice event affected their facility. Hospitals and EDs in Vermont, New Hampshire, and Rhode Island reported higher willingness to use the system than those in Maine, Massachusetts, and Connecticut (Figure 3). Among the 26 (16%) hospitals and EDs that were somewhat or very unlikely to use the system, the leading barriers were sufficient access to specialists in-house or within the health system (n=18, 69%) and reluctance to use new technology or systems during a disaster (n=7, 27%). Potential time delays (n=5, 19%), liability (n=5, 19%), privacy (n=4, 15%), and hospital information system security restrictions (n=4, 15%) were other reported concerns.

Table 3 examines the willingness to use disaster teleconsultation services by ED characteristics. While overall willingness was high, large volume EDs (annual visits ≥40,000) were less likely to use the service than smaller ones. In contrast, all CAHs and nearly all rural hospitals or freestanding EDs were likely to use disaster consultation services. Eighty percent of hospitals and EDs that were likely to use the system also received nondisaster telehealth services.

Discussion

Principal Results

In this regional study, we found that most New England hospitals and EDs had the necessary emergency notification mechanisms, telecommunication infrastructure, and willingness to support the future regional implementation of a disaster teleconsultation system. Although many EDs had access to at least 1 disaster-relevant specialist, 1 in 4 New England hospitals and EDs lacked access to burn specialists, identifying an important gap to target in future service delivery. Rural hospitals, freestanding EDs, and CAHs demonstrated the highest willingness to use this type of service but may require improvements in telecommunication infrastructure to support use in conditions where connectivity is disrupted or infrastructure destroyed. Despite limiting disaster telehealth services to teleconsultation only, 7 in 10 hospitals and EDs would require disaster credentialing before using the service and less than a third of these sites could complete this procedure within 24 hours. This could significantly delay postdisaster access to specialists required for time-critical patient care.

Comparison With Prior Work

Identifying which emergency notification mechanisms are used most frequently by regional hospitals can help RDHRS programs prioritize the most effective communication channels. RDHRS programs are designed to build on local and state assets and emergency response capabilities and provide regional coordination of key health care resources, such as burn centers and pediatric hospitals. Our findings suggest that integrating RDHRS communication strategies with hospital emergency network notification systems activated by state, EMS, and public safety systems would be the most efficient mechanisms for rapid regional communication. Such channels could be used to notify hospitals of the availability of regional disaster services in the aftermath of an event. Formalizing RDHRS programs as regional response entities within the national strategic response plan would facilitate future integration with existing emergency notification systems at the local and state level.

Depending on regional need and availability, RDHRS programs may need to create new disaster telehealth service lines or facilitate mechanisms to expand access to existing ones. Understanding gaps in regional access to disaster-relevant specialty care is necessary to target which service lines need the most urgent development, especially as rural and urban practitioners may perceive service need and use differently [24]. Among New England hospitals and EDs, we found larger gaps in access to burn, toxicology, radiation, and trauma specialists than to infectious disease and critical care specialists. Burn and trauma care are notable examples where disparities in routine access may be worsened by a disaster. For example, after a mass casualty incident, interfacility patient transfers may be delayed due to limited availability of emergency medical services for transportation, and overwhelming volume may limit capacity at receiving specialty hospitals. Regional disparities in access to burn centers have been described [25,26]. Despite the ability to alter triage, care, and transfer decisions [27-29], many burn telehealth programs remain localized without regional or national coordination due to barriers in sustainable funding and license portability [30,31]. Regional variation in access to trauma centers impacts injury mortality and emergency resource usage [32,33]. While trauma telehealth programs support providers who are uncomfortable or unfamiliar with specialty trauma care and improve transfer efficiency for acutely injured patients [34-36], adoption has lagged.

Mass casualty incidents involving radiological and chemical agents also require immediate access to experts in radiological exposure, hazardous materials, and medical toxicology. Although federal guidance emphasizes early mass decontamination during the emergency response to such incidents [37], a qualitative study across 3 US regions found ED clinicians perceived a lack of hospital preparedness for radiological terrorism [38]. Teleconsultation with hazardous material or radiation specialists could be used to support field providers and receiving hospitals, although studies examining the use of telehealth for such incidents are sparse. Teleconsultation with patients for counseling and risk communication after exposure could add public health benefit, as described after the 2011 Fukushima nuclear disaster [39]. Regional poison centers can also be integrated into disaster response infrastructure to leverage available medical toxicology expertise [40]. Like other service lines with low-frequency use, the adoption of routine teleconsultation with medical toxicologists has been limited by reimbursement barriers [41]. Dedicated funding to ensure the correct people, equipment, and administrative supports are maintained during the preparedness portion of the disaster cycle will be essential to ensure effective national strategic response for future events.

Historically, concerns over the cost of technology and service use, and administrative barriers related to interstate license portability and hospital credentialing and privileging requirements have slowed the expansion of telehealth in the United States [12,42-45]. Licensure refers to the process of securing the authority to practice medicine within a state. Credentialing refers to the administrative process of validating the competency of a health care provider by verifying their license, education, certification, and other information to ensure they meet the practice standards required by a hospital. Disaster credentialing is an expedited procedure that can only be used when a hospital's emergency operations plan is activated to facilitate rapid access to outside assistance (eg, medical professionals) to sustain patient care. Our findings highlight how variability in regulatory and administrative practices at the state and hospital level could hobble efforts to integrate telehealth tools into regional disaster medical response. Despite limiting disaster services to peer-to-peer teleconsultation with certified expert providers, 70% of New England hospitals and EDs would require disaster credentialing of teleconsultants before permitting service use with many requiring up to 72 hours to complete this process. This administrative barrier could delay implementation by days to weeks and negate the potential benefits of accessing specialists within hours of a no-notice event, like a mass casualty incident, where interventions and outcomes are critically time sensitive.

Our findings are surprising as peer-to-peer teleconsultation for the purpose of providing expert advice is not subject to the same legal and regulatory requirements as telehealth services that deliver direct patient care [11]. Common licensure exceptions include physician-to-physician consultations, public health services, medical emergencies, and natural disasters [11]. For example, Regional Poison Control Centers represent a widely accepted model where episodic, emergency consultations are delivered via telephone by certified expert personnel across jurisdictions [46]. These consultations are freely and routinely accessible to providers without administrative requirements for hospitals using the service. Whether survey respondents perceived expert teleconsultations via a regional disaster health response system as distinct from telephone consultations via a regional poison control center is unclear. Finally, in the absence of clear guidance on acceptable standards, hospital administrators may vary in their approach to disaster credentialing to avoid potential regulatory penalties and minimize medicolegal risk [12]. We encourage future research to understand the reasons underlying the variability in hospital credentialing practices, as this could have important implications for policy makers.

Creation of a national licensure standard, incentivizing the adoption of existing mechanisms to streamline interstate licensure such as the Interstate Medical Licensure Compact [47], or permitting limited exceptions to telehealth licensure laws could all support the ability to maintain a rapidly deployable network of disaster-relevant specialists at the ready. The Centers for Medicare and Medicaid Services could also incentivize hospitals to adopt mechanisms to streamline disaster credentialing procedures by using rapid third-party verification mechanisms. For example, Provider Bridge, a web-based platform to speed verification of out-of-state health care volunteers, was developed by the Federation of State Medical Boards with temporary funding from the Health Resources and Services Administration and the Coronavirus Aid, Relief, and Economic Security Act [48]. However, cessation of grant funding has left the future of such programs uncertain. We strongly support continued funding and intentional integration of effective pilot programs to ensure investments made to support pandemic response are available for future disaster response.

Successful application of telehealth requires reliable access to high-speed broadband networks and functional telecommunications infrastructure. Broadband refers to various technologies (eg, cable, wireless, satellite, wireless, and mobile) that provide high-speed data transmission and connection to the internet. Prior studies have described disparities in access to broadband coverage in the United States, particularly in rural communities and tribal lands [49,50]. By the most recent Federal Communications Commission estimates, 77% of Americans in rural areas and 72% in tribal lands have broadband access via fixed terrestrial (eg, cable) and mobile (cellular) networks at speeds that can support 2-way video-conferencing as compared to 99% of Americans in urban areas [51]. In this study, most New England hospitals and EDs reported adequate broadband access via fixed and mobile networks to support video streaming in clinical spaces. However, 1 in 5 rural hospitals in New England may lose this capability if fixed networks are disrupted because they have inadequate access to mobile networks within facility walls. More research is required to understand regional capabilities to mobilize satellite or mobile towers when infrastructure is lost.

Telehealth platforms that function at low bandwidth speeds and operate on both fixed and mobile networks will be necessary for resiliency in disasters where telecommunications infrastructure may be damaged or destroyed, or networks overwhelmed by surging demand. Additionally, asynchronous communication mechanisms that remain operational in limited bandwidth settings could also be sufficient to serve some disasters and areas. Federal investment in closing the "digital divide" should include strategies to ensure reliability and redundancy of telecommunications infrastructure in vulnerable facilities in rural areas and tribal lands. A similar approach could support telehealth applications for humanitarian response in resource-limited settings and different cultural or geographic environments.

Widespread adoption and use of telehealth during the COVID-19 pandemic has resulted in broad technology acceptance within the global health care community. In the postpandemic environment, cost may become a lesser barrier as clinical needs push providers and organizations to adopt new models of remote care delivery [52]. We found high willingness to use regional disaster teleconsultation services to access key specialist groups among New England hospitals and EDs. This survey was conducted in 2021 after the first year of the pandemic, when many hospitals were still struggling with large patient surges and workforce shortages and using emergency operations [53,54]. While this may have biased respondents toward expressing greater willingness, their attitudes are arguably informed by real-world experience rather than conjecture. Whether frontline providers and clinicians would express similar levels of willingness to use disaster teleconsultation services is unclear, although simulation-based studies suggest this may hold true [17]. Future research examining attitudes and drivers of the adoption of disaster telehealth services on a provider level, mechanisms to disseminate awareness of service availability, and integration with existing emergency management plans will be needed to ensure service lines will actually be used. Finally, even the hospitals and EDs that are willing to use disaster telehealth services may experience barriers to implementation. Thus, system developers should not only indicate potential demotivating factors, barriers, or weaknesses to implementation but also identify critical acceptance criteria to implement disaster telehealth services on a hospital level.

The motivators and challenges to the implementation of regional disaster telehealth systems for cross-jurisdictional response in the United States parallel applications of telehealth for international humanitarian response [55]. The Sendai Framework for Disaster Risk Reduction 2015-2030 was developed to guide international efforts in disaster risk reduction through coordinated implementation of various measures to reduce vulnerabilities, increase preparedness for response and recovery, and strengthen resilience [56]. In 2022, rapidly deployable disaster telehealth services coordinated by an international, nongovernmental collaborative of digital health, telehealth, disaster response, and medical experts and staffed by clinical volunteers across the globe provided access to health care for Ukrainians displaced by the Russia-Ukraine conflict [57]. This was a powerful demonstration of how a disaster telehealth system could leverage a remote international workforce to support large-scale humanitarian response and supplement in-person field response. However, in the United States, many insurers and state licensing boards only permit telemedical practice with oversight due to the risk of potential abuse. Furthermore, lack of adoption of standards or agreements prevents efficient use of telehealth solutions to support timely "surge capacity" to deliver health services during emergencies because expert volunteers are mired in cumbersome and complicated processes of entering into agreements with their home jurisdictions before they can be digitally "deployed" across jurisdictions. We call for the uniform adoption of national (eg, Uniform Emergency Volunteer Health Practitioners Act) and international standards governing licensure and verification of medical volunteers practicing across jurisdictions to facilitate engagement and avoid implementation delays.

Limitations

This study has potential limitations. First, we defined disaster teleconsultation services as electronic consultations between providers as recognized by the Health Resources and Services Administration [18]. Here, teleconsultants provide peer-to-peer advice only and the bedside clinician makes final patient care decisions. However, some respondents may not have distinguished this from nonconsultative services or other types of routine, nondisaster telehealth services where a remote clinician directs patient care. One possibility is that emergency managers lack knowledge of the credentialing procedures that are the purview of compliance officers and provided erroneous answers. Another possibility is that despite our efforts to define the limited scope of disaster teleconsultation services, respondents were confused by or disagreed with our definitions. If respondents did not distinguish between teleconsultation for advice and telehealth to provide direct patient care, they could perceive credentialing procedures as necessary. Confusion about the service type offered could overestimate variability in disaster credentialing procedures. However, respondents were provided ample opportunity to ask clarifying questions regarding terms and definitions during survey administration, and we did not perceive any confusion to this end.

Second, the data were self-reported by 1 person per site, which may have introduced information bias. However, we mitigated this by contacting emergency managers as respondents, as they are responsible for and knowledgeable about disaster operations and plans for their facilities. Third, the attitudes of hospital emergency managers may not reflect those of frontline clinicians or other hospital administrators, so it is possible our estimates of willingness to use regional disaster telehealth services are inaccurate. Future research should examine the attitudes of additional groups involved in the adoption and implementation of telehealth services for disaster response on a hospital level. Last, this survey was administered in New England, which may not be representative of the other regions. However, diversity in geography and hospital and ED types within the region supports the generalizability of the findings.

Conclusions

In summary, we found that most hospitals and EDs in New England have the necessary access to statewide emergency notification mechanisms, telecommunications infrastructure, and willingness to use a new regional disaster teleconsultation system to access specialists if a large-scale event affected their facility. Even in a relatively resource-rich region, access to burn care was the most limited among numerous disaster-relevant specialty types and should be an early focus for service line development. We also identified significant variability and lack of standardization in hospital credentialing practices, which could delay timely access to teleconsultants and diminish potential benefits for no-notice disasters with time-sensitive outcomes. These findings can inform how health systems and disaster response organizations can coordinate strategic plans to implement and integrate new telehealth tools for regional disaster medical response in New England. We encourage future research on interregional differences in clinical needs, gaps in telecommunications infrastructure, and reasons for variability in disaster credentialing practices at a hospital level. This research is critical to build an effective telehealth capability that supports real-world needs for regional disaster health care response across the United States.

Acknowledgments

The authors would like to thank Lily Y Lu, Sabrina N Robichaud, and Cordelia Zhong for their assistance with data collection, and Gerard Dubois and the Northeast Telehealth Resource Center for expert guidance. This work is funded by Administration for Strategic Preparedness and Response (grant #HITEP180042). Abstract

Background: Studies have shown increasing COVID-19 vaccination hesitancy among migrant populations in certain settings compared to the general population. Hong Kong has a growing migrant population with diverse ethnic backgrounds. Apart from individual-level factors, little is known about the migrants' preference related to COVID-19 vaccines.

Objective: This study aims to investigate which COVID-19 vaccine–related attributes combined with individual factors may lead to vaccine acceptance or refusal among the migrant population in Hong Kong.

Methods: An online discrete choice experiment (DCE) was conducted among adults, including Chinese people, non-Chinese Asian migrants (South, Southeast and Northeast Asians), and non-Asian migrants (Europeans, Americans, and Africans) in Hong Kong from February 26 to April 26, 2021. The participants were recruited using quota sampling and sent a link to a web survey. The vaccination attributes included in 8 choice sets in each of the 4 blocks were vaccine brand, safety and efficacy, vaccine uptake by people around, professionals' recommendation, vaccination venue, and quarantine exemption for vaccinated travelers. A nested logistic model (NLM) and a latent-class logit (LCL) model were used for statistical analysis.

Results: A total of 208 (response rate 62.1%) migrant participants were included. Among the migrants, those with longer local residential years (n=31, 27.7%, for ≥10 years, n=7, 20.6%, for 7-9 years, n=2, 6.7%, for 4-6 years, and n=3, 9.7%, for ≤3 years; *P*=.03), lower education level (n=28, 28.3%, vs n=15, 13.9%, *P*=.01), and lower income (n=33, 25.2%, vs n=10, 13.2%, *P*=.04) were more likely to refuse COVID-19 vaccination irrespective of vaccination attributes. The BioNTech vaccine compared with Sinovac (adjusted odds ratio [AOR]=1.75, 95% CI 1.14-2.68), vaccine with 90% (AOR=1.44, 95% CI 1.09-1.91) and 70% efficacy (AOR=1.21, 95% CI 1.03-1.44) compared with 50% efficacy, vaccine with fewer serious adverse events (1/100,000 compared with 1/10,000; AOR=1.12, 95% CI 1.00-1.24), and quarantine exemption for cross-border travelers (AOR=1.14, 95% CI 1.01-1.30) were the vaccine attributes that could increase the likelihood of vaccination among migrants. For individual-level factors, full-time homemakers (AOR=0.44, 95% CI 0.29-0.66), those with chronic conditions (AOR=0.61, 95% CI 0.41-0.91) and more children, and those who frequently received vaccine-related information from the workplace (AOR=0.42, 95% CI 0.31-0.57) were found to be reluctant to accept the vaccine. Those with a higher income (AOR=1.79, 95% CI 1.26-2.52), those knowing anyone infected with COVID-19 (AOR=1.73, 95% CI 1.25-2.38), those having greater perceived susceptibility of COVID-19 infection (AOR=3.42, 95% CI 2.52-4.64), those who received the influenza vaccine (AOR=2.15, 95% CI 1.45-3.19), and those who frequently received information from social media (AOR=1.52, 95% CI 1.12-2.05) were more likely to accept the vaccine.

Conclusions: This study implies that migrants have COVID-19 vaccination preference heterogeneity and that more targeted and tailored approaches are needed to promote vaccine acceptance for different subgroups of the migrant population in Hong Kong. Vaccination promotion strategies are needed for low-education and low-income migrant groups, migrants with chronic diseases, the working migrant population, homemakers, and parents.

Introduction

COVID-19 vaccination has been implemented worldwide as a crucial public health tool to reduce morbidity and mortality and eventually put an end to social distancing measures and the pandemic as a whole [1]. As of December 29, 2021, about 8.68 billion vaccine doses had been administered worldwide [2], first targeting priority groups and gradually extending vaccination to the general population.

For this campaign to be successful, public acceptance and the willingness to undergo vaccination are needed across the whole population [1,3]; yet research indicates that migrant populations in certain settings are particularly hesitant toward COVID-19 vaccines [4,5]. However, little is known about the migrants' preference related to COVID-19 vaccines [6]; this undermines health equity, since as vulnerable populations, migrants are at a higher risk of COVID-19 infection, hospitalization, and mortality compared to the general population [7].

Previous studies have mainly focused on individual-level factors. They have reported that migrants' socioeconomic conditions and gender have an impact on COVID-19 vaccine acceptance [3,8,9]. Ethnicity-related factors can influence vaccine hesitancy as well [4,9-11]. Moreover, the literature on migrant health suggests that migration history can differently affect access to primary medicine and vaccination uptake [12].

Finally, low vaccine coverage among migrants may be due to limited knowledge of the overall health care system [4]; in addition, during the pandemic, barriers within health care systems usually identified as possible factors affecting migrants' lower access to preventive care and vaccinations have increased [5,9]. Trust in the health care system or in vaccines may affect vaccine uptake as well [4,9,11,13].

Hong Kong is an international city with a growing migrant and ethnic population, which reached 8% of the overall population in 2016, representing a sharp increase of about 70% compared to 2006 [14]. Despite its facade of an international and inclusive city, Hong Kong holds a hegemonic Chinese culture where exclusion is widespread [15]; this may affect migrant population access and attitudes toward vaccines as well.

Although research has focused on individual variables, little is known about how vaccine-related attributes may influence migrants' attitudes toward COVID-19 vaccination. Similar to previous research conducted on the general population [16,17], this study aims to investigate COVID-19 vaccine preferences among the migrant population by identifying which individual factors combined with vaccine-related attributes may lead to vaccine acceptance or refusal. Although most of the literature focuses on the general population, this analysis will provide a more nuanced understanding of migrants' overall attitudes toward vaccines and guide public health efforts to promote COVID-19 vaccination among more diverse groups.

Methods

Study Sample and Data Collection

An online discrete choice experiment (DCE) was conducted among all adults, including Chinese people and non-Chinese migrants in Hong Kong, China, from February 26 to April 26, 2021, the first 2 months after the commencement of the citywide COVID-19 vaccination program of 2 major vaccines. Chinese or non-Chinese residents of Hong Kong aged 18 years or above were eligible to participate in the survey, while those who had a history of being diagnosed with COVID-19 or had received any COVID-19 vaccine were excluded. The participants were recruited using quota sampling for people with different ethnicities according to Hong Kong census data [18], including Chinese, non-Chinese Asians (South Asians, Southeast Asians and Northeast Asians), and non-Asians (Europeans, Americans, and Africans). A web link to the survey was sent to potential participants through the network established in a previous survey, through local nongovernmental organizations that provide social services to socially disadvantaged individuals and migrants, and through persons familiar with the migrant communities. The distribution of ethnicities in the sample was monitored online during the survey to adjust the sampling strategies for the remaining participants, and ceiling limits (quotas) were set for the number of participants with different ethnicities based on the ethnical distribution in the population. The survey was originally designed in English and then forward- and back-translated to other languages and thus was also available in Bahasa Indonesia, Nepali, Urdu, Thai, and traditional Chinese.

Experimental Design

A DCE requires participants to make choices from a series of choice sets described by a number of attributes. The attributes describing the COVID-19 vaccination plans included vaccine brand, efficacy, safety, uptake of vaccine by people around, recommendations from professionals, venue for vaccination, and exemption of quarantine for vaccinated travelers (Table 1), which were generated from prior individual interviews with 45

Hong Kong residents with diverse demographical characteristics and health conditions [19]. In this qualitative study, the confidence in and concerns about the benefits and side effects of the vaccines, vaccine origins and brands, recommendations from health care professionals, social influences of family members and friends, expectations of ease of travel restrictions, and logistics arrangement of vaccination (eg, locations of receiving the vaccines) were frequently reported as factors influencing the participants' willingness to accept the vaccines [19]. The levels of the attributes were determined based on the existing studies on vaccine effectiveness and safety [20-23] and the vaccination practice in Hong Kong [24]. For vaccine brands, all 3 (Sinovac, BioNtech, and AstraZeneca) were planned to be used for vaccination in Hong Kong at the time of the study, although only the former 2 of them were actually launched for the public eventually.

The full factorial design of the 7 attributes involved 648 combinations and 209,628 pairwise choice sets, so it was impossible to adopt the full factorial design in the DCE. The choice sets were designed using the D-optimality algorithm, and a total of 32 choice sets were generated. To further reduce the cognitive burden on participants, these choice sets were divided into 4 blocks, with 8 choice sets in each. The participants were randomly assigned to 1 of the 4 blocks: participants only provided their response to the choice sets in the block they were randomized to. In each choice set, participants were asked to choose 1 of the 3 choices ("vaccination plans"), 2 of which were choices to get a COVID-19 vaccine with different attributes, while the third choice was an opt-out option for accepting neither vaccination plan ("no vaccination"). An example of a choice set is shown in Table 2. The questionnaire was validated in the Chinese language. In total, 12 eligible adults were invited to a pilot survey for refinement of the translation in other languages.

Table 1. Attributes and levels for the DCE[a].

Attribute	Levels
Brand	• Sinovac • BioNTech • AstraZeneca
Probability of COVID-19 infection (efficacy)	• Reduce 50% infections • Reduce 70% infections • Reduce 90% infections
Probability of serious adverse event (safety)	• 1/10,000 • 1/100,000
Vaccine uptake by people around	• Nobody • Friends/colleagues • Family members
Recommendations from professionals	• Recommended by general physicians • Recommended by the government expert panel
Venue for vaccination	• Community hall • Health care facilities • Housing estate/workplace
Quarantine arrangement for vaccinated travelers	• At least 14-day compulsory quarantine • Exempted from the 14-day quarantine

[a] DCE: discrete choice experiment.

Table 2. Example of choice sets.

Attribute	Vaccination plan 1	Vaccination plan 2	Do not receive any vaccination
Brand	Sinovac	BioNTech	None
Probability of COVID-19 infection	Reduce 50% infections	Reduce 90% infections	No reduction
Probability of serious adverse event	1/100,000	1/10,000	No serious adverse event
Vaccine uptake by people around	Family members received the vaccine	No known people received the vaccine	N/A[a]
Recommendations from professionals	Government expert advisory panel	General physicians	N/A
Venue for vaccination	Housing estate/workplace	Community hall	N/A
Quarantine arrangement for vaccinated traveler	At least 14-day compulsory quarantine	Exempted from the 14-day quarantine	At least 14-day compulsory quarantine
Which vaccination plan would you choose?	Plan 1: ☐	Plan 2: ☐	Neither plan: ☐

[a] N/A: not applicable.

Measurement

In addition to measuring the participants' choice of COVID-19 vaccine via the DCE, the questionnaire also collected data on (1) experience, knowledge, and behaviors during the pandemic, such as whether the participant knew anyone infected with COVID-19, and the perceived susceptibility and severity of COVID-19 infection; (2) experience and perceptions related to vaccination, including previous uptake of influenza vaccination and information sources on COVID-19 vaccination; and (3) demographic and socioeconomic status of the participants, including their ethnicity, years of residence in Hong Kong, income level, education level, and employment status.

Ethical Considerations

The study was approved by the Survey and Behavioral Research Ethics Committee of the anonymous university (ref. no. SBRE-20-540). At the start of the survey, an electronic informed consent form was provided to the participants with details of the study purpose, data anonymity, and confidentiality. Those who agreed to join signed it electronically before moving to the questionnaire. Later, a supermarket coupon of HK $100 (US $12.74) was sent to each participant through mail. All the responses were anonymized and contained no personal information about any participant. The data were stored online and secured with passwords.

Statistical Analysis

To find out the preference of all participants for vaccination and its heterogeneity across ethnic groups, a latent-class logit (LCL) model was applied to the entire sample. LCL allocated participants in the survey sample with a similar preference for the vaccination attributes into the same latent class and provided estimates of the preference for each of the classes. The number of latent classes was determined based on the Akaike information criterion (AIC) and Bayesian information criterion (BIC) of the LCL model with the different number of classes. The difference in the preference between the Chinese and non-Chinese participants was explored. Subsequently, the analysis focused on the preference pattern within the non-Chinese migrants due to a substantial difference found between Chinese people and non-Chinese migrants, where the evidence for the latter group was limited.

For migrants, COVID-19 "vaccine refusal" irrespective of vaccine attributes was considered when a participant consistently chose "no vaccination" throughout all 8 choice sets. The vaccine refusal rate across different socialdemographic characteristics and the perception and experience during the COVID-19 pandemic were summarized using cross-tabulation and the chi-square test. To find out the influence of vaccination attributes, a nested logistic model (NLM) was adopted to simulate the choices over the vaccination plans in the DCE survey, which involved 2 decisions, namely (1) whether to accept a COVID-19 vaccine and (2) which COVID-19 vaccine to accept. NLM allowed estimation of the influences of both vaccination attributes and individual-level factors on the vaccine acceptance. The dependent variable was the binary choice (0="not choose", 1="choose") made for each of the alternatives in the DCE choice sets, and the independent variables were vaccination attributes and individual-level factors. The individual vaccine acceptance probability was estimated based on NLM outcomes [25,26]. In addition, sensitivity analysis was performed using the LCL model among migrant participants to find out whether there was any preference heterogeneity.

Results

Sample Characteristics and COVID-19 Vaccine Refusal

In total, 2892 Chinese people and non-Chinese migrants were invited, of which 2392 (82.7%) were eligible. Among them, 434 (18.1%) refused to participate in the survey and 261 (10.9%) did not complete the questionnaire; hence, 2032 (84.9%) valid responses were received.

Figure 1 shows the participant flow of the migrant group. A total of 462 people received the invitation, and 335 (72.5%) were eligible to the survey. Among them, 109 (32.5%) did not agree to participate and 18 (5.4%) did not complete the questionnaire; therefore, 208 (response rate 62.1%) participants were recruited. The characteristics of the participants can be found in Table 3. Of the 208 participants, 143 (68.8%) were female, and 67 (32.2%) were aged 18-29 years, 103 (49.5%) were aged 30-44 years, and 38 (18.3%) were aged 45 years or more. Most of them (n=180, 86.5%) reported their ethnicity as Asian. In addition, 108 (51.9%) of them attained a bachelor’s degree or above. Almost half of them (n=100, 48.1%) had a full-time job, and 33 (15.9%) were full-time homemakers. Furthermore, 76 (36.5%) of them had more than HK$ 30,000 (US $3821.68) as their monthly household income, which was the approximate median monthly household income in Hong Kong in 2020. Only 19 (9.1%) had chronic conditions. For years of residence, 112 (53.8%) had lived in Hong Kong for 10 years or more, while 31 (14.9%) of them had lived here for 3 years or less.

Regarding COVID-19 vaccine refusal irrespective of vaccination attributes (Table 3), participants with longer local residential years, lower education level, and lower income were more likely to refuse COVID-19 vaccination. With regard to ethnicity, Asian participants were more likely to refuse vaccination than non-Asian participants, although this difference was marginal. Full-time homemakers/housewives, those who had chronic conditions, those who did not know anyone having COVID-19, and those who did not receive influenza vaccines were more likely to refuse vaccination irrespective of the attributes, although the differences were not statistically significant. On the contrary, those with greater perceived susceptibility of COVID-19 infection were less likely to refuse vaccination.

Influence of COVID-19 Vaccination Attributes on Vaccine Acceptance Among the Entire Sample

A model with 6 latent classes was applied to test the preference heterogeneity between Chinese people and non-Chinese migrants (Table 4). Using class 6 as a reference, the migrants were much more likely to be assigned to class 1 based on their preference, followed by class 2 and class 4. In class 1, vaccine brand was the most important attribute that affected their choices, where BioNtech was the most preferable brand, followed by vaccine efficacy, venue of vaccination, vaccine uptake by others, and quarantine arrangement for vaccinated travelers. In class 2, vaccine brand, efficacy, safety, and quarantine arrangement for vaccinated travelers shared a similar level of perceived importance based on the respondents' choices, while vaccination at health care facilities and vaccination at the housing estate/workplace were preferable options as well. In class 4, higher vaccine efficacy was more important than the other attributes that lead to vaccine acceptance. The different preference pattern across classes 1, 2, and 4 implied that preference heterogeneity may be found within the migrant group, which is reported in the following sections. Compared to classes 3, 5, and 6, respondents in classes 1, 2, and 4 were more likely to be affected by the venue of vaccination. In class 3, the participants were efficacy oriented, preferred BioNtech and AstraZeneca, and were more likely to be influenced by general physicians with regard to vaccination decisions. In class 5, the participants preferred Sinovac, were more safety oriented, and presented a lower tendency to refuse vaccination than the other classes. Class 6 had the largest class share, where the participants shared similar preferences with participants in class 3 but were not influenced by recommendations from different health care professionals and vaccine uptake by their family members.

Table 4. Preference heterogeneity for COVID-19 vaccination plans in both Chinese people and non-Chinese migrants.

Attribute	Class 1, coefficient[a] (95% CI)	Class 2, coefficient[a] (95% CI)	Class 3, coefficient[a] (95% CI)	Class 4, coefficient[a] (95% CI)	Class 5, coefficient[a] (95% CI)	Class 6, coefficient[a] (95% CI)
Brand (reference=Sinovac)						
BioNtech	3.51[b] (2.97 to 4.06)	0.49[b] (0.33 to 0.65)	1.10[b] (0.87 to 1.32)	1.43[b] (1.05 to 1.81)	–3.59[b] (–4.12 to –3.07)	0.57[b] (0.01 to 1.12)
AstraZeneca	–0.29 (–0.73 to 0.16)	0.69[b] (0.52 to 0.85)	1.29[b] (1.06 to 1.53)	1.41[b] (0.94 to 1.89)	–4.04[b] (–4.58 to –3.50)	0.59[b] (0.03 to 1.15)
Efficacy (reference=50%)						
Reduce 70% infections	1.15[b] (0.83 to 1.48)	–0.03 (–0.16 to 0.10)	0.93[b] (0.69 to 1.16)	2.10[b] (1.73 to 2.48)	–0.01 (–0.44 to 0.41)	0.20 (–0.38 to 0.78)
Reduce 90% infections	0.56[b] (0.05 to 1.07)	0.74[b] (0.58 to 0.91)	2.32[b] (2.06 to 2.59)	3.43[b] (2.93 to 3.94)	0.30 (–0.14 to 0.75)	1.12[b] (0.58 to 1.65)

Influence of COVID-19 Vaccination Attributes on Vaccine Acceptance Among Migrants

Given that substantial preference heterogeneity was found between Chinese people and non-Chinese migrants, the preference of the migrants was further modeled separately. Among the COVID-19 vaccination attributes, brand, efficacy, safety (probability of serious adverse event), and the quarantine arrangement of vaccinated people could affect vaccine acceptance (Tables 5 and 6). Independent from efficacy and safety characteristics, participants were more likely to accept the BioNtech vaccine compared with Sinovac. The vaccine efficacy also made a substantial difference. A vaccine with 90% and 70% efficacy would increase the likelihood of vaccination by 44% and 21%, respectively. Fewer serious adverse events (1/100,000 vs 1/10,000) could also improve the likelihood of vaccination. Apart from brand, efficacy, and safety, if the quarantine for cross-border travelers can be exempted for those who received the vaccine, the likelihood of vaccine acceptance could increase by around 14%.

[a] NLM: nested logistic model.

[b] AOR: adjusted odds ratio.

[c] *P*<.001.

[d] *P*<.05.

For individual-level factors, participants who had been in Hong Kong for more than 7 years were less likely to accept the COVID-19 vaccine compared with those who had been in Hong Kong for less than 3 years. Full-time homemakers, those with chronic conditions and more children, and those who frequently received vaccine-related information from the workplace were found to be reluctant to accept the vaccine. On the contrary, those with a higher income, those knowing anyone infected with COVID-19, those having greater perceived susceptibility of COVID-19 infection, those who received the influenza vaccine, and those who frequently received information from social media were more likely to accept the vaccine.

Based on the model outcomes, the individual probability of the acceptance of vaccines with different characteristics can be estimated [25,26]. According to the estimation, an Asian migrant aged 18-29 years has a 73.6% chance to accept the BioNtech vaccine with 90% efficacy and a 1/100,000 serious adverse event probability when the vaccine is available in a community center, recommended by the government, and received by family members and when the quarantine exemption is in place. The acceptance probability was estimated to be 48.6% for the Sinovac vaccine with 50% efficacy. A non-Asian aged 18-29 years was estimated to have an 87.1% and a 69.8% chance to accept BioNtech and Sinovac vaccines, respectively. The acceptance probability changes with increasing age. For a migrant aged 30-44 years, the acceptance probabilities were estimated to be 88.9% (BioNtech) and 73.0% (Sinovac) among Asian migrants and 95.1% (BioNtech) and 86.9% (Sinovac) among non-Asian migrants. The estimated probabilities were similar for those aged above 45 years, which were 88.2% (BioNtech) and 71.8% (Sinovac) among Asian migrants and 94.8% (BioNtech) and 86.1% (Sinovac) among non-Asian migrants.

Sensitivity Analysis Account for Preference Heterogeneity

Substantial preference heterogeneity was found using a 4-class LCL model (Table 7). The participants had a 50.2% probability of belonging to class 1, where they attached greater importance to brand, efficacy, and exemption of quarantine for vaccinated travelers than the other attributes, as found in the NLM model for the entire study sample, and it was considered the reference group for class membership as it had the largest class size. Compared to class 1 (the reference group), participants in class 2 (16.1% probability) were more likely to live in Hong Kong for 7-9 years and they valued safety and the venue for vaccination, in addition to the 3 attributes mentioned in class 1. They were also likely to refuse vaccination (ie, choosing “no vaccination”). Class 2 and class 4 shared similar characteristics, they were likely to have longer local living experience compared to class 1, while class 4 was slightly more likely to comprise full-time homemakers. In class 4 (22.7% probability), the participants did not have clear preferences for these vaccination attributes.

Preferences in class 3 were quite different from those in classes 1 and 2. In class 3 (11.0% probability), participants preferred AstraZeneca over Sinovac and BioNtech and vaccine uptake by family and friends/colleagues as well as recommendations from experts from the government panel could also improve their COVID-19 vaccine acceptance, while exemption of quarantine did not have an impact on it. Participants in class 3 were more likely to be non-Asians and much less likely to be full-time homemakers.

Table 7. Sensitivity analysis for preference heterogeneity for COVID-19 vaccination plans.

Discussion

Principal Findings

This study investigated both vaccine-related attributes and individual-level factors to fully understand migrants' COVID-19 vaccine preferences in Hong Kong. It also provided an insight into the heterogeneity of the vaccine preference of the migrant population by dividing them into 4 classes.

Attributes

Our DCE study found that brand, efficacy, and quarantine arrangement for vaccinated people to be the most relevant vaccine-related attributes for vaccine acceptance among the migrant population in Hong Kong. The heterogeneity analysis complemented these findings, as half of the participants belonging to class 1 made their preferences based on these attributes. In addition, participants in class 3 preferred AstraZeneca over Sinovac and BioNtech. This indicated that migrants are inclined to use the brand as a proxy of unobserved characteristics in decision-making for vaccine acceptance. Previous research conducted on the US general population similarly showed brand and, specifically, the country where the vaccine was developed as predictors of COVID-19 vaccine acceptance [17,27]. With regard to efficacy, our study showed that the higher the efficacy, the higher the willingness to get vaccinated against COVID-19; this is in line with what emerged from studies in the general and ethnic populations in the United States [27] and the United Kingdom [17], where most of these studies have been conducted. Furthermore, specific migrant and ethnic groups may be persuaded if vaccines are proved to reduce the risk of being infected with COVID-19, as shown by research conducted in the United Kingdom [11]. The exemption of quarantine for vaccinated travelers was a predictor of COVID-19 vaccine acceptancy; this result is understandable within the Hong Kong context, where, upon returning, unvaccinated residents undergo self-paid 21-day compulsory quarantine in designated hotels compared to only 7 days for those vaccinated [28]. Other studies did not mention the quarantine arrangement specifically but more generally confirmed the vaccine would be accepted if it enabled social and family life to return to normal [11]. In addition to Sinovac and efficacy, our study found that a lower likelihood of serious adverse events is an attribute for vaccine acceptance, particularly for class 2 and class 3 participants. Similarly, the literature showed that concerns about vaccine safety and side effects are a predictor of vaccine hesitancy in both general and migrant populations in the United Kingdom [6,10,11].

The vaccine uptake by friends, colleagues, and family members; information from family and friends; and recommendations from the government and health care professionals were insignificant for the entire population sample but significantly affected only class 3 participants' vaccine acceptance. These participants were mostly non-Asian. The existing literature suggests that such recommendations may be welcomed only in the presence of trust toward the government and the health care system [5,6]. In addition, American Hispanics in the United States, for instance, rely on their community network to make decisions about COVID-19 vaccines [29]. Similarly, migrants in the United Kingdom tend to look for information from peers, especially when the government and health care system are not trusted [5]. To promote COVID-19 vaccinations and improve their health care access and quality, efforts should be made to establish more trustworthy relationships between the local government and the health care system with all the migrant populations in Hong Kong.

In this study, based on vaccine attributes, we did not find significant preference differences between the migrant population and the general population. Instead, there was a substantial heterogeneity representing diversity in the preferences of the non-Chinese migrant population in Hong Kong. This implied that while designing COVID-19 vaccination promotion programs for migrants, this diversity should be considered and more targeted strategies should be used for different migrant subgroups. The venue of vaccination was the only significant factor for vaccine acceptance among migrants when compared to the general population, which is consistent with the literature that suggests an inconvenient location would influence hesitancy [30] and minimal travel or comfortable places would reduce hesitancy among undocumented migrants, asylum seekers, and refugees [6]. However, in the sensitivity analysis for preference heterogeneity among the migrant population, only a small proportion of participants in class 2 of our study had an attached preference with the venue of vaccination. These participants also shared characteristics with class 4 participants who did not have a clear preference for vaccine attributes. This means the choices made by these people were quite random, so they were probably overwhelmed by the choice tasks.

Individual-Level Factors

Our results also showed that irrespective of the vaccination attributes, longer residential years, lower education and income, and less perceived COVID-19 infection susceptibility were associated with increased COVID-19 vaccine refusal. These individual-level factors were also related to decreased COVID-19 vaccine acceptance among those whose preferences were linked to vaccine attributes. Participants with more than 7 years of migration history in Hong Kong were least likely to get vaccinated compared to those with a more recent migration history. This aligns with much of the literature on migrant health, where a longer history of migration and host country language proficiency are associated with acculturation in the host society and health care use similar to nationals [12]; vaccine hesitancy among Hong Kong local residents is in fact similarly widespread [31]. Therefore, effective policies and strategies that can boost vaccination acceptance among the broader public will aid in achieving high vaccination uptake among migrants as well. Previous research has also identified the educational level as a predictor of vaccine acceptance [9,11]. In line with most research, a higher income was also associated with higher vaccine acceptance, while a lower income was associated with vaccine resistance [10,27]. Similar to what emerged from the previous literature, knowing someone diagnosed with COVID-19 was a factor for vaccine acceptance [17] and so was high risk perception; conversely, low risk perception was associated with higher hesitancy [30].

In addition, our study also identified other individual-level factors that predict COVID-19 vaccine acceptance among individuals who preferred different vaccine programs. A previous influenza vaccination experience was relevant for COVID-19 vaccine acceptance; this is in line with studies conducted in migrant and general populations in other settings [8,10,17].

Our study also indicated that those participants who often received information from social media were more likely to accept COVID-19 vaccination. Regarding the role of this source of information, the literature is mixed, with varying degrees of results; some studies suggest social media is used to solve confusion from contradicting information [5], while other research suggests it is a source of misinformation among migrants [4,6]. Our study also found that those who received information from the workplace were less likely to get vaccinated. This might be because, on the one hand, these people are employed and healthy and therefore have low risk perception, leading to low vaccine acceptance. On the other hand, working people are exposed to different information sources, including local ones; discussions with their colleagues may also increase their vaccination hesitancy, as there is a decreasing trend in the willingness toward COVID-19 vaccination among general working people in Hong Kong [32]. The promotion of vaccine-related information through this source should be encouraged.

Older age was identified as a factor of vaccine acceptance; specifically, participants aged 30-44 years would be the most likely to get vaccinated, while the youngest cohort (18-29 years old) would be the least likely to join the vaccination campaign. A study in the United Kingdom confirmed the young group (16-24 years old) to be the most hesitant [11]; this hesitancy may be motivated by low risk perception compared to other age groups [30]. COVID-19 vaccination promotion campaigns should target young age group specifically among the migrant population in Hong Kong.

In line with the international literature, the Hong Kong Centre for Health Protection encourages individuals with chronic conditions to get vaccinated against COVID-19, since they are at a higher risk of morbidity and mortality due to COVID-19 infection [33]; however, our study highlighted that people with chronic diseases are less likely to accept vaccines. This result suggests the need to plan COVID-19 vaccination promotion campaigns targeting this high-risk group specifically.

Being a homemaker and having children were indicators of COVID-19 vaccine hesitancy; in the United Kingdom, those living with children are similarly less likely to accept the vaccine [10]. This might be because migrants have a lack of family and social support and, being parents, they are main carers of their children. During COVID-19, the care burden of parents, particularly homemakers and mothers, has increased due to lockdown, school closure, and home schooling. They have busy routines and no time for making appointments and going for vaccination. Moreover, there might be concerns about who will take care of their children in case they have vaccine-related side effects. So, along with providing information about vaccine safety, an outreach approach can be considered for this particular migrant subgroup. Qualitative research is needed to further address the reasons behind this attitude.

In this study, gender was not a predictor of COVID-19 vaccine hesitancy; this is in contrast with previous research in other settings that identified women as being more hesitant compared to men both in the general and in the migrant population [8,10,11,17].

Limitations

Our study had some limitations that should be clarified when interpreting the results. First, the preference of respondents for COVID-19 vaccination is subject to change with time and could be different as the vaccination campaign progresses. It may also have been affected by reported adverse events following immunization for COVID-19, which were not captured in this survey. Second, although we incorporated “Asian”/“non-Asian” as a variable for ethnicity in the analysis (Tables 5 and 6), there were no significant difference in vaccine acceptance between these 2 groups, and due to the limited sample size of ethnicity subgroups and statistical power, we could not further subdivide the ethnicity in our analysis. Instead, the LCL model was used to identify the preference heterogeneity (Table 7), where non-Asian migrant respondents tended to attach more importance to the vaccination of family and friends and preferred AstraZeneca to the other 2 vaccine brands compared to Asian migrants. However, the ethnicity of the respondents could not be further divided in the analysis due to the limited subgroup sample size. Third, although the survey was piloted and refined prior to the formal investigation, there were around 20% respondents (class 4 in the LCL model) who may have been overwhelmed by the cognitive burden of the DCE: their COVID-19 vaccination choice appears to be random. By using the LCL model, we were able to separate them from other groups of respondents and avoid affecting the results.

Conclusion

In summary, this study provided insight into how different COVID-19 vaccine attributes, preferences, and individual-level characteristics of the migrant population could influence their COVID-19 vaccine acceptance. Although vaccine brand, efficacy, safety, and quarantine exemption were the most preferred attributes for the majority of the migrants, we reiterate that there is COVID-19 vaccination preference heterogeneity among migrants and that more targeted and tailored approaches are needed to promote vaccine acceptance for different subgroups of the migrant population in Hong Kong. The increased willingness toward COVID-19 vaccination in the general population will reduce vaccine hesitancy among migrants with long years of living experience in Hong Kong. Vaccination promotional programs for low-education and low-income migrant groups should be designed in different languages. The dissemination of COVID-19 vaccine information, particularly about efficacy and safety, through social media platforms can be continued, and information dissemination at the workplace for the working migrant population should also be considered. Detailed and tailored educational programs should be provided to people with chronic diseases to promote COVID-19 vaccination in this high-risk group. An outreach approach for people with children, particularly homemakers and mothers, can be used. Further follow-up studies, including qualitative interviews, can be conducted with these participants to explore in-depth the reasons behind their COVID-19 vaccination preferences and refusal.

Abstract

Background: Fatal drug overdose surveillance informs prevention but is often delayed because of autopsy report processing and death certificate coding. Autopsy reports contain narrative text describing scene evidence and medical history (similar to preliminary death scene investigation reports) and may serve as early data sources for identifying fatal drug overdoses. To facilitate timely fatal overdose reporting, natural language processing was applied to narrative texts from autopsies.

Objective: This study aimed to develop a natural language processing–based model that predicts the likelihood that an autopsy report narrative describes an accidental or undetermined fatal drug overdose.

Methods: Autopsy reports of all manners of death (2019-2021) were obtained from the Tennessee Office of the State Chief Medical Examiner. The text was extracted from autopsy reports (PDFs) using optical character recognition. Three common narrative text sections were identified, concatenated, and preprocessed (bag-of-words) using term frequency–inverse document frequency scoring. Logistic regression, support vector machine (SVM), random forest, and gradient boosted tree classifiers were developed and validated. Models were trained and calibrated using autopsies from 2019 to 2020 and tested using those from 2021. Model discrimination was evaluated using the area under the receiver operating characteristic, precision, recall, F_1-score, and F_2-score (prioritizes recall over precision). Calibration was performed using logistic regression (Platt scaling) and evaluated using the Spiegelhalter z test. Shapley additive explanations values were generated for models compatible with this method. In a post hoc subgroup analysis of the random forest classifier, model discrimination was evaluated by forensic center, race, age, sex, and education level.

Results: A total of 17,342 autopsies (n=5934, 34.22% cases) were used for model development and validation. The training set included 10,215 autopsies (n=3342, 32.72% cases), the calibration set included 538 autopsies (n=183, 34.01% cases), and the test set included 6589 autopsies (n=2409, 36.56% cases). The vocabulary set contained 4002 terms. All models showed excellent performance (area under the receiver operating characteristic ≥0.95, precision ≥0.94, recall ≥0.92, F_1-score ≥0.94, and F_2-score ≥0.92). The SVM and random forest classifiers achieved the highest F_2-scores (0.948 and 0.947, respectively). The logistic regression and random forest were calibrated (P=.95 and P=.85, respectively), whereas the SVM and gradient boosted tree classifiers were miscalibrated (P=.03 and P<.001, respectively). “Fentanyl” and “accident” had the highest Shapley additive explanations values. Post hoc subgroup analyses revealed lower F_2-scores for autopsies from forensic centers D and E. Lower F_2-score were observed for the American Indian, Asian, ≤14 years, and ≥65 years subgroups, but larger sample sizes are needed to validate these findings.

Conclusions: The random forest classifier may be suitable for identifying potential accidental and undetermined fatal overdose autopsies. Further validation studies should be conducted to ensure early detection of accidental and undetermined fatal drug overdoses across all subgroups.

fatal drug overdose; natural language processing; surveillance; Tennessee; State Unintentional Drug Overdose Reporting System; SUDORS

Introduction

Background

In recent years, incidences of fatal drug overdose have surged in the United States. During the COVID-19 pandemic, the per capita monthly overdose death rate increased by 60% in May 2020 compared with May 2019 [1]. At the state level, Tennessee recorded an increase of 98% from May 2019 to May 2020 and was surpassed by only West Virginia and Kentucky. Since the pandemic, the rate of increase in fatal overdoses has slowed; however, fatal drug overdoses remain a public health concern with a substantial economic burden [2,3]. Provisional national data estimated that 107,622 drug overdose deaths occurred in 2021, an increase of 15% from 2020 [2]. Meanwhile, Tennessee has continued to surpass national trends, recording 3814 overdose deaths in 2021, a 26% increase from 2020 [4]. This stark increase in overdose deaths calls for improved surveillance, intervention, and prevention work to confront the overdose crisis at the state level.

Fatal drug overdose surveillance provides critical information for prevention and intervention. Specifically, surveillance helps identify where fatal overdoses occur, what substances were involved, and whether those trends have changed over time, all of which help make response efforts more targeted and relevant [5]. Data timeliness enables more effective and immediate intervention. The Tennessee Department of Health (TDH) currently conducts fatal drug overdose surveillance through the State Unintentional Drug Overdose Reporting System (SUDORS). SUDORS captures the details associated with accidental and undetermined fatal overdoses using death certificates, death scene investigations, autopsies, toxicology reports, and prescription drug monitoring program data. SUDORS is nested within the National Violent Death Reporting System and is funded by the Overdose Data to Action grant from the Centers for Disease Control and Prevention [6].

Although SUDORS provides a wealth of knowledge pertaining to fatal drug overdoses, a delay of 6 months occurs from the time of death to data collection. The delay is needed for death certificate coding to be completed and autopsy reports to become available for abstraction [7,8]. Notably, recent efforts to facilitate rapid fatal drug overdose surveillance have leveraged natural language processing (NLP). Several studies have explored the application of NLP to social media data for more timely fatal drug overdose surveillance [9-11]. Although potentially available closer to real time, social media data are subject to other challenges such as selection bias (social media users vs nonusers), user privacy settings limiting access to posts, and observer effects altering user behaviors [12]. Other studies have applied NLP to more traditional data sources for surveillance. Using death certificates, some surveillance teams have identified drug overdose deaths from cause of death fields available before the final cause of death coding [13-15]. Other teams have used text from verbal autopsies, which describe interviews with witnesses or relatives, as opposed to forensic autopsies, which detail findings from extensive physical examinations and toxicology tests [16,17]. Text from forensic autopsy reports has been used for the automatic classification of causes of death unrelated to drug overdoses [18]. However, to the best of our knowledge, no studies have leveraged free text in forensic autopsy reports to specifically predict fatal overdoses. Autopsy narrative text is similar to scene evidence descriptions in medicolegal documents, which are available sooner than autopsies.

Objectives

Faster identification of fatal overdoses can facilitate timely prevention and response efforts. In partnership with a research team in Biomedical Informatics at Vanderbilt University Medical Center (VUMC), the TDH sought to use NLP to identify fatal drug overdose deaths using narrative text from forensic autopsy reports.

Methods

Tennessee Fatal Drug Overdose Data Abstraction Process

TDH operates within a decentralized medicolegal death investigation system. Each of the 95 counties reports to 1 of the 5 forensic centers, which send reports to the Tennessee Office of the State Chief Medical Examiner (OSCME). The OSCME manages a repository of autopsy reports from all the forensic centers. Using the International Classification of Diseases, Tenth Revision (ICD-10) codes and keywords in death certificates, the SUDORS team identifies potential fatal overdoses. The SUDORS team obtains access to relevant autopsy reports and manually reviews each report to abstract variables into a REDCap (Research Electronic Data Capture) database (hereafter referred to as the SUDORS database) [19,20]. The SUDORS database contains information such as basic demographics, location of death, cause of death, and death scene information. As part of routine work at the TDH, at least 2 SUDORS abstractors review each case to ensure accurate coding.

Data Sources

NLP models were developed using text from forensic autopsy reports describing all manners of death from 2019 to 2021. Autopsies included all fatal overdose deaths identified by the

SUDORS team (cases) and the remaining other-cause deaths (controls) in the OSCME repository from 2019 to 2021, as of August 31, 2022. Autopsies were in semistructured forms containing common headings (detailed below) and computer-entered text. Autopsies were received as faxes or scans (PDFs) and processed using Adobe Acrobat Pro optical character recognition (OCR; Adobe). The outcome of interest was whether a given autopsy described an accidental or undetermined (ie, could not be definitively declared as accidental) fatal drug overdose, as indicated by the SUDORS team in the SUDORS database.

Narrative sections were defined as free-text portions of the autopsy that included the death scene information and medical history. These sections were commonly preceded by headings such as "summary of case," "summary and interpretation," "summary and opinion," and "narrative summary." The SUDORS team deemed these narrative sections to be the most informative parts of the autopsy report for determining the cause of death. Other data elements in the autopsy report varied substantially in quality (scanned toxicology results from different laboratories) or contained information that was interpreted and summarized in narrative sections (internal examination findings, external examination findings, and toxicology results). As such, this approach was limited to narrative sections to improve generalizability to other data sources in the future, such as medical examiner scene investigation notes, which are similar in content to the autopsy narrative text. This study was conducted before medical examiner notes were made available to the SUDORS team.

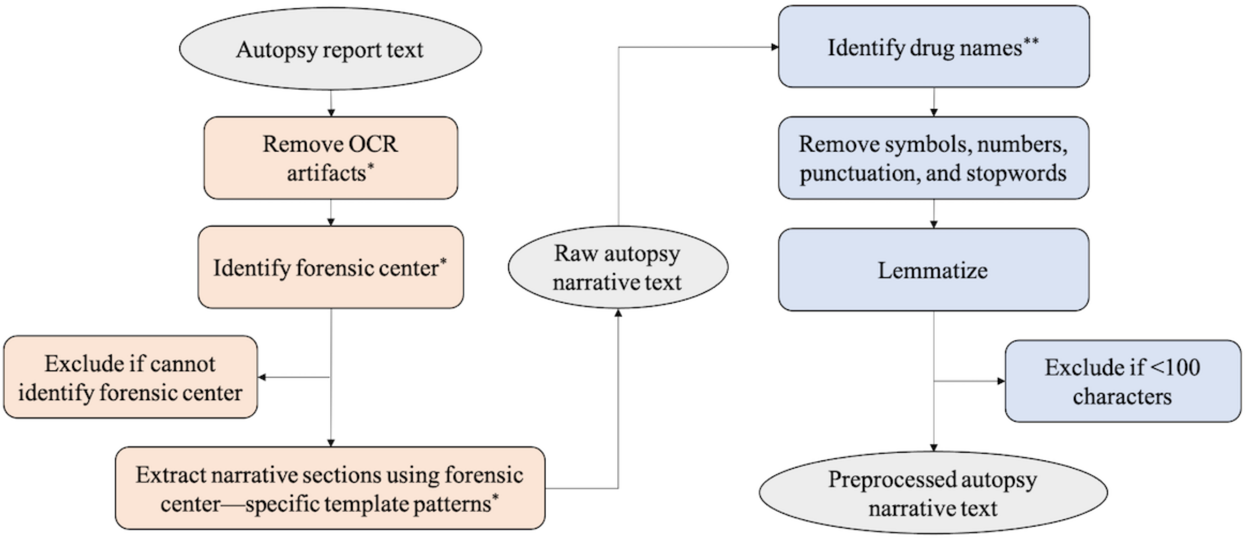
Preprocessing of Narrative Text

Autopsy PDFs were converted to a binary format and parsed page by page into text. Symbols that were likely artifacts of the OCR process (as determined by a manual review) were removed using regular expressions. The autopsy report templates were semistructured and unique to each forensic center. Template text patterns were identified by manual review and used to extract the forensic center issuing the autopsy, as well as relevant narrative sections. Autopsies for which a forensic center could not be identified using this templated language were removed from the data set.

To facilitate the comparison of information across report formats, narrative text was divided into three sections based on location within the autopsy report: (1) an initial narrative (beginning of report), (2) a case summary (middle of report and after internal and external examination findings), and (3) a summary of circumstances (end of report). Narrative sections within the same autopsy report were concatenated such that each report had only one combined narrative section.

The autopsy narrative text was extracted and preprocessed according to the steps outlined in Figure 1. A set of rules were developed using patterns found by manual review and enacted to remove additional artifacts resulting from the OCR process while ensuring the detection of drug names containing hyphens (eg, "4-ANPP" or 4-anilino-N-phenethylpiperidine) as one word rather than separate words ("4" and "ANPP"). Generalized regular expressions were used to identify potential references to drugs to account for novel drug combinations and varying OCR qualities. Words containing a number, hyphen, and letter were identified as potential drugs and combined ("4ANPP"). An exception to this rule was if the string contained "old" or "year," in which case the string likely referred to age rather than a drug ("35-year-old"). The numbers were removed if they were detected in words that were not identified as potential drug names. Punctuation and stop words (with the exception of "none" and "nowhere") were removed, and terms were lemmatized. Reports with fewer than 100 characters were likely not sufficiently processed via OCR and were thus removed from the data set.

Figure 1. Autopsy narrative text extraction (orange) and preprocessing (blue) steps. *Regular expression patterns determined by manual review with input from SUDORS team. **Words with a number, hyphen, and letter were combined (eg, "4-ANPP" or 4-anilino-N-phenethylpiperidine converted to "4ANPP"). An exception was if the string contained "old" or "year" (eg, "35-year-old"). OCR: optical character recognition; SUDORS: State Unintentional Drug Overdose Reporting System.



Modeling Plan

Autopsies from 2019 to 2020 were used for training (95%) and calibration (5%), and autopsies from 2021 were used for testing. This allowed model development to occur while the SUDORS team abstracted information from 2021 autopsies. Bag-of-words models were developed using term frequency–inverse document frequency scoring, which normalizes the word count in a given document based on the prevalence of the word among all documents, such that rarer words are given higher scores. Terms appearing in fewer than 20 documents in the training set or with fewer than 4 characters were excluded.

Logistic regression, support vector machine (SVM), random forest, and gradient boosted tree classifiers were generated. Hyperparameters for SVM, random forest, and gradient boosted trees were tuned with 5-fold cross-validation.

Model Metrics

The area under the receiver operating characteristic (AUROC), precision, recall, F_1-score (equal weighting of precision and recall), and F_2-score (recall weighted heavier than precision) were calculated for the corresponding hold-out data sets. Model error was evaluated using 100 bootstrapped samples, and 95% CIs were generated for each metric. Recall was identified as the most important metric that ensured that all potential cases of fatal overdoses would be reviewed by the surveillance team. Therefore, the F_2-score rather than F_1-score was primarily used to compare model performance.

The SVM, random forest, and gradient boosted tree classifiers achieving the highest F_2-scores were calibrated using Platt scaling, which applies logistic regression to normalize the predicted probabilities from the test set to the expected distribution of probabilities, as determined by the calibration set. The divergence between the predicted and expected probabilities of fatal overdoses was evaluated using the Spiegelhalter *z* test statistic. SHAP (Shapley additive explanations) values were generated for the random forest and gradient boosted tree classifiers [21].

Post Hoc Subgroup Analysis

The random forest classifier, which achieved the highest F_2-score and was calibrated, was used for post hoc subgroup analyses that assessed model performance within the test data set by forensic center, race, age at death, sex, and education level. Individuals in these subgroups were suspected to have varying levels of narrative text available for model prediction [22]. This analysis was also completed using the logistic regression model to ensure that the subgroup performances of the parametric (logistic regression) and nonparametric (random forest classifier) models were evaluated.

Subgroup information was extracted from the SUDORS database and death certificates (for non-SUDORS deaths or controls). In death certificates, race categories were mutually exclusive (ie, a decedent could only be coded as 1 race), whereas in the SUDORS database, more than 1 race could be indicated. To harmonize these data, race was coded as American Indian, Asian, Black, Other, Pacific Islander, or White. Individuals of multiple races were recoded as the most prevalent race within the population. For example, an individual coded as White (prevalence=0.73) and American Indian (prevalence=0.001) was recoded to White to reflect the more prevalent race in the data set. Age at death was recoded into ranges used by the National Center for Health Statistics: ≤14, 15-24, 25-34, 35-44, 45-54, 55-64, and ≥65 years [23]. The sex categories were female, male, and unknown. Education level was coded as 8th grade or less, 9th to 12th grade but no diploma, high school graduate or General Educational Development test, college but no degree, associate’s degree, bachelor’s degree, master’s degree, doctorate or professional degree, or unknown. Within each subgroup, AUROC, precision, recall, F_2-score, cases, controls, and median narrative text length were calculated.

Experimental Setup

This study was conducted in Python (version 3.9.7; Python Software Foundation) and R (version 4.2.0; R Foundation for Statistical Computing). Autopsy PDFs were converted to text using the *extract_text* function in the Python *pdfminer* package (version 20191125). Data preprocessing was performed using the *spaCy* package (version 3.2.4) and the *scispaCy* (version 0.5.0) *en_core_sci_sm* NLP pipeline, which was pretrained on biomedical data and had a vocabulary size of approximately 100K [24]. The models were constructed in Python using *scikit-learn* (version 1.1.1) and *xgboost* (version 1.6.1). The Spiegelhalter *z* test statistic was calculated using *rms* (version 6.3.0) in R, and the SHAP values were generated using SHAP (version 0.41.0) in Python.

Ethical Considerations

This study was a quality improvement project found exempt by the TDH institutional review board.

Results

Overview

An initial set of 17,521 autopsies was obtained for all manners of death from 2019 to 2021. A subset of autopsies (179/17,521, 1%) was removed because of unsuccessful identification of a specific forensic center or insufficient characters (<100 characters) after text preprocessing, including lemmatization. The final data set contained 17,342 autopsies (5912 cases and 11,430 controls). The most common manners of death were *accidental* among cases (5811/5912, 98%) and *natural* among controls (3994/11,430, 35%; Multimedia Appendix 1). Forensic centers were deidentified and denoted as A, B, C, D, and E. Approximately half (8743/17,342, 50.42%) of the total autopsies were obtained from the forensic center A (Table 1). The proportion of fatal overdoses was the highest among autopsy reports from the forensic center C (1229/3007, 40.87%).

Table 1. Cases and controls by forensic center (columns), entire data set.

	Forensic center, n (%)					Total (N=17,342), n (%)
	A (n=8743)	B (n=3717)	C (n=3007)	D (n=1452)	E (n=423)	
Cases	3095 (35.39)	1015 (27.3)	1229 (40.87)	417 (28.72)	156 (36.87)	5912 (34.09)
Controls	5648 (65.6)	2702 (72.69)	1778 (59.13)	1035 (71.28)	267 (63.12)	11,430 (65.91)

Narrative Text Sections

Across forensic centers, narrative text sections remained similar in content (each contained scene evidence and medical history) but had varying levels of missingness (Table 2). Notably, forensic centers A and B shared very similar formats, consisting of an initial narrative and a case summary. Autopsies from forensic centers C and D tended to have an initial narrative and summary of circumstances. Autopsies from forensic center E only presented a summary of circumstances.

Table 2. Sections of narrative text by forensic center in entire data set.

Forensic center	Initial narrative, n (%)	Case summary, n (%)	Summary of circumstances, n (%)	Total characters, median (IQR)
A (n=8743)	8675 (99.22)	8732 (99.87)	3 (0.03)	1287 (1053-1560)
B (n=3717)	3717 (100)	3687 (99.19)	0 (0)	1319 (1119-1566)
C (n=3007)	3007 (100)	0 (0)	2238 (74.43)	2852 (1855-4142)
D (n=1452)	1452 (100)	0 (0)	562 (38.71)	1074 (666-1511)
E (n=423)	0 (0)	0 (0)	423 (100)	462 (273-617)

Model Development

Of the 17,342 autopsies, a subset of 10,215 autopsies was used for training (3342/10,215, 32.72% cases), 538 for calibration (183/538, 34.01% cases), and 6589 for testing (2409/6589, 36.56% cases). A total of 4002 terms from the training data comprised the vocabulary set for the bag-of-words models.

Model Validation

All models achieved AUROC≥0.95, precision≥0.94, recall≥0.92, F_1-score ≥0.94, and F_2-score ≥0.92 (Table 3). The highest recall and F_2-scores were achieved using the SVM (recall=0.948, 95% CI 0.937-0.959; F_2-score =0.948, 95% CI 0.94-0.957) and random forest (recall=0.942, 95% CI 0.933-0.954; F_2-score =0.947, 95% CI 0.939-0.956). The corresponding 95% CIs for these metrics did not overlap with those for logistic regression, suggesting that SVM and random forest achieved significantly higher recall and F_2-scores than logistic regression ($P<.05$). The logistic regression and random forest were calibrated ($P=.95$ and $P=.85$, respectively). The SVM and gradient boosted tree classifiers were miscalibrated ($P=.03$ and $P<.001$, respectively).

The SHAP value analysis indicated that “fentanyl,” “accident,” “toxicity,” and “combined” were among the top features for the random forest (Figure 2) and gradient boosted trees classifiers (Multimedia Appendix 2). “Natural” was most strongly associated with controls.

Table 3. Model discrimination and classification metrics across 100 bootstrapped samples.

	Area under the receiver operating characteristic, median (95% CI)	Precision, median (95% CI)	Recall, median (95% CI)	F_1-score, median (95% CI)	F_2-score[a], median (95% CI)	P value[b]
Logistic regression	0.95 (0.943-0.955)	0.963 (0.954-0.972)	0.92 (0.908-0.928)	0.941 (0.933-0.946)	0.928 (0.918-0.935)	−0.057 (.95)
Support vector machine	0.96 (0.954-0.966)	0.95 (0.936-0.962)	0.948 (0.937-0.959)	0.949 (0.942-0.956)	0.948 (0.94-0.957)	2.17 (.03)
Random forest	0.961 (0.955-0.967)	0.964 (0.954-0.973)	0.942 (0.933-0.954)	0.954 (0.945-0.96)	0.947 (0.939-0.956)	−0.189 (.85)
Gradient boosted trees	0.954 (0.946-0.962)	0.949 (0.935-0.964)	0.937 (0.92-0.953)	0.943 (0.935-0.953)	0.939 (0.926-0.951)	−6.79 (<.001)

Subgroup Analysis

The subgroup analysis revealed similar results for the random forest classifier (Table 4) and logistic regression model (Multimedia Appendix 3), with a few exceptions. Across forensic centers for both models, forensic centers A, B, and C had the highest F_2-scores, whereas forensic centers D and E had the lowest F_2-scores. Across race categories for random forest, F_2-score was highest for Pacific Islander (F_2-score =1) and lowest for American Indian (F_2-score =0.833) and Asian (F_2-score =0.862). The logistic regression model achieved similar metrics but performed better for the American Indian race category (F_2-score =1). Across age groups for the random forest, F_2-score was highest for age groups 15-24 years (F_2-score =0.973) and lowest for ≤14 years (F_2-score =0.6) and ≥65 years (F_2-score =0.789). The same relative order of F_2-scores was preserved for logistic regression, but performance was considerably worse for age group ≤14 years (F_2-score =0.227). Models performed similarly across sex and education levels. Notably, several subgroups included fewer than 20 cases or controls.

Table 4. Random forest discrimination and classification metrics, cases, controls, and narrative section length for each subgroup in the test set (n=6589).

Discussion

Principal Findings

Narrative text was used to construct bag-of-words models (term frequency–inverse document frequency scoring) that predicted whether a given autopsy described a fatal overdose. The structure and details of the scene varied considerably across autopsies. Despite this heterogeneity in autopsy data, the SVM, random forest, and gradient boosted tree classifiers all showed excellent performance. Both SVM and random forest achieved the highest recall and F_2-score, but only the random forest was calibrated.

The terms most strongly associated with fatal overdoses in both the random forest and gradient boosted tree models were aligned with known state-level trends. From 2015 to 2019, the rate of fatal drug overdoses involving fentanyl increased from 2.7 to 16.8 per 100,000 residents in Tennessee [25]. More than half of fentanyl overdoses involved additional substances in 2019. Unsurprisingly, “fentanyl,” “norfentanyl,” “4ANPP” (ie, “4-ANPP” before text preprocessing; a precursor to illicit fentanyl), and “combined” were among the top terms most strongly associated with fatal overdose autopsies. Overdoses have also been increasingly linked to methamphetamine and heroin, both of which are highly predictive of fatal overdoses [25]. This rise in fentanyl- and stimulant-related overdose deaths has also been observed at the national level [23,26].

Forensic center subgroup analysis revealed lower model discrimination on data from forensic centers D and E. These 2 forensic centers contributed the fewest autopsies. It is possible that the models were not given ample opportunities to learn from autopsies contributed by these 2 centers. Model performance may improve with the oversampling of autopsies from these 2 forensic centers. The subgroup analyses by race and age indicated lower F_2-scores for the American Indian and Asian race groups as well as the ≤14 and ≥65 years age groups. These race and age subgroup results differed slightly in the logistic regression analysis, suggesting that the small sample sizes for these subgroups and others warrant additional study.

Subgroup differences in model performance and narrative length are worth additional study, particularly considering the findings of Mezuk et al [22]. In their study, Mezuk et al [22] identified shorter National Violent Death Reporting System narrative lengths for suicide and undetermined deaths among individuals who were male, were older, achieved lower education, and were part of certain racial and ethnic minority groups, compared with their counterparts. These findings suggest that models that use narrative text may generate biased predictions for individuals in certain subgroups. A similar detailed analysis is beyond the scope of this study. Our data did not suggest a noticeable difference in median narrative length across races. However, an analysis of narrative length using the Wilcoxon rank-sum test indicated a significant difference in narrative section length between the Black and White race subgroups ($P<.001$; Multimedia Appendix 4). These shorter sections did not appear to affect model performance, but further studies are needed.

Previous studies have used more complex machine learning methods, such as deep learning on autopsy text, to predict the cause of death ICD-10 codes [14,15,27]. Although such models may incorporate more information to perform generalized cause of death prediction, our models were specific to fatal overdose prediction. More specialized models may be better suited to identify fatal overdoses when the evidence is less clear-cut. For instance, drugs discovered at the death scene may not necessarily be linked to the primary cause of death. Alternatively, a fatal overdose may be the primary cause of death, but the death certificate may only reflect a contributing comorbidity. Our model performance metrics suggested that more advanced machine learning methods were not needed for this prediction task. As indicated by the relatively small size of the vocabulary set in this study (4002 terms across 10,215 autopsies) and subsequently verified by manual review, the language across autopsy reports was fairly standardized and uniform. Perhaps certain combinations of terms (eg, “fentanyl,” “accident,” and “toxicity”) were highly predictive of fatal overdose. Another study used NLP to predict fatal overdoses from free-text fields in Kentucky death certificates [13]. Similar to our study, bag-of-words–based machine learning models were used. However, whereas Kentucky relied on death certificate fields (as few as 2 words), our study used a different data source: autopsy narrative text. These sections ranged from hundreds to thousands of characters in length and provided additional contextual information in the form of scene evidence and medical history.

This work was completed in an academic-public partnership between the TDH and VUMC, where the SUDORS team at the TDH provided domain knowledge, and the Walsh Lab at VUMC provided modeling expertise. The goal was to develop a model that can be run and maintained by the SUDORS team. To this end, a simple modeling pipeline has several advantages. Adobe Acrobat Pro is easy to operate and does not require computer programming skills. Therefore, the OCR process can remain consistent, despite any changes in personnel that may occur. Sections of narrative text were identified using keywords that appeared as headings in autopsy reports. These rules can be modified to ensure the continued extraction of the appropriate autopsy sections, should autopsy templates change in the future. The bag-of-words models were agnostic to word order and less context dependent compared with more complex models such as word2vec. The simplicity of the bag-of-words approach translated into increased robustness to the variable quality of text extracted using OCR. Together, these aspects of the modeling pipeline facilitated the handoff of the code to the TDH SUDORS team and may inform modeling practices in other states.

Limitations

This study has several limitations. The OCR results depended on the quality of the scanned autopsy reports. The OCR was less accurate when the reports were scanned crooked (as reported in the results, no more than 1% of all autopsies were removed for this reason). Sometimes, spaces would be missed (eg, “decedentwas” instead of “decedent was”), misspellings would be introduced, or the OCR would add symbols (often <4 characters long). These tendencies informed the decision to exclude terms appearing in fewer than 20 documents or those having fewer than 4 characters. Although the Adobe Acrobat Pro OCR was sufficient for this study, careful manual reviews should be conducted when applying this tool to different data sources. In addition, the text was extracted using a simple Python function that did not always maintain proper word order when the text spanned multiple columns. As word order was occasionally altered during the OCR text extraction process, the tested models did not consider negation. Although word-order–agnostic models were sufficient for the prediction task presented in this study, more precise text extraction methods may yield at least a modest improvement in recall. Other studies may assess the importance of considering negation in autopsy reports.

Fatal overdoses were identified by the TDH surveillance team through an automated process that involved ICD-10 codes and keyword searches of death certificates, followed by a manual review. Although this process has been improved and tested over the years, it depends on death certificate codes and cause of death text, both of which may be delayed. The NLP-based approach in this study has the potential to overcome this limitation, as it relies on autopsy narrative text (a proxy for medicolegal scene investigation documentation), which is often available much sooner and can provide more contextual information than death certificates. Furthermore, the Tennessee medicolegal death investigation system is decentralized, thus allowing a wide range of variability in the level of detail included in the autopsy narratives. Despite this variation, the content of the information conveyed remained consistent. Finally, this study involved only data from one state health department. Although the studied classifiers performed well, data from other states may require additional preprocessing steps and potentially model retraining.

Future Work

The absence of a standardized autopsy template for all forensic centers added complexity to this prediction task and likely contributes to the additional time spent by the surveillance team in manually abstracting information. The recent adoption of the Medicolegal Death Investigation Log for some jurisdictions throughout the state is a step toward standardization, as this platform offers a common set of data fields for users to complete, in addition to a centralized location for documents to be uploaded. The utility of Medicolegal Death Investigation Log data in NLP models should be investigated in the future.

Efforts to standardize autopsy reports across forensic centers could facilitate the development of NLP tools specifically trained on text from autopsy reports. Such tools may identify scene evidence and naloxone administration more accurately than tools designed for electronic health record data, as described by Harris et al [28]. In the future, more specialized NLP tools could facilitate the automated extraction of public health–related variables for more complex NLP tasks.

Systematic characterization of the differential coverage of information related to scene evidence and medical history conveyed in autopsies from each forensic center may be worthwhile. This analysis may reveal factors contributing to poorer model performance and inform the standardization of statewide autopsy reports. As public health surveillance becomes more automated, it is increasingly important to consider variations conferred by nonstandardized documentation practices.

Given the findings of Mezuk et al [22] related to narrative lengths across different subgroups, future studies might seek to understand such patterns using data from all-cause deaths. Mezuk et al [22] also noted that missingness (ie, the presence or absence of a medical examiner narrative or law enforcement report) was associated with different social variables, such as homeless status, education, race, and ethnicity. These findings from Mezuk et al [22] are worth considering in future work because of the potential downstream effects of predictive models leveraging such biased data. In the case of public health surveillance, the result may be underreporting of deaths in certain groups, thus limiting intervention in communities that may be the most in need. This is particularly important, given the existing disparities exacerbated by the COVID-19 pandemic, which contributed to disproportionately high increases in overdose mortality rates among Black and American Indian or Alaska Native individuals compared with White individuals [29,30]. There is an urgent need to develop predictive models that ensure the appropriate allocation of resources during interventions.

Operationalizing the random forest classifier may facilitate rapid fatal overdose reporting in the future. OCR was performed using the batch processing option accessible through the Adobe Acrobat Pro user interface. The random forest classifier should be easy to scale to larger data sets and reduce overfitting by leveraging ensemble learning methods. Swift reporting can aid in the development of faster prevention and response activities at the community level, which can help curtail the growing number of fatal drug overdoses in Tennessee. Deploying this model could enhance the capacity of TDH to conduct fatal drug overdose surveillance.

Conclusions

Narrative text from Tennessee autopsy reports was used to develop NLP models that predicted the likelihood that a given autopsy described a fatal overdose. Simple bag-of-words–based models were sufficient for identifying potential fatal overdoses for public health surveillance. Additional studies are needed to ensure that the random forest classifier facilitates timely fatal overdose reporting for individuals across all subgroups.

Acknowledgments

The authors acknowledge Molly Golladay and the Office of the State Chief Medical Examiner for providing access to the requested autopsy reports. This work was fully supported by the American Public Health Association (APHA) and Centers for Disease Control and Prevention Data Science Demonstration Project Award to the Tennessee Department of Health. Abstract

Background: Accurate estimation of the influenza death burden is of great significance for influenza prevention and control. However, few studies have considered the short-term harvesting effects of influenza on mortality when estimating influenza-associated excess deaths by cause of death, age, sex, and subtype/lineage.

Objective: This study aimed to estimate the cause-, age-, and sex-specific excess mortality associated with influenza and its subtypes and lineages in Guangzhou from 2015 to 2018.

Methods: Distributed-lag nonlinear models were fitted to estimate the excess mortality related to influenza subtypes or lineages for different causes of death, age groups, and sex based on daily time-series data for mortality, influenza, and meteorological factors.

Results: A total of 199,777 death certificates were included in the study. The average annual influenza-associated excess mortality rate (EMR) was 25.06 (95% empirical CI [eCI] 19.85-30.16) per 100,000 persons; 7142 of 8791 (81.2%) deaths were due to respiratory or cardiovascular mortality (EMR 20.36, 95% eCI 16.75-23.74). Excess respiratory and cardiovascular deaths in people aged 60 to 79 years and those aged ≥80 years accounted for 32.9% (2346/7142) and 63.7% (4549/7142) of deaths, respectively. The male to female ratio (MFR) of excess death from respiratory diseases was 1.34 (95% CI 1.17-1.54), while the MFR for excess death from cardiovascular disease was 0.72 (95% CI 0.63-0.82). The average annual excess respiratory and cardiovascular mortality rates attributed to influenza A (H3N2), B/Yamagata, B/Victoria, and A (H1N1) were 8.47 (95% eCI 6.60-10.30), 5.81 (95% eCI 3.35-8.25), 3.68 (95% eCI 0.81-6.49), and 2.83 (95% eCI –1.26 to 6.71), respectively. Among these influenza subtypes/lineages, A (H3N2) had the highest excess respiratory and cardiovascular mortality rates for people aged 60 to 79 years (20.22, 95% eCI 14.56-25.63) and ≥80 years (180.15, 95% eCI 130.75-227.38), while younger people were more affected by A (H1N1), with an EMR of 1.29 (95% eCI 0.07-2.32). The mortality displacement of influenza A (H1N1), A (H3N2), and B/Yamagata was 2 to 5 days, but 5 to 13 days for B/Victoria.

Conclusions: Influenza was associated with substantial mortality in Guangzhou, occurring predominantly in the elderly, even after considering mortality displacement. The mortality burden of influenza B, particularly B/Yamagata, cannot be ignored. Contrasting sex differences were found in influenza-associated excess mortality from respiratory diseases and from cardiovascular diseases; the underlying mechanisms need to be investigated in future studies. Our findings can help us better understand the magnitude and time-course of the effect of influenza on mortality and inform targeted interventions for mitigating the influenza mortality burden, such as immunizations with quadrivalent vaccines (especially for older people), behavioral campaigns, and treatment strategies.

KEYWORDS

influenza; disease burden; distributed-lag nonlinear model; excess mortality; harvesting effects

Introduction

Seasonal influenza has been associated with a large number of deaths, both in China and globally [1-5]. An accurate gauge of the mortality burden of the seasonal influenza epidemic is of great importance for understanding the impact of influenza, as well as for formulating and adjusting corresponding prevention and control measures [6]. This has been challenging, as laboratory diagnoses of influenza are not routinely made, and it is difficult to distinguish influenza virus infections from other respiratory pathogen infections based on nonspecific clinical symptoms [7]. Additionally, older adults are more likely to die from influenza-triggered complications, but influenza is seldom recorded as the cause of death in the mortality registration system [8]. Therefore, laboratory-confirmed deaths are an underestimate of the mortality burden of influenza [6].

Many studies have assessed the mortality burden of influenza with statistical models [3,6-19]. There have been substantial variations in estimates of influenza-associated excess mortality and in analytical strategies, including the definition of the lag period between influenza activity and mortality [20]. Previous studies have assumed that the lag was zero weeks, months, or years or one week; correspondingly, a simple influenza activity proxy was often included in the model, that is, a proxy lag of 1 week was used [20]. Lytras et al [21] examined the delayed effect of influenza activity on all-cause mortality using a distributed-lag nonlinear model (DLNM), allowing a flexible lag-response relationship between influenza and death. Interestingly, the study detected a short-term harvesting effect between influenza activity and all-cause mortality. Whether such findings can be generalized to other cause-of-death groupings and locations with different circulating influenza strains, health care systems, age structures, and contact patterns needs to be further explored. In addition, previous studies seldom reported potential disparities in influenza-associated excess mortality due to influenza B lineage and sex [19,22].

Guangzhou, a subtropical city in the western Pacific region of southern China (location N 23°8 , E 113°17), is an international transportation hub with a permanent population of approximately 15 million (in 2018) and an area of 7434.4 km^2. Free influenza vaccination has been available for older residents since 2021 in Guangzhou; however, the vaccination coverage rate has been unsatisfactory overall in China [23]. Assessment of the mortality burden of influenza would provide necessary data for evaluating this program. The current study aimed to estimate excess mortality associated with influenza virus subtypes and lineages for different cause-of-death groupings in Guangzhou from 2015 to 2018 across different age groups and sexes using DLNMs.

Methods

Ethical Considerations

This study was approved by the Research Ethics Committee of Southern Medical University (NFYKDX-ER2022012). The need for informed consent was waived because the data were deidentified and aggregated.

Data Sources

Individual data for deaths occurring between January 5, 2015, and December 30, 2018, in Guangzhou were obtained from the Guangzhou Center for Disease Control and Prevention (CDC). Individual death information included the underlying cause of death, age at death, and sex. The daily number of deaths was aggregated. Here, we considered 5 cause-of-death groupings associated with influenza virus infection: all causes (International Statistical Classification of Diseases and Related Health Problems, 10th Revision [ICD-10] codes A00-Z99), respiratory and cardiovascular diseases (ICD-10 codes I00-I99 and J00-J99), respiratory disease (ICD-10 codes J00-J99), pneumonia and influenza (ICD-10 codes J10-J18), and cardiovascular disease (ICD-10 codes I00-I99).

The Guangzhou CDC also provided influenza surveillance data, including the weekly proportions of specimens testing positive for influenza A (H1N1), A (H3N2), B/Yamagata, and B/Victoria, and the weekly proportion of consultations for influenza-like illness (ILI), that is, a body temperature ≥38 °C with cough or sore throat, among outpatient visits at sentinel hospitals in Guangzhou.

Data on annual population size were obtained from the Public Security Bureau of Guangzhou Municipality. We collected data on daily mean temperature and relative humidity from the website of the China Meteorological Data Service Center [24].

Statistical Analysis

We defined a weekly influenza virus activity proxy by multiplying the weekly proportion of consultations for ILI and the proportion of specimens testing positive for different subtypes and lineages, and then multiplying the resulting value by 1000 [25,26]. Then, we converted the weekly proxy to a daily proxy with cubic smoothing splines with 1 *df* per week, determined with generalized cross-validation [21]. The daily population size was estimated by linear interpolation. Daily mean temperature and relative humidity data were used to calculate daily absolute humidity [17], which has been suggested to be a better predictor of influenza virus transmission and survival than relative humidity [27].

A quasi-Poisson regression model was applied to estimate the excess mortality associated with influenza for different cause-of-death groupings, age groups (<60 years, 60-79 years, ≥80 years, and all ages), and sex. The associations of death counts with influenza and temperature were determined using a DLNM [28], as follows:

where Y_t and μ_t were the observed and expected number of deaths on day t, respectively. ϕ is the overdispersion parameter. The logarithm of population (Pop_t), with a fixed regression coefficient of 1, was used as an offset. The influenza activity proxy variables for A (H1N1), A (H3N2), B/Victoria, and B/Yamagata on day t were $Proxy_{H1,t}$, $Proxy_{H3,t}$, $Proxy_{BV,t}$, and $Proxy_{BY,t}$, respectively. Cross-basis $T_{t,l}(.)$ was constructed for the activity proxy variable of each influenza subtype/lineage, assuming a linear relationship between influenza virus activity and population mortality [3,6,13,14,21]. Cross-basis $T_{t,l}(.)$ was constructed for daily temperature ($Temp_t$) on day t with a natural cubic spline with 4 *df* [29]. It should be noted that the lag-response associations for the temperature and influenza virus activity proxies were set up with natural cubic splines with 3 knots placed at equally spaced log values of lags of 30 days to fully capture possible short-term mortality displacement effects (Multimedia Appendix 1) [21,30].

In addition, we controlled the effect of absolute humidity (Hum_t) using a natural cubic spline with 4 *df* [22]. Additionally, we included a categorical variable for the day of the week (Dow_t) and an indicator variable for holidays ($Holiday_t$) in the model. Additional adjustments in the model included a natural cubic spline with 5 *df* for the day of the year (Doy_t; ie, 1-366) and a categorical variable for calendar year ($Year_t$), to control for seasonality and the time trend in death counts, respectively [21].

We present the relative risk (RR) and cumulative RR of death associated with an increase of 10 units in the influenza virus activity proxy relative to an influenza activity proxy of 0 across a lag of 0 to 30 days. The daily number of excess deaths related to influenza was estimated as the difference between the estimated number of deaths given the observed influenza virus activity and the estimate given that the influenza virus did not circulate (ie, the influenza virus activity proxy was 0) [22]. The excess mortality rates (EMRs) associated with influenza for different age groups were estimated by dividing the influenza-related excess death numbers by the corresponding population sizes and then multiplying by 100,000. It should be noted that the EMRs associated with influenza in this study were in units per 100,000 persons per year. We estimated the EMRs that incorporated the lagged effects of influenza on mortality over 0 to 30 days. Meanwhile, we applied Monte Carlo simulations to estimate the 95% empirical CI (95% eCI) of the EMRs, which accounted for autocorrelation using the Newey-West method [31-33].

To detect whether there was a sex difference in influenza-related EMRs, we divided the male EMRs by female EMRs to obtain the male-to-female excess mortality ratios (MFRs) and derived the corresponding 95% CIs using the delta method [22].

To check the robustness of the results, we conducted sensitivity analyses by (1) changing the maximum number of lag days for lag-response relationships between the death and activity proxies of each influenza subtype and lineage, as well as for the relationship between death and temperature; (2) changing the way we controlled the temporal trend in the mortality rate; (3) ignoring the classifications of influenza virus types and influenza B lineages; (4) applying different cross-basis matrices to temperature; and (5) including the influenza virus activity proxy and temperature at a lag of 7 days in the model (Multimedia Appendix 1). All analyses were performed in R (version 4.1.1; R Foundation for Statistical Computing).

Results

There were 199,777 death certificates (86,440 for women and 113,337 for men; 34,229 for the 0-to-59-year age group, 73,552 for the 60-to-79-year age group, and 91,996 for the ≥80-year age group) included in this analysis, of which 105,998 were respiratory/cardiovascular disease deaths, 28,528 were respiratory disease deaths, and 12,255 were pneumonia/influenza deaths. In Guangzhou from 2015 to 2018, influenza viruses circulated every year. In 2015 and 2017, influenza activity peaked in the summer, while in 2016 and 2018, influenza activity was greater in the winter and early spring. A similar pattern was observed for the excess respiratory/cardiovascular disease mortality associated with influenza (Figure 1).

It was estimated that 2198 all-cause deaths, 1786 respiratory/cardiovascular disease deaths, 825 respiratory disease deaths, and 340 pneumonia/influenza deaths were attributable to influenza annually; correspondingly, the annual influenza-associated excess all-cause, respiratory/cardiovascular disease, respiratory disease, and pneumonia/influenza mortality rates were 25.06 (95% eCI 19.85-30.16), 20.36 (95% eCI 16.75-23.74), 9.41 (95% eCI 7.78-10.90) and 3.88 (95% eCI 2.80-4.84) per 100,000 persons, respectively (Table 1). Excess deaths associated with influenza accounted for 4.4% (8791/199,777), 6.7% (7142/105,998), 11.6% (3301/28,528), and 11.1% (1361/12,255) of all-cause, respiratory/cardiovascular disease, respiratory disease, and pneumonia/influenza deaths, respectively. Influenza-associated excess deaths due to respiratory/cardiovascular disease, respiratory disease, and pneumonia/influenza accounted for 81.2% (7142/8791), 37.6% (3301/8791), and 15.5% (1361/8791) of excess all-cause deaths, respectively.

The excess mortality due to various underlying causes associated with influenza varied across age groups. The EMR for each cause of death associated with influenza in people aged ≥80 years was higher than that in people aged 60 to 79 years. However, it should be noted that only influenza-related excess mortality due to respiratory/cardiovascular disease was statistically significant among deaths from all different causes in the 0-to-59-year age group. The EMRs for respiratory/cardiovascular disease for people aged 60 to 79 years and ≥80 years were 45.21 (95% eCI 33.31-56.74) and 452.63 (95% eCI 357.46-544.47) per 100,000 persons, respectively, which was higher than the EMR for people aged 0 to 59 years (91.50, 95% eCI 4.79-165.41). The burden in these two age groups represented 32.9% (2346/7142) and 63.7% (4549/7142) of the excess respiratory/cardiovascular disease deaths attributed to influenza, respectively (Table 1).

Figure 1. Influenza activity and weekly influenza-associated excess respiratory and cardiovascular deaths in Guangzhou, China, from 2015 to 2018. (A) Influenza virus activity proxy (this proxy does not have units). (B) Weekly influenza-associated excess respiratory/cardiovascular deaths. The bars in B represent the estimates of excess influenza-related deaths per week and the shaded areas are the corresponding 95% empirical CIs. The influenza virus activity proxy was calculated by multiplying the weekly proportion of consultations for influenza-like illness and the proportion of specimens testing positive for different subtypes and lineages, and then multiplying the resulting value by 1000.

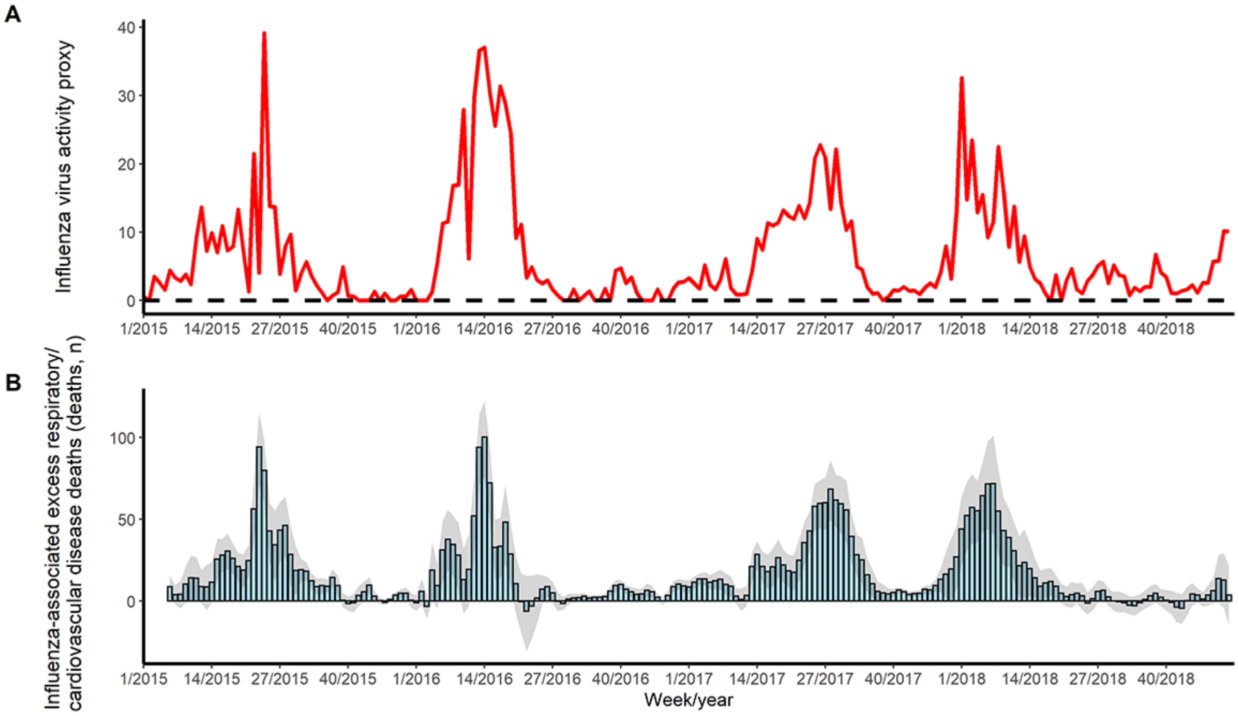

Table 1. Average annual excess mortality rates associated with influenza by cause-of-death grouping and age group in Guangzhou, China, from 2015 to 2018.

Age groups (years) and cause of death	Deaths, n (95% eCI[a])	Rate per 100,000 persons (95% eCI)
0-59		
All causes	64.05 (–105.30 to 226.41)	0.89 (–1.46 to 3.14)
Respiratory/cardiovascular disease	91.50 (4.79 to 165.41)	1.27 (0.07 to 2.29)

[a] eCI: empirical CI.

The difference in influenza-associated excess respiratory/cardiovascular disease mortality rate by sex was not statistically significant. However, the excess respiratory mortality was significantly higher in males than in females, with an MFR of 1.34 (95% CI 1.17-1.54). Conversely, the MFR of influenza-associated EMR for cardiovascular disease was 0.72 (95% CI 0.63-0.82; Table 2). Furthermore, the MFR varied by age group. For excess respiratory deaths related to influenza among those aged 60 to 79 and ≥80 years, the MFRs were 3.03 (95% CI 2.75-3.33) and 1.45 (95% CI 1.41-1.49), respectively, and the MFR was 0.45 (95% CI 0.23-0.89) for people aged 0 to 59 years (Multimedia Appendix 2). For people aged 0 to 59 and 60 to 79 years, the MFRs for excess cardiovascular deaths were 3.24 (95% CI 1.96-5.34) and 2.05 (95% CI 1.90-2.22), respectively. However, for influenza-associated excess cardiovascular deaths in people aged ≥80 years, the MFR was 0.65 (95% CI 0.64-0.67) (Multimedia Appendix 3).

Temporal trends of influenza virus activity varied by subtype and lineage (Figure 2). The EMR for respiratory/cardiovascular disease attributed to influenza A (H3N2) was 8.47 (95% eCI 6.60-10.30) per 100,000 persons, which was higher than the EMR due to influenza A (H1N1) (2.83, 95% eCI –1.26 to 6.71), B/Victoria (3.68, 95% eCI 0.81-6.49), and B/Yamagata (5.81, 95% eCI 3.35-8.25). For people aged 60 to 79 years and those aged ≥80 years, the excess respiratory/cardiovascular disease mortality associated with A (H3N2) was higher than that for other influenza subtypes or lineages. However, for people aged 0 to 59 years, excess influenza-related deaths were dominated by influenza A (H1N1), with excess mortality of 1.29 (95% eCI 0.07-2.32; Table 3).

Between 2015 and 2018, the predominant circulating influenza virus subtypes and lineages varied. Correspondingly, the EMRs per 100,000 persons for respiratory and cardiovascular disease associated with influenza A (H1N1), A (H3N2), B/Victoria, and B/Yamagata ranged between 0.21 (95% eCI –0.13 to 0.54) and 5.62 (95% eCI –2.74 to 13.19), between 0.15 (95% eCI 0.10-0.19) and 21.25 (95% eCI 16.61-25.59), between 0.32 (95% eCI 0.09-0.56) and 9.52 (95% eCI 2.58-16.29), and between 0.63 (95% eCI –0.62 to 1.77) and 10.84 (95% eCI 6.74-14.83), respectively (Figure 2).

The RR of respiratory/cardiovascular disease death associated with influenza virus subtypes/lineages changed with lag time. For influenza A (H1N1), the highest RR occurred on the current day, and there seemed to be a displacement effect during days 2 to 5. This effect lasted approximately 14 days. Similar patterns were observed in the RRs for influenza A (H3N2) and B/Yamagata. For B/Victoria, RR peaked at a lag of 3 days. The displacement effect was observed on days 5 to 13 (Figure 3).

Table 2. Average annual excess mortality associated with influenza by cause-of-death grouping and sex in Guangzhou, China, from 2015-2018.

Underlying cause	Male		Female		Male-to-female excess mortality ratio (95% CI)	*P* value
	Deaths, n (95% eCI[a])	Rate per 100,000 persons (95% eCI)	Deaths, n (95% eCI)	Rate per 100,000 persons (95% eCI)

Figure 2. Annual influenza-associated excess respiratory/cardiovascular mortality rates and influenza activity in Guangzhou, China, from 2015 to 2018. (A) Annual influenza-associated excess respiratory/cardiovascular mortality rates per 100,000 persons by influenza subtype/lineage. (B) Influenza virus activity proxies by influenza subtype/lineage (this proxy does not have units). The dots in A indicate point estimates of excess respiratory/cardiovascular mortality, while vertical line segments indicate the corresponding 95% empirical CIs.

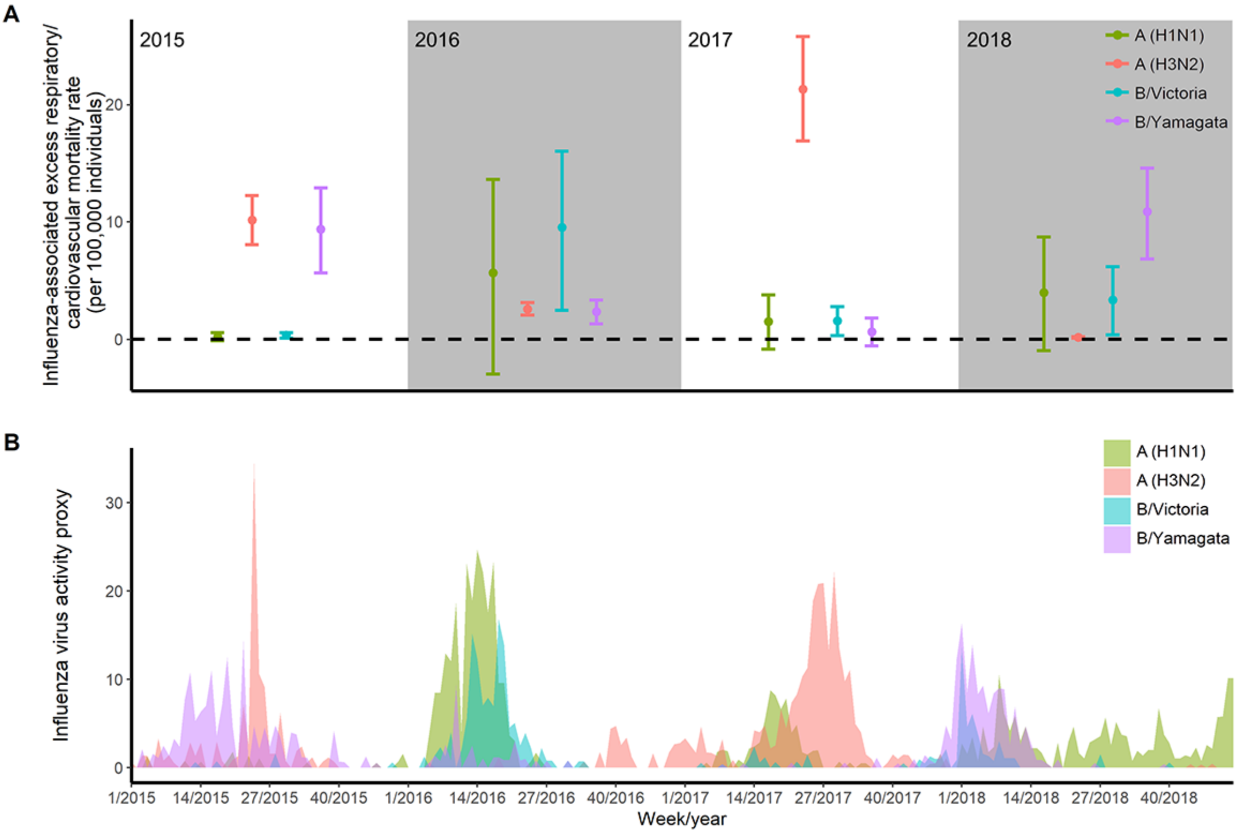

Table 3. Excess respiratory and cardiovascular mortality rates associated with different influenza subtypes and lineages.

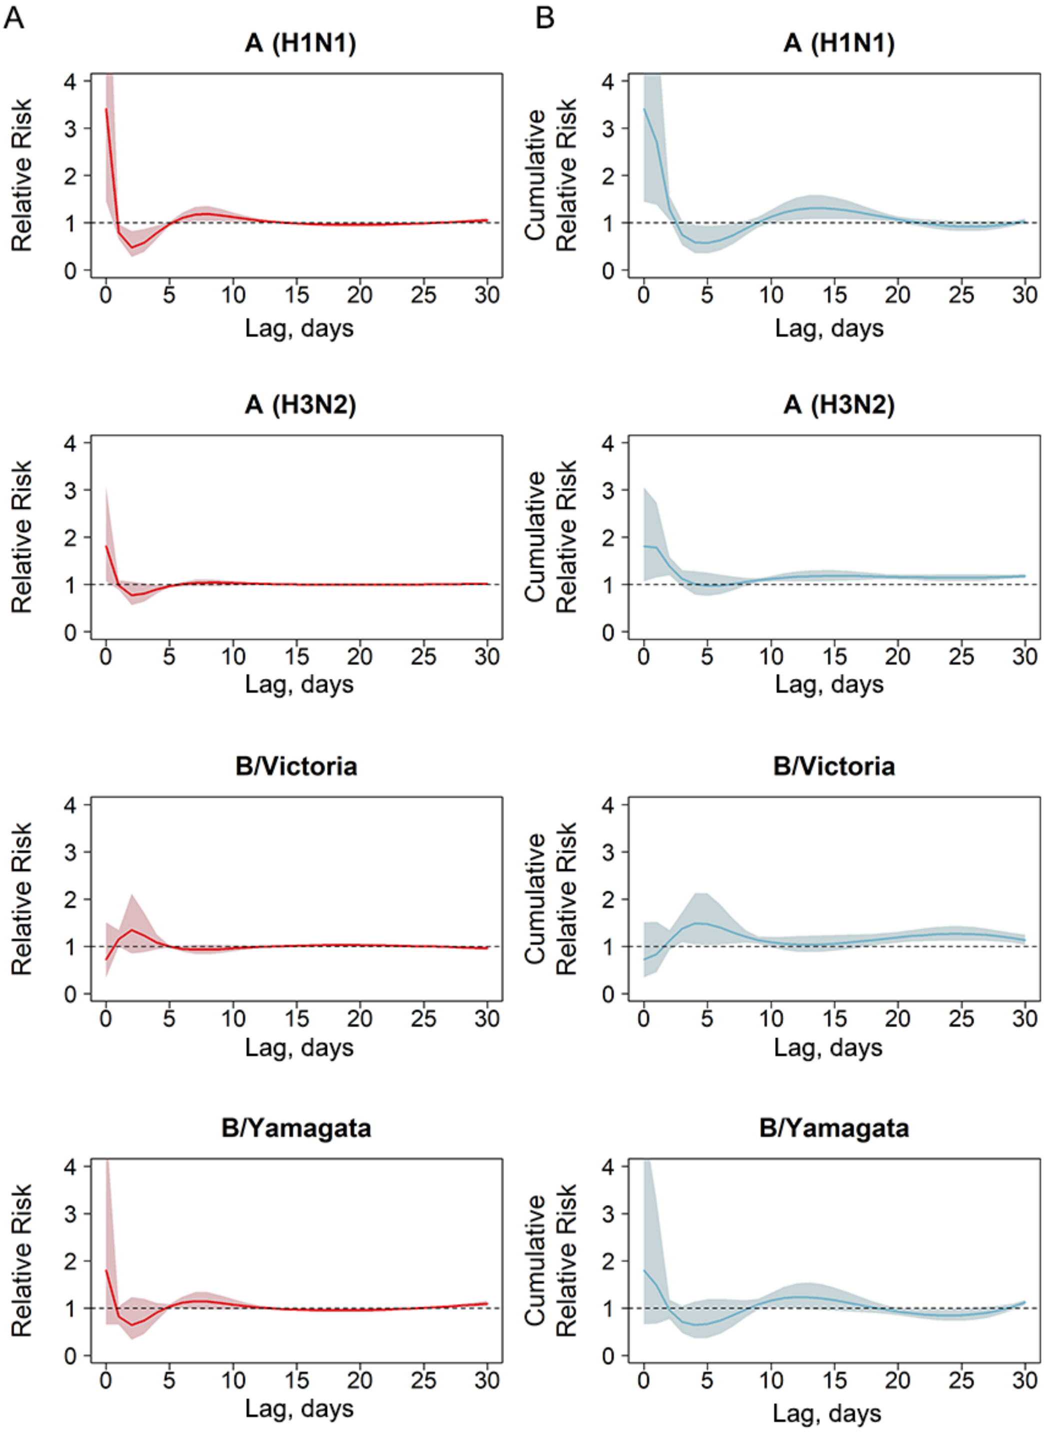
Influenza type or lineage and age groups (years)	Rate per 100,000 persons (95% eCI[a])
A (H1N1)	
0-59	1.29 (0.07 to 2.32)
60-79	5.74 (–8.61 to 19.15)
≥80	55.75 (–60.87 to 166.10)
All ages	2.83 (–1.26 to 6.71)
A (H3N2)	
0-59	0.33 (–0.24 to 0.85)
60-79	20.22 (14.56 to 25.63)
≥80	180.15 (130.75 to 227.38)
All ages	8.47 (6.60 to 10.30)
B/Victoria	
0-59	–0.47 (–1.59 to 0.45)
60-79	7.36 (–2.87 to 16.65)
≥80	88.82 (6.18 to 168.44)
All ages	3.68 (0.81 to 6.49)
B/Yamagata	
0-59	0.02 (–0.78 to 0.74)
60-79	12.87 (4.60 to 20.74)
≥80	138.21 (70.53 to 204.40)
All ages	5.81 (3.35 to 8.25)
All influenza	
0-59	1.27 (0.07 to 2.29)
60-79	45.21 (33.31 to 56.74)
≥80	452.63 (357.46 to 544.47)
All ages	20.36 (16.75 to 23.74)

[a] eCI: empirical CI.

Figure 3. Relative risks and cumulative relative risks of death associated with influenza subtypes/lineages. (A) Relative risks of death on each single day and (B) cumulative relative risks of death associated with an increase of 10 units in influenza virus activity proxy for influenza A (H1N1), A (H3N2), B/Victoria, and B/Yamagata. The solid lines represent the estimates of relative risk over time, and the shaded areas are the corresponding 95% empirical CIs.



Estimates of influenza-associated excess respiratory and cardiovascular disease mortality rates did not change significantly after changing the method of controlling for the temporal trend in mortality rate, changing the maximum lag, or the function used for the lag-response dimension in the cross-basis matrices of influenza and temperature, ignoring the classification of influenza B lineages (Multimedia Appendix 4).

Discussion

Principal Results

In this study, we report excess mortality associated with influenza and its subtypes/lineages from 2015 to 2018 in Guangzhou, a subtropical city of China. We estimate that 1786 respiratory/cardiovascular disease deaths were attributable to influenza annually, accounting for 6.7% (7142/105,998) of all respiratory/cardiovascular disease deaths. We found that influenza-associated excess mortality was higher in the elderly, which is consistent with the conclusions of other studies [1,14,15,21,34].

Variations were observed in the estimates of influenza-associated excess mortality by subtype/lineage. The mortality burden of influenza B/Yamagata was higher than that of B/Victoria, which is consistent with previous studies [6,22,34]. The disparity between the lineages may be due to the elderly being more likely to be infected by influenza B/Yamagata than B/Victoria [35,36]. In 2018, influenza B/Yamagata was the predominant lineage in Guangzhou, and the vast majority of influenza-related excess deaths were attributed to B/Yamagata. Similarly, an outbreak dominated by influenza B/Yamagata was reported in Europe during the 2017-2018 influenza season, causing substantial excess mortality [34]. Together, the evidence implies that influenza B does not necessarily lead to mild illness in humans; the mortality burden of influenza B cannot be ignored. Furthermore, including influenza B lineages in active surveillance would help better understand the epidemiology of influenza B and reduce the excess mortality of influenza by enabling targeted interventions. Vaccination is the most effective way to prevent influenza; however, the vaccination coverage in China is low (9.4%) [23], partly because influenza vaccination is not government funded in many places [37]. During the 2018-2019 influenza season, the quadrivalent inactivated vaccine was approved for the first time in China [38]. In 2019, 30.78 million doses of influenza vaccines were distributed in China, but most of them were trivalent inactivated vaccines [37]. Compared with the trivalent influenza vaccine, the quadrivalent influenza vaccine has a higher antibody protection rate and antibody-positive seroconversion rate against the increased influenza B strain [39,40]. High-risk groups are recommended to receive quadrivalent influenza vaccines when vaccines are available, given the nonnegligible burden of influenza B.

We also noted that the mortality burden of influenza virus subtypes and lineages differed according to age group. For people aged ≥60 years, the fatality rate caused by influenza A (H3N2) was higher than that of A (H1N1), B/Victoria, and B/Yamagata. The risk of influenza virus infection and severe complications, including death, is increased by the stronger antigenic drift and virulence of influenza A (H3N2) [22,41]. However, for people aged 0 to 59 years, influenza A (H1N1) had a greater EMR than other influenza subtypes or lineages, which is in accord with previous studies [22]. The lower mortality burden of influenza A (H1N1) might be due to protection from early life exposure to this subtype [42].

Consistently with previous studies performed in Shanghai, we did not find a statistically significant difference in influenza-related excess respiratory/cardiovascular disease deaths between males and females [22]. However, males had a higher influenza-related excess respiratory mortality rate than females and a lower excess cardiovascular mortality rate. In addition, in people aged 60 to 79 years, it has been found that the influenza-related EMR for respiratory disease or cardiovascular disease in men is higher than in women, and the same situation was found in people aged 65 to 74 years in a US study [19]. However, for people aged ≥80 years, men had higher influenza-related excess respiratory mortality than women, but a lower excess cardiovascular mortality associated with influenza. In the US study, the results of a comparison of point estimates of EMR for the corresponding causes for males and females were consistent with our results, but the difference was not statistically significant [19]. Decreasing testosterone levels and higher respiratory mortality in older men [22,36], or the fact that women may have a different innate or acquired immune response than men due to discrepancies in sex steroid hormones [43], might lead to sex disparities in the severity of illness after influenza virus infection.

Our estimate of average annual influenza-associated excess all-cause mortality (25.06 per 100,000 individuals) was higher than that of previous studies in countries/cities and time periods including Greece from 2013 to 2017 (23.60) [21], Beijing from 2007 to 2013 (19.10) [14], Guangzhou from 2010 to 2012 (14.72) [15], and the United States from 1997 to 2007 (11.78) [19]. However, the estimate was relatively lower than the number of annual average influenza-related excess all-cause deaths in Europe for 2017-2018 (25.40) [34], Chongqing from 2012 to 2018 (33.50) [44], and Shanghai from 2010 to 2015 (27.66) [22]. Factors such as population structure, health status, health care capacity, circulating strains, host immunity, public health interventions (eg, influenza vaccination programs), and social distancing might contribute to these differences [20,22]. In addition to the abovementioned factors that may lead to heterogeneity in the results of different studies, some methodological differences need to be considered. The estimates of influenza-associated excess mortality varied with different analytical strategies, although the disparities were not significant in the sensitivity analysis. Influenza can be divided into different subtypes and lineages to explore the impact of influenza on the health of populations when relevant data are available, which also helps us understand the effects of different influenza subtypes and lineages on mortality.

Previous studies have estimated excess mortality based on the association between influenza activity proxies at a lag of 0, 1, or 2 weeks and mortality [20]. In this study, we used a DLNM to capture the association between influenza and mortality. A sensitivity analysis showed no significant differences between the influenza-associated excess respiratory/cardiovascular disease mortality rates estimated by a DLNM and a model that included linear terms of an influenza virus activity proxy and a natural cubic spline of temperature at a lag of 7 days. DLNMs allow us to consider a flexible lag-response relationship between influenza and death. The time course of influenza effects and potential mortality displacement can be examined with DLNMs [21,30]. We found that many influenza-related respiratory/cardiovascular disease deaths occurred during the initial exposure to influenza A (H1N1), A (H3N2), and B/Yamagata. Therefore, starting antiviral treatment as soon as possible, especially with neuraminidase inhibitors and other means of treatment for critically ill influenza patients, is likely to bring great survival benefits [35]. Taking into account the observed mortality displacement, we estimate that 743, 322, and 510 annual respiratory/cardiovascular disease deaths in Guangzhou were attributable to influenza A (H3N2), B/Victoria, and B/Yamagata, respectively; this indicates that the impact of influenza A (H3N2) and B on mortality is not limited to bringing forward deaths in the short term. Therefore, the mortality burden of influenza should not be overlooked. Efforts are needed to raise awareness of influenza as a severe disease, especially among high-risk groups.

Limitations

This study had some limitations. First, we did not use age-specific influenza virus activity proxies to estimate influenza-associated excess mortality, and a proxy for all-age activity was used instead. Second, the study period was relatively short (ie, 4 years), which may have influenced the comparison of the mortality burden of different influenza subtypes and lineages. This is mainly because the virology data included samples that tested positive for influenza B, but information on lineage was unavailable before 2015. Data from 2019 onwards were not collected. Moreover, we did not consider the influence of factors such as respiratory syncytial virus and vaccination coverage on the estimate of influenza-associated excess mortality, since such data were not available.

Conclusion

In conclusion, after considering the observed mortality displacement, influenza was associated with substantial mortality in Guangzhou, occurring predominantly in the elderly. The mortality burden of influenza B, particularly B/Yamagata, cannot be ignored. Contrasting sex differences were found in influenza-associated excess mortality from respiratory diseases and from cardiovascular diseases, and the underlying mechanisms need to be investigated in further studies. Our findings can help us better understand the magnitude and time-course of the effect of influenza on mortality and inform targeted interventions for mitigating the influenza mortality burden, such as immunizations with quadrivalent vaccines (especially for older individuals), behavioral campaigns, and treatment strategies.

Abstract

Background: Seasonal influenza activity showed a sharp decline in activity at the beginning of the emergence of COVID-19. Whether there is an epidemiological correlation between the dynamic of these 2 respiratory infectious diseases and their future trends needs to be explored.

Objective: We aimed to assess the correlation between COVID-19 and influenza activity and estimate later epidemiological trends.

Methods: We retrospectively described the dynamics of COVID-19 and influenza in 6 World Health Organization (WHO) regions from January 2020 to March 2023 and used the long short-term memory machine learning model to learn potential patterns in previously observed activity and predict trends for the following 16 weeks. Finally, we used Spearman correlation coefficients to assess the past and future epidemiological correlation between these 2 respiratory infectious diseases.

Results: With the emergence of the original strain of SARS-CoV-2 and other variants, influenza activity stayed below 10% for more than 1 year in the 6 WHO regions. Subsequently, it gradually rose as Delta activity dropped, but still peaked below Delta. During the Omicron pandemic and the following period, the activity of each disease increased as the other decreased, alternating in dominance more than once, with each alternation lasting for 3 to 4 months. Correlation analysis showed that COVID-19 and influenza activity presented a predominantly negative correlation, with coefficients above –0.3 in WHO regions, especially during the Omicron pandemic and the following estimated period. The diseases had a transient positive correlation in the European region of the WHO and the Western Pacific region of the WHO when multiple dominant strains created a mixed pandemic.

Conclusions: Influenza activity and past seasonal epidemiological patterns were shaken by the COVID-19 pandemic. The activity of these diseases was moderately or greater than moderately inversely correlated, and they suppressed and competed with each other, showing a seesaw effect. In the postpandemic era, this seesaw trend may be more prominent, suggesting the possibility of using one disease as an early warning signal for the other when making future estimates and conducting optimized annual vaccine campaigns.

KEYWORDS

COVID-19; influenza; negative correlation; seesaw effect; respiratory infectious disease; epidemiological trends

Introduction

Influenza was primarily characterized as a seasonal epidemic before the COVID-19 pandemic. Stringent public health and social interventions (PHSMs) were implemented in early 2020 to contain the spread of SARS-CoV-2, and influenza activity also declined [1-3]. However, during the latest winter and spring, influenza re-emerged and had a three-year-high level of activity in China [4] and other countries [5] at the same time that there was reduced virulence of Omicron and easing of PHSMs. Under the same natural conditions and PHSMs in a region, there seems to be a subtle relationship between these 2 respiratory infections. For example, they have been found to cocirculate and to coinfect people [6], but most study subjects have been COVID-19 patients [6,7]. General population-based epidemiological patterns and regularities have not yet been fully explored.

Member countries of the World Health Organization (WHO) regions update influenza activity data weekly in the FluNet, a web-based global influenza virology surveillance tool first introduced in 1997 [8]. The WHO divides member countries into 6 regions based on their location, including the African region (AFRO), Eastern Mediterranean region (EMRO), European region (EURO), Americas region (AMRO), Southeast Asian region (SEARO), and Western Pacific region (WPRO) [9]. Since January 2020, a subset of member countries in each region have also reported their national test positivity rates for SARS-CoV-2 on a weekly basis. Influenza sentinel surveillance systems were leveraged to integrate SARS-CoV-2 testing in specimens from influenza surveillance sources. The genomic sequencing of SARS-CoV-2 from representative and systematically sourced sentinel specimens has been expedited to monitor the trends and prevalence (ie, proportions) of existing and emerging circulating and cocirculating genetic variants (ie, clades) and to improve the geographic and demographic representativeness and timeliness of SARS-CoV-2 genetic-sequence data in publicly accessible databases to inform PHSMs [10].

Most studies have conducted epidemiological analyses and estimation of COVID-19 or influenza by leveraging infectious disease dynamics models [11-13] (eg, the susceptible-exposed-infected-removed model), but few have predicted trends based on longer time series and machine learning during the past 3 years. These models help tackle multimodal data and are increasingly being used in auxiliary diagnosis and other medical areas [14,15]. They are composed of different networks with various connections, referred to as neural networks or neural-like networks, to achieve automated learning and prediction by mimicking the neural network construction of the human brain. This method is highly adaptable and can adjust itself to diverse data sets, thus adapting itself to different application scenarios. Secondly, deep learning avoids human specification by automatically extracting data features and processing them. This is highly scalable and can improve simulation performance by increasing the network layers and nodes to cope with larger-scale data and more complex problems [16]. Therefore, more learning models could be introduced into infectious disease surveillance and studies.

In this study, we examined global changes in COVID-19 and influenza activity since 2020, aiming to assess the correlation between COVID-19 and influenza activity and estimate upcoming trends with the help of a deep learning model. The findings may provide a theoretical reference for the epidemiological patterns of these 2 respiratory infectious diseases and insights for future interventions.

Methods

Summary of the Study Design

In this study, we retrospectively described the dynamics of COVID-19 and influenza in the 6 WHO regions from January 2020 to March 2023 and used a neural network model to learn potential patterns of previously observed activity to predict trends for the next 16 weeks. Finally, based on an epidemiological perspective, Spearman correlation coefficients were used to assess the past and future correlations. The analysis was performed using Python (version 3.9.6; Python Software Foundation).

Data Source

The test positivity rate was used as an accurate indicator of disease activity; this method used the number of positive tests as the numerator and the specimens processed as the denominator. We extracted the weekly test positivity rates for influenza and SARS-CoV-2 from reports to FluNet between January 12, 2020, and March 26, 2023 [10], covering the AFRO, EMRO, EURO, AMRO, SEARO, and WPRO. The detailed raw data names and sources are presented in Multimedia Appendix 1, Table S1.

Model Construction

Based on the 3-year activity of COVID-19 and influenza, we used a long short-term memory (LSTM) machine learning model to estimate trends in the following 16 weeks. LSTM is widely applied to stock and sales forecasting, specializing in a unique memory cell structure that can process long time-series information more effectively than other net models. It can be trained directly on the series without smoothness requirements, reducing the need for artificial intervention and enhancing objectivity [16]. The LSTM transforms the traditional neurons of a neural network into store cells, which are capable of storing and transmitting the hidden information in a time series (Figure 1).

The LSTM converts conventional neurons into a storage unit containing a matrix of 3 gating devices: input gate, forgetting gate, and output gate. These combine to control the data information flow and store the hidden information in the time series [17], hence solving the gradient disappearance [18,19] (Figure 1).

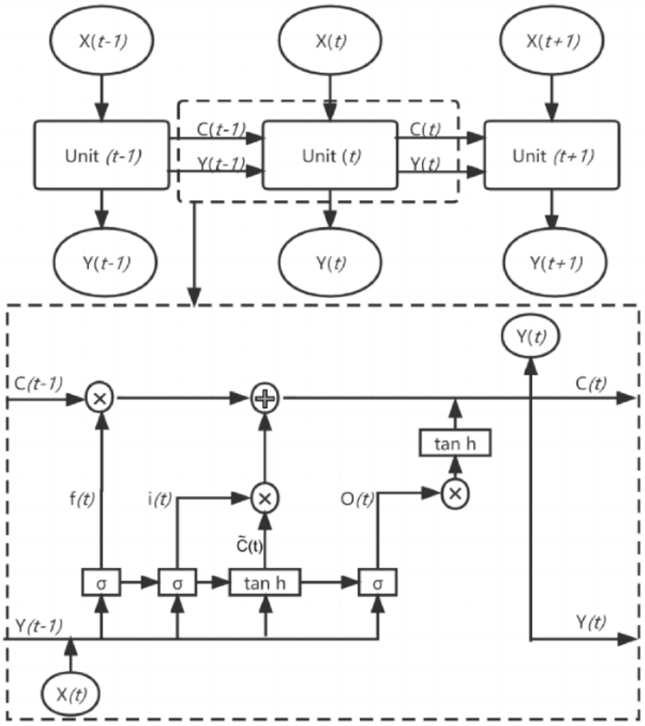
First, the forgetting gate filters the information in the unit C_{t-1} at the previous moment t–1, and how much of its C_{t-1} information is retained depends on the forget gate f_t that has the range [0, 1]; f_t is set as 1 or 0 and in between, with the information of C_{t-1} corresponding to all retained, all forgotten, and partially forgotten proportions, respectively. In the forgetting gate unit equation (equation 1), let W_f, X_t, y_{t-1}, and b_f denote the weight of the forgetting gate, the input at time t, the hidden state at time t–1, and the bias of the forget gate. The sigmoid activation function is σ (equation 2).

Second, the input gate represents the information acquired at the moment t. It determines how much information from the input X_t at the moment t can be saved in the unit C_t (equations 3 and 4). W_i and W_c are the weights of the input gates. The biases of the input gates are b_i and b_c, and tanh is the activation function (equation 5).

Third, the update of the unit status C_t (equation 6) depends on two parts: One is the product of the unit status C_t at the moment t–1 and the forget gate f_t, namely the retained information, and the other part is the product of the input unit status $\tilde{C}_t$ at the present moment t and the input gate i_t, namely the new information obtained. $\tilde{C}_t$ is the input node at time t.

Fourth, the output gate is used to output the hidden status y_t at the moment t (equations 7 and 8). W_o and b_o are the respective weights and biases of the output gates.

Figure 1. Schematic diagram of the long short-term memory neural network framework. The neural network consists of many units. The dashed box shows one of the unit structures, containing the forgetting gate, the input gate, and the output gate control system. The circles intersected by arrows in the dotted box denote multiplication or addition corresponding to the formula for the method.



Model Performance Evaluation and Selection of Optimal Parameters

To enhance the model prediction accuracy and scalability, we used the mean absolute percentage error and root mean squared error as evaluation indicators to determine the optimal proportion of training set and test set, as well as step size, layers, nodes, and algorithms [20,21], for different regions. The selection process is detailed in Multimedia Appendix 1, Tables S2-S6.

Correlation Analysis

We referred to the WHO list of the currently circulating variants of concern of SARS-CoV-2 [22] and the study objectives to uniformly divide all regions into 5 time periods to analyze the correlations: these periods covered the original strain (January 2020 to November 2020), cocirculation of a multivariant strain (referred to as “others”; December 2020 to April 2021), Delta (May 2021 to November 2021), Omicron (November 2021 to March 2023), and the period estimated by the models (March 2023 to July 2023). The starting and ending dates of variant pandemics in different regions differed slightly. In the 6 WHO regions, the Spearman nonparametric analysis of COVID-19 and influenza activity was conducted sequentially to identify whether the epidemiological patterns were correlated across the 5 time periods mentioned above. The correlation analysis was not intended to reveal causality but rather to identify and explain significant trends.

Ethical Statement

As only published data were used for this study, ethical approval was not necessary.

Results

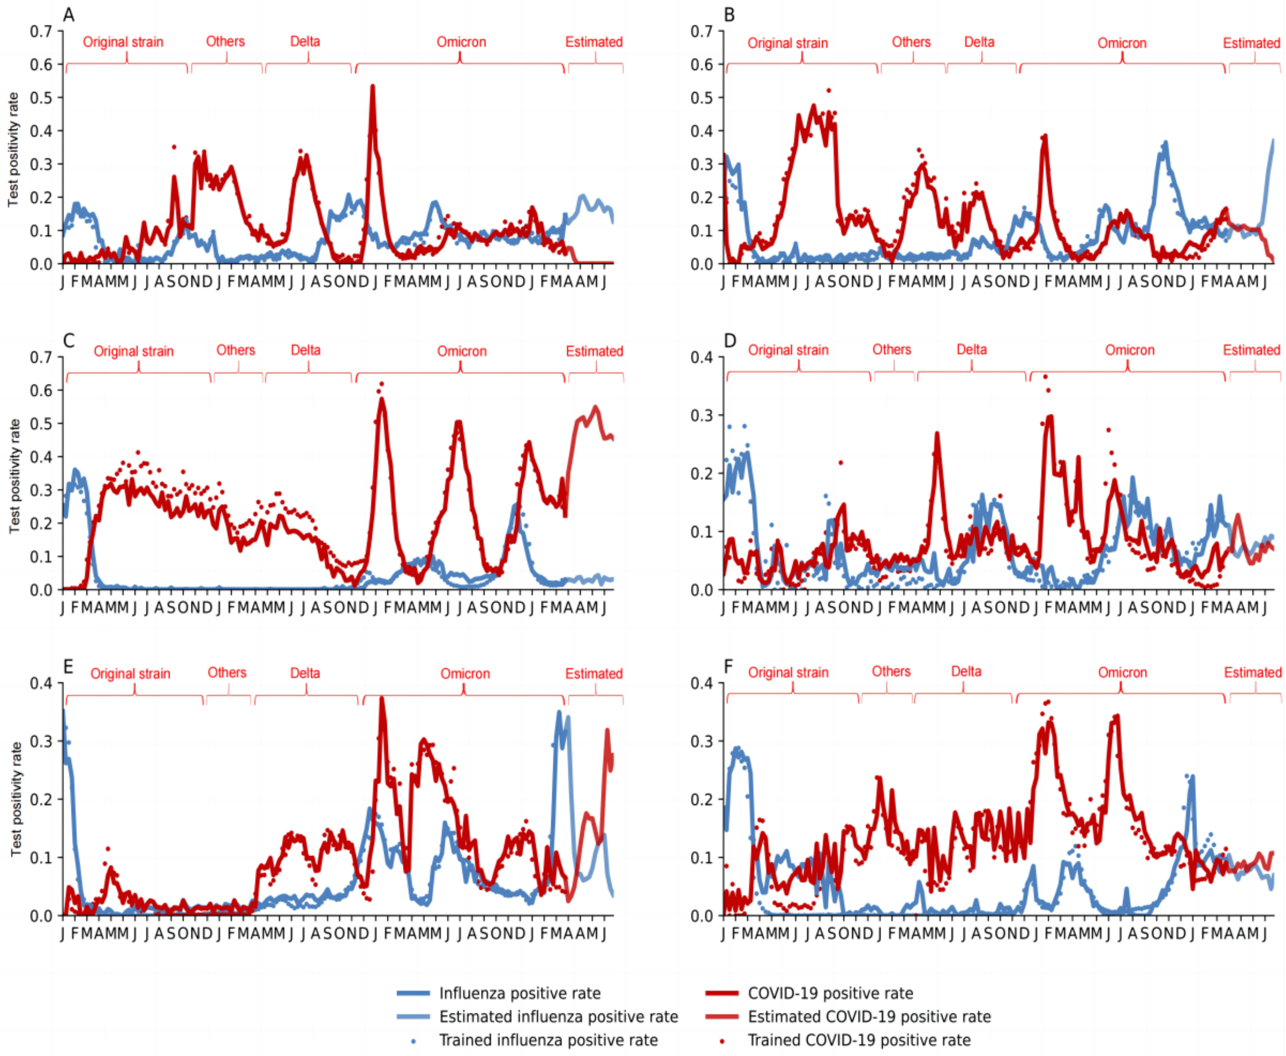
Description of Past Trends

Before the Delta variant emerged, the activity of the original strain and other variants of SARS-CoV-2 was higher than that of influenza in the 6 regions. Among the regions, SARS-CoV-2 activity was observed in AFRO, EMRO, and AMRO at a high level (peaking at over 30%), and influenza activity was at a low level (peaking at about less than 10%). Both fluctuated with low activity levels (less than 15% overall), but influenza activity was relatively lower in SEARO, WPRO, and EURO.

Following the emergence of Delta as the globally dominant strain, influenza activity began to increase in WHO regions, but in the AMRO and EURO, activity was less than 10% and remained below that of Delta. In the other 4 WHO regions, Delta activity reached a peak (over 30%) and then declined to below 10%, and the decline was accompanied by a step-up in influenza activity to 10% to 20% until the advent of Omicron.

During the first 3 months of the Omicron pandemic, influenza activity in the 6 regions first declined alongside soaring Omicron activity and then increased immediately when Omicron plummeted, whereas the influenza test positivity rate overall was consistently lower than that of Omicron. Thereafter, their trends were identical; each declined as the other rose. This occurred 1 to 2 more times, being more apparent in EMRO, AMRO, WPRO, and EURO; each alternation, when influenza activity was higher than Omicron or vice versa, lasted for about 3 to 4 months (Figure 2).

Figure 2. The observed and estimated activity of COVID-19 and influenza. Figures A-F correspond to the following regions of the World Health Organization: African, Eastern Mediterranean, Americas, Southeast Asia, Western Pacific, and European. Periods are set for the original strain (Jan 2020-Nov 2020), "others" (Dec 2020-Apr 2021), Delta (May 2021-Nov 2021), Omicron (Nov 2021-Mar 2023), and the model-estimated period (Mar 2023-July 2023). The horizontal coordinate intervals are divided by month and labeled with the first letter of the month.



Estimated COVID-19 and Influenza Trends

We estimated the dynamics of COVID-19 and influenza activity for 16 weeks after the study observation end point (March 26, 2023). The estimation was that they would be alternatingly prevalent at less than 40% positivity rates, except for AMRO (over 40%). In SEARO and EURO, it was estimated that influenza and COVID-19 activity would be closely matched, with both hovering around 10% positivity rates; in AFRO and EMRO, influenza activity would rise from 10% to about 20% to 30%, while COVID-19 activity would decrease from similar levels to less than 5%, and COVID-19 activity would no longer be consistently higher than influenza. Conversely, influenza could decrease to below 10% in AMRO and WPRO as COVID-19 activity might go up to above 30% (Figure 2).

Correlation Between COVID-19 and Influenza Activity in Different Time Periods

The Spearman coefficients were calculated for different phases of COVID-19 and influenza activity. In our study, correlation coefficients less than 0.3, 0.3 to less than 0.6, and more than or equal to 0.6 were considered weak, moderate, and strong correlations, respectively. Statistically, COVID-19 and influenza were moderately and negatively correlated in EMRO, AMRO, and WPRO during the original-strain pandemic (–0.355, –0.593, –0.448) and also in EMRO (–0.358) during the multivariant mixed pandemic, while they were transiently, strongly, and positively correlated in EURO and WPRO (0.621 and 0.667). During the Delta pandemic, the 2 diseases were moderately and negatively correlated in AFRO, EMRO, and AMRO (–0.472, –0.422, –0.351). During the Omicron pandemic, they were moderately and negatively correlated in EMRO, AMRO, and SEARO (–0.403, –0.370, –0.469) and highly negatively correlated in EURO (–0.702). Similarly, in the estimated 16-week trend, they showed more significant and highly negative correlations in AFRO, EMRO, and WPRO (–0.724, –0.791, –0.600) and a moderate negative correlation in EURO (–0.474). Overall, COVID-19 and influenza activity were significantly negatively correlated, with coefficients greater than 0.3, especially during the Omicron pandemic and in the upcoming period. No significant correlation was found for other pandemic phases and WHO regions (Figure 3).

Figure 3. Spearman correlation coefficients for COVID-19 and influenza in different World Health Organization regions. Positive and negative correlations are shown in blue and red, respectively, with darker colors indicating a stronger correlation at the same significance level. AFRO: African region; AMRO: Americas region; EMRO: Eastern Mediterranean region; EURO: European region; SEARO: Southeast Asian region; WPRO: Western Pacific region. *$P<.01$, **$P<.05$, ***$P<.001$.

Discussion

Principal Findings

This study analyzed the dynamics of COVID-19 and influenza in 6 WHO regions over the past 3 years and estimated them in the following 16 weeks. We found that early in the pandemic, when COVID-19 was emerging as an infectious disease, influenza activity stayed below 10% for more than 1 year in the 6 WHO regions. Subsequently, influenza activity gradually rose as Delta activity dropped, but still peaked at a level below that of Delta. Omicron alternated with influenza as the dominant disease. The trend of one disease declining as another rises has been named the seesaw effect [23] and was clearly apparent in the epidemiological patterns of the 2 infectious diseases in this study, characterized by increasing magnitude and frequency, with each alternation have a duration of about 3 to 4 months, suggesting a competitive relationship. The seesaw effect of alternating dominance is likely to become more conspicuous in the postpandemic era. Negative correlation coefficients for different WHO regions and time periods statistically complement the validation of this effect.

Our quantitative analysis based on epidemiological indicators (test positivity rates from the population) showed the dynamic patterns of the 2 respiratory diseases, which have similar transmission modes. The generation and variation of the seesaw effect could be related to numerous factors. On the one hand, from a biological perspective, respiratory viruses share the same host; therefore, viruses compete with each other for susceptible cells in the host. Cells invaded by one respiratory virus produce immune interference that drives uninfected neighboring cells to adopt a protectively antiviral status [24,25], making the host resistant or only partially susceptible to subsequent viruses. One example is the significant decrease in rhinovirus prevalence in patients during peak influenza activity [26]. On the other hand, this effect varies in magnitude and duration across regions, which could be driven by the different intensity of PHSMs adopted in different countries [27-30] and time periods [31], differences in vaccination and natural infection status, or variant strain properties. For example, the earliest adoption of strict nonpharmaceutical interventions in China not only controlled the spread and dissemination of the original strain [32], but also reduced influenza activity by 82%, and by 64% in the north and south [3]. Interestingly, after the PHSMs, influenza activity in China in the latest winter was at a low level because of the rapid rise in Omicron infections in the population at the same time, and after the Omicron test positivity rate dropped, influenza activity jumped sharply, to over 50%. This once again suggests that driving factors influence the magnitude of the seesaw effect and the timing of its onset. In addition, the higher virulence of the original strain attacked individuals more and longer [6], resulting in less opportunity for influenza virus infection; thus, absolute suppression occurred in the first year of the COVID-19 pandemic. The more moderate virulence and lower severity of Delta and Omicron allow the possibility of infecting the host with influenza, which may explain why influenza activity increased after the Delta pandemic and was able to dominate during the Omicron period.

During the multivariant pandemic period, the dynamics of COVID-19 and influenza had short-term positive correlations in EURO and WPRO, while negative correlations were not significant in other regions. Temporary phenomena mediated by complex factors, such as the sudden appearance of variants, require more evidence to unravel their underlying mechanisms. Similar phenomena have been observed in other studies: there are reports of coinfection with SARS-CoV-2 and influenza A in some countries [33-36], and meta-analyses based on the November 2019 to August 2021 period [37] all showed coinfection with both diseases. Nevertheless, most study subjects have been COVID-19 patients or laboratory animals rather than the general population [37,38], with a low proportion of observed coinfections (about 1%) or small sample sizes [39] before and during the Omicron pandemic [37,40]. Inevitably, the positive correlation for susceptibility to coinfection at the individual level or in some high-risk populations might lead to serious clinical outcomes [41]; therefore, much larger, sample-based meta-studies are warranted to explore the reasons for this phenomenon to prevent and control it or to meet the potential surge in hospital visits and demand. In addition, it is worth noting that other respiratory infectious diseases have been threatening humans. Further research on the interactions between respiratory pathogens other than COVID-19 and influenza remains to be done. Regardless of the fate of COVID-19, influenza, or other respiratory pathogens, necessary personal protection and vaccination should be implemented.

Our study provided qualitative and quantitative assessments of the interaction between COVID-19 and influenza. We identified a seesaw effect between COVID-19 and influenza activity based on a competitive effect from an epidemiological perspective, echoing viral antagonism from a historical pathogenic perspective. This finding can be used to guide disease surveillance, early warning, and intervention; for example, real-time surveillance of viral dynamics can be used to estimate trends in other diseases or stagger vaccinations in response to alternating epidemics or pandemics.

Limitations

There are some limitations to mention. First, the high uncertainty of viral variation, changes in influenza visit behavior triggered by early and rigorous interventions, the decline in SARS-CoV-2 tests in some countries, and other unforeseen factors all interfered with the observed positive test numbers for the 2 diseases studied. Hence, we used the test positivity rate rather than the number of positive tests as an indicator of activity and divided the time periods to minimize the negative impact. Second, the raw data may not fully represent the overall trend in each area because of the limited number of member countries that periodically report to the WHO. Nevertheless, there is no more authoritative data source for COVID-19 and influenza activity.

Conclusions

Influenza activity and former seasonal epidemiological patterns were shaken by the COVID-19 pandemic. Their activities were inversely correlated to a moderate or greater degree, and they suppressed and competed with each other, showing a seesaw effect. In the postpandemic era of COVID-19, seesaw trends will be more prominent, prompting the possibility of using one disease as an early warning signal for the other for future estimates; this could be used to conduct optimized annual vaccine campaigns.

Acknowledgments

We sincerely thank all the member of the Infectious Diseases Team at the School of Population Medicine and Public Health, Chinese Academy of Medical Sciences and Peking Union Medical College. This study was supported by the Non-profit Central Research Institute Fund of the Chinese Academy of Medical Sciences (2021-RC330-002) and the Chinese Academy of Medical Sciences Innovation Fund for Medical Sciences (2021-I2M-1-044, 2020-I2M-1-001). The funding sources had no role in data collection or interpretation or decisions relating to data publication.

Data Availability

The data are available in the FluNet repository [10]. The code generated and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

QW and LF conceptualized and designed the study. QW, JY, PD, YS, and JQ performed data collection. QW, M Jia, and WL performed data analysis and model construction. QW and M Jiang wrote the first draft. LF and WY supervised the project. All authors read and approved the final manuscript. Authors LF and WY (yangweizhong@cams.cn) are cocorresponding authors for this article.

Conflicts of Interest

None declared.

Abstract

Background: During the COVID-19 pandemic, infodemic spread even more rapidly than the pandemic itself. The COVID-19 vaccine hesitancy has been prevalent worldwide and hindered pandemic exiting strategies. Misinformation around COVID-19 vaccines is a vital contributor to vaccine hesitancy. However, no evidence systematically summarized COVID-19 vaccine misinformation.

Objective: This review aims to synthesize the global evidence on misinformation related to COVID-19 vaccines, including its prevalence, features, influencing factors, impacts, and solutions for combating misinformation.

Methods: We performed a systematic review by searching 5 peer-reviewed databases (PubMed, Embase, Web of Science, Scopus, and EBSCO). We included original articles that investigated misinformation related to COVID-19 vaccines and were published in English from January 1, 2020, to August 18, 2022. We excluded publications that did not cover or focus on COVID-19 vaccine misinformation. The Appraisal tool for Cross-Sectional Studies, version 2 of the Cochrane risk-of-bias tool for randomized trials (RoB 2), and Critical Appraisal Skills Programme Checklist were used to assess the study quality. The review was guided by PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) and registered with PROSPERO (CRD42021288929).

Results: Of the 8864 studies identified, 91 observational studies and 11 interventional studies met the inclusion criteria. Misinformation around COVID-19 vaccines covered conspiracy, concerns on vaccine safety and efficacy, no need for vaccines, morality, liberty, and humor. Conspiracy and safety concerns were the most prevalent misinformation. There was a great variation in misinformation prevalence, noted among 2.5%-55.4% in the general population and 6.0%-96.7% in the antivaccine/vaccine hesitant groups from survey-based studies, and in 0.1%-41.3% on general online data and 0.5%-56% on antivaccine/vaccine hesitant data from internet-based studies. Younger age, lower education and economic status, right-wing and conservative ideology, and having psychological problems enhanced beliefs in misinformation. The content, format, and source of misinformation influenced its spread. A 5-step framework was proposed to address vaccine-related misinformation, including identifying misinformation, regulating producers and distributors, cutting production and distribution, supporting target audiences, and disseminating trustworthy information. The debunking messages/videos were found to be effective in several experimental studies.

Conclusions: Our review provides comprehensive and up-to-date evidence on COVID-19 vaccine misinformation and helps responses to vaccine infodemic in future pandemics.

Introduction

Background

The COVID-19 pandemic has become the most threatening global health issue for almost 3 years [1]. As a cost-effective measure to protect people, governments have implemented various policies to promote the COVID-19 vaccination. However, as of early 2022, the global acceptance rate of the COVID-19 vaccination was only 67.8% [2]. Considering the powerful capability of the omicron variant to escape neutralizing antibodies elicited by current vaccines, the current vaccine acceptance rate is not enough to control the omicron variant [3,4]. It is thus necessary to investigate the negative factors that hinder the COVID-19 vaccination and take actions to increase vaccine coverage.

Vaccine acceptance is determined by contextual influences, individual/social group influences, and vaccine- and vaccination-specific issues [5]. Among all these factors, influences of infodemic and vaccine misinformation deserve more attention for the COVID-19 vaccination. An infodemic is an overabundance of information including misinformation in digital and physical environments, which makes it hard to find trustworthy sources and reliable guidance during a disease outbreak [6]. In the era of social media, the dissemination of information, especially misinformation, has been intensified [7]. During the COVID-19 pandemic, COVID-19 infodemic spread even more rapidly than the pandemic itself. The COVID-19 infodemic had jeopardized public trust in the pandemic response strategies such as vaccination and attracted attention from governments and health agencies across the world [8]. It is difficult but urgent to terminate and resolve the infodemic to promote the vaccination.

Misinformation is referred to false or inaccurate information deliberately intended to deceive [9]. It originates from rumors, websites and social media, works of fiction, governments, politicians, and vested interests [10,11]. Misinformation around COVID-19 vaccines is a noteworthy component of contextual influences on vaccine acceptance or hesitancy [12,13]. It can distort people's perception of COVID-19 vaccines [14], exaggerate the probability of adverse events following vaccination [15], and lead to extreme political sentiments [16]. COVID-19 vaccine hesitancy, partially driven by misinformation, heavily hindered the pandemic exiting strategies worldwide.

Some reviews have summarized COVID-19–related infodemic and misinformation during the pandemic, but there is a lack of systematic evidence focusing on COVID-19 vaccine misinformation. For instance, Ries [17] synthesized the mechanisms and impacts of COVID-19 infodemic. Gabarron and colleagues [18] summarized the types of COVID-19–related misinformation and its possible consequences. A few studies focused on misinformation about COVID-19 vaccines, but they mainly evaluated its influence on vaccine hesitancy [19,20]. However, no evidence systematically summarized the distribution of COVID-19 vaccine misinformation in the population, what features it has, and how to fight against it.

Objective

We aimed to synthesize global evidence on misinformation related to COVID-19 vaccines, including its prevalence, features, influencing factors, impacts, and solutions for combating misinformation around COVID-19 vaccines. Specifically, the following questions guided our inquiry: How prevalent was COVID-19 vaccine misinformation across regions and populations? What types and features did the misinformation have? Where did the misinformation come from? How was it distributed among the general population? What factors affected misinformation believing and spreading? How did the misinformation influence vaccine hesitancy and behaviors? How to fight against vaccine misinformation in a future pandemic? This systematic review would enrich the evidence regarding vaccine misinformation and inform response strategies when new vaccines are introduced in future pandemics.

Methods

Search Strategy and Selection Criteria

According to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, we conducted a systematic review of empirical articles on COVID-19 vaccine misinformation. The PRISMA checklist can be found in Multimedia Appendix 1. The review protocol was registered with PROSPERO (registration number CRD42021288929). This review was developed based on 5 peer-reviewed databases (PubMed, Embase, Web of Science, Scopus, and EBSCO). We used keywords related to COVID-19 vaccines and misinformation to identify empirical articles published in English from January 1, 2020, to August 18, 2022.

To identify the keywords of "misinformation," we referred to the codebook by Kata [10], a widely recognized study on the classification of vaccine misinformation. We also referred to the fact sheet of COVID-19 vaccine misinformation published by the US Centers for Disease Control and Prevention (CDC) and collected the keywords on their websites to match the emerging misinformation about COVID-19 vaccines [21]. Using the keywords above, we piloted literature search in PubMed and Web of Science, and further refined the keywords according to literature searching results. The search strategy (Multimedia Appendix 2) consisted of 2 major concepts: COVID-19 vaccine and misinformation, which contains the general descriptions of misinformation (such as "misinformation," "infodemic," "myth") and specified descriptions of some certain misinformation (such as "fertility," "toxic," "freedom").

Original observational or interventional articles that investigated misinformation related to COVID-19 vaccines were included.

We excluded studies that (1) investigated non-COVID-19 vaccines or the COVID-19 pandemic instead of COVID-19 vaccines, (2) did not investigate misinformation, and (3) did not focus on COVID-19 vaccine misinformation. We also excluded the following article types: conference abstract, editorial, letter, commentary, correspondence, study protocol, and review.

Data Screening and Extraction

We exported identified articles from databases, imported them into EndNote 20 (Clarivate Analytics), and removed the duplicates. Two reviewers (SH and SZ) first screened titles and abstracts independently to include articles meeting the inclusion criteria. The full texts of included studies after initial screening were scrutinized to assess the overall eligibility based on the inclusion and exclusion criteria by 2 independent reviewers (SH and SZ). When discrepancies in article inclusion emerged between the 2 reviewers, they engaged in discussion with a third researcher (XZ) to reach a consensus.

For eligible studies, data were independently extracted by 2 reviewers (SH and SZ), and inconsistencies or disagreements were reconciled in data extraction. Besides the study characteristics (region and period, study design, data sources, target population, sample size, and analysis methods), we extracted 4 outcomes of interest for each included study: (1) the types, sources, and prevalence of COVID-19 vaccine misinformation; (2) factors that affect the believing and spreading of COVID-19 vaccine misinformation; (3) the impact of misinformation on vaccine hesitancy and behaviors; and (4) proposed solutions for combating misinformation.

Classification of Study Types, Populations, and Phases

In this systematic review, we covered 4 types of study design: survey-based study, internet-based study, interview, and experiment. Survey-based study included cross-sectional or follow-up studies conducted among population using questionnaires; and internet-based study referred to studies that acquired publicly available information thought the internet. The prevalence and impact of COVID-19 vaccine misinformation might be different between the vaccine hesitant/refusal group and the general population. Thus, each type of studies was divided into 2 subgroups according to their study population's prior defined attitudes toward COVID-19 vaccines: the antivaccine/vaccine hesitant group and the general population group.
