We used a database provided by the National Health Insurance Service (NHIS), a single insurer in Korea [17]. The NHIS provides a mandatory universal insurance system that covers ~97% (about 51 million) of the Korean population and medical aid to ~3% (about 1.5 million) of the population in the lowest income bracket. NHIS provides a free biennial cardiovascular health screening for all insured individuals. Hence, the NHIS retains an extensive data set of the entire Korean population that includes demographics; medical treatment and procedures; disease diagnosis according to the International Classification of Diseases, 10th revision (ICD-10) codes; and the results of health screenings consisting of a self-questionnaire on health behavior, anthropometric measurements, and laboratory test results.

Study Population

Among individuals who underwent a health screening in 2009-2012, we identified 2,745,689 individuals with type 2 diabetes: (1) those with a previous history of type 2 diabetes which was defined as ICD-10 code (E11-14) diagnosis with at least 1 claim for prescription of antidiabetic agents before the health screening or (2) those with fasting plasma glucose 126 mg/dL at the health screening. This definition was based on the consensus of relevant findings widely used in previous studies [18,19]. We then selected current smokers (n=758,049) according to the World Health Organization definition of current smoker [20]. Among these, 485,547 underwent a follow-up health examination within 2 years. We excluded those who had previously been diagnosed with (1) any cancer (n=54,192); (2) myocardial infarction, atrial fibrillation, or valvular heart diseases (n=18,205); or (3) HF (n=9757) before the second health screening. Those with at least 1 missing variable used in the study were also excluded (n=33,891). To reduce the effect of reverse causality, we applied a 1-year lag time by excluding participants who were diagnosed with HF (n=2463) and who

https://publichealth.jmir.org/2024/1/e46450
A total of 365,352 participants were included in the primary analysis (Figure 1).

**Flowchart for participant recruitment.**

- **Participants (≥20 years) with type 2 diabetes who underwent health screening in 2009-2012 (n=2,745,689)**
- **Participants who currently smoke (n=758,049)**
- **Participants who had a follow-up screening within 2 years (n=485,547)**
  - Previous history
    - Cancer (n=54,192)
    - Myocardial infarction, atrial fibrillation or valvular heart disease (n=18,205)
    - Heart failure (n=9757)
  - Incomplete information (n=33,891)
  - Follow-up <1 year (n=4150)
- **Participants eligible for inclusion (n=365,352)**
- **Followed up from 1 year after the second screening date to the date of incident heart failure, death or outmigration, or the end of the study period (December 31, 2018), whichever came first.**

**Ethical Considerations**

This study was approved by the institutional review board of Samsung Medical Center (IRB SMC 2022-07-072). The review board waived the requirement for written informed consent from the patients because the data are public and anonymized under confidentiality guidelines.

**Definition of Change in Amount of Smoking Cigarettes**

Information on smoking status was obtained from a self-administered questionnaire completed as a part of the NHIS health screening. The participants who identified themselves as current smokers were asked to provide their daily smoking amount (average number of cigarettes per day) and smoking duration in years. According to the number of cigarettes per day at the time of the first screening, participants were categorized into three groups: (1) light smokers (<10 cigarettes per day), (2) moderate smokers (10-19 cigarettes per day), and (3) heavy smokers (≥20 cigarettes per day). Each of the 3 groups was then divided into 5 subgroups by comparing the number of cigarettes per day between the first screening and the follow-up screening. The subgroups were (1) quitters (those who completely ceased smoking), (2) reducers I (those who reduced the number of cigarettes by 50% or more), (3) reducers II (those who reduced the number of cigarettes by 20% or more and less than 50%), (4) sustainers (those who reduced the number of cigarettes by less than 20% or increased by less than 20%), and (5) increasers (those who increased the number of cigarettes by 20% or more).

**Outcome: Ascertainment of HF and Follow-Up**

The end point of the study was a newly diagnosed case of HF. HF was defined as the first hospitalization under a primary diagnosis of ICD-10 code I50 as used in previous studies [21-23]. The study participants were followed up from 1 year after the second screening date to the date of incident HF, death or outmigration, or the end of the study period (December 31, 2018), whichever came first.

**Covariates**

We considered socioeconomic position as a potential covariate including income level and place of residence. Household income was categorized into quartiles based on insurance premium levels with those covered by Medical Aid being merged into the lowest income quartile. Alcohol consumption was classified as none, mild (<15 g of alcohol per day), moderate (15-30 g of alcohol per day), and heavy (≥30 g of alcohol per day). Regular exercise was defined as >30 minutes of moderate physical activity at least 5 times per week or >20 minutes of strenuous physical activity at least 3 times per week [24]. BMI was calculated as subject weight (kg) divided by square of height (m$^2$).
Hypertension was defined as a history of a claim (I10-13 or 15 codes) and antihypertensive medication or systolic blood pressure ≥140 mm Hg or diastolic blood pressure ≥90 mm Hg. Dyslipidemia was defined as a history of a claim with E78 codes and lipid-lowering medications, or total cholesterol level ≥240 mg/dL. Chronic kidney disease was defined as a glomerular filtration rate <60 mL/minute per 1.73 m² as estimated by the Modification of Diet in Renal Disease equation. Chronic obstructive pulmonary disease was defined as a claim with J41-44 codes, and stroke was defined as a claim with codes I63-64.

**Statistical Analysis**

Cox proportional hazards regression analysis was performed to evaluate the association between smoking behavior change and incident HF. Model 1 was unadjusted. Model 2 was adjusted for age, sex, income, area of residence, alcohol consumption, duration of smoking, physical activity, BMI, and comorbidities (hypertension, dyslipidemia, chronic kidney disease, chronic obstructive pulmonary disease, and stroke). Model 3 was further adjusted for fasting glucose level, duration of type 2 diabetes, and insulin use. Stratification analyses by smoking levels at the first examination (light, moderate, and heavy smoker), type 2 diabetes severity (duration of type 2 diabetes: new-onset, <5 years, and 5 years, the number of oral antidiabetic agents taken: 0, 1-2, and 3, and use of insulin), age (20-64 years and 65 years), and sex were performed to assess the association of change in smoking behavior with incidence of HF. Statistical analyses were performed using SAS (version 9.4; SAS Institute Inc), and a P value <.05 was considered statistically significant.

**Results**

**Baseline Characteristics of the Study Population**

Table 1 shows the baseline characteristics according to the change in smoking behavior. During the 2 years before initiation of the study, 44.5% (n=162,645) of current smokers sustained their smoking amount, 18.6% (n=67,843) became quitters, 20.7% (n=75,615) reduced their smoking amount (n=27,987, 7.7% and n=47,628, 13% in reducer I and reducer II groups, respectively), and the remaining 16.2% (n=59,249) increased their smoking amount. Compared to sustainers, quitters tended to be older, women, nondrinkers, and light smokers, engage in more regular exercise, have more comorbid conditions and longer duration of type 2 diabetes, and use multiple oral antidiabetic agents and insulin.

Change in Smoking Behavior and HF

During a median follow-up of 5.1 (IQR 4.0-6.1) years, there were 13,879 HF cases (7.8 per 1000 person-years). Table 2 shows the associations between change in smoking behavior and the risk of HF, with sustainers as a reference group.

There was no overall difference in HF risk between increasers and sustainers (adjusted hazard ratio [aHR] 1.02, 95% CI 0.97-1.07), but heavy smokers who increased their level of smoking had a 13% higher HF risk (aHR 1.13, 95% CI 1.04-1.24). In the case of reducers, the risk of HF was not reduced but rather increased slightly (aHR 1.14, 95% CI 1.08-1.21, for reducer I; aHR 1.03, 95% CI 0.98-1.09, for reducer II). Conversely, quitters had a lower risk of incident HF after adjusting for confounding factors including type 2 diabetes severity (aHR 0.90, 95% CI 0.86-0.95). When stratified by smoking level at the first screening, moderate-to-heavy smokers who became quitters had a lower risk of HF than sustainers (aHR 0.90, 95% CI 0.83-0.98 for moderate smoker; aHR 0.89, 95% CI 0.83-0.94 for heavy smoker).
Table 2. Associations of smoking behavior change (2009–2011) with heart failure during 5.1 years of follow-up (N=365,352).

aQuitters are those who ceased smoking; reducer I are those who reduced the number of cigarettes by 50% or more; reducer II are those who reduced the number of cigarettes by 20% or more; sustainers are those who reduced the number of cigarettes by less than 20% or increased by less than 20%; increasers are those who increased the number of cigarettes by 20% or more.
bIR: incidence rate per 1000 person-years.
cModel 1: unadjusted.
dHR: hazard ratio.
eModel 2: adjusted for age, sex, socioeconomic position (income level and place of residence), alcohol consumption, duration of smoking, physical activity, BMI, and comorbidities (hypertension, dyslipidemia, chronic kidney disease, chronic obstructive pulmonary disease, and stroke).
fModel 3: Model 2 + adjusted for fasting glucose level, duration of type 2 diabetes, and use of insulin.
gN/A: not applicable.
hLight smoker: <10 cigarettes per day; moderate smokers: 10-19 cigarettes per day; heavy smokers: ≥20 cigarettes per day.

Stratified Analysis

Figure 2 presents the associations between smoking behavior change and risk of HF incidence according to type 2 diabetes severity. Smoking cessation remained predictive of a lower incidence of HF, regardless of the duration of type 2 diabetes, number of oral antidiabetic agents, and use of insulin. In stratified analyses according to age and sex, the results were also consistent with the main findings (Table 3).
Figure 2. Association of smoking behavior change (2009-2012) with the incidence of heart failure stratified by (A) duration of type 2 diabetes, (B) number of oral antidiabetic agents, and (C) use of insulin. HRs are adjusted for age, sex, socioeconomic position (income level and place of residence), alcohol consumption, duration of smoking, physical activity, BMI, comorbidities (hypertension, dyslipidemia, chronic kidney disease, chronic obstructive pulmonary disease, and stroke), fasting glucose level, duration of type 2 diabetes, and use of insulin. HR: hazard ratio; quitter: those who ceased smoking; reducer I: those who reduced the number of cigarettes by 50% or more; reducer II: those who reduced the number of cigarettes by 20% or more and by less than 50%; sustainer: those who reduced the number of cigarettes by less than 20% or increased by less than 20%; increaser: those who increased the number of cigarettes by 20% or more.

*Quitters are those who quit smoking; reducer I are those who reduced the number of cigarettes by 50% or more; reducer II are those who the number of cigarettes by 20% or more and less than 50%; sustainer are those who reduced the number of cigarettes by less than 20% or increased by less than 20%; increaser are those who increased the number of cigarettes by 20% or more.

IR: incidence rate per 1000 person-years.

Model 1: unadjusted.

HR: hazard ratio.

Model 2: Adjusted for age, sex, socioeconomic position (income level and place of residence), alcohol consumption, duration of smoking, physical activity, BMI, and comorbidities (hypertension, dyslipidemia, chronic kidney disease, chronic obstructive pulmonary disease, and stroke).

Model 3: Model 2 + adjusted for fasting glucose level, duration of type 2 diabetes, and use of insulin.

Sex: not applicable.

Discussion

Principal Findings

In this large cohort study with repetitive measurements of smoking behavior, we found that increasers, particularly those who were initially heavy smokers, were associated with higher risks of HF than sustainers. In the case of reducers, the incidence of HF was not decreased but slightly increased. Smoking cessation was associated with a decreased risk of incident HF among moderate-to-heavy smokers with type 2 diabetes. Our stratified analyses also demonstrated that smoking cessation...
was consistently associated with a lower HF risk among type 2 diabetes with various characteristics.

The association between smoking and atherosclerotic coronary artery disease, a major cause of HF [7], is well established. The acute prothrombotic, proadrenergic, and proinflammatory properties of smoking are believed to underlie smoking-associated atherosclerosis and cardiovascular disease [11]. In addition, smoking directly leads to left ventricular hypertrophy. In vitro, nicotine stimulates the proliferation of endothelial cells and vascular smooth muscle cells [25], and chronic inhalation of carbon monoxide induces cardiac hypertrophy [25]. Consistently, we showed that heavy smokers with type 2 diabetes who increased their amount of smoking during 2 consecutive screenings had a higher risk of HF than those who sustained their smoking amount. In type 2 diabetes, hyperglycemia, insulin resistance, and hyperinsulinemia trigger a cascade of deleterious effects that contribute to the development of HF via ischemic cardiomyopathy and diabetic cardiomyopathy [26,27]. There have been many studies showing that the onset and progression of macrovascular and microvascular complications of type 2 diabetes are highly associated with smoking [28]. Therefore, it is possible that smoking and type 2 diabetes interact and further increase the risk of HF.

Harm reduction strategy is aimed at reducing the adverse health effects of smoking by reducing the number of cigarettes smoked each day [29]. However, no evidence that cardiovascular risks are reduced by smoking reduction have been provided [29-31]. Consistently, we found that smoking reduction among patients with type 2 diabetes had no benefit for reducing HF risk. Type 2 diabetes itself is a high-risk condition of HF and also interrelates with smoking in relation to cardiovascular events [14]. Thus, the threshold at which smoking affects the development of HF appears to be low, and smoking reduction may not be sufficient to reduce the risk of HF. Moreover, substantial smoking reduction of ≥50% worsened rather than leaving unchanged HF risk, particularly in heavy smokers. The disease burden attributable to smoking is undoubtedly highest in heavy smokers. For heavy smokers, the effect of smoking may persist after reducing smoking, leading to further deterioration of cardiovascular health. Another possible explanation for this phenomenon is that smoking is primarily a nicotine-seeking behavior, and smokers who reduce tend to compensate by smoking more of each cigarette and by taking more and deeper puffs [29]. This results in a much smaller proportional reduction in nicotine intake (and in the intake of associated tar and other toxins) than the reduction in number of cigarettes suggests [29]. The results of this study support health warnings that there is no safe level of smoking for preventing cardiovascular disease including HF. Smokers with type 2 diabetes need to have a goal of complete smoking cessation, even from heavy smoking, substantially reduced the risk of HF.

Smoking cessation consistently decreased the risk of HF even after various stratifications. Interestingly, while the risk of HF among patients with type 2 diabetes usually increases with age and severity or duration of type 2 diabetes, the preventive effect of smoking cessation on HF was also observed among young participants, those with new-onset type 2 diabetes, and those taking fewer oral antidiabetic agents without insulin use. These findings suggest that increased HF risk associated with smoking among patients with type 2 diabetes can be attenuated by smoking cessation.

Current guidelines, such as those of the American Diabetes Association, emphasize that smoking cessation is a major target for the prevention of type 2 diabetes–associated cardiovascular diseases [38]. However, many patients continue to smoke even after a diagnosis of type 2 diabetes [39]. The success rate of smoking cessation among type 2 diabetes is not high, with some studies reporting cessation to be under 20% [40]. In addition to cardiovascular disease, we showed that smoking cessation had a consistent effect on reducing the risk of HF, regardless of type 2 diabetes severity. This study which demonstrates the additional hazards of HF associated with continued smoking and the benefits of smoking cessation among patients with type 2 diabetes provide direct evidence for the need for clinical practitioners to intervene to change smoking behavior.

**Limitations**

There are several limitations of our study. First, we defined type 2 diabetes from health claim data not from clinical records and, therefore, could be subject to the risk of under- or overascertainment. However, we used the diagnosis code and medication records together, which have been shown to have high accuracy [41]. Second, since smoking behaviors were based on self-reported questionnaire without using biochemical verification, misclassification from recall or social desirability bias could exist. However, self-reported smoking behavior has been shown to reverse smoking-associated endothelial dysfunction, which reduces the cardiovascular disease risk of smoking soon after cessation [6]. Smoking-associated alterations of the myocardium, such as left ventricular remodeling and dysfunction, were also reversible after smoking cessation [9]. We confirmed that smoking cessation, even from heavy smoking, substantially reduced the risk of HF.

It is well known that smoking and type 2 diabetes interrelate. Type 2 diabetes is one of the smoking-related diseases, and smoking cessation reduces the risk of type 2 diabetes [34-36]. In type 2 diabetes, glycemic control tends to worsen after quitting, which can last up to 3 years [37]. Consistently, in this study, analyzing 2-year interval changes, quitters were prescribed more glucose-lowering therapies but did not show a greater decrease in fasting glucose than other groups, which possibly reflects worsened short-term glycermic control in quitters (Table S1 and S2 in Multimedia Appendix 1). Therefore, the reduced risk of HF from smoking cessation is mainly from the effect of smoking cessation per se, and the benefits of smoking cessation may outweigh the lighter, temporarily increased glycermic control from smoking cessation with respect to HF among patients with type 2 diabetes. If we could track quitters over a longer period, long-term quitters might achieve improved glycermic control.
been reported to be relatively accurate with 87.5% sensitivity and 89.2% specificity [42]. Third, because we used administrative data, we did not have sufficient clinical information on HF including phenotypes of incident HF, etiology of HF, or plasma brain natriuretic peptide levels.

**Conclusions**

In this large population-based cohort study, we demonstrated that increasing smoking amount was associated with a higher risk for HF compared to maintaining smoking amount, while smoking cessation was associated with a lower risk of HF among patients with type 2 diabetes. There was no benefit from the reduction in smoking amount. These findings suggest that smoking cessation should be reinforced to prevent HF in populations at high risk and with type 2 diabetes.

Abstract

Background: The status of prostate-specific antigen (PSA) screening is unclear in China. Evidence regarding the optimal frequency and interval of serial screening for prostate cancer (PCa) is disputable.

Objective: This study aimed to depict the status of PSA screening and to explore the optimal screening frequency for PCa in China.

Methods: A 13-year prospective cohort study was conducted using the Chinese Electronic Health Records Research in Yinzhou study’s data set. A total of 420,941 male participants aged ≥45 years were included between January 2009 and June 2022. Diagnosis of PCa, cancer-specific death, and all-cause death were obtained from the electronic health records and vital statistic system. Hazard ratios (HRs) with 95% CIs were estimated using Cox regression analysis.

Results: The cumulative rate of ever PSA testing was 17.9% with an average annual percent change (AAPC) of 8.7% (95% CI 3.6%-14.0%) in the past decade in China. People with an older age, a higher BMI, higher waist circumference, tobacco smoking and alcohol drinking behaviors, higher level of physical activity, medication use, and comorbidities were more likely to receive PSA screening, whereas those with a lower education level and a widowed status were less likely to receive the test. People receiving serial screening ≥3 times were at a 67% higher risk of PCa detection (HR 1.67; 95% CI 1.48-1.88) but a 64% lower risk of PCa-specific mortality (HR 0.36; 95% CI 0.18-0.70) and a 28% lower risk of overall mortality (HR 0.72; 95% CI 0.67-0.77). People following a serial screening strategy at least once every 4 years were at a 25% higher risk of PCa detection (HR 1.25; 95% CI 1.13-1.36) but 70% (HR 0.30; 95% CI 0.16-0.57) and 23% (HR 0.77; 95% CI 0.73-0.82) lower risks of PCa-specific and all-cause mortality, respectively.

Conclusions: This study reveals a low coverage of PSA screening in China and provides the first evidence of its benefits in the general Chinese population. The findings of this study indicate that receiving serial screening at least once every 4 years is beneficial for overall and PCa-specific survival. Further studies based on a nationwide population and with long-term follow-up are warranted to identify the optimal screening interval in China.

Introduction

Globally, prostate cancer (PCa) is the second-most commonly diagnosed male cancer, with an estimated 1.41 million new cases and 0.37 million deaths reported in 2020 [1]. In China, among all cancers, PCa ranks sixth in incidence and seventh in mortality [2], which have been increasing rapidly over the past decades [3]. The aging population and the widespread use of prostate-specific antigen (PSA) testing could partially explain the significant increase in disease burden.

The uptake of PSA testing has been well characterized in Western countries. In Switzerland, for example, the coverage rate of PSA screening has increased to 70% [4]. In the United Kingdom, 55.3% of men aged 40-75 years have undergone at least 1 PSA screening [5]. In the United States, 32.1% of men aged 50 years or older have had PSA screening for routine reasons [6]. On the contrary, anecdotal evidence suggests a low PSA screening rate in most Asian countries [7]. A wide range of factors have been associated with screening behavior in the general population. For instance, people with an older age, a family history of PCa, and a high BMI were more likely to receive PSA testing, whereas socioeconomic deprivation, heavy smoking, and comorbid diabetes were associated with a lower likelihood of PSA testing [5].

PSA screening policy and guidelines to date have been well established in the West, including the recommendation statement of screening for prostate cancer by the US Preventive Services Task Force [8], the National Comprehensive Cancer Network’s guidelines for Prostate Cancer Early Detection [9], European Association of Urology–European Association of Nuclear Medicine–European Society for Radiotherapy & Oncology–European Society of Urological Radiology–International Society of Geriatric Oncology Guidelines on Prostate Cancer [10]. However, PSA screening also leads to overdiagnosis and overtreatment of insignificant PCa, which has been increasingly criticized [11]. Several large randomized controlled trials (RCTs) have suggested that such screening contributes to little benefit for overall and cancer-specific survival, especially when taking its efficiency or cost-effectiveness into account [12]. In China, the effect of PSA screening is poorly understood, and few epidemiological studies have depicted the rate and trend of PSA testing from a population-based perspective.

On the other hand, a consensus on screening strategy has yet to be determined. Some studies suggest that one-time PSA screening is not beneficial [13], while others suggest that annual screening is not cost-effective [14]. The optimal frequency and interval for serial screening remains to be concurred. Kobayashi et al [15] reported an appropriate interval of ≥3 years for PSA rescreening, while Shao et al [16] concluded that more frequent PSA testing could aggravate the risk of overdiagnosis. In well-known clinical trials, no consensus on screening intensity has been established. For example, one-time screening was applied in the Cluster Randomised Trial of PSA Testing for Prostate Cancer; annual screening was undertaken in the Prostate, Lung, Colorectal and Ovarian Cancer Screening trial; and screening once every 2-4 years was performed in the European Randomised Study of Screening for Prostate Cancer [12].

Given a paucity of evidence regarding the depiction of PSA testing, and the benefits of different screening strategies in China, we performed a population-based prospective cohort study using electronic health records (EHRs) data. The primary aims of this study are to evaluate the effects of PSA screening and to explore the optimal screening frequency and interval in the Chinese population.

Methods

Study Setting and Population

Data for this study were obtained from the Chinese Electronic Health Records Research in Yinzhou (CHERRY) study, the first population-based cohort study linking big data of integrated individual-level EHRs. Detailed information regarding the study design, inclusion criteria, data collection, and procedure of the study is published previously [17]. Briefly, the CHERRY study to date has comprised a total of more than 1 million permanent residents living in Yinzhou, an economically advanced region of southeastern China. Participants were included in the CHERRY study if they (1) registered in the system, (2) were older than 18 years on January 1, 2009, (3) were living in Yinzhou for more than 6 months, and (4) provided consent to participate in the study. The data set of the CHERRY study was integrated from the population census, primary care, electronic medical records, health check, surveillance, and vital statistic, where all health-related activities (eg, inpatient and outpatient visits) within the region were recorded.

As 45 years is the initiation age for PCa screening recommended by the National Cancer Center of China [18], we accordingly included male participants aged ≥45 years in this study. We further excluded those (1) aged <45 years at recruitment (n=189,333), (2) who consented to participate but died before enrollment in the cohort (n=574), and (3) with illogical recorded information (eg, recorded death occurred before the uptake of PSA testing; n=19); 420,941 eligible participants were retained in the final analysis. A 3×3 matrix data quality assessment framework proposed by Weiskopf et al [19] was further applied to comprehensively evaluate the data quality of the data set. A detailed data quality assessment report is presented in Multimedia Appendix 1. The flowchart of this study is shown in Figure 1.
Serum PSA was tested using an immunoenzymatic assay with the World Health Organization’s international standard or the Hybritech Standard based on different protocols among hospitals [20]. The value and date of each PSA test were extracted from the CHERRY study’s data set. We then developed a series of variables related to PSA screening. Ever screening was defined as ever having any PSA test or not (ever vs never). The subsequent variables were related to screening strategy and were thus restricted to those ever-having a PSA test. Number of PSA screenings was defined as a total count of screenings during the follow-up years; this variable was further categorized into 3 groups (1, 2, and ≥3) for comparison. Four variables were proxies of screening frequency: receiving 1 PSA test at least annually (yes or no), receiving 1 PSA test at least biennially (yes or no), receiving 1 PSA test at least triennially (yes or no), and receiving 1 PSA test at least quadrennially (yes or no). Screening interval was defined as the average interval of having serial tests (irregular, 1 year, 2 years, 3 years, and 4 years). Detailed definitions of the abovementioned variables are provided in Table S1 in Multimedia Appendix 1.

Outcomes of Interest
Participants were followed up for morbidity and mortality using records linked with the regional system of disease surveillance, chronic disease management, and EHRs based on diagnostic codes from the ICD-10 (International Statistical Classification of Diseases, Tenth Revision). The primary outcomes of this study were prostate cancer (C61) and PCa-specific death. The secondary outcome was all-cause death.

Covariates
Sociodemographics (age, education level, and marital status), anthropometric factors (BMI and waist circumference [WC]), lifestyle (smoking, drinking, and physical activity [PA]), use of medications (5-α reductase inhibitors), and comorbidity were included and used for adjustment in the analyses. Detailed definitions of the covariates are provided in Table S1 in Multimedia Appendix 1.

Statistical Analysis
Descriptive statistics were summarized using means (SD) or median (IQR) values for continuous variables (normally or nonnormally distributed) and number (percentage) values for categorical variables. Follow-up person-years (PYs) were calculated from the date of cohort inception for the nonscreening group and the date of the initial PSA test for the screening group to either the date of PCa diagnosis, death, loss to follow-up, or June 15, 2022, whichever occurred first.

Temporal trends in the annual rate of first PSA screening were estimated by joinpoint regression models [21]. The direction and magnitude of the trends were assessed by the annual percentage change (APC) and average annual percent change (AAPC) with corresponding 95% CIs. Missing values were presumed to be missing at random and were filled by multiple imputations based on chained equations. Cox proportional hazards models were used to estimate the hazard ratios (HRs) and 95% CIs for PSA screening on PCa incidence, cause-specific mortality, and overall mortality. The proportional hazards assumption was tested on the basis of Schoenfeld residuals. Cox models were stratified by age-at-risk of PCa or death accordingly (5-year intervals; model 1), and HRs were adjusted for sociodemographics, anthropometric factors, lifestyle, medications, and comorbidities (model 2), and were additionally adjusted for baseline PSA values and age at the first PSA test (model 3) according to the proposed directed acyclic graph (Figure S1 in Multimedia Appendix 1). In addition, the E-value was calculated to assess the robustness of the main results against unmeasured confounders [22].
All $P$ values were 2-sided and were considered significant when less than .05. The abovementioned analyses were performed using Stata (version 17.0; StataCorp), Joinpoint software (version 4.8.0.1; National Cancer Institute), and R statistical software (version 4.1.2; Foundation for Statistical Computing).

**Ethical Considerations**

The study was approved by the institutional review board of the University of Hong Kong (UW 22-766). All procedures were performed in accordance with the tenets of the 1964 Declaration of Helsinki and its later amendments or comparable ethical standards. Informed consent has been obtained from all participants before the study.

**Results**

**Baseline Characteristics**

Among the 420,941 participants included in the study, the overall mean age was 50.4 (SD 11.9) years. After a total of 3,177,289 person-years of follow-up, 2160 men were diagnosed with PCa (incidence rate 0.68 per 1000 PYs), 92 men died from PCa (cause-specific mortality rate 0.03 per 1000 PYs), and 20,781 men died from all causes (overall mortality rate 6.78 per 1000 PYs). The mean BMI was 22.9 (SD 3.1) kg/m$^2$, and 1.8% (n=3900) of them had a high WC. In terms of socioeconomic factors, 3.5% (n=14,297) of men had a bachelor’s degree or above, and 92.0% (n=221,845) of them were married. Long-term medication use (n=5319, 1.9%) and comorbidities (n=33,220, 12.1%) were observed in a small proportion of men. Smoking and drinking alcohol was prevalent among 21.3% (n=48,731) and 23.1% (n=52,916), respectively. Detailed characteristics of the study participants are shown in Table 1.
Table 1. Characteristics of the study participants (N=420,941).

PSA Screening

Overall, 17.9% (n=75,362) of participants ever attended PSA testing. Among them, 51.1% (n=38,527), 22.1% (n=16,686), and 26.7% (n=20,149) underwent testing 1, 2, and ≥3 times; two-thirds of them (63.2%, n=47,654) attended PSA screening without regularity; about one-sixth of them (16.8%, n=12,686) had a baseline PSA value of 3 ng/mL or above and had their first test at the age of 75 years or older (17.9%, n=13,514). A detailed description of PSA screening by age stratification is provided in Table 2.

During 2010-2021, the annual rates of first PSA testing ranged from 0.85% to 3.45%. Joinpoint regression analyses suggested a significant increasing tendency of uptake of PSA testing during the past 12 years (AAPC 8.70%; 95% CI 3.61-14.04; P=.001). The increase in trend in the later 6 years (APC 15.65%; 95% CI 7.97-23.88; P=.002) was 5-fold faster than that in the prior 6 years (APC 3.23%; 95% CI –5.58 to 12.86; P=.43; Figure S2 in Multimedia Appendix 1).

Figure 2 shows several common factors that could influence PSA screening behavior. Age (HR 1.02; 95% CI 1.02-1.02; P<.001), BMI (HR 1.02; 95% CI 1.01-1.02; P<.001), high WC (HR 1.31; 95% CI 1.23-1.40; P<.001), tobacco smoking (HR 1.91; 95% CI 1.88-1.95; P<.001), alcohol drinking (HR 1.78; 95% CI 1.74-1.81; P<.001), physical activity (HR 1.10, 95% CI 1.06-1.15; P<.001 for occasional PA and HR 1.05; 95% CI 1.01-1.09; P=0.01 for frequent PA), medication use (HR 3.16, 95% CI 3.02-3.30; P<.001), and comorbidity (HR 1.09; 95% CI 1.07-1.10; P<.001) were associated with higher probability of receiving a PSA test, while those with lower education levels (HR 0.90; 95% CI 0.85-0.95; P<.001) and with a widowed status (HR 0.68; 95% CI 0.61-0.76; P<.001) may be less likely to receive a PSA test.

Statistics were restricted to those who ever had a PSA screening.
Irregular screening referred to attending screening without regularity over time.
Effects of PSA Screening in the General Population

Compared to nonattendees, screening attendees were at 70-, 16-, and 6-fold higher risk of PCa incidence, PCa death, and overall death, respectively, in the crude model (Tables S2-S4 in Multimedia Appendix 1). After adjustment for age, education, marital status, BMI, high WC, smoking, drinking, PA, medication use, and comorbidity, we found that attendees were still at 35-, 11-, and 1.2-fold higher risk of PCa incidence (HR 35.87; 95% CI 31.82-40.85; \( P < .001 \)), PCa death (HR 11.94; 95% CI 7.69-18.54; \( P < .001 \)), and overall death (HR 1.27; 95% CI 1.20-1.35; \( P < .001 \)), respectively.

PSA Screening Strategy and PCa Incidence

All statistics on screening strategy were restricted to individuals ever having had a PSA test (n=75,362). In the full adjustment model, people receiving a PSA test more than 3 times were at a 67% higher risk of PCa detection than those having had a PSA test once (HR 1.67; 95% CI 1.48-1.88; \( P < .001 \)). Frequent attendees were at a higher risk of PCa detection (HR 3.60; 95% CI 3.15-4.10; \( P < .001 \)) for having a PSA test at least annually; HR 1.75; 95% CI 1.57-1.93; \( P < .001 \) for having a PSA test at least biennially; HR 1.40; 95% CI 1.28-1.55; \( P < .001 \) for having a PSA test at least triennially; and HR 1.25; 95% CI 1.13-1.36; \( P < .001 \) for having a PSA test at least quadrennially. People receiving serial screening with a 1-year interval were at a higher risk of PCa detection (HR 3.53; 95% CI 3.03-4.06; \( P < .001 \)), but those with a 2-year interval were at no significant risk of PCa detection (HR 1.07; 95% CI 0.94-1.22; \( P = .29 \)), while those with 3- and 4-year intervals were at a lower risk of PCa detection (HR 0.80; 95% CI 0.69-0.94; \( P = .006 \) for a 3-year interval; HR 0.61; 95% CI 0.49-0.76; \( P < .001 \) for a 4-year interval; Figure 3; Table S5 in Multimedia Appendix 1).

**Figure 3.** Adjusted Cox regression model for prostate-specific antigen screening strategy on prostate cancer (PCa) incidence, PCa-specific mortality, and overall mortality. HR: hazard ratio; PSA: prostate-specific antigen.
PSA Screening Strategy and PCa-Specific Mortality

People receiving PSA screening more than 3 times were at a lower risk of PCa-specific mortality than those receiving PSA testing once (HR 0.36; 95% CI 0.18-0.70; P=0.002). We further found a 26% decreased risk with every additional PSA screenings (HR 0.74; 95% CI 0.61-0.89; P=0.001). Frequent attendees were at a 24%-70% lower risk of PCa death (HR 0.76; 95% CI 0.18-3.25; P=0.72 for at least an annual PSA screening; HR 0.68; 95% CI 0.33-1.38; P=0.29 for at least a biennial screening; HR 0.41; 95% CI 0.22-0.79; P=0.007 for at least a triennial screening; HR 0.30; 95% CI 0.16-0.57; P<0.001 for at least a quadrennial screening). People receiving serial screening with a 3-year interval were at a significant lower risk of PCa death than with other intervals (HR 0.15; 95% CI 0.04-0.62; P=0.009). Such significance was not identified in other interval groups due to low statistical power (Figure 3 and Table S6 in Multimedia Appendix 1).

PSA Screening Strategy and Overall Mortality

People receiving PSA screening more than 3 times were at a lower risk of overall death than those receiving PSA screening once (HR 0.72; 95% CI 0.67-0.77; P<0.001). Furthermore, we found a 3% lower risk with every additional PSA screenings (HR 0.97; 95% CI 0.95-0.99; P=0.001). People receiving at least annual (HR 2.68; 95% CI 2.41-2.97; P<0.001) and biennial PSA screening (HR 1.39; 95% CI 1.30-1.49; P<0.001) were at a higher risk of overall death, while those receiving at least triennial (HR 0.97; 95% CI 0.90-1.03; P=0.28) and quadrennial PSA screening (HR 0.77; 95% CI 0.73-0.82; P<0.001) were at lower risks of overall death. Compared to people with irregular screening intervals, those with a 1-year interval were at a 136% higher risk of overall death (HR 2.36; 95% CI 2.11-2.64; P<0.001), while those with extended intervals were at a 9%-74% lower risk of overall death (HR 0.91; 95% CI 0.84-0.99; P=0.03 for those with a 2-year interval; HR 0.43; 95% CI 0.38-0.48; P<0.001 for those with a 3-year interval; HR 0.26; 95% CI 0.21-0.32; P<0.001 for those with a 4-year interval; Figure 3 and Table S7 in Multimedia Appendix 1).

Discussion

This prospective cohort study including 420,941 male participants suggests that the cumulative rate of ever PSA testing was 17.9% in the past decade, with an upward secular trend in China. Evidence provided by this study supports the benefit of regular screening (in particular, at least once every 4 years) for overall and cancer-specific survival among individuals attending repeated PSA screening.

This study revealed a low coverage of PSA screening in the Chinese population, which was consistent with the results of several prior studies. So et al [23] reported a 9.5% uptake rate of PSA testing among men in Hong Kong, while Lin et al [24] reported a proportion of 29.4% of men in Taiwan who had self-reported having received a PSA test. Lacking knowledge of or misconceptions about PCa and PSA screening, as well as insufficient health promotion, may account for the issue of low PSA uptake coverage in China [23]. As for other Asian countries, except for Japan [25], the uptake rate of PSA screening was at a similarly low level (eg, 16.9% in Iran and 0.4% in the Philippines) [26,27]. Some studies indicate that PSA testing behavior is highly determined by a variety of demographics and lifestyle factors [23,28]. In this study, we identified that Chinese men with older age, a higher BMI, high WC, smoking behavior, drinking behavior, occasional PA, medication use, and comorbidity were more likely to undergo PSA testing, whereas those with lower education background and under widowed were less likely to have undergone PSA testing. These findings help to depict a clearer picture of the status and correlates of PSA testing behavior, which provides important credence for PSA screening practice in China.

We did not find a survival benefit of PSA screening uptake in the general population as well as among annual screeners in this cohort study. One explanation was the self-selection bias [29]. People who attended PSA screening, particularly annual attendees, were more likely to be older, have unhealthy lifestyles, and be in poor physical condition; in turn, these factors were associated with increased PCa mortality. Furthermore, some nonattenders may be potential later screening attendees should they live longer or have long-term follow-up.

The existence of immortal time bias influenced the calculation of true effects on PSA screening [30]. Evidence regarding the optimal screening frequency or interval remains unclear worldwide. In general, annual screening was recommended by guidelines in the United States, while a 2-year interval in Australia, a 3-year interval in Japan, and a 4-year interval in Canada [31]. In Europe, even an 8-year interval was proposed for those who were not at risk [10]. In China, the Anti-Cancer Association Genitourinary Cancer Committee recommends a 2-year interval for serial PSA screening [32]. Several studies have supported the benefit of a moderate expansion for the screening interval. Gulati et al [33] reported that a biennial screening could reduce 2.4% of overdiagnoses and half of the false-positive rate. Leeuwen [34] stated that a 2-year screening interval significantly decreased the advanced PCa incidence. Heijnsdijk [14] indicated that screening with a 2- to 3-year interval was the most cost-effective strategy. As for the survival benefit between annual screening and interval screening, a prior meta-analysis showed that interval screening every 2-4 years was associated with a significantly lower risk of cancer-specific death (incidence rate ratio 0.79; 95% CI 0.69-0.91) than annual screening (incidence rate ratio 1.05; 95% CI 0.87-1.24) [12]. This study suggests a survival benefit of an extended-interval screening strategy, which is consistent with our findings.

In this study, we could not observe significantly lower risks of either PCa-specific mortality or all-cause mortality for people receiving serial screening at least once every 1-3 years. The main reason was cases with limited outcomes in these groups, resulting in relatively lower statistical power. To increase statistical power, participants were dichotomized on the basis of ever having undergone PSA screening once every 4 years. Expectedly, we observed a 70% decreased risk of PCa-specific death and a 23% decreased risk of all-cause death in this group. The result was robust against any unmeasured confounders (E-values are 6.12 for PCa death and 1.92 for overall death; Table S8 in Multimedia Appendix 1). This finding supports evidence that suggests a 2-year screening interval is cost-effective.
serial screening with at least 1 screening every 4 years to improve PCa survival among Chinese men.

Some limitations should be acknowledged in this study. First, selection, information, and immortal time biases were unavoidable in this cohort study, but a large sample size, rigorous analytic strategy, and protracted time frame of follow-up can increase the reliability of our findings. Second, information regarding covariates was poorly documented in the database, but we have used a multiple imputation approach to deal with the missing value. Third, unmeasured confounders may influence the accuracy of the estimates, but E-values were applied to assess the robustness of the results against unmeasured bias, making our findings more reliable and interpretable. Fourth, the limited number of cases of PCa onset and PCa death in the current data set led to insufficient statistical power to identify the optimal PSA screening interval. With longer-term follow-up available and more cases reaching the end point, a significant optimal screening interval would be identified in the future. Finally, the study population was derived from a single municipal district. The implementation of PSA screening and the incidence of PCa may vary greatly in different regions in China. Further studies based on a nationwide population with higher representativeness are warranted.

In conclusion, this large-scale population-based cohort study reveals a cumulative uptake rate of 17.9% for PSA testing, depicts an upward secular trend of screening attendance, and suggests an optimal screening frequency of at least 1 screening every 4 years for serial PSA testing in China. Findings of this study clarify the status of the PSA screening practice, strengthen the evidence base for an extended interval strategy for serial screening, and provide insights into the improvement of PCa survival for patients, health professionals, and policy makers.

Abstract

Background: Ischemic heart disease (IHD) is the leading cause of death among noncommunicable diseases worldwide, but data on current epidemiological patterns and associated risk factors are lacking.

Objective: This study assessed the global, regional, and national trends in IHD mortality and attributable risks since 1990.

Methods: Mortality data were obtained from the Global Burden of Disease 2019 Study. We used an age-period-cohort model to calculate longitudinal age curves (expected longitudinal age-specific rate), net drift (overall annual percentage change), and local drift (annual percentage change in each age group) from 15 to >95 years of age and estimate cohort and period effects between 1990 and 2019. Deaths from IHD attributable to each risk factor were estimated on the basis of risk exposure, relative risks, and theoretical minimum risk exposure level.

Results: IHD is the leading cause of death in noncommunicable disease–related mortality (118.1/598.8, 19.7%). However, the age-standardized mortality rate for IHD decreased by 30.8% (95% CI –34.83% to –27.17%) over the past 30 years, and its net drift ranged from –2.89% (95% CI –3.07% to –2.71%) in high sociodemographic index (SDI) region to –0.24% (95% CI –0.32% to –0.16%) in low-middle–SDI region. The greatest decrease in IHD mortality occurred in the Republic of Korea (high SDI) with...
net drift –6.06% (95% CI –6.23% to –5.88%), followed by 5 high-SDI nations (Denmark, Norway, Estonia, the Netherlands, and Ireland) and 2 high-middle–SDI nations (Israel and Bahrain) with net drift less than –5.00%. Globally, age groups of >60 years continued to have the largest proportion of IHD-related mortality, with slightly higher mortality in male than female group. For period and birth cohort effects, the trend of rate ratios for IHD mortality declined across successive period groups from 2000 to 2004 and birth cohort groups from 1985 to 2000, with noticeable improvements in high-SDI regions. In low-SDI regions, IHD mortality significantly declined in female group but fluctuated in male group across successive periods; sex differences were greater in those born after 1945 in middle- and low-middle–SDI regions and after 1970 in low-SDI regions. Metabolic risks were the leading cause of mortality from IHD worldwide in 2019. Moreover, smoking, particulate matter pollution, and dietary risks were also important risk factors, increasingly occurring at a younger age. Diets low in whole grains and legumes were prominent dietary risks in both male and female groups, and smoking and high-sodium diet mainly affect male group.

Conclusions: IHD, a major concern, needs focused health care attention, especially for older male individuals and those in low-SDI regions. Metabolic risks should be prioritized for prevention, and behavioral and environmental risks should attract more attention to decrease IHD mortality.

Introduction

Ischemic heart disease (IHD) is the leading cause of death among noncommunicable diseases (NCDs) and cardiovascular diseases (CVDs) in the world, accounting for 9.14 million deaths in 2019 [1,2]. The United Nations set, as part of the Sustainable Development Goals, a global target to reduce by one-third the total premature mortality (ages 30-70 years) from NCDs by 2030 [3]. However, the trend and distribution of IHD-related mortality vary greatly in countries from high sociodemographic index (SDI) to low SDI [4]. In Central Asia, the age-standardized mortality rate (ASMR) increased by 16.7% from 1990 to 2017 [5]. By contrast, in Korea, Japan, and China, the ASMR decreased significantly in both male and female groups during this time period [6,7].

Rapid economic development and social advancements have greatly increased the incidence of metabolic risk factors, such as hypertension, hyperlipidemia, diabetes, obesity, and aging, which have largely contributed to the majority of IHD-related deaths shifting from developed to developing countries [2,8]. However, the relative contribution of risk factors to mortality from IHD varies with age, sex, metabolic state, behavior, geographical area, and environmental exposure, and therefore different interventions may be required to effectively address these risk factors [9].

Previous studies have also explored IHD epidemic trends over time in many countries [2,10]. However, typical statistical analysis cannot break down the risks when estimating mortality. Therefore, the age-period-cohort (APC) model was developed to improve the traditional method for mortality description and analysis, which separates age effects, period effects, and cohort effects and quantifies the influence of age, time, and birth cohort factors on mortality rate [11,12]. In this study, we used data from the Global Burden of Disease 2019 Study (GBD) to assess the time trends in IHD mortality at the global, regional, and national levels and associations with age, period, and birth cohort using the APC model over the past 30 years. We also aimed to shed light on attributable risk factors for IHD at global, regional, and national levels to support policy makers making informed decisions about the potential benefits of risk reduction policies.

Methods

Data Sources

GBD, coordinated by the Institute for Health Metrics and Evaluation, which assessed the global burden of 369 diseases and injuries and 87 risk factors in 204 countries and territories from 1990 to 2019, provided a unique opportunity to understand the global burden and landscape of IHD mortality [13,14]. In our study, we obtained the publication estimates of deaths for IHD with “ischemic heart disease” from the “cause blank” of the GBD website across 204 countries and territories [2,13]. The statistical code used for GBD estimation is publicly available on the internet [15]. The GBD study uses deidentified data, and a waiver of informed consent was reviewed and approved by the University of Washington Institutional Review Board. All results and original data sources used to compute estimates are publicly available on the internet [16].

SDI was used to quantify the development level for each location year, which is scaled from 0 to 1, with higher values indicating high SDI levels. GBD assigned 204 countries and territories into 5 groups by SDI quintiles: low SDI, low-middle SDI, middle SDI, high-middle SDI, and high SDI [13,14].

Statistical Analyses

The overall temporal trends in mortality over the study period were assessed by all-age mortality rate (AAMR), ASMR, percentage of mortality, and the relative change in percentage between 1990 and 2019. We calculated ASMR with global age-standard population data from GBD [14].

APC models were developed to determine independent effect estimates of age, period, and birth cohort on IHD mortality [17]. Net drift and local drift are important parameters in the APC models. Net drift represents the overall log-linear trend by period and birth cohort, which indicates the overall annual percentage change of the expected age-adjusted rates over time. Local drift represents the log-linear trend by period and cohort for each
age group, which indicates the annual percentage change. The longitudinal age curve indicates the expected age-specific rate in a reference cohort adjusted for period effects, which was assigned to 19 age groups using successive 5-year age intervals from 15-19 years to over 95 years among individuals with IHD. The age effects represent a differing risk of the outcome associated with different age brackets. The period effects represent variations in the outcome over time that influence all age groups simultaneously. The mortality and population data were arranged into consecutive 5-year periods from 1990 to 2019, with the mid-year of the 2000-2004 survey year as the reference period group [18]. Cohort effects are the ratio of age-specific rates of mortality risks, which were arranged into consecutive 5-year cohorts from the 1895 cohort to the 2000 cohort, as referenced by the mid-year of birth (1945 cohort) [18]. All analyses were conducted with 3 sex groups: the male group, the female group, and both groups (male and female).

A total of 87 risk factors associated with IHD-related death were selected in accordance with the World Cancer Research Fund grades of convincing or probable evidence [19,20]. To estimate the IHD-related deaths attributable to a specific risk, these IHD-related deaths were multiplied by the population attributable fractions (PAF) for the IHD risk-outcome pair for a given sex, age, year, and location. PAF show that the proportion by which the deaths would decrease in a specific year if the exposure to a risk factor in the past was equal to the theoretical minimum risk exposure level, which were adjusted by other risk factors included in this study [21,22].

We obtained the estimated parameters from the APC web tool (freely available R tools) provided by the National Cancer Institute of the United States, the methodological details of which have been described previously [23]. We hypothesized that changes in age, period, and birth cohort would mainly affect IHD mortality. The Joinpoint Trend Analysis Software (version 4.9; National Cancer Institute) was used to determine the average annual percentage change in IHD mortality from 1990 to 2019 [24]. Wald chi-square tests were adapted for the significance of the estimable parameters and functions. Statistical tests were 2-sided, and a P value <.05 was considered significant. We performed all the analysis in R software (version 3.6.3; R Foundation for Statistical Computing).

Ethical Considerations

Ethics approval and consent are not required because the original data in this study were aggregated and nonidentified, which are freely available from the GBD Study.

Results

Overview and Trends for IHD Mortality

In 2019, IHD was the leading cause of NCD-related AAMR in the global and each SDI quintile, accounting for 118.10 deaths per 10,000 (95% UI [uncertainty interval] 125.93-110.51) population worldwide (Table 1 and Figure 1A). IHD-related AAMRs were lower in low-SDI quintiles and about 35% higher in male group than female group. IHD had the largest proportion of NCD-related mortality with 19.7% (118.1/598.8) in all ages and maintained this dominant proportion in the >50-year-old age group (Figure 1B).

Globally, the number of mortalities for IHD increased by 60.43% from 1990 to 2019, and the ASMR for IHD decreased by 30.8%, with marked reduction in high-SDI (–58.68%) and high-middle–SDI (–35.28%) regions (Table 2). However, ASMR for IHD increased in 4 lower-income GBD regions, with a percentage change of 15.75% in East Asia, 11.71% in Central Asia, 8.31% in Oceania, and 4.63% in Southern Sub-Saharan Africa (Table 2).

Over the past 30 years (1990-2019), the IHD mortality rate increased in the older age groups (>60 years), but the increase declined in later periods that occurred mainly in the high-SDI regions (Figure S1 in Multimedia Appendix 1). There was a relatively declining risk of IHD mortality in cohorts born before 1945 in high-SDI regions, but the risk remained high in the low-SDI regions (Figure S1 in Multimedia Appendix 1). Similar to the trend by global and 5 SDI quintiles, IHD ASMRs across nations increased with age and declined between 1990-1994 and 2015-2019 (Figures S1A-S1F in Multimedia Appendix 1).

There was a downward trend of mortality for IHD in high-SDI countries across successive birth cohorts, but it fluctuated and trended to increase with aging in low-SDI countries (Figures S2A-S2F in Multimedia Appendix 1).

Among 204 countries and territories in 2019, ASMRs for IHD in 107 countries were higher than the global average, 32 of which were more than 2-fold higher (Figures 2A and 2B and Table S1 in Multimedia Appendix 2). The highest ASMR for IHD was observed in Uzbekistan (707.51, 95% UI 638.23-780.68 per 100,000 population; middle SDI) with the largest increase of 119.01% (95% UI 96.32%-143.33%) over 30 years, followed by Azerbaijan (middle SDI) with 35.76% (95% UI 19.27%-54.74%) increase, and Tajikistan (low-middle SDI), with 82.1% (95% UI 53.66%-116.8%) increase. However, the net drift increased in Uzbekistan (1.98%, 95% CI 1.8%-2.17%), decreased in Azerbaijan (–0.95%, 95% CI –1.23% to –0.68%), and was essentially unchanged in Tajikistan (0.52%, 95% CI 0.13%-0.9%). In Qatar (high SDI), deaths related to IHD increased by 203.32% (95% CI 126.08%-308.55%), with a net drift of –3.69% (95% CI –4.28% to –3.09%). In Guam (high SDI) and Liberia (low SDI), ASMR in IHD decreased by 14.32% (95% CI –29.31% to 2.29%) and 14.04% (95% CI –33.47% to 10.41%), but the net drifts in mortality were 0.27% (95% CI –0.88% to 1.44%) and –0.36% (95% CI –0.77% to 0.05%), respectively. China and India, the 2 most populous countries, had the largest number of deaths with 1.87 (95% CI 1.61-2.13) million and 1.52 (95% CI 1.31-1.75) million, respectively, with relatively modest change of net drifts, 0.13% in China and –0.48% in India. These results show that IHD mortality trends were uneven across countries and not strictly commensurate with SDI levels. The directions of change in IHD mortality trends were uneven across countries and not strictly consistent with net drift from the APC model, suggesting the necessity to differentiate the relative contributions of period and cohort effects in IHD mortality.

Figure 2. The age-standardized mortality in 2019 and net drift of mortality during 1990-2019 for ischemic heart disease in 204 countries and territories. 
(A) World map of age-standardized mortality for ischemic heart disease in 2019. (B) World map of net drifts for ischemic heart disease mortality, that is, estimated annual percentage change of mortality from the age-period-cohort model. Net drift captures components of the trends attributable to calendar time and successive birth cohorts.

### Time Trends for IHD Mortality in APC Test

Globally, the overall net drift for IHD mortality was $-1.15\%$ (95% CI $-1.21\%$ to $-1.09\%$), which was greater in the female ($-1.33\%, \; 95\% \; CI \; -1.41\%$ to $-1.25\%$) than in the male group ($-1.04\%, \; 95\% \; CI \; -1.11\%$ to $-0.96\%$), with local drifts fluctuating downward across all age groups ($<0\%; \; P<.001$; Tables S2 and S3 in Multimedia Appendix 2 and Figure 3A).

The global local drift went below the net drift after the 55- to 59-year-old age group and reached nadirs in 65- to 69-year-old age group ($-1.54\%, \; 95\% \; CI \; -1.59\%$ to $1.48\%$) and >95-year-old age group ($-1.61\%, \; 95\% \; CI \; -1.79\%$ to $-1.43\%$). Among SDI quintiles, IHD mortality was substantially reduced in high-SDI (net drift $-2.89\%, \; 95\% \; CI \; -3.07\%$ to $-2.71\%$)
high-middle–SDI (net drift –2.00%, 95% CI –2.17% to –1.83) regions, especially between the ages of 40 and >95 years and 35-69 years (local drift –2.0%), respectively. However, the reductions in IHD mortality in low-SDI regions were less striking, with the death risk increasing with age, especially in the low-SDI region.

Figure 3. Time trends and age-period-cohort effects on ischemic heart disease mortality by global and sociodemographic index (SDI) quintiles, 1990-2019. (A) Net and local drifts of ischemic heart disease mortality (estimates from age-period-cohort models) for 19 age groups (5-9 to >95 years), 1990-2019. The dots and shaded areas indicate the annual percentage change of mortality (%) and the corresponding 95% CIs. The topmost black horizontal line marks “0” change. The horizontal discontinuous lines show overall annual percentage changes in mortality (net drifts), with yellow for female, gray for male, and blue for both. The continuous solid lines show annual percentage changes from 5-9 to >95 years (local drifts), in male (gray), female (yellow), and blue for both. (B) Temporal change in the relative proportion of ischemic heart disease mortality across age groups, 1990-2019. (C) Age effects are shown by the fitted longitudinal age curves of mortality (per 100,000 person-years) adjusted for period deviations. (D) Period effects are shown by the relative risk of mortality (mortality rate ratio) and computed as the ratio of age-specific rates (adjusted for age and nonlinear period effects) from 1990-1994 to 2015-2019 (2000-2004 as the referent period). (F) Cohort effects are shown by the relative risk of mortality and computed as the ratio of age-specific rates (adjusted for age and nonlinear period effects) from the 1895 cohort to the 2000 cohort, with the referent cohort set at 1945. The dots and shaded areas denote mortality rates or rate ratios and their corresponding 95% CIs.

At the national level, 43 countries and territories had increased trends (net drifts ≥0.0%) and 29 had modest reductions (–0.5 to 0.0%) in mortality from IHD (Figure 2B and Figures S3A-S3F in Multimedia Appendix 1). There were 9 nations with net drifts >1.00%, with 2 from middle-SDI (Philippines and Uzbekistan), 5 from low-middle–SDI (Lesotho, Zimbabwe, the Dominican Republic, Timor-Leste, and Kenya), and 2 from low-SDI (Mozambique and Guinea) regions. Large decreases in IHD mortality were estimated in 90 nations (net drift <–2.00%), in which the biggest decline occurred in the Republic of Korea (high SDI) with net drift –6.06% (95% CI –6.23% to –5.88%), followed by nations from 5 high-SDI (Denmark, Norway, Estonia, the Netherlands, and Ireland) and 2 high-middle–SDI (Israel and Bahrain) regions with net drift –5.00%. With significant decreases in IHD-related deaths over the past 30 years, Saint Lucia (net drift –3.21%, 95% CI –5.33% to –1.04%) and Equatorial Guinea (–2.9%, 95% CI –3.75% to –2.03%) were typical countries in middle-SDI, the Maldives (–4.03%, 95% CI –4.98% to –3.06%) and Belize (–2.18%, 95% CI –3.34% to –0.93%) in low-middle–SDI, and Afghanistan (–1.35%, 95% CI –1.43% to –1.27%) and Yemen (–1.05%, 95% CI –1.14% to –0.95%) in low-SDI regions. Temporal changes in the age distribution of death number and death percent, as an indirect marker of IHD population survival, are shown in Figures 3B and 3C and Figures S4A-S4F and S5A-S5F in Multimedia Appendix 1.

Sex variations in time trends of IHD mortality are presented in some regions and nations with local drifts. Globally, the local drift in male group resembled that in female group, reaching

(page number not for citation purposes)
the bottom in the age group of 65-69 years (female: –1.64%, 95% CI –1.71% to –1.56%; male: –1.51%, 95% CI –1.58% to –1.43%), but the reduction in IHD mortality in male group aged 45 years or younger was not as steep as in female group, which was more pronounced in low-SDI regions (Figure 3A). For high- and high-middle–SDI regions, the improvements in trends in IHD mortality were mostly similar in male and female groups (Figures S3B and S3C in Multimedia Appendix 1). It is worth noting that in American Samoa (high-middle SDI), female group had a significantly higher IHD mortality than male group. For lower-income nations (middle, low-middle, and low SDI), the time trends for IHD mortality were greater in female than male group in many countries (Figures S3D-S3F in Multimedia Appendix 1).

APC Effects on IHD Mortality
For age effect, IHD mortality increased with age, with a sharp increase in the later years of life (>60 years; Figure 3D). Similar patterns of IHD mortality trends were found across different SDI quintiles, with modestly higher mortality in male than female group, but high-SDI region showed an overall lower mortality across all age groups, with a nadir between 60 and 90 years of age. For period and cohort effects, trends of rate ratios for IHD mortality declined across successive period groups (refer to 2000-2004) and birth cohort groups (refer to 1985-2000) and showed similar directions in SDI quintiles, with noticeable improvements in high-SDI region (Figures 3E and 3F). In low-SDI regions, IHD mortality declined significantly for female group but fluctuated horizontally for male group (middle SDI and low-middle SDI) across successive periods. For cohort effects, sex differences (decline in female greater than male) were more remarkable in those born after 1945 in middle- and low-middle–SDI regions, and after 1970 in low-SDI region.

APC effects for IHD mortality in the top 5 countries and Brazil, according to the rank of gross domestic product obtained from the International Monetary Fund in 2019 [25], are shown in Figure 4. The United States, Japan, Germany, and Brazil had decreased trends for IHD mortality but with less age effects and declining period and cohort risks. China had significantly increased risks in people aged 75 years or older and those born before 1945. India also had high mortality among those aged 40 years or older, with little difference among period groups. The age, period, and cohort effects on IHD mortality across 21 GBD regions and 204 countries and territories are shown in Figures S6A-S6F, S7A-S7F, and S8A-S8F in Multimedia Appendix 1.
Risk Factors for Mortality From IHD

Across the top 26 risk factors (5 metabolic, 16 behavioral, and 5 environmental), with PAF, high systolic blood pressure (SBP), air pollution, and 3 other metabolic risks (high low-density lipoprotein [LDL] cholesterol, high fasting plasma glucose [FPG], and BMI) were the key contributors to IHD mortality in all SDI regions (Figure 5A and Figures S9A-S9H in Multimedia Appendix 1). In 2019, high SBP and LDL cholesterol were the 2 leading risk factors, contributing to 53.20% (95% CI 43.38%-62.76%) and 41.41% (95% CI 31.48%-52.05%) in global total deaths, respectively. From 1990 to 2019, the high FPG contribution to IHD mortality increased markedly in global and 5 SDI quintiles. During the same period, the high SBP risk increased slightly in 3 low-SDI regions but decreased in high- and high-middle–SDI regions, especially in the high-SDI region (Figure 5B). High LDL cholesterol and high BMI were prominent among young people, while high FPG and kidney dysfunction were prominent in older people (Figure 6).

Behavioral risks associated with increased IHD mortality included smoking, 13 dietary risks, low physical activity, and alcohol use. The proportion of deaths from IHD that was attributable to smoking, which was the third hazard in 3 low-SDI regions, varied substantially by sex: 29.96% (95% CI 28.74%-31.33%) in male compared with 12.23% (95% CI
11.27%-13.30%) in female (Figure 5), and was concentrated in the population 35-64 years of age (>35%; Figure 6). Dietary risks decreased with age, in which diets low in whole grains and legumes were prominent (Figure 6), and the risk of a high-sodium diet was more skewed toward male than female (Figure 5C). The risk of low physical activity increased with age (Figure 6). Interestingly, alcohol use had noticeable protective effects for IHD at the global and national levels (Figure 6 and Figures S9A-S9H in Multimedia Appendix 1).

Particulate matter pollution, an environmental risk, was the third-highest specific risk factor for IHD mortality in 3 low-SDI regions (Figure 5) and the third factor in several GBD regions (Eastern, Western, Central Sub-Saharan Africa, and South Asia; Figure S9A in Multimedia Appendix 1), but only the 12th in high-SDI regions (Figure 5), the risk of which increased with age (Figure 6). The older individuals were more susceptible to low temperatures, and lead exposure was more hazardous in low-SDI regions (Figure 6). The ranks, time trends, sex differences, and age trends of regional and national risk factors for IHD mortality are shown in Figures S9A-S9G, S10A-S10D, S11A-S11C, and S12A-S12B in Multimedia Appendix 1.
Figure 5. Top risk factors with population attributable fractions and time trends among the most specific Global Burden of Disease 2019 Study risks for mortality from ischemic heart disease (IHD). (A) Ranked contribution of the top 26 risk factors to the age-standardized death rate of ischemic heart disease by global and sociodemographic index (SDI) quintiles, 2019, for combined sex, female, and male. (B) Time trends of the top 10 risk factors to the age-standardized death rate of ischemic heart disease by global and SDI quintiles, 1990 to 2019, for combined sex, female, and male. (C) Time trends of the top 10 risk factors for mortality from ischemic heart disease with the ratio of male to female by global and SDI quintiles, 1990 to 2019. Risk factors are ranked according to colors (leading risk factor for age-standardized death=dark red; lowest risk factor for age-standardized death=dark blue). LDL: low-density lipoprotein.
Figure 6. The trends of population attributable fractions for 26 factors with age by global and sociodemographic index (SDI) quintiles, 2019, for both sexes combined. LDL: low-density lipoprotein.

Discussion

Overview

This report is the first to use the APC model to analyze temporal trends in IHD mortality on a global scale and across 204 countries and territories. Globally, the total number of IHD-related deaths increased over the past 30 years and continued to be the leading cause of NCD deaths in 2019. By contrast, ASMR decreased, with the biggest decline in mortality in high-SDI regions. Aging is an independent risk factor for mortality from IHD, with noticeable sex differences in period and cohort risks in lower-income countries. Although metabolic risks were the leading factors for mortality from IHD worldwide in 2019, smoking, particulate matter pollution, and dietary risks were also important risk factors, increasingly occurring at a younger age. Diets low in whole grains and legumes were
prominent dietary risks, regardless of sex, while smoking and a high-sodium diet were more frequent in the male than female group.

The trends for mortality from IHD varied across different regions and countries and were not completely commensurate with SDI levels. Overall, high-SDI regions and countries had higher mortality rate for IHD, but with an impressive annual downward trend. However, ASMR increased in Guam (high SDI) and Ukraine (high-middle SDI), whereas a significant decrease occurred in lower-income countries, for example, Rwanda, Ethiopia, and Afghanistan. In higher-income countries, hypertension, hyperlipidemia, diabetes, and obesity have gradually become an increasing threat, which are key risk factors accounting for a large proportion of the mortality rate [26-31]. However, newer modalities of disease prevention and a better-integrated health care system contributed to the greatest reduction in IHD mortality in higher-income countries. For lower-income countries, the Westernized lifestyle with increased metabolic risks and severe air pollution is causing IHD to emerge as a growing health hazard [32-36]. A previous study showed that CVD mortality was much higher in patients with diabetes in lower- than higher-income countries. This increased risk was not altered even when risk factors such as physical inactivity, smoking, BMI, and hypertension and treatments are taken into account [37] but may be related to the fact that lower-income countries are severely underresourced in the number of health care providers, technological infrastructure, and implementation of treatment [38-40]. Therefore, countries with different degrees of SDI, especially lower-income countries with more complex and challenging situations, need to formulate appropriate prevention and intervention strategies based on local health-related resources.

The marked upsurge of IHD mortality in people aged 65 years or older shows that aging is an independent risk factor for mortality from IHD [41,42]. Aging is a nonmodifiable risk factor for IHD, with cellular senescence and vascular aging accounting for atherosclerosis, which is the primary cause of IHD [43,44]. The older individual is susceptible to immune dysfunction and chronic metabolic diseases, which increase the risk of IHD mortality [45]. We found that risk due to low physical activity increased with age, which was associated with CVD mortality [46]. Furthermore, the aging of the population caused by low birth rate and longer life expectancy also indirectly leads to an increase in IHD mortality [14]. In China, IHD mortality, controlled for period and cohort effects, increased sharply after the age of 70 years, where 65.6% of the health burden were projected to occur in older adults in 2050 [47]. The age at which there is a rapid rise in mortality is also delayed in other SDI countries where death trends are increasing, such as Ukraine, the Philippines, Lesotho, and Mozambique, among others. These data suggest that prevention and treatment strategies and multidisciplinary management for IHD in the older population should be a major focus of health systems.

The period and cohort effects on IHD mortality have shown an overall downward trend, which may be attributable to the implementation of better public health policies and improvements in health care [48]. Social stability, improvement in living standards, and advances in medical technologies (medical green channels, eg, Chest Pain Center, advanced interventional techniques, medical devices, and therapeutic drugs) have contributed to the improvement in survival rates of patients with IHD [49,50]. However, unfavorable period and cohort effects continue in some countries, especially in those with lower income. From 1990 to 2019, the high SBP contribution to IHD mortality increased slightly in low-SDI regions, but the risk related to high FPG increased across 5 SDI quintiles. Hazards for IHD mortality caused by high LDL cholesterol, particulate matter pollution, high BMI, and 13 dietary risks are mainly concentrated in the younger age group. The United States (high SDI) is one example of a country that has begun to control air pollution, reducing by more than 80% the atmospheric particulate matter concentration in 2017; the Clean Air Act was passed in 1970 and amended in 1977 and 1990 [51]. China (middle SDI) and India (low-middle SDI) also showed a decline in household air pollution–attributable IHD mortality with a series of measures to decrease air pollution [52-53]. One recent study showed that greater adherence to healthy eating patterns, as recommended by the Dietary Guidelines for Americans, was consistently associated with lower risk of total and IHD-caused mortality [54]. Okinawans, 65 years of age or older, have a lower risk for metabolic diseases and mortality, which may be related to the traditional Okinawan diet consisting of 85% calories from carbohydrates and 9% from protein [55]. The above reports show that current resources are largely inadequate to manage patients with IHD in many countries, and health care strategies from countries with significant improvements in IHD mortality may serve as a model for countries at the same level.

The association between alcohol use and IHD remains an open question. On the one hand, alcohol consumption has been proven to be a leading risk factor for disease burden, but on the other hand, some researchers have suggested that low levels of alcohol consumption can have a beneficial effect on IHD outcomes [56]. Our analysis showed that alcohol use had noticeable protective effects for IHD, but the effect was small compared with the other attributable burdens in those locations. Although the results of our analysis are consistent with previous analyses [56,57], it does not prove that higher alcohol consumption is beneficial for IHD. When considered with overall health risks, alcohol use was strongly associated with cancer, injuries, and communicable disease. Factors such as sex, ethnicity, alcohol consumption, and frequency also need to be considered in future analyses [58].

Sex differences in IHD mortality trends have gradually emerged, especially in lower-income countries [39,60]. In this study, we found that risks from smoking, a diet high in sodium, and particulate matter pollution were greater in male than female individuals globally. By contrast, risks from kidney dysfunction were greater in female than male individuals in high-SDI regions, and risks from high BMI were higher in female than male individuals in low-SDI regions. The traditional risk factors linked to sex-related determinants may be related to shifting roles and relations under the double burden of employment and caregiving responsibilities, which exacerbate the burden of IHD, especially in developing countries [61-64]. However, high-SDI regions had the lowest ratio of male-to-female IHD mortality.
attributable to smoking, suggesting that smoking control programs and policies are becoming successful in high-income countries [65,66]. These indicate that country-specific strategies to incorporate sex determinants into health research are essential to the improvement in IHD mortality.

There are several limitations to this study. First, the gathering and quality of data sources are different across countries in GBD. Limitations in some low- and middle-income countries are unavoidable, such as unavailable or incomplete data, delayed and inaccurate reporting, and misclassified coding [1]. Second, although the time trends analysis was performed across about 30 years, this research was based on cross-sectional data from GBD, which was not a cohort study. Third, mortality data with different trends at the global and national level were analyzed, but subnational differences were not calculated. Moreover, the national data on health system quality, including medication use, interventional operation implementation, and access to medical care were not included in the data source in this study.

In addition, SDI as a composite indicator of income per capita is time-varying, but this study only used SDI of 2019 for the analysis of data from 1990 to 2019 due to data acquisition limitations. Finally, the mortality data for IHD presented in this report were collected before the COVID-19 pandemic. Studies have reported that COVID-19 can induce CVD and increase the risk of death in those with preexisting CVD [67,68], which may be a key focus for IHD mortality analysis in the future.

Conclusions
Although there have been reductions in IHD mortality over the past 30 years, especially in high-SDI regions and countries, IHD remains the leading cause of global mortality from NCDs. Aging is highly correlated with IHD-related death. Sex-related differences in period and cohort risks occurred across higher- and lower-income countries. Metabolic risks were the leading factors for IHD mortality worldwide in 2019, followed by smoking, particulate matter pollution, and dietary risks.

Abstract

Background: The onset of the COVID-19 pandemic in the United States in March 2020 caused a dramatic change in the way many people lived. Few aspects of daily life were left undisturbed by the pandemic’s onset as well as the accompanying policies to control the spread of the disease. Previous research has found that the pandemic may have significantly impacted the mental health of lesbian, gay, bisexual, transgender, and queer (LGBTQ) individuals—potentially more so than other individuals. However, the pandemic did not affect all areas of the United States at the same time, and there may be regional variation in the impact of the onset of the pandemic on depressive symptoms among LGBTQ individuals.

Objective: To assess regional variation of the impact of the pandemic, we conducted a time series analysis stratified by US geographic region to examine symptoms of depression and anxiety among a sample of primarily cisgender gay and bisexual men before and after the onset of the COVID-19 pandemic in the United States.

Methods: In total, 5007 participants completed assessments as part of the Together 5000 study, an ongoing prospective cohort study. Depressive and anxiety symptoms were measured using the Patient Health Questionnaire-4. Patient Health Questionnaire-4 scores were graphed as a function of days from March 15, 2020. Locally estimated scatterplot smoothing trend lines were applied. A sieve-bootstrap Mann-Kendall test for monotonic trend was conducted to assess the presence and direction of trends in the scatterplots. We then compared the observed trends to those observed for 1 year prior (2018-2019) to the pandemic onset using data collected from the same sample.

Results: Significant positive trends were detected for the Northeast (P=.03) and Midwest (P=.01) regions of the United States in the 2020 assessment, indicating that symptoms of anxiety and depression were increasing in the sample in these regions immediately prior to and during the onset of the pandemic. In contrast, these trends were not present in data from the 2018 to 2019 assessment window.

Conclusions: Symptoms of anxiety and depression increased among the study population in the Northeast and Midwest during the beginning months of the COVID-19 pandemic, but similar increase was not observed in the South and West regions. These trends were also not found for any region in the 2018 to 2019 assessment window. This may indicate region-specific trends in anxiety and depression, potentially driven by the burden of the pandemic and policies that varied from region to region. Future studies should consider geographic variation in COVID-19 spread and policies as well as explore potential mechanisms by which this could influence the mental health of LGBTQ individuals.

KEYWORDS
COVID-19 pandemic; lesbian, gay, bisexual, transgender, and queer; LGBTQ; mental health; depression; anxiety; time series; gay and bisexual men; cisgender gay; pandemic; gay
Introduction

The onset of the COVID-19 pandemic in the United States in early 2020 represented a nearly unprecedented disruption in daily life for many Americans. Widespread disruptions were present in nearly every facet of daily life, including in workplaces, schools, and social settings. Mandatory business closures and recommended social distancing were implemented with some heterogeneity in the United States. Many states in the Northeast, Midwest, and West implemented stay-at-home orders in March 2020 prior to Southern states, where the pandemic later took hold in the summer [1].

Several large studies have linked the onset of the pandemic to a significant increase in the symptoms of depression and anxiety in US adults [2-5]. Other studies have found that lesbian, gay, bisexual, transgender, and queer (LGBTQ) people may be particularly vulnerable to developing symptoms of depression and anxiety relative to non-LGBTQ populations [6]. For instance, a study of cannabis users conducted during the pandemic found that the LGBTQ cannabis users were more likely to report symptoms of depression and anxiety [7]. Similarly, a national longitudinal cohort study of LGB adults found increased anxiety and depression symptoms among participants after the beginning of the pandemic [8]. Additionally, a study of LGBTQ college students found that nearly half had unmet mental health needs during the first few months of the pandemic [6]. These findings may be due to being confined in uncomfortable home situations or isolation from friends, which may have disparate impacts on LGBTQ individuals compared to others [9]. However, other studies have found decreased anxiety symptoms and no differences in depressive symptoms before and after the start of the pandemic [10].

Recently, researchers have proposed potential mechanisms by which the onset of the COVID-19 pandemic may have disproportionately affected LGBTQ people. A web-based study in Germany during the pandemic found that depressive symptoms were mediated by loneliness [11], while a study of Mexican LGBTQ people found that perceived social support also acted as a mediator [12]. Taken together, it appears that a lack of access to supportive friends and other members of the LGBTQ community, and the accompanying loneliness, may be one mechanism through which the COVID-19 pandemic, and associated lockdowns, had a greater impact on LGBTQ individuals compared to others.

Despite several studies finding that LGBTQ people were more likely to experience symptoms of depression and anxiety with the onset of the COVID-19 pandemic, we have been unable to identify any studies that examined trends in symptoms and anxiety over time for the period. Time series studies have been used to examine trends in mental health leading up to and immediately following the 2016 US presidential election [13], in mental health referrals during the pandemic [14,15], and in suicide mortality also during the COVID-19 pandemic [16]. However, to our knowledge, no study has examined symptoms of depression and anxiety in an LGBTQ population during the onset of the COVID-19 pandemic in the United States using a time series approach.

The aim of this study was to examine the effects of the onset of the first wave of the COVID-19 pandemic on a population of primarily gay and bisexual men, but also transgender men and transgender women as well as nonbinary people, using time series analysis. Given the heterogeneity of the burden of cases and in COVID-19 policies, analyses were stratified by US census region. We hypothesized that regions that were more impacted by the early onset of the COVID-19 pandemic or had more stringent pandemic control policies or recommendations (eg, the Northeast) would show an increase in symptoms of depression and anxiety as the pandemic progressed.

Methods

Study Population

Participants were members of Together 5000, a US national cohort of primarily cisgender gay and bisexual men at risk for HIV recruited from sexual networking applications. Members of the cohort complete yearly web-based surveys as well as at-home HIV testing beginning in 2017 and running through the onset of the pandemic. The yearly web-based surveys assessed a variety of health-related domains such as socioeconomic factors, drug and alcohol use, sexual behaviors, food and housing insecurity, and mental health measures. A detailed profile of the study procedures and participants has been published elsewhere [17].

Measures

Data Collection

Data for this study were primarily taken from participants’ 24-month assessment. These assessments began on November 20, 2019 (~116 days), and ran through August 15, 2020 (~153 days)—with some participants completing their assessment prior to the onset of the COVID-19 pandemic in the United States and others completing it after. We defined the onset as March 15, 2020, which roughly coincides with the beginning of the week in which many local and state governments announced mandatory closure of nonessential businesses and schools [18-20]. To establish whether a similar trend would be observed in prior yearly assessments, we compared 24-month results to participants’ 12-month assessment (all of which were conducted prior to the pandemic). Survey completion dates were calculated relative to March 15, 2019, and ranged from November 7, 2018 (~127 days), to June 24, 2019 (~101 days).

Demographics

On the baseline survey, race and ethnicity information was assessed using a list of common racial and ethnic categories for participants to select all that apply. Participants were also given the ability to specify their own race or ethnicity. These options were recoded to a 4-category variable representing Black, Hispanic, White, and multiracial or others. To assess current gender identity, participants were asked their assigned sex at birth as well as their current gender identity. Participants had the option of writing in their own gender identity. The variable
was then recoded into 5 categories: cisgender man, cisgender woman, transgender man, transgender woman, or others or nonbinary. Finally, participants were asked to select the best option for their sexual orientation: gay, queer, or homosexual; bisexual; straight or heterosexual; or others. This variable was not recoded prior to analysis.

Region
Participants self-reported their zip codes at baseline and were able to provide updated zip codes during the 12- and 24-month assessments. These zip codes were coded into state of residence, which in turn were categorized according to US census regions [21].

Patient Health Questionnaire-4
The 4-item Likert-type Patient Health Questionnaire-4 (PHQ-4) was used to assess symptoms of anxiety and depression. The Patient Health Questionnaire-2, a measure of depression, and Generalized Anxiety Disorder-2, a measure of anxiety, constitute the PHQ-4. The reliability and validity of the PHQ-4 in the general population have been previously established [22]. The PHQ-4 is scored from 0 to 12, with an increasing score indicating increasingly severe anxiety and depressive symptomology. The continuous measure was used for analyses.

Statistical Analysis
PHQ-4 scores were stratified by US census region of residence and then plotted as a function of the survey completion date for participants completing the 24-month assessment, which ran from November 20, 2019, to August 15, 2020. A locally estimated scatterplot smoothing trend line with 95% CI was applied. A sieve-bootstrap Mann-Kendall test for monotonic trends was conducted to assess the presence and direction of trends in the scores. All steps of this analysis were then repeated for the 12-month assessment for comparison.

Analyses were conducted in R (version 4.1.0; R Foundation for Statistical Computing). Plots and trend lines were created using the ggplot2 package [23], while the test for trend was conducted using the funtimes package [24].

Ethical Considerations
All procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional review board (Institutional Review Board of the City University of New York Graduate School of Public Health and Health Policy, IRB file #2017-0893) and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards. All participants provided informed consent for data collection at each assessment. Participant data were deidentified and stored in an encrypted closed network. Participants received US $25 Amazon gift cards for completing study assessments.

Results
In total, 5007 participants completed the 24-month assessment survey and resided in 1 of the 4 US census regions. An additional 22 participants completed the survey but resided in a US territory and were not included in these analyses. Of these 5007 participants, 784 (15.6%) resided in the Northeast, 780 (15.6%) resided in the Midwest, 2285 (45.6%) resided in the South, and 1158 (23.1%) resided in the West.

Demographically, 507 (10.1%) participants were Black, 1213 (24.2%) were Hispanic, 2677 (53.5%) were White, and 610 (12.2%) were another race or multiracial. The mean age of the sample at the 24-month assessment was 32.9 (SD 7.5) years. The sample was primarily cisgender men with 4885 (97.6%) identifying as such, with the remaining 122 (2.4%) participants identifying as transgender men, transgender women, or nonbinary. A substantial proportion of the sample identified as gay, queer, or homosexual (n=4291, 85.7%) or bisexual (n=660, 13.2%), with the remainder identifying as others. Full demographics as well as PHQ-4 scores stratified by demographic variables are presented in Table 1.

The mean PHQ-4 score at the 24-month assessment was 4.0 (SD 3.0), while the mean PHQ-4 score at the 12-month assessment was 3.7 (SD 2.4). A paired t-test revealed this difference to be statistically significant (t_{4653}=2.99; P=.019), indicating an overall increase in PHQ-4 scores between the 12-month assessment and the 24-month assessment.

Survey completion dates for the 24-month assessment were calculated relative to the onset of the COVID-19 pandemic, with 0 representing March 15, 2020. These dates ranged from November 20, 2019, to August 15, 2020. Individual participant Generalized Anxiety Disorder–Patient Health Questionnaire scores were then plotted as a function of survey completion dates stratified by US census region.

The locally estimated scatterplot smoothing trend line in PHQ-4 scores for the Northeast revealed a trend downward in the days immediately prior to the onset of the pandemic with an upturn in scores following the onset (Figure 1). This trend was significant (τ=0.12; P=.03). A small, steady increase in scores was also observed among participants in the Midwest, beginning prior to the pandemic onset and continuing through to the summer (τ=0.14; P=.01). No trends are immediately apparent in the trend lines for the South and West, and tests for trends were not statistically significant (Table 2).

To establish whether a similar trend would be observed in other yearly assessments, the same analysis was conducted for the 12-month assessment (Figure 2). Inspection of the figure reveals a decrease in scores for participants in the Northeast after March 15, 2019, followed by a sharp upturn at the end. Midwest participant scores decreased markedly shortly after March 15, 2019. A small, nonsignificant oscillation in scores was observed among Western participants. No clear trend was observed in scores among Southern participants. All tests for monotonic trends were nonsignificant for 2019 (all P>.05; Table 2), indicating, compared to 2020, there was no observed trend in PHQ-4 scores over time.

Discussion

Principal Findings

The region-stratified time series analysis of symptoms of depression and anxiety in the days leading up to and following the onset of the COVID-19 pandemic in the United States revealed significant positive trends among participants in the Northeast and Midwest. These trends were not observed in the South or West, nor were they present the previous year.

The disparate impact of the COVID-19 pandemic on the Northeast [25] as well as heterogeneous COVID-19 policies across the United States may explain the observed trends. Other studies have found that lockdown policies, along with adherence to them, may have resulted in increased depressive symptoms [26].

Comparison to Prior Work

The findings of significant positive trends in symptoms of depression and anxiety during the onset of the COVID-19 pandemic were consistent with similar studies that found an increased prevalence of depression and anxiety among the general population as well as LGBTQ people during the COVID-19 pandemic [2,6]. However, to our knowledge, this is the first time-series analysis of symptoms of anxiety and depression conducted in an LGBTQ population with data before and after the onset of the COVID-19 pandemic in the United States as well as the first study to identify a regional trend in this population.

Other time series studies have shown the impact of the COVID-19 pandemic on related mental health constructs. A UK study found a significant decrease in referrals to mental health services during the start of the pandemic, although this study was not focused specifically on sexual minorities [14]. Another study of the general population found a decrease in emergency department visits for psychiatric issues [27]. The decrease in mental health service use combined with increased symptoms could indicate a clear, unmet need for mental health care during the beginning of the COVID-19 pandemic. It is important to consider that the pandemic may have had differential effects on sexual minority individuals based on stigma and vulnerabilities. For instance, young adults who had to return to their parents’ homes as a result of the pandemic were found to have faced greater psychological distress [28]. Future studies could explore whether the observed regional effects were modified by changes in living arrangement. Another potential effect modifier could be social support that other studies have found as an important protective effect for sexual minority populations against depressive symptoms [29].
Limitations

There are some limitations to this study. Survey completion dates were used in calculating days relative to March 15, 2020, and March 15, 2019. It is possible for participants to have started the survey, completed the PHQ-4, and then not completed the survey in its entirety until several days later; however, we do not believe this would have tremendously impacted responses in a meaningful way nor were there enough participants who started before March 15, 2020, and completed it after March 15, 2020, to have had a discernible impact on aggregate results. There may also be other important factors that affect the mental health of sexual minority populations that were not included in this study such as internalized homonegativity [30], social connectedness [31], and minority stress [32]. Finally, the study population was primarily cisgender gay and bisexual men and therefore does not represent the full spectrum of LGBTQ individuals.

Conclusions

We found evidence of increased depression and anxiety symptoms among a sample of primary cisgender gay and bisexual men during the initial onset of the COVID-19 pandemic in 2020 in the Midwest and Northeast regions of the United States. This trend was not similar among the same study population the previous year nor among participants in the South or West regions of the United States.

Abstract

Background: Anxiety disorders (ADs) are the most common mental illness with high prevalence, chronicity, and comorbidity. Despite rapid economic and cultural development, the global incidence of ADs continues to increase, with predominance in male individuals.

Objective: To address the above issues, we analyzed the dynamic trends of the global incidence and disease burden of ADs from 1990 to 2019 and their different effects on age, period, and birth cohort and predicted the future trend of AD incidence.

Methods: The data were obtained from the Global Burden of Disease study in 2019. A joinpoint regression model was used to calculate the annual percent change in AD incidence, and age-period-cohort analysis was used to estimate the independent effects of age, period, and cohort. Nordpred age-period-cohort analysis was used to predict the incidence of ADs from 2020 to 2044.

Results: The age-standardized incidence rate of ADs increased by 1.06% for both sexes, and the age-standardized disability-adjusted life-year (DALY) rate (ASDR) decreased by 0.12%. Joinpoint regression indicated that increments in average annual percent changes in the age-standardized incidence rate (0.068 vs 0.012) and ASDR (0.035 vs –0.015) for ADs globally were higher among male individuals than female individuals. The age-period-cohort analyses revealed that the relative risk (RR) of the incidence and DALYs of ADs among people of different sexes increased with age in adolescence and middle age and then decreased. For the period effect, the RR of incidence decreased, whereas the RR of DALYs increased in both sexes. Moreover, the RR of the incidence gradually increased and DALYs slowly decreased with birth year for both male and female individuals. New cases of ADs in male individuals are predicted to increase in the coming 25 years.

Conclusions: This study provided the changing trend of the global incidence and disease burden of ADs in the past 3 decades, indicating that early prevention and effective control cannot be ignored. We analyzed the age-period-cohort effect of potential trends in ADs and predicted future incidence trends. The results suggest that we should take active intervention measures, focusing on high-risk groups and developing effective management and control policies to reduce the global burden of disease.

KEYWORDS
age-period-cohort analysis; anxiety disorders; incidence; disability-adjusted life-years; DALYs; joinpoint regression model; prediction
Introduction

Anxiety disorders (ADs) form the most common group of mental disorders, which are characterized by excessive and enduring fear, anxiety, or avoidance of perceived threats and can also include panic attacks [1], with generalized ADs being the most common AD seen in primary care [2]. This is based on the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) and the International Classification of Diseases, 11th Edition (ICD-11) diagnostic systems, which categorize ADs based on key symptoms at 3 levels such as cognitive, emotional, and somatic, including separation anxiety, selective mutism, specific phobias, social AD, panic disorder, agoraphobia, and generalized AD [1,3]. The lifetime prevalence rates of AD have reached 34% [4], and ADs generally start in childhood or adolescence [5,6]. Most patients with ADs often have comorbid ADs and other mental disorders, especially depression [7] and somatic disorders such as heart disease, hyperthyroidism, asthma, and epilepsy [8-10]. Importantly, ADs are 2 times more prevalent among female individuals than male individuals [11]. The high prevalence, chronicity, and comorbidity of ADs led the World Health Organization to rank ADs as the ninth leading health-related cause of disability [12]. ADs not only seriously affect patients’ daily functioning and quality of life but also impose a heavy burden on society and account for 3.3% of the global burden of disease (GBD) [13,14].

According to the large-scale World Mental Health Surveys, the prevalence of ADs was highest in high-income countries, especially in Australia, the United States, and European countries [15,16]. Estimated from the 2010 cost model, over €74 billion (US $81.64 billion) was largely due to indirect costs such as disability for 30 European countries [13]. Even if there is insufficient evidence to show that the prevalence of ADs is increasing, the burden of disease cannot be ignored. ADs are still an important global public health problem.

At present, there are relatively few studies on the global trend in the prevalence of ADs, and they use only traditional descriptive analysis of age-specific incidence or mortality data at different times, which cannot eliminate or control for the interaction among age, period, and cohort factors. The joinpoint regression (JPR) model is mainly used to analyze the time trend of incidence and mortality and to analyze the burden of disease, which can better reflect the change in the epidemic trend and its impact [17,18]. The age-period-cohort model improved the traditional descriptive analysis method to estimate the risk of disease incidence or mortality and its trend while adjusting for age, period, and cohort [18,19].

Therefore, this study analyzed data from the GBD 2019 study. The JPR model was used to explore the temporal trends in the incidence and disability-adjusted life-year (DALY) rates of ADs globally and to explore the net age, period, and cohort effects with the age-period-cohort model. Meanwhile, the prediction of the incidence of ADs in the next 25 years based on these data can provide a scientific basis for the evaluation of AD prevention and treatment to reduce the disease burden caused by ADs.

Methods

Data Sources

Data on AD trends during 1990-2019 were retrieved from the World Health Organization GBD estimates. GBD data are derived from private and public organizations worldwide that collect data through surveys, reports, scientific literature, censuses, and other methods. The study has provided improved standardized methods and a comprehensive assessment of incidence and DALYs for 369 diseases and injuries and 87 risk factors in 204 countries and territories. Further details of the general methodologies for the GBD have been described elsewhere [20-22], and data and the protocol for the 2019 GBD can be accessed through the Global Health Data Exchange GBD Results Tool. All GBD 2019 analyses adhered to the Guidelines for Accurate and Transparent Health Estimates Reporting [23].

Ethical Considerations

This study used data from the GBD Study 2019, which was approved by the institutional review board of the University of Washington. Original data were collected with informed consent from study participants or with a waiver from the institutional review board. As this was a secondary analysis of publicly available data, no further review by an institutional review board was required following the data use agreement of The Institute for Health Metrics and Evaluation.

Statistical Analysis

Overall Temporal Trends Analysis of Global

Data on the global and regional incidence of ADs from 1990 to 2019 were extracted from the GHDx database, including crude incidence (CIR), DALYs, age-standardized incidence, and age-standardized DALYs of ADs in the all-age group. Data are reported as estimates with 95% uncertainty intervals (UIs). Age-standardized incidence rates (ASIRs) and age-standardized DALY rates (ASDRs) were used to assess the temporal trend of the global incidence of ADs from 1990 to 2019. The ASIR and ASDR in the GBD database were standardized based on 2019 global population data [20].

JPR Analysis

JPR model analysis was applied to estimate the trends in AD prevalence from 1990 to 2019. As proposed by Kim et al [24], joinpoint analysis can automatically divide longitudinal variations into different segments by segmented regression and identify the segment trends with statistical significance. Regression fitting was performed on the natural logarithm of the prevalence and mortality rate in different segments, and then the annual percent changes (APCs) and their 95% CIs were calculated for each period. The global trend was described by the average annual percent changes (AAPCs). The APCs and AAPCs were considered statistically significant by nonoverlapping 95% CIs and P<.05 compared to the null hypothesis of no variation. We applied the JPR program (version 4.8.0.1) from the Statistical Research and Applications Branch of the Surveillance Research Program of the US National Cancer Institute.
Age-Period-Cohort Analysis

The age-period-cohort model was used to estimate the relative risk (RR) of the population in a given year and the cumulative health risk since birth. The model allowed analysis of the independent effects of age, period, and cohort on temporal trends in incidence and DALY rate due to ADs and other forms of ADs. The age-period-cohort model provides a useful parametric framework that can complement standard nonparametric descriptive methods. This analysis model has been used and recognized in many previous studies [18,19]. In this model, the data collected were stratified into age groups of 5 consecutive years and periods of 5 consecutive years. The incidence rate and DALY rate of AD in 5 consecutive age groups (0-5 years), 5 consecutive periods (1990-1994 to 2015-2019), and 5 consecutive birth cohorts (1990-2015) were recorded. Age-period-cohort analysis using the intrinsic estimation method provided coefficient estimates for age, period, and cohort effects. These coefficients are converted to exponential values \[\text{exp}(\text{coefficient})=\text{ecoefficient}\], representing the RR of incident AD and AD-related DALY rates for a specific age, period, or birth cohort relative to the mean for all ages, periods, or birth cohorts [25]. Age-period-cohort analysis was performed using STATA software (version 15.0; StataCorp).

Incidence Rate Predicted

This study predicted the incidence rate of ADs from 2020 to 2044 by running a Nordpred age-period-cohort analysis by sex

Figure 1. Trends in the sex-specific incidence and DALY rate of ADs globally during 1990-2019. (A) ASIR of ADs and (B) ASDR of ADs. AD: anxiety disorder; ASDR: age-standardized DALY rate; ASIR: age-standardized incidence rate; DALY: disability-adjusted life-year.

JPR Analysis

The joinpoint model was applied to divide the temporal trends in AD incidence into several segments and estimate the APCs by sex. As displayed in Table 1 and Figure 2A, the ASIR of ADs among male individuals declined first (\(\text{APCs}_{1990-1999}=-0.12\%\)), significantly increased (\(\text{APCs}_{2005-2010}=0.67\%\)), and then increased thereafter (\(\text{APCs}_{2010-2014}=0.03\%\) and \(\text{APCs}_{2014-2019}=0.35\%\)). In contrast, the ASIR underwent 3 increases (\(\text{APCs}_{1995-2000}=0.64\%\), \(\text{APCs}_{2005-2010}=0.19\%\), and \(\text{APCs}_{2015-2019}=0.25\%\)) and 3 declines (\(\text{APCs}_{1990-1995}=-0.06\%\), \(\text{APCs}_{2000-2005}=-0.47\%\), and \(\text{APCs}_{2010-2015}=-0.43\%\)) among female individuals, as shown in Figure 2B. Moreover, the trend in the ASDR was consistent with the change in the ASIR (Table 1; Figure 2C and D). Over the entire study period, the ASIRs of ADs were 0.068% (95% CI 0.35-1.0) among male individuals and 0.012% (95% CI 0.8-1.0) among female individuals (Table 1; Figure 2A and B).

Results

Global Trends in the ASIRs and ASDRs of ADs From 1990 to 2019

The ASIR of ADs showed a slightly fluctuating upward trend, increasing from 579.30 (95% UI 467.81-702.90) per 100,000 in 1990 to 585.45 (95% UI 474.21-709.53) per 100,000 in 2019, with an increase of 1.06%. The growth rate of the ASIR was higher in male individuals than female individuals, although the incidence rate for female individuals is about 1.4 times higher than that of male individuals. Among them, the ASIR increased by 1.92% in male individuals and 0.43% in female individuals (Figure 1A).

The trend of ASDR for ADs was relatively stable from 360.55 (95% UI 250.82-492.46) per 100,000 in 1990 to 360.12 (95% UI 248.60-494.44) per 100,000 in 2019, decreased by 0.12%. The ASDR increased by 0.90% in male individuals and decreased by 0.6% in female individuals (Figure 1B).
Figure 2. Joinpoint regression analysis of the sex-specific age-standardized incidence and disability-adjusted life years rate for ADs in global from 1990 to 2019. (A) Age-standardized incidence rate (ASIR) for males; (B) Age-standardized incidence rate (ASIR) for females; (C) Age-standardized DALYs rate (ASDR) for males; (D) Age-standardized DALYs rate (ASDR) for females. For a higher-resolution version of this figure, see Multimedia Appendix 1.

**Age-Period-Cohort Analysis**

**Age Effect**

Table 2 and Figure 3A and B show the longitudinal age curve of the incidence and DALY rates of ADs. After adjusting for period effects, in the reference cohort, the incidence of ADs showed 2 upward and downward trends with age in the reference cohort, similar to an M-shaped curve. Among both male and female individuals, individuals aged 10-14 years had the highest incidence of ADs. The second peak occurred at ages 40-44 years for male individuals and at ages 35-39 years for female individuals. In addition, the DALY rate of ADs was highest at 15-19 years of age for male individuals and 20-24 years of age for female individuals, and then the DALY rate decreased with age.
Table 2. RRs of the incidence and disability-adjusted life-year (DALY) rates of anxiety disorders globally from 1990 to 2019 due to age, period, and cohort effects.

**Figure 3.** RRs of the incidence and disability-adjusted life-year (DALY) rate of anxiety disorders globally from 1990 to 2019 due to age, period, and cohort effects. (A) Age effects on incidence, (B) age effects on DALY rate, (C) period effects on incidence, (D) period effects on DALY rate, (E) cohort effects on incidence, and (F) cohort effects on DALY rate. RR: relative risk.

**Period Effect**
Table 2 and Figure 3C and D show the estimated period effects by sex during the whole study period. Regarding the incidence, the period effects showed a downward trend from 1990-1994 to 2000-2004 for male individuals, with the period RR decreasing from 1.02 to 0.98 and then slightly increasing in 2015-2019. However, the period RR slightly increased from 1990-1994 to 1995-1999 for female individuals, and then it decreased. Regarding the DALY rate, the period RR showed similar increasing patterns for both sexes (increased by 13.63% for male individuals and 11.70% for female individuals).

**Cohort Effect**
The risk of ADs increased slowly with the year of birth for both sexes (Table 2; Figure 3E). Specifically, from the 1990-1994 to 2015-2019 birth cohorts, the RR of AD incidence substantially increased by 57.34% for female individuals. However, the cohort RR slightly increased by 17.32% from 1990-1994 to 1995-1999 for male individuals and then slightly
fluctuated. Regarding the DALY rate, the period RR showed similar decreasing patterns for both sexes (decreased by 40.94% for male individuals and 42.64% for female individuals), as shown in Table 2 and Figure 3F.

Predicted Trends of ADs in 2020-2044
We predicted that the future ASIR of ADs would be relatively stable, but the trend would be the opposite for male individuals compared to female individuals. However, the incidence among male individuals will increase, and the incidence among female individuals will gradually decrease (Figure 4).

Discussion
Principal Findings
ADs are some of the most common mental disorders, and their prevalence and disease burden are affected by population growth trends, socioeconomic level, the natural environment, and other factors [5]. Our research analyzed the long-term trend in the incidence and DALY rate of ADs globally; evaluated the potential effects of age, period, and birth cohort; and predicted the prevalence trends in the next 25 years. This study provides guidance for the development of effective prevention and control policies.

In 1990, the CIR of ADs was 581.81 per 100,000, and it increased to 592.20 per 100,000 in 2019 (an increase of 1.79%). The DALY rate in 1990 was 348.81 per 100,000, and it increased to 370.61 per 100,000 in 2019 (an increase of 6.25%). This trend shows that ADs are still a global public health issue that cannot be ignored and that we need to strengthen the prevention and timely diagnosis and treatment of affected populations.

Our research showed that compared with the increase in the CIR and DALY rate, the increase in the ASIR of ADs was smaller, and the ASDR was slightly lower from 1990 to 2019. JPR model analysis showed that the trends of ASIR and ASDR were consistent in both sexes. Generally, the incidence of ADs and their DALYs should be very similar because DALYs are years of life lost plus years lived with disability, and years of life lost only accounts for a very small proportion of ADs in terms of DALYs because ADs are not a fatal disease. Therefore, it was not surprising that the ASDR would be very similar to the ASIR. Notably, the ASIR and ASDR decreased substantially between 2000 and 2005 for both sexes. This downward trend may be due to the rapid development of the global economy and culture, the great improvement of medical standards, and the declining birth rate [20].

In terms of incidence, the ASIR was higher among female individuals than among male individuals in 2019. This was consistent with the results of previous studies [11,26]. In 2015, a systematic review of prevalence studies showed that female individuals were twice as likely as male individuals to have ADs [4], which indicated that more female individuals are affected by ADs than male individuals worldwide. A strong body of evidence implicates sex hormone fluctuations in female individuals as the major biological factor driving sex differences in anxiety risk [11,26,27]. The ASDR among female individuals
was also higher than that among male individuals, which is in line with a higher prevalence among female individuals than among male individuals. In addition, mental health knowledge has increased considerably, and stigma has decreased in countries that allow male individuals to talk about their feelings, seek help, and overcome the “rule”: male individuals drink and female individuals become depressed or anxious [28]. However, the ASIR of ADs was relatively stable (AAPCs 0.012%) and the ASDR decreased (AAPCs –0.015%) among female individuals, while both the ASIR (AAPCs 0.068%) and ASDR (AAPCs 0.035%) increased among male individuals. This may reveal a potentially increasing burden of ADs among male individuals.

Age-period-cohort model analysis showed that the upward trend in AD incidence was affected by age, period, and cohort. Age is an important demographic risk factor, and adolescents and middle-aged individuals are at high risk of ADs, similar to an M-shaped curve. The period effect showed that the overall incidence rate showed a downward trend, while the DALY rate showed an upward trend. The incidence of ADs increased, while the DALY rate decreased by year of birth.

Regarding the age effect, the RR of AD incidence was the highest in the age group of 10-14 years for both sexes, and the RR of the DALY rate was highest in the age group of 15-19 years among male individuals and in the age group of 20-24 years among female individuals. These findings were supported by a previous review [29]. Studies have shown that the high incidence of ADs among adolescents is closely related to genetic factors [30,31], higher vulnerability caused by hormonal processes, and adverse childhood experiences (serious illness, parental separation and emotional maltreatment, and physical and sexual abuse) [32-35]. Furthermore, the risk of ADs incidence among male individuals aged 40-44 years and female individuals aged 35-39 years was similar to that among adolescents, and then the risk decreased with age. The high risk of middle-aged people may stem from occupational pressure, family relationships, economic burdens, physical status, and other factors [36-38].

The period effect is usually caused by a series of complex historical events and environmental factors. We observed upward trends in the risk of developing ADs over time among male individuals after 2004. Notably, the incidence of ADs among male individuals increased rapidly during 2005-2010 and continued to increase until 2019 according to joinpoint analysis. This may be due to environmental changes and a more rapid pace of life [39,40]. During the study period, the world experienced a bird flu pandemic, rising oil prices, repeated terrorist attacks, and more severe natural disasters [41-44]. However, the period effect showed that the incidence of ADs among female individuals decreased over time after 1999, which was consistent with the reduction in incidence from 2000 to 2005 in the JPR analysis. The decline in incidence among female individuals may be due to higher levels of education, higher socioeconomic status, and a relative decline in fertility [38,45-47]. Compared with the incidence rate, the RR of the DALY rate increased over time in both sexes. This trend may be explained by the higher lifetime prevalence of ADs and the low and limited treatment rates in the early stage, which makes most patients with early-onset ADs develop a persistent course [48,49]. Long-term persistence or repeated attacks aggravate the degree of the disease and are prone to comorbidities and physical diseases, which increase the disability rate of these patients in the later stage [15]. Studies have found a lack of associations between sociodemographic characteristics and AD persistence, such as socioeconomic status and level of education, and inconclusive results for other socioeconomic factors, such as sex and age, although these characteristics were repeatedly found to be associated with the onset and prevalence of ADs [5].

The cohort effect on the incidence of ADs revealed continuous upward trends in later birth cohorts for both male and female individuals. The possible reason was that the later birth cohorts faced greater pressures, such as environmental degradation, dwindling resources, and economic depression. In contrast, the DALY rate of ADs decreased with birth year. The reason may be that the latest birth cohort was better educated, had better health care, and was more aware of health and disease prevention than the earliest birth cohort.

The predicted trend of AD incidence in our study over the next 25 years is consistent with the current trend, with a downward trend among female individuals and an upward trend among male individuals. This trend calls for us to pay more attention to the risk of ADs, especially among male individuals, and formulate effective prevention and treatment policies to reduce the incidence of ADs and thus reduce the disease burden.

In summary, between 1990 and 2019, the incidence of ADs among male and female individuals worldwide was dynamic. Overall, the global incidence rate among male individuals increased significantly while that among female individuals decreased significantly. According to age-period-cohort analysis, the incidence of the age effect showed an M-shaped curve. That is, adolescents and middle-aged people had the highest incidence. In addition, the incidence of ADs among male individuals will continue to increase soon. In this regard, we should pay more attention to the prevalence of ADs among male individuals, provide greater intervention and treatment for female individuals, and identify adolescent and middle-aged risk groups to support the timely initiation of intervention measures and effectively reduce the disease burden of ADs. At the same time, the COVID-19 pandemic has heightened anxiety, increasing the incidence of ADs and their disease burden [50]. Therefore, multiple interventions should be used aggressively to alleviate anxiety and promote mental health during the COVID-19 pandemic [51].

Limitations

This study has limitations. First, GBD data are modeled at a higher setting and are derived from the analysis of limited raw data. Nevertheless, the results of this study rely heavily on the outcome data of the GBD study 2019. Second, the age-period-cohort model is the mathematical method used, and it does not fully reflect the reality of the situation. In addition, the GBD data do not include groups that are transgender. Therefore, the results should be interpreted with caution.
Conclusions
In summary, ADs are becoming more common in both male and female individuals, and the disease burden in male individuals has increased slightly, indicating that early prevention and effective control cannot be ignored. The incidence of the age effect showed an M-shaped curve, and the incidence of ADs in male individuals will continue to increase soon. This suggests that we should take active intervention measures, focusing on high-risk groups, and develop effective management and control policies to reduce GBD.

Abstract

Background: Chronic kidney disease (CKD) poses a significant global public health challenge. While lipoprotein(a) (Lp[a]) has been established as a significant factor in cardiovascular disease, its connection to CKD risk remains a topic of debate. Existing evidence indicates diverse risks of kidney disease among individuals with various renal function indicators, even when within the normal range.

Objective: This study aims to investigate the joint associations between different renal function indicators and Lp(a) regarding the risks of incident CKD in the general population.

Methods: The analysis involved a cohort of 329,415 participants without prior CKD who were enrolled in the UK Biobank between 2006 and 2010. The participants, with an average age of 56 (SD 8.1) years, included 154,298/329,415 (46.84%) males. At baseline, Lp(a) levels were measured using an immunoturbidimetric assay and classified into 2 groups: low (<75 nmol/L) and high (≥75 nmol/L). To assess participants’ baseline renal function, we used the baseline urine albumin-to-creatinine ratio (UACR) and estimated glomerular filtration rate (eGFR). The relationship between Lp(a), renal function indicators, and the risk of CKD was evaluated using multivariable Cox regression models. These models were adjusted for various factors, including sociodemographic variables, lifestyle factors, comorbidities, and laboratory measures.

Results: A total of 6003 incident CKD events were documented over a median follow-up period of 12.5 years. The association between elevated Lp(a) levels and CKD risk did not achieve statistical significance among all participants, with a hazard ratio (HR) of 1.05 and a 95% CI ranging from 0.98 to 1.13 (P=.16). However, a notable interaction was identified between Lp(a) and UACR in relation to CKD risk (P for interaction=.04), whereas no significant interaction was observed between Lp(a) and eGFR (P for interaction=.96). When compared with the reference group with low Lp(a) and low-normal UACR (<75 nmol/L), the group with high Lp(a) and low-normal UACR exhibited a nonsignificant association with CKD risk (HR 0.98, 95% CI 0.90-1.08; P=.74). By contrast, both the low Lp(a) and high-normal UACR (≥10 mg/g) group (HR 1.16, 95% CI 1.08-1.24; P<.001) and the high Lp(a) and high-normal UACR group (HR 1.32, 95% CI 1.19-1.46; P<.001) demonstrated significant associations with increased CKD risks. In individuals with high-normal UACR, elevated Lp(a) was linked to a significant increase in CKD risk, with an HR of 1.14 and a 95% CI ranging from 1.03 to 1.26 (P=.01). Subgroup analyses and sensitivity analyses consistently produced results that were largely in line with the main findings.

Conclusions: The analysis revealed a significant interaction between Lp(a) and UACR in relation to CKD risk. This implies that Lp(a) may act as a risk factor for CKD even when considering UACR. Our findings have the potential to provide valuable
insights into the assessment and prevention of CKD, emphasizing the combined impact of Lp(a) and UACR from a public health perspective within the general population. This could contribute to enhancing public awareness regarding the management of Lp(a) for the prevention of CKD.

**KEYWORDS**
lipoprotein(a); chronic kidney disease; renal function; urinary albumin-to-creatinine ratio; glomerular filtration rate

**Introduction**
Chronic kidney disease (CKD), a significant contributor to cardiovascular disease (CVD) and mortality, affected approximately 697.5 million individuals worldwide, with a prevalence of 9.1% in 2017 [1,2]. In public health and clinical research, CKD is typically diagnosed using the estimated glomerular filtration rate (eGFR) and urine tests to detect the presence of albumin or protein or a combination of both [3]. As per recommendations [3], a diagnosis of CKD can be made when the eGFR is <60 mL/min/1.73 m² and is combined with albuminuria, usually defined as a urinary albumin-to-creatinine ratio (UACR) ≥30 mg/g.

Lipoprotein(a) (Lp(a)) is a particle resembling low-density lipoprotein (LDL), comprising a large glycoprotein apolipoprotein(a) bound to an apolipoprotein B100 molecule [4]. The adverse impact of Lp(a) on CVD has been robustly substantiated by epidemiological, experimental, and genetic studies [5,6]. By contrast, the association between Lp(a) and the risk of CKD is still a topic of debate, with inconsistent findings reported in both observational studies and Mendelian randomization studies [7-14]. As a result, Lp(a) has not yet been incorporated into current guidelines or public health policies for CKD prevention, detection, management, or surveillance [3,15]. A deeper understanding of the role of Lp(a) in CKD could enhance public initiatives for the prevention and risk management of CKD. Therefore, further explorations are needed to investigate the relationship between Lp(a) and CKD risk.

Remarkably, no previous studies have investigated the association between the risk of CKD and Lp(a) in conjunction with eGFR or UACR, despite both measures being commonly used as indicators of renal function [8-10]. Heterogeneous risks of CKD have been observed in participants with different baseline eGFR or UACR measures, even when these 2 indicators were within the normal range [16-19]. For example, evidence has suggested that a UACR value in the high-normal range (10-30 mg/g) is significantly associated with the progression of CKD and renal failure when compared with the low-normal group (<10 mg/g) used as a reference [17,18,20]. While some previous studies generally adjusted for renal function indicators in their regression models, the association between Lp(a) and CKD risk was estimated based on an average level of renal function indicators. Therefore, the inconsistent associations between Lp(a) and CKD risk may, at least in part, depend on participants’ varying renal function levels across different studies.

In this study, our objective was to investigate the combined associations of Lp(a) and renal function indicators in relation to CKD risk among participants without a history of CKD from the UK Biobank cohort study. Exploring the potential interplay between Lp(a) and renal function may provide new evidence for assessing and preventing CKD risk in the general population from a public health perspective. This research could contribute to raising public awareness about the importance of managing Lp(a) for CKD prevention.

**Methods**

**Study Population**
Information about the UK Biobank study has been extensively documented in prior literature and is available on the official website [21,22]. In summary, the UK Biobank is a comprehensive cohort study that encompasses biological and medical data from approximately half a million residents in the United Kingdom since 2006. Enrolled participants provided written informed consent, and the study received approval from the North West Multi-Centre Research Ethics Committee.

A total of 502,411 participants were included in our analyses. Exclusions were made for participants with missing data on eGFR (n=33,141), UACR (n=13,408), or Lp(a) (n=81,863), as well as those with renal dysfunction at baseline, including a diagnosis of CKD, an eGFR<60 mL/min/1.73 m², or a UACR≥30 mg/g (n=44,584). Consequently, the final analysis included 329,415 participants. The participant selection process is depicted in Figure S1 in Multimedia Appendix 1.

**Outcomes**
Within the UK Biobank, incident disease status and death information were determined through linkage with hospital in-patient data, cancer registry records, and death registry records. Our primary outcome focused on event-free survival time to the first moderate to severe CKD event. CKD events included stages 3-5 and end-stage renal disease (ESRD), identified by ICD-10 (10th revision of the International Statistical Classification of Diseases and Related Health Problems) codes N18.0, N18.3, N18.4, and N18.5, ascertained from hospital in-patient records in either the primary or the secondary position. The secondary outcomes in our study encompassed the individual components of CKD, specifically CKD stage 3, CKD stage 4, and CKD stage 5 as well as ESRD. All participants were monitored from the date of recruitment (spanning from 2006 to 2010) to the occurrence of a CKD diagnosis, death, or the conclusion of the follow-up period (September 30, 2021, for England; July 31, 2021, for Scotland; and February 28, 2018, for Wales), whichever transpired first.
Exposures

Serum Lp(a) levels were assessed using an immunoturbidimetric assay (Beckman Coulter AU5800; Randox Laboratories). In accordance with guidelines, Lp(a) was categorized into 2 groups: low (<75 nmol/L) and high (≥75 nmol/L) [4,9,23]. Serum creatinine (mmol/L) and urinary creatinine (mmol/L) were determined through enzymatic analyses (Beckman Coulter AU5800). The eGFR was computed using the serum creatinine–based Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation [24]. UACR was calculated as the ratio of urinary albumin (in mg/L) to urinary creatinine, with the former measured by an immunoturbidimetric assay (Beckman Coulter AU5400). As per recommendations, we classified both eGFR (low-normal, <90 mL/min/1.73 m² and high-normal, ≥90 mL/min/1.73 m²) and UACR (low-normal, <10 mg/g and high-normal, ≥10 mg/g) into 2 groups [3].

Other Independent Variables

Additional baseline independent variables considered comprised sociodemographic factors, lifestyle details, comorbidities, medication use, and laboratory samples. Sociodemographic factors included age (in years), sex (male or female), Townsend Deprivation Index (TDI), ethnicity (White, Mixed, Asian, Black, Chinese, and others), college degree or higher (yes or no), and residential area (urban or rural).

Lifestyle variables were BMI, smoking status (never, previous, or current smoker), alcohol drinking status (never, previous, or current drinker), regular vitamin supplement consumption (yes or no), mineral supplement use (yes or no), and coffee intake (yes or no). Comorbidities comprised a previous history of cancer, nonhypertensive CVD, depression, diabetes mellitus (DM), hypertension, high cholesterol, and use of drugs (anti-diabetic drugs, anti-hypertensive drugs, or cholesterol-lowering drugs). Laboratory samples included high-density lipoprotein (HDL)-cholesterol (HDL-C), LDL-cholesterol (LDL-C), triglycerides (TGs), C-reactive protein (CRP), glycated hemoglobin (HbA₁c), and urate. Table S1 in Multimedia Appendix 1 provides details on the aforementioned variables.

Data on sociodemographic factors and lifestyles were obtained through participant self-reports at baseline interviews. Information on baseline comorbidities and drug usage was gathered from participant self-reports, hospital in-patient records at baseline, and the relevant treatment/medication received. Laboratory samples, including blood and urine, were collected during participant recruitment.

Statistical Analyses

Baseline characteristics of the included participants were presented as mean (SD) for continuous variables or percentage (percentage) for categorical variables. Chi-square and independent t tests (2-tailed) were performed to compare categorical and continuous variables, respectively, stratified by low and high Lp(a) groups.

Effect modification analyses were conducted to assess whether the impact of the high Lp(a) group on CKD risk varied within the strata of eGFR or UACR. We observed significant modifications by UACR (P=0.02 for relative excess risk due to interaction), indicating that the association between Lp(a) and CKD risk was influenced by UACR levels, while no significant modifications were found by eGFR (P=0.12 for relative excess risk due to interaction; refer to Tables S2 and S3 in Multimedia Appendix 1). When considering Lp(a), UACR, and eGFR as continuous variables, a significant interaction was observed only between Lp(a) and UACR (P=0.03), while no significant interaction was found between Lp(a) and eGFR (P=0.27) concerning CKD risk (refer to Table S4 in Multimedia Appendix 1). Subsequently, we delved into exploring the joint effect of Lp(a) and UACR on the risk of CKD through further analyses categorizing participants into 4 groups: low Lp(a) and low-normal UACR, low Lp(a) and high-normal UACR, high Lp(a) and low-normal UACR, and high Lp(a) and high-normal UACR.

Multivariable Cox proportional hazards models were used to explore the joint associations between Lp(a), UACR, and the risk of CKD, using the low Lp(a) and low-normal UACR group as the reference. The fully adjusted models included covariate adjustments for age, sex, BMI, TDI, college degree, ethnicity, area, smoking and drinking status, regular intake of coffee, vitamin and mineral supplements, personal medical history of cancer, CVD, depression, DM, hypertension, high cholesterol, drugs for DM, hypertension, high cholesterol, systolic blood pressure, HDL-C, LDL-C, TGs, HbA₁c, CRP, urate, and eGFR. The variables included in the models were selected based on clinical expertise, prevailing research practices, and statistical knowledge [7-12]. The results were presented as hazard ratios (HRs) along with their corresponding 95% CIs. Additionally, a parsimonious model was used, adjusting only for age, sex, BMI, comorbidities, use of drugs, and eGFR, to evaluate the consistency of results with those from the fully adjusted models.

Subgroup analyses were performed to investigate the relationship between Lp(a), UACR, and CKD risk, stratified by sex (male vs female), age (<65 vs ≥65 years), medical history of DM (yes vs no), medical history of hypertension (yes vs no), and medical history of high cholesterol (yes vs no). In the subgroup analysis involving participants with DM, additional adjustment was made for their DM duration, considering the close association between DM duration and kidney function [25].

Several sensitivity analyses were conducted to assess the robustness of the main results. Initially, considering the potential correlation between LDL-C and Lp(a), we conducted the same analyses in multivariable models, excluding LDL-C to mitigate potential multicollinearity. Additionally, a sensitivity analysis was performed by further adjusting for moderate-to-vigorous physical activity and sleep patterns. Sleep pattern was defined based on a previous study using the UK Biobank cohort and incorporating 5 sleep behaviors: chronotype, duration, insomnia, snoring, and excessive daytime sleepiness [26]. Furthermore, we adjusted for family history of kidney diseases and the use of drugs for kidney diseases, including angiotensin-converting enzyme inhibitors and angiotensin receptor blockers, in another sensitivity analysis. Although comorbidities, including obesity,
DM, and hypertension at baseline, were adjusted for in the models, it is possible that some participants without these comorbidities at baseline developed them during the 12.5-year follow-up. To address this, we conducted a sensitivity analysis by excluding participants who were free of these comorbidities at baseline but developed obesity, DM, or hypertension during the follow-up. This was done to minimize the dynamic impact of these comorbidities on the association between Lp(a), UACR, and CKD risk. We conducted a Fine-Gray competing risk analysis, treating all-cause mortality as a competing event for CKD [27]. To address reverse causation, we repeated the Cox regression analyses after excluding CKD events that occurred within the first year and the first 3 years of follow-up. Additionally, as another sensitivity analysis, we used multiple imputation techniques for missing data (seed=12345) to assess the robustness of the main findings. According to the guideline [28], participants with normal indicators (eGFR≥60 mL/min/1.73 m² and UACR<30 mg/g) can be further diagnosed with CKD stage 1 or 2 if they exhibit other markers of kidney damage (eg, hematuria, electrolyte abnormalities, or structural abnormalities detected by imaging such as polycystic or dysplastic kidneys). Unfortunately, due to the unavailability of specific disease markers, we were unable to fully identify participants who should be diagnosed with CKD stage 1 or 2 at baseline. Consequently, we conducted another sensitivity analysis by including participants with a baseline eGFR≥90 mL/min/1.73 m² in the analyses to exclude those with suspected CKD stage 1 or 2.

All tests were 2-sided with a significance level of .05. Statistical analyses were performed using SAS software version 9.4 (SAS Institute Inc.) and R software version 4.1.2 (R Foundation).

**Ethical Considerations**

The UK Biobank study was approved by the North West Multicenter Research Ethics Committee (reference number: 16/NW/0274). All participants provided written consent before enrollment. The present analysis has received an exemption from the Research Ethics Committee of Guangdong Second Provincial General Hospital (reference number: 2022-KY-KZ-119-01) because it was a secondary analysis based on open data according to current regulations.

**Results**

A total of 329,415 participants (mean age 56 years; n=175,117, 53.15% females) without prior CKD were included in the analyses. Among them, 258,388 (78.44%) had low Lp(a), while 71,027 (21.56%) had high Lp(a). Table 1 and Table S5 in Multimedia Appendix 1 provide descriptions and comparisons of baseline characteristics. Participants with high Lp(a) exhibited higher BMI, HDL-C, LDL-C, and HbA₁c levels, and were more likely to have a previous history of CVD and high cholesterol compared with the low Lp(a) group.

</table>
There were 6003 incident CKD events recorded, with a median follow-up of 12.5 years and a total of 4,011,201 person-years. Table 2 (also see Multimedia Appendix 2) presents the results for the independent associations between Lp(a), UACR, and CKD risk. The high Lp(a) group showed a nonsignificant association with an elevated CKD risk (HR 1.05, 95% CI 0.98-1.13; \( P = .16 \)) compared with the low Lp(a) group. By contrast, the high-normal UACR group was significantly associated with a 20% increased risk of CKD compared with the low-normal UACR group (HR 1.20, 95% CI 1.13-1.27; \( P < .001 \)). Similar results were observed when treating Lp(a) and UACR as continuous variables (see Table S4 in Multimedia Appendix 1).

\(^a\)Lp(a): lipoprotein a.
\(^b\)UACR: urine albumin-creatinine ratio.
\(^c\)HR: hazard ratio.
\(^d\)Fully adjusted model adjusted for age, sex, body mass index, Townsend Deprivation Index, college degree, ethnicity, area, smoking and drinking status, regular intake of coffee, vitamin and mineral supplement, personal medical history of cancer, cardiovascular disease, depression, diabetes, hypertension, high cholesterol, drugs for diabetes, hypertension, high cholesterol, systolic blood pressure, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, triglycerides, glycated hemoglobin (HbA\(_1c\)), C-reactive protein, urate, and estimated glomerular filtration rate.
\(^e\)Baseline Lp(a) was categorized into low (<75 nmol/L) and high (≥75 nmol/L) groups. Baseline UACR within the normal range was classified into low-normal (0-9.9 mg/g) and high-normal (10-29.9 mg/g) groups.

The joint associations between Lp(a) and UACR, as demonstrated through the 4 groups generated from their cross-categorization, with low Lp(a) and low-normal UACR as the reference group, are shown in Table 2. Among participants with low-normal UACR, a nonsignificant association was observed between high Lp(a) and CKD risk (HR 0.98, 95% CI 0.90-1.08; P=.74). When compared with the low Lp(a) and low-normal UACR group, both the low Lp(a) and high-normal UACR and high Lp(a) and high-normal UACR groups were significantly associated with increased risks of CKD, with HRs of 1.16 (95% CI 1.08-1.24; P<.001) and 1.32 (95% CI 1.19-1.46; P<.001), respectively. Table S2 in Multimedia Appendix 1 shows that a significant association between Lp(a) and increased CKD risk was only observed in the high-normal UACR group (HR 1.14, 95% CI 1.03-1.26; P=.01), but not in the low-normal UACR group (HR 0.98, 95% CI 0.90-1.08; P=.74). Similar results from the parsimonious model were found to support our main findings (Table S6 in Multimedia Appendix 1).

When treating UACR as a continuous variable, increased HRs regarding the relationship between the high Lp(a) group and CKD risk were observed as UACR elevated (Figure 1), indicating that an increased UACR modifies the propensity of high Lp(a) toward CKD risk when compared with low Lp(a).
Figure 1. HRs for the high Lp(a) group regarding the risk of chronic kidney disease at different levels of UACR. CKD: chronic kidney disease; HR: hazard ratio; lower 95%: lower limit of 95% CI; Lp(a): lipoprotein(a); UACR: urine albumin-to-creatinine ratio; upper 95%: upper limit of 95% CI.

Figure 2 shows the joint associations between Lp(a) and UACR with the risk of CKD in different subgroups. Results similar to the main findings were observed within different strata of sex, previous history of DM, and high cholesterol. Among participants aged ≥65 years or without a previous history of hypertension, both the low Lp(a) and high-normal UACR (P=.08 for participants aged ≥65 years and P=.07 for participants without hypertension) and high Lp(a) and high-normal UACR (P=.10 for participants aged ≥65 years and P=.14 for participants without hypertension) groups were nonsignificantly associated with increased risks of CKD. Sensitivity analyses yielded largely similar results to the main findings (Figure 3 and Tables S7 and S8 in Multimedia Appendix 1).
Figure 2. Stratified analyses of joint associations between baseline Lp(a) and UACR regarding the risk of chronic kidney disease. *Baseline Lp(a) was categorized into low (<75 nmol/L) and high (≥75 nmol/L) groups. Baseline UACR within the normal range was classified into low-normal (0-9.9 mg/g) and high-normal (10-29.9 mg/g) groups. HR: hazard ratio; Lp(a): lipoprotein(a); UACR: urine albumin-to-creatinine ratio.

Figure 3. Further analyses of joint associations between baseline Lp(a) and UACR regarding the risk of CKD. *Baseline Lp(a) was categorized into low (<75 nmol/L) and high (≥75 nmol/L) groups. Baseline UACR within the normal range was classified into low-normal (0-9.9 mg/g) and high-normal (10-29.9 mg/g) groups. ACEI: angiotensin-converting enzyme inhibitor; ARB: angiotensin receptor blocker; CKD: chronic kidney disease; DM: diabetes mellitus; Lp(a): lipoprotein(a); UACR: urine albumin-to-creatinine ratio.

Table S9 in Multimedia Appendix 1 shows results for secondary outcomes (5615 with CKD stage 3, 393 with CKD stage 4, and 252 with CKD stage 5 and ESRD), with similar findings to the primary outcome in general.

Discussion

Principal Findings

In this study based on data from a prospective cohort, our principal findings are as follows: (1) high Lp(a) was nonsignificantly associated with increased CKD risk among all participants; (2) there was a significant interaction between Lp(a) and UACR but not between Lp(a) and eGFR; (3) when taking low Lp(a) and low-normal UACR as the reference, the high-normal UACR groups with any Lp(a) level were significantly associated with an increased risk of CKD, with no significant risks observed in the high Lp(a) and low-normal UACR group; (4) among those with high-normal UACR, high Lp(a) was associated with a significant increase in CKD risk; and (5) when treating UACR as a continuous variable, increased HRs regarding the relationship between Lp(a) and CKD risk were observed as UACR elevated.

Our study shows that the association between Lp(a) and CKD risk was nonsignificant among the general population without previous CKD in both categorical and continuous forms. Indeed, the relationship between Lp(a) and CKD risk has been explored, with inconsistent findings reported. One Chinese cohort study, including 6257 adults, showed that elevated Lp(a) was significantly associated with an increased risk of reduced renal function [10]. Nevertheless, the DiaGene study, including participants with type 2 DM, found that neither the high baseline Lp(a) group (also defined as ≥75 nmol/L) nor 2 related Lp(a) single-nucleotide polymorphisms were significantly related to the risk of incident nephropathy [9]. Inconsistent findings have also been reported in several Mendelian randomization studies. For instance, the study by Zheng et al [14] supported the causal role of Lp(a) in CKD development, while another study did not detect a significant association between Lp(a) and the risk of nephropathy [13]. These discrepant findings may partly be due to the heterogeneity of the target populations, outcome definitions, and statistical analyses. Although some previous studies adjusted for renal function indicators as covariates in their models [7-10,12], the relationship between Lp(a) and CKD risk was indeed assessed based on the average level of renal function in their populations. Thus, previous studies found different associations between Lp(a) and the risk of CKD, probably depending on the various average levels of renal function at baseline.

By contrast, we found a significant interaction between Lp(a) and UACR, and more specifically, a synergistic effect between Lp(a) and UACR on the risk of CKD. Interestingly, when the UACR value exceeded 10 mg/g approximately, the relationship between high Lp(a) and CKD risk became significant (Figure 1 and Table S2 in Multimedia Appendix 1), supporting the modification of UACR to the association between Lp(a) and CKD risk. Of note, Lp(a) together with other lipid and lipoprotein concentrations such as LDL particles had been reported to associate with UACR elsewhere, even among participants with a normal UACR range [29-31]. Therefore, it was plausible that UACR could act downstream on the pathway from Lp(a) to CKD. To address this concern, we performed a post hoc mediation analysis using a generalized linear model with 100 bootstrapping times [32,33]. The total effect of Lp(a) on CKD risk was 0.199 (95% CI 0.007-0.399), with the average direct effect of 0.195 (95% CI 0.008-0.373) and the average causal mediation effect through UACR of 0.004 (95% CI –0.005 to 0.014), indicating a nonsignificant mediation effect. This could further support the joint relationship between Lp(a) and UACR regarding CKD risk from a public health perspective.

Nevertheless, why the relationship between Lp(a) and CKD risk depended on UACR remained largely unknown. A possible
mechanism might be that elevated Lp(a) could be linked to increased synthesis of proteins in the liver due to proteinuria [34], where high UACR could be closely associated with proteinuria. There appeared to be an interaction between Lp(a) and hypertension regarding CVD outcomes [35], where hypertension had been reported to be significantly associated with elevated normal UACR [36]. Nevertheless, no significant subgroup effect by the existence of hypertension was found in our subgroup analysis (Figure 2). Of note, evidence from basic science might help explain the interaction. Lp(a) could enhance the expression of adhesion molecules in endothelial cells and aggravate normal endothelial function [37,38]. UACR serves as a common marker of endothelial and kidney function [39], and is reported to be an earlier and greater marker for some kidney outcomes than eGFR [40-42]; therefore, the detrimental effect of Lp(a) on the progression of CKD may be only significantly observed in those with high-normal UACR who had impaired renal function of clearance and self-recovery. However, the underlying mechanisms of the effects of Lp(a) and UACR on CKD risk have not been extensively elucidated, necessitating additional population studies for further exploration and clarification.

In participants aged over 65 years, high-normal UACR groups showed a nonsignificant association with CKD risk (Figure 2), consistent with findings from a large collaborative meta-analysis [19]. Moreover, the relationship between Lp(a) and CKD risk in patients with DM has been extensively investigated, yielding inconsistent results [11]. In our study, among participants with a history of DM, a significant association between Lp(a) and CKD risk was observed in the high-normal UACR group, but not in the low-normal UACR group (Figure 2). Hence, once more, examining the interaction between Lp(a) and UACR concerning CKD risk in participants with DM could contribute to understanding the prior inconclusive results in public health studies, where diverse baseline renal function existed across populations. Nonetheless, it is crucial to approach the results of our subgroup analyses with caution, considering their exploratory nature and their role in generating hypotheses.

CKD has emerged as a significant public health concern, characterized by a widespread prevalence and a substantial global disease burden [43]. The imperative now is to urgently improve early detection and preventive measures for CKD, given the considerable costs associated with therapy and the elevated mortality rates linked to advanced CKD stages [43]. Providing clarity on the role of Lp(a) could contribute significantly to public initiatives focused on preventing and managing the risks associated with CKD. Nevertheless, it is noteworthy that Lp(a) remains unaddressed in existing public health policies or guidelines for CKD [3,15]. It is widely acknowledged that serum Lp(a) levels are predominantly genetically determined, showing no significant associations with environmental or lifestyle factors [44,45]. While certain medications, such as muvalaplin, have shown effectiveness in lowering Lp(a) levels, their safety, tolerability, and cost-effectiveness still lack comprehensive clarity [46-48]. Addressing these uncertainties calls for more extensive and prolonged clinical trials in the future. Hence, there is a particular need for public health interventions, focusing on improving the management of both Lp(a) and UACR, as well as enhancing the accessibility of kidney health therapies. Furthermore, there is a necessity for quantitative assessment to determine the CKD risk attributed to Lp(a) in diverse populations. Such evaluations could strengthen the case for considering Lp(a) in the screening and management protocols for CKD. Similarly, should our findings be externally validated, the incorporation of Lp(a) into strategies could aid in targeting populations at a heightened risk of CKD, thereby bolstering efforts in CKD prevention.

**Strengths**

Our study carries several strengths. First, we leveraged data from a nationwide cohort, providing a substantial amount of information for our analyses. The application of rigorous methodology underpins the validity and robustness of our results. Notably, this study represents the first attempt to explore the connection between Lp(a), UACR, and the risk of CKD. By doing so, we aimed to elucidate the intricate relationship between Lp(a) and CKD risk within the general population, offering valuable insights for CKD risk assessment and prevention. This perspective, grounded in public health, sheds light on the role of Lp(a) and a renal function indicator in shaping strategies for CKD prevention.

**Limitations**

Several limitations should be acknowledged. First, owing to the observational design of our study, it is crucial to recognize that potential bias or confounding effects could not be entirely mitigated, and establishing a causal relationship between Lp(a) and CKD risk was beyond the scope of our investigation. Second, because both Lp(a) and UACR data were gathered at baseline, our analyses could not explore whether Lp(a) serves as a marker for UACR in the context of CKD risk. In addition, our study lacked the capacity to analyze changes in Lp(a) and UACR concerning the risk of CKD. Furthermore, Lp(a) measurements were conducted using a widely available immunoassay method, potentially introducing measurement errors due to the heterogeneity of isofrom size when compared with the gold-standard method used by the Northwest Lipid Metabolism Diabetes Research Laboratory [49]. Similarly, there might be measurement errors for UACR, calculated as the ratio between urinary albumin and creatinine. The assays used for urinary albumin and creatinine involved an immunoturbidimetric method and enzymatic analysis, respectively [50]. As CKD outcomes were determined using records from hospital in-patient data, cancer registries, and death registries, there is a possibility that CKD events were inadequately estimated due to underdiagnosis, misdiagnosis, or incorrect coding, the extent of which remains unknown. In addition, it is important to note that the UK Biobank, from which our participants were drawn, had over 90% (309,923/329,415, 94.08%) of individuals identifying as White. As a result, the generalizability of our study results to other racial groups may be compromised.

**Conclusions**

A notable interaction was identified between Lp(a) and UACR concerning the risk of CKD. This implies that Lp(a) may serve as a risk factor for CKD even when considering the influence of UACR. Our results offer valuable insights into the assessment

https://publichealth.jmir.org/2024/1/e50415
and prevention of CKD, emphasizing the combined role of Lp(a) and UACR from a public health perspective within the general population. This perspective can contribute to enhancing public awareness regarding the management of Lp(a) for the prevention of CKD.

Abstract

Background: The coronavirus disease 2019 (COVID-19) pandemic has negatively affected the social fabric.

Objective: We evaluated the associations between personal social networks and neurological function in people with multiple sclerosis (pwMS) and controls in the prepandemic and pandemic periods.

Methods: During the early pandemic (March-December 2020), 8 cohorts of pwMS and controls completed a questionnaire quantifying the structure and composition of their personal social networks, including the health behaviors of network members. Participants from 3 of the 8 cohorts had additionally completed the questionnaire before the pandemic (2017-2019). We assessed neurological function using 3 interrelated patient-reported outcomes: Patient Determined Disease Steps (PDDS), Multiple Sclerosis Rating Scale-Revised (MSRS-R), and Patient-Reported Outcomes Measurement Information System (PROMIS) Physical Function. We identified the network features associated with neurological function using paired 2-tailed $t$ tests and covariate-adjusted regressions.

Results: In the cross-sectional analysis of the pandemic data from 1130 pwMS and 1250 controls during the pandemic, having a higher percentage of network members with a perceived negative health influence was associated with worse disability in pwMS (MSRS-R: $\beta=2.181$, 95% CI 1.082-3.279; $P<.001$) and poor physical function in controls (PROMIS Physical Function: $\beta=-5.707$, 95% CI $-7.405$ to $-4.010$; $P<.001$). In the longitudinal analysis of 230 pwMS and 136 controls, the networks of all participants contracted, given an increase in constraint (pwMS-prepandemic: mean 52.24, SD 15.81; pwMS-pandemic: mean 56.77, SD 18.91; $P=.006$. Controls-prepandemic: mean 48.07, SD 13.36; controls-pandemic: mean 53.99, SD 16.31; $P=.001$) and a decrease in network size (pwMS-prepandemic: mean 8.02, SD 5.70; pwMS-pandemic: mean 6.63, SD 4.16; $P=.003$. Controls-prepandemic: mean 8.18, SD 4.05; controls-pandemic: mean 6.44, SD 3.92; $P<.001$), effective size (pwMS-prepandemic: mean 3.30, SD 1.59; pwMS-pandemic: mean 2.90, SD 1.50; $P=.007$. Controls-prepandemic: mean 3.85, SD 1.56; controls-pandemic: mean 3.40, SD 1.55; $P=.01$), and maximum degree (pwMS-prepandemic: mean 4.78, SD 1.86; pwMS-pandemic: mean 4.32, SD 1.92; $P=.01$. Controls-prepandemic: mean 5.38, SD 1.94; controls-pandemic: mean 4.55, SD 2.06; $P<.001$). These network changes were not
associated with worsening function. The percentage of kin in the networks of pwMS increased (mean 46.06%, SD 30.34% to mean 54.36%, SD 30.16%; \( P = .003 \)) during the pandemic, a change that was not seen in controls.

**Conclusions:** Our findings suggest that high perceived negative health influence in the network was associated with worse function in all participants during the pandemic. The networks of all participants became tighter knit, and the percentage of kin in the networks of pwMS increased during the pandemic. Despite these perturbations in social connections, network changes from the pre-pandemic to the pandemic period were not associated with worsening function in all participants, suggesting possible resilience.

neurology; neurodegenerative disease; multiple sclerosis; personal networks; COVID-19

**Introduction**

**Background**

Multiple sclerosis (MS) is a chronic autoimmune disease affecting the central nervous system, leading to neurodegeneration and neurological disability [1,2]. Despite notable advancement in elucidating the factors influencing MS susceptibility, the mechanisms underlying disability accumulation are less well defined [3]. In addition to genetic predisposition, modifiable environmental factors such as personal networks play a key role in shaping health outcomes for people living with neurological diseases [4].

Personal social network features can affect the health outcomes of people living with neurological diseases, including stroke, traumatic brain injury, and MS [5-8]. In people with MS (pwMS), advantageous personal network structures (e.g., larger network size and more diffuse connections among network members) are associated with better language function and larger regional brain volume [9]. Conversely, adverse personal networks are associated with increased social isolation and loneliness, which may in turn exert direct biological effects by altering inflammation, recovery from injury, and resilience against neurodegeneration [10-18].

Our prior research implicates personal social networks as a potentially modifiable environmental contributor to neurological disability in pwMS [19,20]. Importantly, the vulnerability of pwMS to social isolation and loneliness exacerbated during the coronavirus disease 2019 (COVID-19) pandemic [21,22]. Physical distancing measures, stay-at-home orders, and travel restrictions imposed during the pandemic led to the contraction of personal social networks, increased social isolation and loneliness, excessive reliance on virtual communication, and alterations in the frequency and nature of social interactions [23-28]. Understanding how personal social network structure (e.g., network size and density) and composition (e.g., demographics and health behaviors of the network members) changed during the pandemic and assessing the impact of these changes on disability accumulation in MS could potentially inform novel interventions that may improve the quality of life and health outcomes for pwMS.

**Objectives**

In this study, we compared the personal social networks of pwMS and controls during the COVID-19 pandemic and identified network features associated with increased disability accumulation. Further, we examined changes in personal social networks due to the COVID-19 pandemic in a subset of individuals with prepandemic data.

**Methods**

**Study Cohort**

During the pandemic, the multicenter Multiple Sclerosis Resilience to COVID-19 (MSReCOV) Collaborative recruited new pwMS and healthy controls through the University of Pittsburgh Medical Center (UPMC), Columbia University Irving Medical Center (CUIMC), University of Buffalo Medical Center, University of Pennsylvania, and Yale University [29-32]. In addition, pwMS and controls were recruited from 2 existing clinic-based cohorts (one at UPMC and another at CUIMC) and from a national cohort of first-degree relatives of pwMS (Genes and Environment in Multiple Sclerosis [GEMS] study) [33-38]. The inclusion criteria were adults aged \( \geq \) 18 years either with or without a neurologist-confirmed diagnosis of MS.

For the cross-sectional analysis, we included pwMS and healthy controls from the MSReCOV study as well as 3 previously established cohorts (clinic cohorts at UPMC and CUIMC as well as the GEMS cohort). We deployed a modified personal network (PERSNET) questionnaire (Multimedia Appendix 1) between March 2020 and December 2020 to assess demographic, clinical, and personal social network features through a secure web-based platform (REDCap [Research Electronic Data Capture]) [39].

For the longitudinal analysis, we leveraged PERSNET data collected before the COVID-19 pandemic (2017-2019) from the 3 existing cohorts (clinic cohorts at UPMC and CUIMC as well as the GEMS cohort) for comparison with the early pandemic data in the same participants (Figure 1A) [20].
Figure 1. Overview of study design. (A) Schematic illustration of study populations and survey data collection using REDCap (Research Electronic Data Capture). (B) Personal social network features as exposure, as illustrated by a representative network of a hypothetical participant. (C) Patient-reported outcomes of neurological disability or physical function.

Ethical Considerations
The institutional review board of each enrolling site approved the study (UPMC: STUDY21100060 and STUDY20040160; CUIMC: AAAS9668; University of Buffalo Medical Center: MOD00008107; University of Pennsylvania: 843454; and Yale University: HIC 200027987). All participants provided informed consent. Participants completed the survey anonymously through a secure privacy-compliant platform [39]. Participation was voluntary. To ensure confidentiality, deidentified data were used for analysis. The study did not provide compensation for survey completion.

Personal Network Metrics
We deployed an updated version of the PERSNET survey, adapted from the foundational General Social Survey [5-7,19,20,40]. In the PERSNET survey, participants identified individuals in their personal social network with whom they discuss personal matters or socialize or from whom they derive social support. These individuals could have any professional or personal relationship with the participant (e.g., coworker, parent, sibling, spouse, or child). We assessed the structure and composition of each participant’s network [41,42].

Network structure includes 6 quantitative features: size (number of individuals in the network, excluding the index person), density (sum of ties, excluding the index person’s ties, divided by all possible ties), constraint (a more granular density that assesses the extent to which the index person is connected to individuals who are connected to one another), effective size (number of nonredundant network members), and maximum degree and mean degree (highest and average number of ties, respectively, belonging to a network member).

Network composition quantifies the demographic characteristics and health behaviors of network members. Network demographics include the percentage of kin (percentage of network members who are family), SD of age (age range of network members), diversity of sex (proportion of sexes from 0 to 1, where 0 indicates a single sex and 1 indicates an equal ratio of men and women), and diversity of race (similar proportion of represented races, where 0 indicates a single race). Network health behaviors include the percentage of network members who smoke, consume alcohol, exhibit poor dietary habits, lead sedentary lifestyles, and exert perceived negative health influence. Other network composition features include the frequency, duration, and the living distance of network member from the index person, which quantify the depth of the relationships. Compositional features account for network size.

Neurological Outcomes
To assess the status of neurological function, we used 3 interrelated patient-reported outcomes (PROs). The Patient Determined Disease Steps (PDDS) scale indicates the extent of gait impairment and correlates with the clinician-determined Expanded Disability Status Scale (EDSS). PDDS scores range from 0 to 8, where 0 corresponds to normal, and 8 indicates bedbound status [43]. The Multiple Sclerosis Rating Scale-Revised (MSRS-R) assesses the global neurological symptom burden, including walking, function in the extremities, vision, speech, swallowing, cognition, sensation, bladder function, and bowel function [44,45]. Each symptom domain score ranges from 0 to 4, where 0 indicates no impairment, and 4 indicates severe impairment. Higher cumulative MSRS-R scores (0-32) indicate greater neurological symptom burden and worse neurological function. Patient-Reported Outcomes Measurement Information System (PROMIS) Physical Function (version 1.2) is a generalizable measure of physical function also validated for pwMS [46,47]. PROMIS Physical Function is reported as a normally distributed T-score on a scale ranging from 0 to 100, where 50 represents the average for the US population and higher scores indicate better function. Whereas PDDS and MSRS-R are specific for pwMS, PROMIS is applicable to both pwMS and controls. All participants completed PRO assessment when completing the PERSNET survey during the pandemic, whereas a subset also completed the PROs before the pandemic.

Covariates
We considered the following confounding factors that could potentially influence neurological function: age, sex, race, ethnicity, disease duration, employment, education, occupation, income, marital status, and cohabitant status. Race was categorized as African or African American, American Indian or Alaska Native or Native Hawaiian or other Pacific Islander, Asian, White, multiracial, or other. Ethnicity was categorized as Hispanic (or Latinx) and non-Hispanic. Because of the
relatively small number of racial and ethnic minority participants in our cohorts, race and ethnicity were dichotomized as non-Hispanic White versus otherwise (encompassing individuals of Hispanic and non-European descent) in subsequent analyses. Disease duration was defined as the time from the first self-reported neurological symptom onset to the time of the most recent PRO assessment. Employment status was categorized as employed for wages, self-employed, out of work and looking for work, out of work but not currently looking for work, homemaker, student, military, retired, or unable to work. Education level was classified based on the highest level of education achieved: some high school or less, high school graduate, some college, associate degree, bachelor’s degree, or graduate degree. Occupation was categorized as business owner, executive or manager, professional, sales or clerical worker, service worker, or other. Annual household income level included the following brackets: ≤US $19,999, US $20,000 to US $34,999, US $35,000 to US $49,999, US $50,000 to US $64,999, US $65,000 to US $79,999, US $80,000 to US $94,999, US $95,000 to US $109,999, US $110,000 to US $124,999, and ≥US $125,000. Marital status was categorized as married or unmarried. Cohabitation status was categorized as living alone versus otherwise. In the subset with prepandemic data, the time elapsed between prepandemic and pandemic PERSNET assessments ranged from 1 to 4 years. Some covariates were missing because certain questions (e.g., employment status, income) in the PERSNET survey were made optional to reduce patient discomfort when completing the questionnaire.

To select the informative covariates, we examined the correlation between these features and PROs in univariate analyses (Figure S1 in Multimedia Appendix 2). We included features that met the following predefined criteria as covariates for downstream analyses: feature presence in >70% of pwMS, a Pearson correlation coefficient of ≥0.1, and a nominal statistical significance (P < .05) in association with all 3 PROs. We identified age, disease duration, employment, and income as meeting the criteria and adjusted these covariates in regression models involving pwMS. For analyses involving controls, we adjusted for age, employment, and income but not disease duration because it does not apply to controls. For the longitudinal analyses, we further adjusted for the time elapsed between prepandemic and pandemic PERSNET assessments as well as study cohort as additional covariates for consistency with our previous analysis [19,20].

Statistical Analysis
We performed two types of analyses: (1) cross-sectional comparison between pwMS and controls during the COVID-19 pandemic and (2) longitudinal analysis of pwMS and controls during the COVID-19 pandemic when compared to their prepandemic baseline.

For the cross-sectional analysis, we first compared the personal networks of pwMS and controls using paired 2-tailed t tests. Next, we examined the association between network features (structure and composition) and PROs in pwMS in covariate-adjusted regression models. Given that the PROMIS Physical Function measure is generalizable across health and disease, we further assessed the association between network features and PROMIS Physical Function scores in controls for comparison. In a joint analysis of the pandemic data that include both pwMS and controls, we performed a moderation analysis to assess whether having an MS diagnosis influenced the association between network features and PROMIS Physical Function scores [48-50].

For the longitudinal analysis, we examined the within-subject differences in network features in pwMS and controls during the pandemic when compared to the most proximal prepandemic baseline (i.e., the closest value before the pandemic as baseline) using paired t tests. Next, we assessed the association of change in network features (i.e., pandemic value minus prepandemic baseline) in relation to the latest available PROs (during the pandemic) in pwMS using covariate-adjusted regressions and an omnibus test [20,38]. For the omnibus test, we combined the P values derived from the covariate-adjusted regressions for each PRO. Using the Fisher combined probability test, we calculated the chi-squared statistic and compared the observed values with the expected empirical distribution. To further interrogate these relationships, we generated a quantile-quantile (Q-Q) plot of the observed versus expected P values of the associations between the longitudinal changes in each network feature (pandemic value minus prepandemic baseline) and each PRO (the latest available score during the pandemic). The 95% CIs of the Q-Q plot were obtained from the empirical P value distribution generated by 10,000 permutations of the null hypothesis. We used 10,000 permutations, given the large number of network features and the sample size [19,20]. We performed similar longitudinal analysis in controls using PROMIS Physical Function for comparison. Raw P values were adjusted by Bonferroni correction for multiple comparisons. All statistical analyses were performed using R software (version 3.6.0) [51].

The code for this project is available on GitHub [52].

Results
Participant Characteristics
The cross-sectional analysis included 1130 pwMS (age: mean 50.7, SD 12.1 y) and 1250 controls (age: mean 44.3, SD 12.1 y; Table 1). Participants were predominantly women (pwMS: 925/1130, 81.86%; controls: 960/1250, 76.80%) and non-Hispanic White (pwMS: 1043/1130, 92.30%; controls: 1208/1250, 96.64%), pwMS were less likely to be employed (544/1130, 48.14%) than controls (876/1250, 70.08%). The disability burden among pwMS was mild to moderate (PDDS score: mean 1.85, SD 2.12; MSRS-R score: mean 7.55, SD 5.49; PROMIS Physical Function score: mean 46.4, SD 10.82).

The longitudinal analysis included 230 pwMS and 136 controls. Similar to the cross-sectional analysis, controls were younger (age: mean 50.4, SD 11.7 y for pwMS and mean 43.1, SD 12.6 y for controls), had higher levels of education (163/225, 72.4% of pwMS and 103/114, 90.4% of controls completed college) and employment (pwMS: 98/223, 43.9%; controls: 81/114, 71.1%), and had higher annual household income than pwMS.

### Cross-Sectional Analysis of the Pandemic Period

First, we compared the network features of pwMS and controls during the COVID-19 pandemic (Table 2). In this unadjusted analysis, pwMS had higher density, higher constraint, smaller effective size, a higher percentage of kin, a lower percentage of people known for <6 years, lower percentage of network members who live >15 miles (>24 km) away, and lower percentage of network members who drink in their social networks when compared to controls. pwMS and controls reported similarly high percentages of their network members with a perceived negative health influence (pwMS: mean 36.16%, SD 30.43%; controls: mean 36.34%, SD 30.16%).

a pwMS: people with multiple sclerosis.

b Italicized P values met the significance threshold (P<.002; α=.05, corrected for 18 comparisons).

Next, we examined the association between each structural and compositional network feature in relation to PDDS, MSRS-R, and PROMIS Physical Function scores in pwMS during the pandemic, after adjusting for age, disease duration, employment, and income in linear regression models (Table 3). pwMS who had a higher percentage of network members with a perceived negative health influence had higher MSRS-R scores, indicating greater MS symptom burden and disability (β=2.181, 95% CI 1.082-3.279; P<.001). None of the specific network health behavior features (e.g., smoking, alcohol use, bad diet, and sedentary lifestyle) that might be construed as a negative health influence showed a statistically significant association with MSRS-R scores. No other network feature had a significant association with any of the PROs after Bonferroni correction.
Table 3. Cross-sectional analysis of personal social network features in relation to patient-reported outcomes in people with multiple sclerosis during the COVID-19 pandemic.

aPDSS: Patient Determined Disease Steps.
bMSRS-R: Multiple Sclerosis Rating Scale-Revised.
cPROMIS: Patient-Reported Outcomes Measurement Information System.
dThe smaller sample size in this analysis when compared to the overall cohort size was due to the requirement for participants who had complete data elements for network feature, neurological outcome, and all covariates.
Adjusted for potential confounders (as identified in Figure S1 in Multimedia Appendix 2), including age, disease duration, employment, and income.

Italicized $P$ value met the significance threshold ($P<.00092; \alpha=.05$, corrected for 54 comparisons).

For comparison, we examined the association between each network feature and PROMIS Physical Function scores during the pandemic in controls (Table S2 in Multimedia Appendix 2). We adjusted for age, employment, and income, whereas disease duration was not applicable for controls. We found that a lower maximum degree ($\beta=0.383$, 95% CI 0.141-0.626; $P=.002$), a higher percentage of network members who smoke ($\beta=-4.846$, 95% CI $-7.919$ to $-1.774$; $P=.002$), and a higher percentage of network members with a perceived negative health influence ($\beta=-5.707$, 95% CI $-7.405$ to $-4.010$; $P<.001$) were associated with lower PROMIS Physical Function scores (worse physical function) in controls. Given that the percentage of network members with a perceived negative health influence was associated with MSRS-R scores in pwMS and with PROMIS Physical Function scores in controls, respectively, this important compositional network feature that assesses the perception of negative health influences in the personal social network may contribute to physical impairment in both pwMS and controls.

Moderation Analysis Assessing the Role of Having an MS Diagnosis

We performed a moderation analysis to examine whether having an MS diagnosis influences the strength and direction of the association between network features and PROMIS Physical Function score during the COVID-19 pandemic (Figure 2A, Table S4 in Multimedia Appendix 2). In this joint analysis combining pwMS and controls, an MS diagnosis moderated the direction and strength of the association between several network features (diversity of race, percentage of network members who live $>15$ miles [$>24$ km] away, percentage of network members who drink, and percentage of network members with a perceived negative health influence) and PROMIS Physical Function score. For diversity of race, the moderating effect of an MS diagnosis was marginally significant ($\beta=-5.878$, 95% CI $-10.889$ to $-0.868$; $P=.02$) such that this network feature was not significantly associated with physical function in either pwMS (slope=$-2.968$, 95% CI $-6.893$ to 0.956; $P=.14$) or controls (slope=$2.910$, 95% CI $-0.224$ to 6.044; $P=.07$; Figure 2B). Having a higher percentage of network members who live $>15$ miles ($>24$ km) away was associated with worse physical function in pwMS (slope=$3.890$, 95% CI 1.852-5.928; $P<.001$) but not in controls (slope=$-0.772$, 95% CI $-2.765$ to 1.221; $P=.45$; Figure 2C), given the moderating effect of an MS diagnosis. Similarly, having a higher percentage of network members who drink was associated with worse physical function in pwMS (slope=$3.716$, 95% CI 1.392-6.039; $P=.002$) but again not in controls (slope=$-0.982$, 95% CI $-2.966$ to 1.003; $P=.33$; Figure 2D). For percentage of network members with a perceived negative health influence, both groups exhibited the same direction of association with physical function, but pwMS had a smaller magnitude of the association (slope=$-2.174$, 95% CI $-4.019$ to $-0.329$; $P=.02$) than controls (slope=$-6.601$, 95% CI $-8.494$ to $-4.708$; $P<.001$; Figure 2E).
Figure 2. Role of multiple sclerosis (MS) diagnosis in moderating the association between personal social network features and Patient-Reported Outcomes Measurement Information System (PROMIS) Physical Function scores in people with MS (pwMS) and controls. (A) In a moderation analysis, we examined the association between each network feature and PROMIS Physical Function after combining the data from pwMS and controls and after adjusting for age, employment, and income as covariates and further investigated whether having an MS diagnosis moderated the direction or strength of this association. An MS diagnosis moderated the direction of the association between (B) diversity of race, (C) percentage who live >15 miles (>24 km) away, and (D) percentage who drink and PROMIS Physical Function, as well as the strength of the association between (E) percentage of people with a perceived negative health influence and PROMIS Physical Function. Values on x-axis indicate the 25th, 50th, 75th percentile.
Longitudinal Analysis Comparing the Pandemic Period With the Prepandemic Baseline

We conducted a longitudinal analysis using a subset of pwMS and controls who completed the PERSNET survey both before and during the pandemic. During the pandemic, both pwMS and controls reported a lower percentage of people contacted weekly when compared to the prepandemic baseline (decrease from mean 23.48%, SD 24.95% to mean 14.89%, SD 24.95% for pwMS, \( P < .001 \); decrease from mean 30.34%, SD 26.35% to mean 18.78%, SD 22.2% for controls, \( P < .001 \)), reflecting the widespread social isolation during the pandemic (Table 4). When compared to the prepandemic baseline in both pwMS and controls, there was a reduction in network size (pwMS-prepandemic: mean 8.02, SD 5.70; pwMS-pandemic: mean 6.63, SD 4.16; \( P = .003 \); Controls-prepandemic: mean 8.18, SD 4.05; controls-pandemic: mean 6.44, SD 3.92; \( P < .001 \)), effective size (pwMS-prepandemic: mean 3.30, SD 1.59; pwMS-pandemic: mean 2.90, SD 1.50; \( P = .007 \); Controls-prepandemic: mean 3.85, SD 1.56; controls-pandemic: mean 3.40, SD 1.55; \( P = .01 \)), and maximum degree (pwMS-prepandemic: mean 4.78, SD 1.86; pwMS-pandemic: mean 4.32, SD 1.92; \( P = .01 \)). Controls-prepandemic: mean 5.38, SD 1.94; controls-pandemic: mean 4.55, SD 2.06; \( P < .001 \)), as well as an increase in constraint (pwMS-prepandemic: mean 52.24, SD 15.81; pwMS-pandemic: mean 56.77, SD 18.91; \( P = .006 \); Controls-prepandemic: mean 48.07, SD 13.36; controls-pandemic: mean 53.99, SD 16.31; \( P = .001 \)). These findings indicate contraction in personal social networks for both pwMS and controls during the pandemic period. There was an increase in the percentage of kin (from mean 46.06%, SD 29.34% to mean 54.36%, SD 30.16%; \( P = .003 \)) in the networks of pwMS during the pandemic, which was not seen in controls.

Finally, we examined whether changes in network features due to the pandemic (i.e., pandemic value minus the most proximal prepandemic baseline) in pwMS were associated with the PROs during the pandemic (Figure 3). We found no significant association between changes in network features and the latest available pandemic PROs. As a confirmation of these findings, there was no difference between the observed and expected distribution of the \( P \) values of association between changes in network features and pandemic PROs in the permuted omnibus test (PDDS: \( P = .88 \), MSRS-R: \( P = .29 \), and PROMIS Physical Function: \( P = .28 \)).

<sup>b</sup>pwMS: people with multiple sclerosis.
Figure 3. Quantile-quantile plots demonstrating longitudinal changes in personal social network features (due to the COVID-19 pandemic) in relation to patient-reported outcomes during the pandemic in people with multiple sclerosis. Comparison of observed and expected associations between the difference in each quantitative structural and compositional personal social network feature (pandemic value minus prepandemic baseline) in relation to each of the 3 measures of neurological and physical function status—(A) Patient Determined Disease Steps (PDDS), (B) Multiple Sclerosis Rating Scale-Revised (MSRS-R), and (C) Patient-Reported Outcomes Measurement Information System (PROMIS) Physical Function—during the pandemic in people with multiple sclerosis after adjusting for age, disease duration, employment, income, study cohort, and time lapse between prepandemic and pandemic personal network questionnaire (PERSNET) survey assessments. Expected \( P \) values (–log10 \( P \) value) were plotted on the x-axis and observed \( P \) values (–log10 \( P \) value) on the y-axis. The gray area encompasses the 95% CIs. Points outside the gray area were considered statistically significant without adjustment for multiple comparisons.

Discussion

Principal Findings

Our quantitative assessment of the personal social network environment of pwMS during the early COVID-19 pandemic has several key findings. First, a higher percentage of network members with a perceived negative health influence was associated with greater neurological symptom burden in pwMS and worse physical function in controls during the pandemic, validating our prepandemic findings and suggesting a shared contribution of this important social environmental feature toward physical function in pwMS and controls. The magnitude of this association was larger in controls than in pwMS. Second, the personal social networks of pwMS and controls both experienced contraction during the COVID-19 pandemic when compared to the prepandemic baseline, and the personal networks of pwMS comprised a higher percentage of kin than those of controls during the pandemic. The percentage of people contacted weekly or less also decreased for both pwMS and controls, suggesting increased social isolation overall. Finally, changes in personal network features related to the COVID-19 pandemic (when compared to the prepandemic baseline) in pwMS were not associated with worsening disability during the pandemic, suggesting an element of neurological resilience despite the significant perturbation in social environment and connections.

Our study design has several novel aspects. First, this is the first known direct comparison of the personal social networks of pwMS and controls during the height of the COVID-19 pandemic when public health measures enacted to reduce contagion were widespread. Second, this is the first effort to longitudinally quantify changes in the personal networks of pwMS and controls due to the pandemic. Third, this study evaluated the differential impact of having an MS diagnosis on the associations between personal social network features and clinical outcomes in terms of both strength and directionality. Finally, this largest cross-sectional and longitudinal quantitative examination of the association of personal networks in relation to neurological and physical functions (not just in pwMS) explored the potential of neurological resilience secondary to social perturbation in the setting of the COVID-19 pandemic.

The finding of the association between a higher percentage of network members with a perceived negative health influence and worse neurological disability in pwMS and worse physical function in controls during the COVID-19 pandemic validated our prior findings from the prepandemic period [20]. These findings are unlikely to be spurious, given the relatively high proportion of participants (both pwMS and controls) whose network members have a perceived negative health influence. We hypothesize that having a higher percentage of network members with a perceived negative health influence in one’s social network could indicate low perceived social support and negative illness perception, which are both associated with worse psychosocial and health outcomes [53-59]. Moreover, this may decrease an individual’s likelihood of engaging in healthy behaviors (e.g., minimal alcohol consumption, abstinence from smoking, regular exercise, healthy diet, and medication adherence) that may reduce overall comorbidities, MS-related disease activity, and neurological disability accumulation.

During the pandemic, the personal social networks of both pwMS and controls contracted when compared to the prepandemic period, as indicated by the decrease in network size, effective size, and maximum degree. Although changes in the density of the personal social networks were minimal, constraint increased in both pwMS and controls, providing...
further evidence for network contraction. The contraction of personal social networks was driven by the pruning of weak ties in the social network. In our analysis, the strength of the ties was quantified by assessing the frequency of interaction (percentage contacted weekly or less), the duration of contact (percentage known for <6 y), and the proximity (percentage who live >15 miles [<24 km] away) of network members. Although there was no change in the duration of contact or the proximity of network members for both pwMS and controls, there was a statistically significant decrease in the frequency of contact (percentage contacted weekly or less) in both groups. The reduction in the network size and frequency of contact suggests that both pwMS and control participants interacted less with weak ties in their network based on our method of assessment of tie strength. In the context of the early COVID-19 pandemic, it is conceivable that all participants kept their social circles tight knit and interacted predominantly with close contacts to minimize potential COVID-19 exposure.

The previously reported association between tightly knit personal social networks and worse physical function was not observed in this study [20]. We postulate several explanations. First, the contraction of social networks in pwMS as well as controls during the pandemic when compared to the prepandemic baseline is likely attributable to public health measures aiming to prevent the spread of COVID-19. Personal social networks contracted and became tighter knit among pwMS during the pandemic, whereas there was greater diversity (e.g., higher effective network size and lower constraint) in the personal networks of pwMS before the pandemic. In our prior cross-sectional study, the direction of the association between network features and physical function could not be fully determined [20]. It is possible that pwMS with better neurological and physical function might have had more diverse personal social networks before the pandemic, but the overall contraction of social networks during the pandemic among pwMS might have masked the association between tightly knit networks and worse physical function. Future longitudinal analyses examining the change in network features from the pandemic period to the postpandemic period may provide insight if the network diversity reverts to the prepandemic baseline versus if the new baseline persists. Second, because the contraction of personal social networks during the pandemic was a relatively recent (as of the data collection) effect and the pandemic, there may not have been sufficient time for the onset of observable changes in neurological function. An assessment of neurological function at future time points could inform the long-term impact of social network changes due to the pandemic. Finally, the lack of an association between tight-knit personal networks and physical function suggests potential resilience of pwMS in coping with social changes attributable to the pandemic [57-60]. Although having tight-knit networks is typically associated with negative health outcomes, tight-knit networks may be advantageous in the context of minimizing COVID-19 exposures. In pwMS, these tight-knit networks saw an increase in the percentage of kin, which was not seen in controls. Having the support of kin could potentially help preserve neurological function in pwMS (e.g., family members help patients to get to clinic or rehabilitation visits or increase medication adherence). The differential impact of the COVID-19 pandemic and social isolation policies may have led pwMS to minimize social contact and restrict themselves to their tight-knit circle, given their higher risk of severe manifestations of COVID-19 [29-32].

The moderation analysis examined the interacting effect of having an MS diagnosis on the association between personal social networks and PROs in a joint analysis of pwMS and controls. An MS diagnosis moderated the association between specific personal social network features and physical function with respect to the direction (i.e., diversity of race, percentage of people who live >15 miles [<24 km] away, and percentage of people who drink) or strength (i.e., percentage of people with a perceived negative health influence) of the associations. Some of the differences in the results between the moderation analysis and the cross-sectional analysis for pwMS could be due to the inclusion of an MS diagnosis as a moderator variable (affecting the strength and direction of the association between network features and PROs) and inability to adjust for disease duration in this joint analysis because this covariate is not applicable for controls. Notably, a lower percentage of people who live >15 miles (>24 km) away and a lower percentage of people who drink within the personal networks of pwMS (but not controls) were each associated with worse physical function. pwMS with low physical function may need more support, which may explain their personal networks comprising a low percentage of people who live far away and a high proportion of kin who are more likely to live in the same household or in the vicinity. pwMS with low physical function may also be more inclined to seek out individuals whose healthy behaviors (e.g., minimal alcohol consumption) could have a positive health influence. The association between a higher percentage of people with a perceived negative health influence and worse physical function in pwMS (and controls) persisted. Interestingly, having higher perceived negative health influences had more of an impact on physical function in controls than in pwMS. We hypothesize that this effect is weaker in pwMS due to the likely resilience of pwMS, given their experience with a chronic neurological disease and having support from tight-knit circles, especially during the pandemic [60-63]. As pwMS have tight-knit networks with a high percentage of kin, it is conceivable that they have better support systems than controls. Interventions that empower individuals with the knowledge, skills, and support to effectively reduce the impact of perceived negative health influences (e.g., education on stress management and coping strategies) may be beneficial in the general population.

Strengths and Limitations
This study has several strengths. First, the longitudinal analysis of changes in personal social networks due to the pandemic in comparison with the prepandemic baseline had a within-subject design. Consequently, we postulated that changes in network features suggestive of personal network contraction in the same participants during the pandemic (compared to their prepandemic baseline) is likely attributable to the pandemic, possibly because of the necessary public health measures. Second, we used three independent but interrelated PROs as a pragmatic method to assess the real-world status of neurological disability and physical function during the early pandemic period when clinical research participation became severely restricted.
These validated PROs, two specifically for MS and one generalizable across health and disease, have shown strong correlations with physician-rated measures of neurological function (e.g., EDSS) in prior studies [43-47]. Third, we conducted both cross-sectional and longitudinal analyses in not only pwMS but also in controls, which enabled a comparison of the differential impact of the pandemic on their personal social networks. Fourth, the moderation analysis examining the role of having an MS diagnosis on the association between network features and physical function enabled an exploration of the strength and directionality of these complex relationships. Finally, we leveraged a large multicenter data set representative of the northeastern and mid-Atlantic regions of the United States with greater geographic diversity than prior studies, potentially increasing the generalizability of the study findings.

Our study also has limitations. First, the direction of the association between the percentage of people with a perceived negative health influence and physical function cannot be determined because we cannot infer causality. Therefore, it is possible that participants with greater disability or worse physical function could perceive that their personal network members exert a negative health influence. Conversely, participants with a higher percentage of network members with a perceived negative health influence could have greater disability or worse physical function. This limitation could be addressed by testing causality in future intervention studies. For example, in persons with a high percentage of people with a negative influence in the personal social network, we can compare the efficacy of interventions engaging the social network of the index person (e.g., providing closer monitoring of medication adherence and more encouragement to promote healthy behaviors) against the standard of care. Second, we did not assess the health status of network members as perceived by the index participant (e.g., if a network member was in bad or good health) or examine the association between the health status of the index participant and the perceived health status of their network members. This limitation could be addressed by incorporating relevant questions in future versions of the PERSNET survey. Third, the sample size of the longitudinal analysis was limited by the relatively modest number of participants with available quantified prepandemic personal networks as baseline. As such, the study did not have sufficient power for subgroup analysis stratified by demographic or clinical subtypes. Last, we sampled participants’ personal networks and neurological and functional status at one time point during the COVID-19 pandemic. The COVID-19 cases varied across areas and throughout the pandemic, whereas participants resided in urban, suburban, and rural environments that were differentially affected during the pandemic. Nevertheless, most of the study populations shared broader geographic regions (northeastern and mid-Atlantic United States) and completed the study response during the early period of the pandemic when federal- and state-level mandates were relatively uniform in terms of stay-at-home orders, physical distancing, and other mitigation guidelines.

Conclusions
In conclusion, this study highlights the impact of the COVID-19 pandemic on personal social networks in pwMS and controls. Our findings generate important hypotheses for testing future interventions that may modify personal social networks to improve health outcomes. Future longitudinal studies examining the long-term impact of the COVID-19 pandemic on the evolution of personal social networks and neurological outcomes in people with chronic neurological disorders such as MS are warranted.

Abstract

Background: Visceral adipose tissue plays an active role in the pathogenesis of type 2 diabetes and vascular dysfunction. The lipid accumulation product (LAP), visceral adiposity index (VAI), and Chinese VAI (CVAI) have been proposed as simple and validated surrogate indices for measuring visceral adipose tissue. However, the evidence from prospective studies on the associations between these novel indices of visceral obesity and diabetic retinopathy (DR) remains scant.

Objective: This study aimed to investigate the longitudinal associations of LAP, VAI, and CVAI with incident DR in Chinese patients with diabetes.

Methods: This was a prospective cohort study conducted in Guangzhou in southern China. We collected baseline data between November 2017 and July 2020, while on-site follow-up visits were conducted annually until January 2022. The study participants consisted of 1403 patients with a clinical diagnosis of diabetes, referred from primary care, who were free of DR at baseline. The LAP, VAI, and CVAI levels were calculated by sex-specific equations based on anthropometric and biochemical parameters. DR was assessed using 7-field color stereoscopic fundus photographs and graded according to the modified Airlie House Classification scheme. Time-dependent Cox proportional hazard models were constructed to estimate the hazard ratios with 95% CIs. Restricted cubic spline curves were fitted to examine the dose-response relationship between the 3 indices of visceral obesity and diabetic retinopathy (DR) remains scant.

Results: The mean age of study participants was 64.5 (SD 7.6) years, and over half (816/1403, 58.2%) were female. During a median follow-up of 2.13 years, 406 DR events were observed. A 1-SD increment in LAP, VAI, or CVAI was consistently associated with increased risk for new-onset DR, with a multivariable-adjusted hazard ratio of 1.24 (95% CI 1.09-1.41; \( P=0.001 \)), 1.22 (95% CI 1.09-1.36; \( P<0.001 \)), and 1.48 (95% CI 1.19-1.85; \( P=0.001 \)), respectively. Similar patterns were observed across tertiles in LAP (\( P \) for trend=.001), VAI (\( P \) for trend<.001), and CVAI (\( P \) for trend=.009). Patients in the highest tertile of LAP,
VAI, and CVAI had an 84%, 86%, and 82% higher hazard of DR, respectively, compared to those in the lowest tertile. A nonlinear dose-response relationship with incident DR was noted for LAP and VAI (both $P$ for nonlinearity<.05), but not for CVAI ($P$ for nonlinearity=.51). We did not detect the presence of effect modification by age, sex, duration of diabetes, BMI, or comorbidity (all $P$ for interaction>.10).

Conclusions: Visceral obesity, as measured by LAP, VAI, or CVAI, is independently associated with increased risk for new-onset DR in Chinese patients with diabetes. Our findings may suggest the necessity of incorporating regular monitoring of visceral obesity indices into routine clinical practice to enhance population-based prevention for DR.

Introduction

Diabetes is an important global public health priority, with an estimated adult prevalence of 10.5% in 2021, rising to 12.2% in 2045 worldwide [1,2]. It poses an enormous threat to health and health care due to the associated mortality, disability, and costly long-term complications [3-5]. As one of the most common microvascular complications, diabetic retinopathy (DR) affects more than one-third of patients with diabetes and remains the leading cause of preventable visual impairment and blindness in working-age adults [6-9]. Given the growing prevalence of diabetes on a global scale [2,10], people at risk for DR are projected to increase rapidly over the coming decades [11]. Identifying modifiable risk factors for DR becomes critically imperative to inform clinical practice and public health recommendations in the context of addressing the ongoing epidemic of DR [12,13].

Observational epidemiologic studies have suggested hyperglycemia and hypertension as major risk factors for DR [6,14]; whereas clinical trial data demonstrated that stand-alone intensive control of blood glucose and blood pressure (BP) might not suffice to significantly reduce DR risk [15]. Meanwhile, genetic data show that the development of type 2 diabetes and obesity share environmental exposures and mechanisms [16]. Despite the established relationship between obesity and type 2 diabetes [17,18], meta-analyses of the association between overweight or obesity and DR have yielded mixed results [19-21]. Recent studies have reported that the distribution of adipose tissue rather than the total amount of fat is more important in the pathogenesis of insulin resistance, diabetes, and vascular dysfunction [22-25], thereby suggesting that visceral adipose tissue (VAT), in contrast to subcutaneous adipose tissue (SAT), tends to play a greater role in the development of DR. Nevertheless, previous studies mainly focused on generalized adiposity (as defined by the BMI) [26] or simple abdominal adiposity (as defined by waist-to-hip ratio [WHR]) [27,28], instead of more specific visceral adiposity.

At present, computed tomography (CT) and magnetic resonance imaging (MRI) techniques have been regarded as the “gold standard” for direct measurement of VAT [29]. Although the imaging technique has been used in large-scale studies in the West, such as the UK Biobank [30], it is less likely to be routinely adopted owing to its expensiveness and complex procedures [31]. Dual-energy x-ray absorptiometry (DEXA) and bioelectrical impedance analysis (BIA) have been used alternatively in epidemiological surveys [32,33]. However, access to these modalities to assess VAT, on top of the routine measures in clinical practice, may require trained technicians and dedicated facilities, with additional workload on health care in low-resource settings [29].

The lipid accumulation product (LAP), visceral adiposity index (VAI), and Chinese visceral adiposity index (CVAI), which could be easily implemented, have therefore been proposed as surrogate indices of VAT for wider use. The validation of these novel indices, when compared to traditional anthropometric adiposity measures, has demonstrated higher accuracy of visceral obesity discrimination and better prediction of type 2 diabetes [34-38]. However, findings from existing studies, mostly using a cross-sectional design, on associations between these indices of visceral obesity and DR are largely inconsistent [39-41]. More evidence from prospective studies is required to address this area of controversy. Therefore, we aimed to investigate the longitudinal associations of 3 validated visceral obesity indices, that is, LAP, VAI, and CVAI, with incident DR in patients with diabetes.

Methods

Study Design and Participants

This is an ongoing prospective cohort study among Chinese patients with diabetes conducted in Guangzhou in southern China. The study design was reported in detail elsewhere [28,42]. In brief, the participants consisted of primary care patients aged between 30 and 80 years with a clinical diagnosis of type 2 diabetes. All participants were referred through a generalist-specialist alliance consisting of 18 community health centers to a national-leading tertiary hospital specializing in ophthalmology (Zhongshan Ophthalmic Center), where a dilated, comprehensive eye examination was provided free of charge at baseline and at annual follow-up visits. The presence of type 2 diabetes was assessed by the attending primary care physician according to the Chinese Diabetes Society guideline and the World Health Organization recommendation when fasting plasma glucose ≥7.0 mmol/L; 2-hour plasma glucose ≥11.1 mmol/L during a 75-g oral glucose tolerance test; or hemoglobin A1c (HbA1c) ≥6.5% [43,44]. All participants had their HbA1c tested at the Zhongshan Ophthalmic Center to ensure that all enrolled patients who were not on
The indices were calculated based on demographics satisfactory correlations with VAT measured using CT scans LAP, VAI, and CVAI, all of which have demonstrated Visceral obesity was assessed using 3 validated indices, that is, Assessment of Visceral Obesity Indices provided in Multimedia Appendix 1.

Information on the definition and categorization of variables is Epidemiology Collaboration equation for Asians [52]. Detailed rate (eGFR) was calculated using the Chronic Kidney Disease automated, high-performance liquid chromatography system (Cobas 8000, Roche Diagnostics). HbA1c was measured using an automatic biochemistry modular analyzer (Cobas 8000, Roche Diagnostics). Waist circumference (WC) was taken at the midpoint between the lower margin of the last palpable rib and the top of the iliac crest, while hip circumference was measured at the largest circumference around the buttocks, both to the nearest 0.1 cm. Waist-to-height ratio (WHR) was calculated as WC (cm) divided by height (cm). The WHR was calculated as WC (cm) divided by hip circumference (cm). BP was measured in a seated position after a 10-minute rest by routinely validated automatic sphygmomanometers (HEM-907, Omron). The arm with the higher BP values was used. The average of 2 BP readings, 1-2 minutes apart, was recorded. Serum creatinine and lipid profiles, including plasma cholesterol and triglycerides, were directly measured using an automatic biochemistry chromatography system (G8, Sysmex Corporation). The estimated glomerular filtration rate (eGFR) was calculated using the Chronic Kidney Disease Epidemiology Collaboration equation for Asians [52]. Detailed information on the definition and categorization of variables is provided in Multimedia Appendix 1.

Visceral obesity was assessed using 3 validated indices, that is, LAP, VAI, and CVAI, all of which have demonstrated satisfactory correlations with VAT measured using CT scans [34,36]. The indices were calculated based on demographics (sex and age), anthropometrics (BMI and WC), and metabolic parameters (triglycerides and high-density lipoprotein cholesterol). The detailed formulas were described in Multimedia Appendix 1. Given the lack of consensus regarding the optimal cutoff point for identifying visceral obesity and the considerable disparities in the amount of VAT between males and females, the 3 indices were divided into sex-specific tertiles when treated as categorical variables.

Fundus Examination and Grading of DR
All study participants had color stereoscopic fundus photographs of seven standard fields taken in each eye after pupil dilation using a digital retinal camera (Canon CR-2). The photographs were graded at the Zhongshan Ophthalmic Center using the modified Airlie House Classification scheme as adapted for the Early Treatment Diabetic Retinopathy Study (ETDRS) [53]. A total of 2 trained ophthalmic specialists independently graded the fundus photographs, with disagreements (<8%) being resolved by the decision of a senior ophthalmologist. The grading of DR was determined based on the worst eye, ranging from the ETDRS classification levels from 10 to 85, that is, levels 10-20 (no apparent DR), level 35 (mild nonproliferative DR [NPDR]), levels 43-47 (moderate NPDR), level 53 (severe NPDR), and levels 61-85 (proliferative DR) [53]. Incident DR was defined as eyes with no apparent DR at baseline in which any DR was newly diagnosed at follow-up.

A more precise evaluation of retinal pathology in diabetic macular edema (DME) was performed with a swept-source optical coherence tomography device (DRI-OCT Triton, Topcon). The swept-source optical coherence tomography volume was captured in a 3D scan pattern over a 6x6 mm area for all eyes. The presence of DME, which was assessed separately from that of DR, was characterized by retinal thickening or hard exudates in the posterior pole that can develop at any stage of DR [54]. Given that the vision-threatening DR (VTDR) includes severe NPDR, proliferative DR, or DME [55,56], the presence of DME was taken into account in the sensitivity analysis.

Statistical Analysis
The Pearson correlation coefficient was examined for the 3 visceral obesity indices (ie, LAP, VAI, and CVAI) and the conventional obesity measures (ie, BMI, WC, WHtR, and WHR), respectively. Patients enrolled at baseline were followed until they were diagnosed with any DR or the recorded attendance at the most recent follow-up visits until January 2022, whichever came first. The incidence density was reported as the number of outcome events per 100 person-years. Time-dependent Cox proportional hazard models were constructed to explore the associations of LAP, VAI, and CVAI with incident DR at follow-up. The 3 visceral obesity indices and all other covariates, except for sex and education level, were considered time-varying variables in the main analysis. The model construction was described in detail in Multimedia Appendix 1.

Hazard ratios (HRs) with 95% CIs were estimated from the crude and adjusted models. Model 1 was adjusted for sex, age, and duration of diabetes. Model 2 was further adjusted for...
education level, current smoking, regular drinking, BMI, BP, HbA$_{1c}$, low-density lipoprotein cholesterol, eGFR, and use of insulin. Variable selection was determined from our previous knowledge of sociodemographic factors, health-related lifestyles, and anthropometric and biochemical parameters [6,9,14,55]. The proportional hazards assumption for model fit was tested using the scaled Schoenfeld residuals. The variance inflation factors were examined to ensure the absence of multicollinearity (ie, all variance inflation factors <5) in the regression model. We further modeled data as restricted cubic splines (RCSs) with 4 knots, located at the 5th, 35th, 65th, and 95th percentiles following the Akaike information criterion [57] of LAP, VAI, and CVAI, respectively, to assess the shape of the association between the 3 visceral obesity indices and risk of DR. We performed separate Cox regression analyses across patient subgroups according to sex (female vs male); age (<65 vs ≥65 years old); duration of diabetes (<10 vs ≥10 years); BMI (<24 vs ≥24 kg/m$^2$); and the presence of concurrent medical conditions including hypertension (yes vs no), dyslipidemia (yes vs no), and decreased renal function (yes vs no) to investigate the potential effect modifiers. The interaction between visceral obesity and the stratifying variable was explored by inserting a 2-factor interaction term into the regression model.

A series of sensitivity analyses were performed. First, we added the presence of DME to the outcome of interest, which was redefined as new-onset DR or DME at follow-up in patients free of both DR and DME at baseline. Second, we excluded patients who had incident DR within the first year of follow-up to account for the possible reverse causality bias. Third, we estimated HR from the Cox regression models without adjustment for BMI to avoid the plausible bias associated with over-adjustment. Fourth, we incorporated WC as a covariate in the regression model to detect whether the visceral obesity indices may have a role independent of abdominal obesity. We also estimated HR from time-fixed Cox regression models, in which baseline values of LAP, VAI, and CVAI were used to ascertain whether associations between visceral obesity indices and incident DR may vary from the time-dependent main analysis. Analyses were conducted using Stata (version 15.1; StataCorp LLC) and R (version 4.2.2; Core Team). A 2-tailed $P<.05$ was considered statistically significant.

**Ethical Considerations**

Data anonymization was performed by removing all patient identifiers from the data set before data analysis. Ethics approval was granted by the Zhongshan Ophthalmic Center Medical Ethics Committee (2017KYPJ094) at Sun Yat-Sen University as per the Declaration of Helsinki 2013. All participants provided written, informed consent.

**Results**

**Characteristics of Study Participants**

Of the 1403 patients included in the final analysis, slightly over half (816/1403, 58.2%) were female. The mean (SD) age of patients was 64.5 (7.6) years at baseline. The median (IQR) values of LAP, VAI, and CVAI were 48 (29.12-77.22), 2.69 (1.54-4.43), and 118.18 (94.77-141.17), respectively. During a median follow-up period of 2.13 years, we documented 406 new-onset DR events (ie, 289 cases of mild NPDR, 116 cases of moderate NPDR, and 1 case of severe NPDR), with an incidence density of 15.71 per 100 person-years. Patients who experienced new-onset DR at follow-up tended to be female, younger, with a longer duration of diabetes, on insulin, and had higher HbA$_{1c}$ and greater visceral obesity at baseline than their counterparts (Table 1). The correlation matrix showed statistically significant correlations among LAP, VAI, CVAI, BMI, WC, WHtR, and WHR (Table S1 in Multimedia Appendix 1). The sex distribution, duration of diabetes, lifestyle behaviors, comorbidity status, and levels of the majority of anthropometric and biochemical measurements were comparable between patients excluded during follow-up and those included in the final analysis, albeit slightly younger (64.45 vs 65.23 years) and with better glycemic control in the final sample (Table S2 in Multimedia Appendix 1).
Table 1. Baseline characteristics of study participants by incident diabetic retinopathy (DR) at follow-up. The 2-sample t test, Mann-Whitney U test, or chi-square test, where appropriate, was used for between-group comparison.

### Association of Visceral Obesity Indices With Incident DR

A 1-SD increment in LAP, VAI, or CVAI was consistently associated with increased risk for DR, with a multivariable adjusted HR (aHR) of 1.24 (95% CI 1.09-1.41; \( P = .001 \)), 1.22 (95% CI 1.09-1.36; \( P < .001 \)), and 1.48 (95% CI 1.19-1.85; \( P = .001 \)) respectively (Table 2). Similar patterns were observed across tertiles in LAP (\( P \) for trend<.001), VAI (\( P \) for trend<.001), and CVAI (\( P \) for trend=.009). Patients in the highest tertile of LAP, VAI, and CVAI had an 84% (aHR=1.84; 95% CI 1.30-2.62), 86% (aHR=1.86; 95% CI 1.35-2.57), and 82% (aHR=1.82; 95% CI 1.16-2.86) higher hazard of new-onset DR, respectively, compared to those in the lowest tertile (Table 2). A positive, nonlinear dose-response relationship with incident DR was noted for LAP and VAI (both \( P \) for nonlinear trend<.05), but not for CVAI (\( P \) for nonlinear trend=.51; Figure 1).

#### Table 2. Time-dependent Cox proportional hazard models with and without adjustment for covariates. The crude model referred to time-dependent Cox proportional hazard models with no adjustment. Model 1 was adjusted for sex, age, and duration of diabetes. Model 2 was then further adjusted for education level, current smoking, regular drinking, BMI, blood pressure, hemoglobin A1c, serum cholesterol level, estimated glomerular filtration rate, and use of insulin.

\(^d\)N/A: not applicable.
Dose-response relationships were examined using RCS with 4 knots, located at the 5th, 35th, 65th, and 95th percentiles of LAP, VAI, and CVAI, respectively. The solid line represents the fitted curve, and the shaded areas represent the 95% CI bands. Time-dependent Cox proportional hazard models were adjusted for sex, age, duration of diabetes, education level, current smoking, regular drinking, BMI, BP, HbA1c, serum cholesterol level, eGFR, and use of insulin (test for overall trend: LAP P=.001, VAI P<.001, and CVAI P=.006; test for nonlinear trend: LAP P=.048, VAI P=.002, and CVAI P=.51).

Subgroup Analyses

When patients were classified by sex, age, duration of diabetes, BMI, and the presence of concurrent hypertension, dyslipidemia, and decreased renal function, the associations of a 1-SD increment in LAP, VAI, and CVAI with new-onset DR observed in the main analysis remained consistent across all patient subgroups. Multivariable-adjusted Cox models, in which interactions between visceral obesity and the stratifying variables were explored, showed no evidence of effect modification by age, sex, duration of diabetes, BMI, or comorbidity (all P for interaction>.10; Figure 2).

Sensitivity Analyses

Of the 1380 patients with diabetes free of DR and DME at baseline, 414 patients had incident DR or DME at follow-up (ie, 387 cases of DR alone, 16 cases of DME alone, and 11 cases of DR combined with DME). Separate analyses for incident DME (n=27) and VTDR (n=28; including 1 case of severe NPDR) as distinct outcomes were not performed due to the small number of events. The associations of LAP, VAI, and CVAI with incident DR remained unchanged when new-onset DME was added to the outcome of interest or when patients who had new-onset DR within the first year of follow-up were excluded. The strength of associations between visceral obesity indices and incident DR tended to be somewhat attenuated in Cox models without adjustment for BMI; however, the results remained significant (Figure 3).
Sensitivity analysis 1 was performed with time-dependent Cox regression models (n=1380), in which the outcome of interest was redefined as new-onset DR or DME, with models adjusted for sex, age, duration of diabetes, education level, current smoking, regular drinking, BMI, BP, HbA1c, serum cholesterol level, eGFR, and use of insulin. Sensitivity analysis 2 was performed with multivariable-adjusted, time-dependent Cox regression models (n=1320), in which patients who had incident DR within the first year of follow-up were excluded. Sensitivity analysis 3 was performed with multivariable-adjusted, time-dependent Cox regression models (N=1403), in which BMI was not adjusted for in the analysis.

The multivariable-adjusted hazard of incident DR at follow-up associated with LAP, VAI, and CVAI remained significant when WC was incorporated as a covariate in the time-dependent Cox model, as well as in the time-fixed Cox model in which baseline values of visceral obesity indices were used (Table S3 in Multimedia Appendix 1).

Figure 3. Associations of lipid accumulation product (LAP), visceral adiposity index (VAI), and Chinese VAI (CVAI) with incident diabetic retinopathy in the main analysis and sensitivity analyses. aHR: adjusted hazard ratio.

Discussion
Principal Findings
In this prospective cohort study conducted in southern China, we demonstrated longitudinal associations between 3 novel indices of visceral obesity and the incidence of DR in patients with diabetes. During a median follow-up of over 2 years, elevated levels of LAP, VAI, and CVAI were all independently associated with increased risk for new-onset DR, with positive dose-response trends. Our data suggested that visceral obesity was a significant risk factor for DR, with the associations independent of generalized and abdominal obesity. Multivariable-adjusted, time-dependent Cox regression models showed no evidence of effect modification by sex, age, duration of diabetes, BMI, and the presence of concurrent hypertension, dyslipidemia, and decreased renal function.

Comparison With Existing Literature
A recent systematic review of population-based cohort studies reported an annual incidence of DR ranging from 2.2% to 12.7% worldwide [58], while this study showed a slightly higher incidence rate. The differences might be explained by heterogeneity in the use of 7-field color stereoscopic fundus photographs for DR detection and in patient characteristics (eg, in terms of duration of diabetes) across studies. Over one-third of patients in this study had diabetes for more than 10 years and might be at a more advanced stage of diabetes with higher risks for DR.

The association between obesity and DR has been previously reported in a large number of studies, albeit with equivocal findings [19-21]. The lack of consensus may be due to the failure to address the mutually confounding effect resulting from the strong interrelation between generalized and abdominal obesity [27]. Obesity measures that account for the distribution of adipose tissue, and more specifically, visceral adiposity, have been considered a potentially stronger indicator for the risk of DR [25]. Positive associations between visceral obesity and DR have been reported in clinic-based studies among both Japanese and Singaporean adults with type 2 diabetes [59,60]. In contrast, the community-based Jogjakarta Eye Diabetic Study [61] reported opposite findings from Indonesian adults with type 2 diabetes, while a null association between visceral obesity and DR was observed in French patients with diabetes [62]. Plausible explanations for contradictory results include the use of different measurement methods (eg, CT [59], MRI [62], and BIA [60,61]), racial or ethnic disparities, and studies with relatively small sample sizes.

Simple and validated surrogate indices for measuring VAT, such as LAP [34,50], VAI [35], and CVAI [36], have been proposed given the resource availability and time constraints in routine clinical settings. A cross-sectional study in northern China reported positive associations of LAP and CVAI with DR among adults with type 2 diabetes [40], whereas another study with a similar design showed an inverse association between LAP and DR [39]. Cross-sectional community-based findings in eastern China, however, indicated nonsignificant associations of LAP, VAI, and CVAI with DR [41]. A lack of significant associations between visceral obesity indices and DR was also reported from a northern Chinese cohort of patients with type 2 diabetes [63], based on a time-fixed Cox model in which information on the duration of diabetes was not collected and the number of outcome events of DR as assessed by 4-field fundus photographs was much smaller (ie, 90 vs 406 cases) than that in this study, which took into account the time-varying...
effect in the Cox model with DR assessed by color stereoscopic fundus photographs of 7-standard fields.

To date, few studies have characterized the dose-response relationship between visceral obesity indices and DR using RCS functions. We found consistent associations of LAP, VAI, and CVAI with risk for DR, which appeared to indicate the presence of dose-response. Given that the shape of the RCS curve is largely influenced by the location and number of knots, the exploration of a specific threshold per se was not the focus of this study. We observed a nonlinear dose-response curve for LAP and VAI, but not for CVAI. This may be in part due to the inclusion of age as a component in the calculation of CVAI [36], yet further research is needed to better understand how different components used for the calculation of these surrogate indices are interacted with in basic molecular mechanisms and key pathogenic processes that drive abnormalities and lesions in the diabetic retina [64].

To our knowledge, this was one of the first studies using a prospective design to investigate the longitudinal associations of LAP, VAI, and CVAI with new-onset DR simultaneously while evaluating potential nonlinear associations. The anthropometric measurements, laboratory tests, and dilated-pupil retinal ophthalmoscopic examinations were performed annually by a regularly trained team of clinical staff who followed standard operating procedures with quality control. We adopted Early Treatment Diabetic Retinopathy Study 7-field color stereoscopic fundus photography, which has long been the gold standard for DR detection [12], to ensure the absence of DR in patients at baseline enrollment and the accurate capture of DR events during follow-up. The use of time-varying measures of visceral obesity indices and covariates in the Cox models took into account the plausible effects of time-varying exposure over the study period. The analyses were systematically performed using the 3 visceral obesity indices as continuous variables and in tertiles, with a consistent methodology adopted to deal with residual confounding and reverse causality. An extensive range of sensitivity analyses based on time-dependent and time-fixed multivariable-adjusted Cox models yielded little difference in estimated associations between visceral obesity indices and the incidence of DR, suggesting the robustness of our findings.

**Underlying Biological Mechanisms**

Although the biological mechanisms underlying the association between visceral obesity and DR are not yet fully understood, several hypotheses have been proposed. First, it was found that VAT adipocytes are more metabolically active and have greater lipolytic activity compared to SAT adipocytes [65]. Visceral fat accumulation is associated with a greater tendency to hyperglycemia, hyperinsulinemia, hypertriglyceridemia, and increased apolipoproteins B-rich lipoproteins, all of which could play a role in diabetes-related microvascular complications [65,66]. Second, evidence showed that VAT is more infiltrated with inflammatory cells (macrophages) than SAT [67] and is more capable of generating proinflammatory cytokines such as tumor necrosis factor-α, C-reactive protein, and interleukin-6 [65], which are involved in the pathological mechanisms leading to vascular dysfunction [24]. In addition, the plasminogen activator inhibitor-1, which is expressed more in VAT than SAT, has also been proven to be associated with increased susceptibility to DR [68,69]. Third, elevated vascular endothelial growth factor concentrations associated with visceral fat accumulation have been shown to be a potent mediator of angiogenesis and vascular permeability [11] and play a pivotal role in the retinal microvascular complications of diabetes [70,71]. Taken together, an excess of visceral fat could be linked to a state of chronic systemic inflammation and metabolic abnormalities, thereby predisposing patients to the complex progression of retinal vascular diseases [72].

**Implications for Research and Practice**

A recent review concluded that known risk factors for complications of diabetes appear to have limited implications as predictors of retinopathy development or progression [11]. This study provides novel, prospective evidence of the positive association between visceral obesity indices and new-onset DR. Given that stand-alone intensive control of blood glucose and BP might not suffice to significantly reduce DR risk [15], our findings suggest the necessity for regular monitoring of visceral adiposity apart from blood glucose and pressure. As visceral adiposity tends to be ignored by the general public, efforts should be made to increase awareness of the adverse effects of an excess of visceral fat on vascular permeability and growth. This may require tailored health education for high-risk patient groups to improve adherence to healthy lifestyles, thereby reducing excessive visceral fat. This is in line with the most recent American Diabetes Association guideline that advocates lifestyle improvement and obesity management in patients with diabetes [17,73].

From a public health perspective, routine monitoring of visceral obesity indices that are validated and easily implemented in low-resource settings may assist in identifying a broader range of patients who are at risk for DR. This would allow for early detection and timely intervention to avoid irreversible vision loss. As direct access to imaging modalities may not be widely feasible in daily practice [29], alternative approaches using surrogate indices that are broadly applicable to detect and measure intra-abdominal (visceral) fat distribution have gained increasing popularity. This study demonstrates the potential utility of visceral obesity indices, calculated using routinely available demographic, anthropometric, and biochemical measures, in predicting new-onset DR outcomes in remote or rural settings in low- and middle-income countries. Of note, our findings did not indicate which of the 3 indices was superior to one another but rather suggested opportunities for preventing DR through the application of these indices in risk assessment and management. Further interventional studies aimed at examining the effectiveness of continuous monitoring of visceral obesity indices for the prevention of DR are expected to offer important insights into the long-term management of diabetes and inform targeted public health intervention strategies and clinical guidelines.

**Limitations**

This study has some limitations that merit consideration. First, the VAT was not directly measured using CT or MRI or estimated using DEXA or BIA due to the resource constraints; instead, sex-specific equation-based indices that were previously

https://publichealth.jmir.org/2024/1/e48120
shown to be valid and reliable were used [34-36]. Second, the association of visceral obesity indices with incident DR may be underestimated, as the retinopathy outcome may not occur during the study period. Third, nearly one-third of patients enrolled at baseline were lost to follow-up or had missing outcome data. They appeared to be slightly older and had poorer glycemic control compared to their counterparts who attended follow-up, which might undermine the relationship between visceral obesity indices and incident DR in the final analysis despite largely comparable baseline characteristics concerning sex, duration of diabetes, lifestyles, comorbidity, and the majority of clinical measurements. Fourth, a separate analysis for incident DME or VTDR alone was not performed due to the small number of events. Fifth, we cannot rule out the possibility of residual bias because of confounding by unmeasured factors. Last but not least, the generalizability of our findings in Chinese diabetes to other patient populations should be interpreted with caution. Given that the present study was originally centered around evaluating the potential of visceral obesity indices in predicting new-onset DR rather than serving as a comprehensive validation with DEXA or BIA per se, further investigations on the basis of imaging techniques in a larger series of multiethnic patients are warranted to strengthen the evidence for the visceral adiposity-DR relationship.

In conclusion, this study provides prospective evidence that visceral obesity as measured by LAP, VAI, or CVAI is significantly associated with increased risk for new-onset DR, independent of generalized and abdominal obesity in Chinese patients with diabetes. Our findings may suggest the necessity of incorporating regular monitoring of visceral obesity indices in clinical practice to enhance population-based prevention for DR.

Abstract

Background: Baseline sleep duration is associated with cancer risk and cancer-specific mortality; however, the association between longitudinal patterns of sleep duration and these risks remains unknown.

Objective: This study aimed to elucidate the association between sleep duration trajectory and cancer risk and cancer-specific mortality.

Methods: The participants recruited in this study were from the Kailuan cohort, with all participants aged between 18 and 98 years and without cancer at baseline. The sleep duration of participants was continuously recorded in 2006, 2008, and 2010. Latent mixture modeling was used to identify shared sleep duration trajectories. Furthermore, the Cox proportional risk model was used to examine the association of sleep duration trajectory with cancer risk and cancer-specific mortality.

Results: A total of 53,273 participants were included in the present study, of whom 40,909 (76.79%) were men and 12,364 (23.21%) were women. The average age of the participants was 49.03 (SD 11.76) years. During a median follow-up of 10.99 (IQR 10.27-11.15) years, 2705 participants developed cancers. Three sleep duration trajectories were identified: normal-stable (44,844/53,273, 84.18%), median-stable (5877/53,273, 11.03%), and decreasing low-stable (2552/53,273, 4.79%). Compared with the normal-stable group, the decreasing low-stable group had increased cancer risk (hazard ratio [HR] 1.39, 95% CI 1.16-1.65) and cancer-specific mortality (HR 1.54, 95% CI 1.18-2.06). Dividing the participants by an age cutoff of 45 years revealed an increase in cancer risk (HR 1.88, 95% CI 1.30-2.71) and cancer-specific mortality (HR 2.52, 95% CI 1.22-5.19) only in participants younger than 45 years, rather than middle-aged or older participants. Joint analysis revealed that compared with participants who...
had a stable sleep duration within the normal range and did not snore, those with a shortened sleep duration and snoring had the highest cancer risk (HR 2.62, 95% CI 1.46-4.70).

Conclusions: Sleep duration trajectories and quality are closely associated with cancer risk and cancer-specific mortality. However, these associations differ with age and are more pronounced in individuals aged <45 years.

Introduction
Sleep, a body and brain repair agent, plays a vital role in development, growth, and metabolism [1]. Regular and high-quality sleep can promote brain waste clearance, memory recovery, immune health, and normal nutrient metabolism. Correspondingly, sleep disorders may seriously affect the health and quality of life of patients [2].

Unfortunately, sleep disorders are one of the most common issues in today’s society. The World Health Organization has reported that approximately 27% of the population experiences sleep disorders. Therefore, scientists have conducted extensive studies on sleep disorders, most of which have focused on rapid eye movement (REM) sleep behavior disorders [3] or sleep disorders caused by diseases such as obstructive sleep apnea (OSA) [4]. Recently, an authoritative study has identified sleep duration as 1 of the 6 key elements of sleep health [5]. Sleep duration is associated with the occurrence and prognosis of various diseases. Dong et al [6] reported that insufficient or excessive sleep duration can increase the risk of depression. In terms of metabolic health, decreased sleep duration is associated with a higher risk of and a higher severity score for metabolic syndrome [7]. Dynamic changes in sleep duration can also bring significant changes to the body. In experimental research, sleep-deprived mice experience disruptions in their blood sugar homeostasis, which is restored to normal when sleep is regained. Cohort studies have also confirmed this point [8]. A study on shift work showed a strong correlation between irregular sleep duration and type 2 diabetes, obesity, heart disease, and cancer [9]. Nevertheless, in most of these studies, the sleep duration of participants was assessed at a single time to determine their cancer risk or even mortality, which is biased. To the best of our knowledge, various factors affect sleep, including the external environment (sound, light, and air quality), depression, anxiety, and age [10]. When considering age, approximately 50% of the older population experiences sleep disorders. Changes in sleep patterns and circadian dysrhythmia are considered part of aging [11]. Sleep duration and quality significantly decrease with age. Surprisingly, compared with young people, lack of sleep in older people has less effect on performance [12]. Therefore, it is likely that a single sleep survey will estimate the risk of disease and death erroneously. For the first time, we measured the sleep duration trajectory by monitoring the sleep of participants from 2006 to 2010 and then elucidated the association of sleep duration trajectories with cancer risk and cancer-specific mortality.

Methods
Study Participants
All participants were from the Kailuan cohort, part of an ongoing prospective study in Tangshan, China (ChiCTR-TNRC-11001489, registered at the Chinese Clinical Trial Registry). As previously described [13], the Kailuan cohort was initiated in 2006, when Kailuan General Hospital collaborated with 11 other hospitals to conduct physical examinations on 101,510 participants; the examinations included clinical examinations, health questionnaires, imaging, and laboratory tests. Thereafter, participants were followed up and periodically resurveyed every 2 years, and relevant indicators were recorded [14]. In this study, to construct the sleep duration trajectory, we included individuals who consecutively participated in the physical examinations from 2006 to 2010 (n=57,927); 3492 participants with missing covariates such as snoring, sedentary lifestyle, marital status, education, waist circumference (WC), BMI, and other covariates were excluded. Furthermore, 254 participants with cancer or cancer at baseline and 908 participants with missing sleep duration information were excluded. Finally, 53,273 participants were included in this study (Figure 1).
Ethical Considerations
This study was conducted according to the principles of the Declaration of Helsinki and its revised version and was approved by the ethics committee of Kailuan General Hospital with the code sjtkyll-lx-2021(39). All participants agreed to participate in the study and provided written informed consent.

Exposure and Covariates
All participants were invited to the hospital to fill out the Pittsburgh Sleep Quality Index (PSQI) sleep questionnaire survey (Multimedia Appendix 1) [15]. They reported their sleep status over the past 6 months. Information about the participants’ average sleep duration (3-15 h, excluding naps) was extracted from the questionnaire as exposure. For participants who reported approximate sleep duration, the average value was calculated (for example, 6-7 h was considered 6.5 h). The covariates were age, sex, BMI, WC, marital status, education level, sedentary time, physical activity, smoking, drinking, hypertension, diabetes, snoring, salt intake, family history of tumors, high-sensitivity C-reactive protein (CRP), total cholesterol (TC), triglycerides (TG), and digestive system cancer–related factors (fatty liver, gallstones, cirrhosis, and hepatitis B virus infection). Multimedia Appendix 1, Table S1 presents the definitions of all covariates.

Outcome Assessment
The electronic medical records from provincial vital statistics offices, the Tangshan medical insurance system, and the Kailuan Social Security Information System were used to determine the time of tumor occurrence and death of participants as well as specific causes of death. Cancer was diagnosed via pathology or imaging. All diagnoses were recorded using the International Classification of Diseases, 10th revision (Multimedia Appendix 1). The follow-up time was from the date of completion of the investigation in 2010 until the occurrence of cancer, death, or the last follow-up date (December 31, 2021), whichever came first.

Statistical Analyses
Statistical analyses were conducted using SAS (version 9.4; SAS Institute) or R (version 4.2.0; R Foundation for Statistical Computing). All $P$ values were 2-sided, and a $P$ value of <.05 was considered statistically significant.

Self-reported sleep duration trajectories were constructed for participants from 2006 to 2010 using latent mixed modeling, which was performed using Proc Traj in SAS. The construction of the trajectories was gradual. First, we established 5 types of trajectories and then compared them with 4, 3, 2, and 1 trajectories. The Bayesian information criterion was used to evaluate the fit of each trajectory model. Furthermore, models with different functional forms were evaluated based on the significance levels of cubic, quadratic, and linear terms. Continuous variables with normal distributions were expressed as mean (SD) and compared between groups using a 1-way ANOVA. Data with skewed distributions were expressed as median (IQR) and compared using the Kruskal-Wallis test. Categorical variables were expressed as n (%); between-group comparisons were made using the chi-square test. At the same time, Bonferroni correction was used for multiple comparison corrections. After satisfying the proportional hazard ratio assumption, Cox proportional hazards regression models were used to describe the association of different trajectories with cancer risk and cancer-specific mortality. In the adjusted model, the covariates were adjusted. Furthermore, the effect of some potential factors on the risk of digestive system cancers was considered [14,16,17]. Therefore, we additionally adjusted for...
liver cirrhosis, hepatitis B, gallstones, and gallbladder polyps for digestive system cancers. Because significant differences were observed in sleep patterns and effects between young people and middle-aged and older people [18], we first divided the participants into young people (aged <45 years) and middle-aged and older people (aged ≥45 years) to conduct the study. After observing that sleep duration was more closely related in young people, we conducted more detailed analyses, including subgroup and sensitivity analyses, in participants aged <45 years. For subgroup analysis, previously reported potential modifiers, such as snoring, sex [19], BMI [20], and regular physical exercise [21], were selected. Simultaneously, to clarify the joint effect of sleep quality and sleep duration trajectory, snoring and sleep duration trajectory were combined and the participants were regrouped. In sensitivity analyses, participants who developed cancer within 1 year of follow-up, those with hepatitis B infection, those with regular physical activity, those with a family history of tumor, and those who used sleep medication at least once during the past month were excluded. Furthermore, the variables were adjusted for other components in the PSQI. To avoid bias owing to temporal changes, we also adjusted for time-varying covariates. Finally, to avoid overestimation of cancer risk by death as a competing event, we repeated the analysis using a competing risk model (Multimedia Appendix 1).

Results

Baseline Characteristics

A total of 53,273 participants were included in this study, of whom 40,909 (76.79%) were men and 12,364 (23.21%) were women. The average age of the participants was 49.03 (SD 11.76) years. During a median follow-up of 10.99 years, 2705 participants developed cancers (Multimedia Appendix 1, Table S2); 518 of them were younger than 45 years (Multimedia Appendix 1, Table S3) and 2187 were aged 45 years or older (Multimedia Appendix 1, Table S4). According to the sleep duration of participants from 2006 to 2010, we constructed 3 trajectory patterns. A total of 84.18% (44,844/53,273) of the participants were categorized into the normal-stable group (mean sleep duration range 7.32-7.46 h), 11.03% (5877/53,273) into the increasing median-stable group (mean sleep duration range 5.23-6.09 h), and 4.79% (2552/53,273) into the decreasing low-stable group (mean sleep duration range 5.01-7.48 h) (Figure 2). Among the participants overall (Table 1) and those younger than 45 years (Multimedia Appendix 1, Table S5), the increasing median-stable and decreasing low-stable groups were older, had higher WC and TC, and were more likely to drink, snore, and have fatty liver than the normal-stable group, but had similar BMI, CRP, and TG levels. However, among middle-aged and older participants (Multimedia Appendix 1, Table S6), those in the increasing median-stable and decreasing low-stable groups were older; had higher TC; were more likely to have a sedentary lifestyle, snore, have fatty liver, and consume a high-salt diet; and had lower TG, WC, and BMI compared with participants in the normal group. The Bonferroni correction indicated that when conducting pairwise comparisons among the 3 groups, there were differences in age, education, and alcohol use (Multimedia Appendix 1, Table S7).

Association Between Sleep Duration Trajectory and Cancer Risk

For all participants, no significant change in cancer risk was observed in the increasing median-stable group (HR 0.97, 95% CI 0.84-1.11); however, in the decreasing low-stable group, overall cancer risk for the participants increased significantly, by 39% (HR 1.39, 95% CI 1.16-1.65). Interestingly, after dividing the participants based on the age criterion (45 years), this trend was only present among young people (HR 1.88, 95% CI 1.30-2.71) rather than middle-aged or older participants (HR 1.17, 95% CI 0.96-1.42). Among participants younger than 45 years, those in the decreasing low-stable group were at an overall increased risk of cancer compared with those in the normal-stable group (HR 1.88, 95% CI 1.30-2.71) (Table 2). Among cancer types, participants in the decreasing low-stable group only showed an increased risk of lung cancer (HR 1.51, 95% CI 1.08-2.12), pancreatic cancer (HR, 3.08, 95% CI 1.05-9.08), and stomach cancer (HR 2.06, 95% CI 1.10-3.87) (Multimedia Appendix 1, Table S8). Similarly, the risk of lung cancer (HR 3.64, 95% CI 1.64-8.09), esophageal cancer (HR 4.92, 95% CI 1.08-12.16), pancreatic cancer (HR 7.16, 95% CI
1.83-31.62), liver cancer (HR 3.68, 95% CI 1.04-8.03), and digestive system cancer (HR 2.43, 95% CI 1.23-4.81) increased among participants younger than 45 years in the decreasing low-stable group and not among the middle-aged or older participants (Multimedia Appendix 1, Figure S1).

aIR: incidence rate per 1000 person-years.  
bThe model was adjusted for continuous (age, BMI, waist circumference, c-reactive protein, total cholesterol, triglycerides, and sleep duration in 2010) and categorical (sex, marital status, education level, sedentary time, physical activity, smoking, alcohol use, hypertension, diabetes, snoring, salt intake, and family history of tumor) variables.

Association Between Sleep Duration Trajectory and Cancer-Specific Mortality

Similar to the findings on sleep duration trajectories and cancer risk, for all participants, compared to the normal-stable group, individuals in the decreasing low-stable group had a significantly higher risk of cancer-specific mortality (HR 1.54, 95% CI 1.18-2.06). The same phenomenon was also observed among participants aged <45 years, where individuals in the decreasing low-stable group had a significantly higher risk of cancer-specific mortality (HR 2.52, 95% CI 1.22-5.19). However, no such association was found among participants aged ≥45 years (HR 1.28, 95% CI 0.94-1.75) (Table 3).

aMR: mortality rate per 1000 person-years.  
bThe model was adjusted for continuous (age, BMI, waist circumference, c-reactive protein, total cholesterol, triglycerides, and sleep duration in 2010) and categorical (sex, marital status, education level, sedentary time, physical activity, smoking, alcohol use, hypertension, diabetes, snoring, salt intake, and family history of tumor) variables.
Subgroup Analysis and Joint Analysis

We did not find any interactions between sleep duration trajectory and snoring (P for interaction .16), sex (P for interaction .80), overweight (P for interaction .50), and regular physical activity (P for interaction .90) (Multimedia Appendix 1, Table S9) in the subgroup analysis; however, in the joint analysis (Multimedia Appendix 1, Table S10), participants in the decreasing low-stable group were at the highest risk of cancer, especially those who snored (HR 2.62, 95% CI 1.46-4.70).

Additional Analyses

The competing risk model showed that after considering death as a competitive event, a closer association between sleep duration trajectory and cancer risk was observed. In both the cause-specific hazard functions (CSHF) model and the subdistribution hazard functions (SDHF) model, when compared to the normal stable group, participants in the decreasing low-stable group had an elevated risk of lung cancer (CSHF HR 2.42, 95% CI 1.07-5.53; SDHF HR 2.23, 95% CI 1.17-5.25), esophageal cancer (CSHF HR 4.07, 95% CI 1.12-14.89; SDHF HR 4.05, 95% CI 1.13-15.03), pancreatic cancer (CSHF HR 7, 95% CI 1.40-42.319; SDHF HR 6.88, 95% CI 1.38-27.6), liver cancer (CSHF HR 3.37, 95% CI 1.19-9.66; SDHF HR 3.08, 95% CI 1.08-10.40), digestive system cancers (CSHF HR 1.93, 95% CI 1.05-3.62; SDHF HR 1.99, 95% CI 1.23-5.53), and overall cancer risk (CSHF HR 2.01, 95% CI 1.39-3.17; SDHF HR 1.97, 95% CI 1.12-3.08) (Multimedia Appendix 1, Table S11). Finally, after performing multiple sensitivity analyses and adjusting for time-varying covariates, the results remained robust. Compared to the normal-stable group, participants in the decreasing low-stable group still had an increased risk of lung cancer, esophageal cancer, pancreatic cancer, liver cancer, digestive system cancers, and overall cancer risk (Multimedia Appendix 1, Table S12).

Discussion

Principal Findings

To the best of our knowledge, this is the first prospective study investigating age-related differences in the association of sleep duration trajectories with cancer risk and cancer-specific mortality. Compared with middle-aged and older individuals, young people in this study showed a closer association between sleep duration trajectories and the aforementioned risks. Despite some participants having baseline sleep durations within the normal range, once their sleep duration decreased, the aforementioned risks increased accordingly. Additionally, individuals with decreasing low-stable and normal-stable sleep duration trajectory and snoring had the highest risk of cancer.

Sleep duration is the most intuitive and concise indicator for evaluating sleep quality. A Mendelian randomization study from the UK Biobank showed that shorter sleep duration was associated with a higher risk of digestive tract cancers, such as stomach and pancreatic cancers [22], and most studies are in agreement with this study. In terms of cancer-related deaths, previous meta-analyses showed that compared with individuals who sleep for 7 to 8 hours, those who sleep for 4 to 5 hours were at an increased risk of cancer mortality [9]. Li et al. [23] found an association between short sleep time and a 24% increase in lung cancer mortality. However, there is no consensus due to the existence of contradictory results. A multicenter study from Japan showed that compared with 7 hours of sleep, less than 5 hours of sleep did not seem to affect the incidence rate or mortality of cancer [24]. Several meta-analyses also showed no relationship between sleep duration and breast cancer or overall cancer risk [25,26].

We speculate that the heterogeneity in these results may be because of population-specific factors. Svensson et al. [27] conducted one of the largest studies in Asia on the association between sleep duration and mortality, and the results indicated that age, an important modifier, greatly affected the association between sleep duration and prognosis. Another large prospective study was consistent with the abovementioned study, showing that shorter sleep duration increased the mortality rate in individuals younger than 65 years but not in those aged 65 years or older, and the effect of sleep duration on mortality was highest among younger individuals and negatively correlated with age [28]. These results are interesting and enlightening. We initially found an association between sleep duration trajectory and overall cancer risk in the entire population; however, the results differed significantly when the participants were stratified by age. Sleep duration changes only affected the cancer risk and mortality of participants younger than 45 years.

We hypothesize that this outcome is because of age-related differences in sleep patterns, because aging itself is probably accompanied by advanced sleep timing, shortened nocturnal sleep duration, and increased awakenings [29]. Therefore, changes in nocturnal sleep duration may have a lesser effect on older adults. Conversely, significant fluctuations in the sleep duration of young individuals may imply underlying issues in their physiological functioning. Mechanistically, regarding the central nervous system, as individuals age, neurotoxic substances accumulate, leading to cortical thinning and brain white-matter degeneration; additionally, the age-related dysregulation of neurotransmitters, including serotonin and adenosine, which are involved in sleep regulation, impairs the central sleep regulatory system [30]. Considering hormones and circadian rhythms, aging is closely related to a decrease in sex hormone levels. Studies have shown a significant correlation between decreased testosterone levels and shortened sleep duration and increased sleep fragmentation in older adults [31]. Cortisol, a hormone related to circadian rhythms, regulates sleep, and older adults often exhibit abnormalities in their cortisol rhythm, particularly an earlier peak in nocturnal cortisol levels, which leads to increased nocturnal awakenings and decreased slow-wave sleep [29]. The level of melatonin, an essential hormone that regulates circadian rhythms, differs depending on age, showing significantly reduced peak levels in older adults in comparison with younger individuals [32]. Therefore, fluctuations and changes in nocturnal sleep duration in older adults do not necessarily imply any disease but may simply be a normal aging-related progression. However, some studies have shown that changes in sleep patterns in older adults may increase the risk of lung cancer to some extent [33]. Nonetheless, these results do not indicate that sleep is unimportant in...
middle-aged and older adults. We can only cautiously conclude that compared with younger individuals, relying solely on sleep duration to assess the prognosis of middle-aged and older adults may lack sensitivity, and a comprehensive evaluation of their sleep patterns is crucial.

Compared with age, a factor that was associated with contradictory results, sleep quality is a critical factor. Zhang et al [19] reported similar results by conducting a 22-year prospective cohort study, finding that the effect of changes in sleep duration on colon cancer risk only existed in individuals who snored. Additionally, snoring can also increase the risk of physical weakness. A Chinese study showed that for participants with prefrailty, unhealthy sleep patterns such as snoring increased the risk of frailty by 42% [34]. In attempting to explore the underlying mechanisms, one study entered our field of view [35], which found that snoring or OSA can exacerbate intermittent hypoxia in mouse models and activate the key oxidative stress factor Bach1 in the body, thereby promoting the proliferation, invasion, and migration of lung cancer cells. Simultaneously, these factors promote the stemness of cancer cells and increase the degree of malignancy.

This study has the following limitations. First, the Kailuan cohort is a male-dominated cohort in northern China, which may not represent a general population because sleep differs across races and sexes [36]. Second, when evaluating sleep quality, we only included snoring, whereas REM sleep behavior disorder, restless leg syndrome, and OSA were not included in this study. Third, the information regarding sleep duration was obtained through questionnaires and participants’ recall; thus, the results may be affected by recall bias.

Conclusions

In conclusion, sleep duration trajectories are closely associated with the risk of cancers, as well as cancer-specific mortality. However, these associations vary with age and are more pronounced in individuals younger than 45 years. Furthermore, the joint analysis indicated that individuals in the decreasing low-stable sleep duration trajectory group who snored had the highest risk of cancer. The continuous monitoring of sleep duration may be of significant value in making diagnoses in young individuals.

Abstract

Background: Previous studies have confirmed the separate effect of arterial stiffness and obesity on type 2 diabetes; however, the joint effect of arterial stiffness and obesity on diabetes onset remains unclear.

Objective: This study aimed to propose the concept of arterial stiffness obesity phenotype and explore the risk stratification capacity for diabetes.

Methods: This longitudinal cohort study used baseline data of 12,298 participants from Beijing Xiaotangshan Examination Center between 2008 and 2013 and then annually followed them until incident diabetes or 2019. BMI (waist circumference) and brachial-ankle pulse wave velocity were measured to define arterial stiffness abdominal obesity phenotype. The Cox proportional hazard model was used to estimate the hazard ratio (HR) and 95% CI.

Results: Of the 12,298 participants, the mean baseline age was 51.2 (SD 13.6) years, and 8448 (68.7%) were male. After a median follow-up of 5.0 (IQR 2.0-8.0) years, 1240 (10.1%) participants developed diabetes. Compared with the ideal vascular function and nonobese group, the highest risk of diabetes was observed in the elevated arterial stiffness and obese group (HR 1.94, 95% CI 1.60-2.35). Those with exclusive arterial stiffness or obesity exhibited a similar risk of diabetes, and the adjusted HRs were 1.63 (95% CI 1.37-1.94) and 1.64 (95% CI 1.32-2.04), respectively. Consistent results were observed in multiple sensitivity analyses, among subgroups of age and fasting glucose level, and alternatively using arterial stiffness abdominal obesity phenotype.

Conclusions: This study proposed the concept of arterial stiffness abdominal obesity phenotype, which could improve the risk stratification and management of diabetes. The clinical significance of arterial stiffness abdominal obesity phenotype needs further validation for other cardiometabolic disorders.

KEYWORDS

arterial stiffness; baPWV; brachial-ankle pulse wave velocity; cohort analysis; obesity and abdominal obesity; type 2 diabetes
Introduction

The latest estimates showed that there were 537 million adults with diabetes worldwide in 2021, which was expected to reach 783 million by 2045 [1], leading to a heavy socioeconomic burden with huge costs for glucose therapy and complications treatment [2,3]. Therefore, early detection and prevention of diabetes are of great importance, which requires the precise identification of risk markers to promote the risk stratification and management of diabetes onset.

Multifactorial risk factor evaluation and management is a recommended strategy for preventing diabetes and its complications. Arterial stiffness is an age-related process that results from adverse changes in the structure and function of the elastic arterial vessel wall [4]. Previous studies have shown a close relationship between increased arterial stiffness and diabetes [5]. Arterial stiffness is an important risk factor for diabetes [6-8] and diabetes could accelerate the process of arterial stiffness, conversely [9]. At the same time, it is well known that obesity is commonly associated with a range of metabolic abnormalities, including insulin resistance, atherogenic dyslipidemia, and metabolic syndrome [10]. By far, obesity is the most important modifiable risk factor for diabetes onset and glucose intervention [11], formulating the term “diabesity” to describe the combined adverse health effects and close relationship between obesity and diabetes [12]. Obesity is defined as a common chronic disorder due to excess body fat and has become a global epidemic issue [13]. The diagnosis and classification of obesity are usually based on BMI and waist circumference for abdominal obesity. Of note, not all individuals with obesity are at the same risk of metabolic complications, leading to the concept of metabolic health obesity phenotype [14,15]. Although individuals with obesity in a metabolically healthy state have a relatively reduced risk of developing diabetes, they are still at a higher risk compared to the metabolically healthy normal-weight group [15]. Thus, the assessment of metabolic health obesity phenotype allows for better identification of people at different risk of diabetes onset. Of note, the metabolic health status assessment needs a complex physical examination and blood test. On the contrary, arterial stiffness measurement using pulse wave velocity is a simple, repeatable, and noninvasive process [16]. However, the combined effect of obesity and arterial stiffness status on diabetes onset has not been fully investigated to date.

Therefore, this study proposed the concept of arterial stiffness obesity phenotype and investigated the joint effect of increased arterial stiffness and abdominal obesity on incident diabetes. We hypothesized that arterial stiffness abdominal obesity phenotype could better stratify the risk of diabetes onset in the general population.

Methods

Study Population and Design

This study used data from the Beijing Xiaotangshan Examination Center [17], which is a large-scale longitudinal cohort study investigating the risk factors and biomarkers of cardiometabolic disorders. Beijing Xiaotangshan Examination Center included participants undergoing physical examinations from 2008, which is still ongoing and forms dynamic open cohort data with annual resurveys. In this study, a total of 12,505 participants aged 18 years or older who underwent the first comprehensive health examination without diabetes between 2008 and 2013 were primarily included as baseline. Then, we excluded 207 participants due to being underweight (n=126), being 18 years of age or younger (n=22), or lacking fasting glucose data (n=59) at baseline. Finally, 12,298 participants were selected and annually followed to incident diabetes or the end of 2019, including 8184 participants with available data on waist circumference as shown in Figure 1.
Figure 1. Flowchart of this study. This cohort study included 12,298 eligible participants from 2008 to 2019 in Beijing, China.

Data Collection and Definition

The data on demographic characteristics, lifestyle, disease history, and medication use were collected through a standard questionnaire and face-to-face interview. Educational level was categorized as illiteracy or primary school (primary), middle school or high school (secondary), and bachelor’s degree or above (third). Smoking and drinking status was divided into current or not. Physical activity was defined as having moderate or intense activity at work or during leisure time more than 4 times and 80 minutes each week. The disease history of dyslipidemia and hypertension was self-reported.

The physical examination and biochemical data were measured by the trained staff and acquired from the electronic record system of Beijing Xiaotangshan Hospital, including height, weight, waist circumference, and blood pressure. BMI was calculated as weight in kilograms divided by height in meters squared. Obesity was defined as BMI ≥28 kg/m², and abdominal obesity was defined as waist circumference ≥90 cm for male individuals and ≥85 cm for female individuals, using the standard for the Chinese population. The concentrations of fasting glucose and glycated hemoglobin A₁c (HbA₁c) were tested using the automatic biochemical analyzers Roche Cobas C 701 and SYSMEX HLC-723G8. Diabetes was defined as fasting glucose ≥7.0 mmol/L, HbA₁c ≥6.5%, or use of any glucose-lowering medication or self-reported diagnosis history of diabetes.

Arterial stiffness was measured by brachial-ankle pulse wave velocity (baPWV) using the Omron Colin BP-203RPE III device (Omron Health Care). Elevated arterial stiffness was defined as baPWV ≥1400 cm/s, as previously described. The ankle-brachial index (ABI) was calculated as the pressure ratio between posterior tibial artery and brachial artery.

Arterial Stiffness Abdominal Obesity Phenotype

Arterial stiffness obesity phenotype was divided into four groups: (1) normal arterial stiffness and no obesity (NASNO), (2) normal arterial stiffness and obesity (NASO), (3) elevated arterial stiffness and no obesity (ASNO), and (4) elevated arterial stiffness and obesity (ASO). On the other hand, waist circumference is another index to reflect the accumulation of abdominal fat, which is more closely associated with the risk of diabetes. Thus, arterial stiffness abdominal obesity phenotype was divided into four groups: (1) normal arterial stiffness and no abdominal obesity (NASNAO), (2) normal arterial stiffness and abdominal obesity (NASAO), (3) elevated arterial stiffness and no abdominal obesity (ASNAO), and (4) elevated arterial stiffness and abdominal obesity (ASAO).

Statistical Analysis

Baseline characteristics were described using mean (SD) and frequency (proportion) according to arterial stiffness abdominal obesity phenotype. The incidence rate and cumulative incidence of diabetes were calculated.

We used Kaplan-Meier curves to present the cumulative hazard of diabetes onset stratified by arterial stiffness obesity and arterial stiffness abdominal obesity phenotype. The effect of arterial stiffness (or obesity) on incident diabetes was evaluated stratified by obesity (arterial stiffness) status. Then, the Cox proportional hazard model was used to explore the longitudinal association of arterial stiffness abdominal obesity phenotype.
with incident diabetes. Hazard ratios (HRs) and 95% CIs were calculated in the following models: model 1 was primarily adjusted for age and sex, and model 2 was further adjusted for education level, physical activity, current smoking, current drinking, dyslipidemia or not, hypertension or not, mean arterial pressure (MAP), and fasting glucose concentration. We adjusted the level of MAP in the regression analysis as MAP was more dependent on baPWV level compared to systolic blood pressure and diastolic blood pressure. The interaction effect between arterial stiffness and abdominal obesity was tested as a multiplicative term. We performed multiple sensitivity analyses, including additionally adjusting HbA\textsubscript{1c} levels, excluding participants using antihypertensive medication, or repeating analyses among participants with an ABI >0.9. To address the dynamic changes of arterial stiffness abdominal obesity phenotype between baseline and follow-up, we repeated the analyses among participants of stable arterial stiffness abdominal obesity status. In addition, the effect of arterial stiffness abdominal obesity phenotype on diabetes onset was explored in subgroups of sex, age, and baseline fasting glucose level.

All statistical analyses were performed using R software (version 4.1.0; R Foundation for Statistical Computing), and a 2-sided \( P \) value <.05 was considered statistically significant.

**Ethical Considerations**

This study was conducted in accordance with the principles of the Declaration of Helsinki and approved by the Ethics Committee of the Beijing Xiaotangshan Center (XTS021431). The study data were anonymous. All participants provided written informed consent before taking part in this study.

**Results**

Of the 12,298 participants, the mean baseline age was 51.2 (13.6) years, and 8448 (68.7%) were male. Table 1 shows the detailed baseline characteristics according to arterial stiffness obesity phenotype, and characteristics according to arterial stiffness abdominal obesity phenotype are shown in Table S1 in Multimedia Appendix 1. During a median follow-up of 5.0 (IQR 2.0-8.0) years, diabetes occurred in 1240 participants. The incidence rates were 9.57, 27.83, 30.32, and 50.55 per 1000 person-years among NASNO, NASO, ASNO, and ASO groups (Table S2 in Multimedia Appendix 1) and 6.85, 20.04, 24.42, and 48.10 per 1000 person-years among NASNAO, NASAO, ASNAO, and ASAO groups, respectively (Table S3 in Multimedia Appendix 1).
Table 1. Baseline characteristics of 12,298 participants according to arterial stiffness obesity phenotype. This cohort study included eligible participants from 2008 to 2019 in Beijing, China. SI conversion factor: to convert fasting plasma glucose to mg/dL, multiply by 18.0.

\(^a\)NASNO: normal arterial stiffness and no obesity.
\(^b\)NASO: normal arterial stiffness and obesity.
\(^c\)ASNO: elevated arterial stiffness and no obesity.
\(^d\)ASO: elevated arterial stiffness and obesity.
\(^e\)Calculated as weight in kilograms divided by height in meters squared.
\(^f\)Waist circumference was measured only in 8184 participants.
\(^g\)Abdominal obesity was defined as a waist circumference of \(\geq 90\) cm for male individuals and \(\geq 85\) cm for female individuals. Due to data missing on waist circumference, the total numbers of NASNA, NASO, ASNO and ASO were 4237, 940, 2232 and 768, respectively.
\(^h\)MAP: mean arterial pressure.
\(^i\)MAP = \(1/3 \times \) systolic pressure + \(2/3 \times \) diastolic pressure.
\(^j\)HbA\(_1\)c: glycated hemoglobin A\(_1\)c.

Figure 2 presents the cumulative hazard of incident diabetes according to arterial stiffness obesity phenotype and arterial stiffness abdominal obesity phenotype. Of note, people with obesity had a significantly higher risk of diabetes onset regardless of arterial stiffness status (\(P<.001\); Figure S1A and B in Multimedia Appendix 1). Equally, those with elevated arterial stiffness had a higher risk of diabetes regardless of obesity status (Figure S1C and D in Multimedia Appendix 1). Figure S2A-D in Multimedia Appendix 1 present the mutual effect of arterial stiffness and abdominal obesity.
Figure 2. Kaplan-Meier curves of incident diabetes according to arterial stiffness obesity (left) phenotype and arterial stiffness abdominal obesity (right) phenotype. The left and right sides include 12,298 and 8184 eligible participants, respectively, from 2008 to 2019. ASAO: elevated arterial stiffness and abdominal obesity; ASNAO: elevated arterial stiffness and no abdominal obesity; ASNO: elevated arterial stiffness and no obesity; ASO: elevated arterial stiffness and obesity; NASAO: normal arterial stiffness and abdominal obesity; NASNAO: normal arterial stiffness and no abdominal obesity; NASNO: normal arterial stiffness and no obesity; NASO: normal arterial stiffness and obesity.

In the joint model, both continuous BMI (adjusted HR 1.06, 95% CI 1.04-1.07; \(P < .001\)) and baPWV (adjusted HR 1.18, 95% CI 1.11-1.25; \(P < .001\)) levels were significantly associated with diabetes onset. In the adjusted model, the highest risk of incident diabetes was observed in the ASO group (HR 1.94, 95% CI 1.60-2.35), followed by ASNO (HR 1.63, 95% CI 1.37-1.94) and NASO (HR 1.64, 95% CI 1.32-2.04) groups, compared with NASNO (Table 2). The interaction terms of general obesity and arterial stiffness were statistically significant \((P < .05)\). Similarly, ASAO had the highest risk (HR 2.30, 95% CI 1.71-3.11), followed by NASAO (HR 1.30, 95% CI 0.95-1.78) and ASNAO (HR 1.67, 95% CI 1.20-2.32) groups, compared with NASNAO.
Table 2. Association of arterial stiffness abdominal obesity phenotype with incident diabetes.

**Discussion**

**Overview**

In this study, we proposed the concept of arterial stiffness obesity phenotype using noninvasive and simple measurements. We found that arterial stiffness obesity phenotype could improve the risk stratification of diabetes onset. People with ASO had the highest risk of incident diabetes, independent of their baseline glucose level. The results remained consistent among multiple sensitivity analyses and subgroups of sex, age, and fasting glucose level.

Many studies have suggested a relationship between arterial stiffness and diabetes, indicating that arterial stiffness could predict the development of diabetes [5,6,8]. A Kailuan study of 14,159 participants found that arterial stiffness appeared to precede the increase in fasting glucose [7]. Notably, the independent association between arterial stiffness and diabetes was not consistent among all studies. A large prospective observational study of Japanese company employees found that atherosclerosis was observed only in those with diabetes combined with hypertension, and the increased arterial stiffness may not be associated with the onset of diabetes or prediabetes alone [20]. On the other hand, obesity is an important risk factor involved in the etiopathogenesis of diabetes and is the most important culprit of insulin resistance [21,22]. In a meta-analysis in the United States and Europe, men with obesity had a 7-fold higher risk of diabetes, and women with obesity had a 12-fold higher risk [23]. A longitudinal study from the United Kingdom investigated 369,362 participants aged between 2 and 15 years and found that most of the patients with diabetes were obese (47.1%) [24]. Similar results have been found in other countries [25]. Studies have shown that the distribution of adipose tissue is a key factor in the development of insulin resistance, independent of the stage of obesity [26]. A growing body of evidence suggests that obesity cannot be assessed by BMI. Individuals of normal weight but with excess visceral adipose tissue are at high risk of diabetes, while individuals with obesity who can expand their subcutaneous adipose tissue mass, especially in the hip and femoral regions, may be at much lower risk than expected [11]. Thus, both excess body weight (BMI) and ectopic fat (such as abdominal obesity) determine the risk of diabetes onset. This study supplemented the evidence about the combined effect of arterial stiffness and obesity or abdominal obesity on the incident diabetes using a larger cohort. Compared with the ideal vascular function and nonobese group, the highest risk of diabetes was observed in the elevated arterial stiffness with obesity or abdominal obesity group. Additionally, there exists a potential interaction effect between general obesity and arterial stiffness on diabetes onset.

Metabolic health obesity phenotype has been proposed as a health index [27]. In general, people with different metabolic health obesity phenotypes have a differentiated risk of type 2 diabetes, cardiovascular diseases, and all-cause mortality [28-32]. The number and severity of metabolic abnormalities could further identify the risk of adverse outcomes [33,34]. In terms of diabetes, data suggest that the risk of developing diabetes is 5-20 times higher in metabolically unhealthy people with obesity than in the metabolically healthy nonobese group, and the risk is 4 times higher for the metabolically healthy obese group [35]. However, the definition of metabolic health status needs physical examinations (blood pressure), blood test (glucose and lipid), and a questionnaire survey (disease history and medication use). In this study, we proposed the concept of arterial stiffness abdominal obesity phenotype to stratify people...
at different risks of diabetes onset. The measurements of arterial stiffness and obesity status are simple, fast, and noninvasive, which enhance the applicability of arterial stiffness abdominal obesity phenotype in the risk stratification and management of diabetes.

Potential mechanisms linking arterial stiffness and diabetes include endothelial dysfunction, chronic inflammation, oxidative stress, microvascular dysfunction, and shared genetic background [7,8,36]. First, endothelial dysfunction is associated with arterial stiffness [37]. Arterial stiffness may lead to increased arterial pulse pressure and pulsation shear, resulting in endothelial dysfunction and metabolic dysregulation [38]. It has been suggested that endothelial dysfunction can cause the development of diabetes, and there is a common pathway that may link arterial stiffness and endothelial dysfunction to the development of diabetes, or possibly that these 2 factors reinforce each other [8,39]. Second, arterial stiffness may lead to microvascular dysfunction, which in turn leads to damage to low-resistance organs (eg, the pancreas), resulting in reduced tissue perfusion, including insulin-mediated muscle perfusion. This will lead to impaired glucose metabolism, insulin resistance, and an elevated fasting glucose level [7,40]. In this process, endothelial dysfunction and impaired endothelium-dependent vasodilation may exacerbate insulin resistance by limiting glucose delivery to key target tissues [41]. Third, increased oxidative stress and chronic low-grade inflammation may be common risk factors for atherosclerosis and diabetes [42,43].

The mechanisms underpinning the relationship of obesity with diabetes are only partially understood. Most of the hypotheses about obesity causing diabetes in recent years have been based on the coexistence of insulin resistance. Randle et al [44], for the first time, explained the relationship between obesity and diabetes by the “glucose-fatty acid cycle,” proposing a theory that obesity inhibits the glycolytic enzymes pyruvate dehydrogenase, phosphofructokinase, and hexokinase, thus causing an imbalance in glucose metabolism [45]. Another hypothesis is that adipose tissue is a secretory organ that produces and releases a variety of factors that may lead to insulin resistance. Most of the data suggested that tumor necrosis factor alpha (TNF-α) plays a mediating role [46]. Upregulated TNF-α induces multiple adverse effects, such as impaired insulin signaling and inhibition of glucose transporter type 4 expression, which inhibits glucose uptake [47]. TNF-α could reduce the expression of lipocalin, a protein that is abundantly expressed in adipocytes and has direct anti diabetic and antiatherosclerotic effects [48]. In addition, there are several hypotheses about signaling pathways of adipose tissue inflammation [49], endoplasmic reticulum stress [50], oxidative stress [51], and accumulation of immune cells [52], which are related to insulin resistance and insulin secretion.

This cohort study proposed the concept of arterial stiffness abdominal obesity phenotype to stratify the risk of incident diabetes. However, the results should be interpreted in the context of limitations. First, baPWV measures the stiffness of both the elastic aorta and muscular artery, and other index of arterial stiffness such as carotid-femoral pulse wave velocity was not collected in this study. Second, this was an observational study design, and we were unable to claim the causal effect of arterial stiffness obesity groups on diabetes onset. Third, although we adjusted for the important confounding factors, including fasting glucose level, there was still a possibility of residual confounding bias, such as dietary factors. The observed results require further validation in other populations.

**Conclusions**

The findings indicated the combined effect of arterial stiffness and obesity status on diabetes onset, independent of fasting glucose level. This study proposed the concept of arterial stiffness abdominal obesity phenotype, providing a noninvasive and simple panel for the risk stratification and potential management of diabetes.

Abstract

Background: Health care avoidance in the COVID-19 pandemic has been widely reported. Yet few studies have investigated the dynamics of hospital avoidance behavior during pandemic waves and inferred its impact on excess non–COVID-19 deaths.

Objective: This study aimed to measure the impact of hospital avoidance on excess non–COVID-19 deaths in public hospitals in Hong Kong.

Methods: This was a retrospective cohort study involving 11,966,786 patients examined between January 1, 2016, and December 31, 2021, in Hong Kong. All data were linked to service, treatment, and outcomes. To estimate excess mortality, the 2-stage least squares method was used with daily tallies of emergency department (ED) visits and 28-day mortality. Records for older people were categorized by long-term care (LTC) home status, and comorbidities were used to explain the demographic and clinical attributes of excess 28-day mortality. The primary outcome was actual excess death in 2020 and 2021. The 2-stage least squares method was used to estimate the daily excess 28-day mortality by daily reduced visits.

Results: Compared with the prepandemic (2016-2019) average, there was a reduction in total ED visits in 2020 of 25.4% (548,116/2,142,609). During the same period, the 28-day mortality of non–COVID-19 ED deaths increased by 7.82% (2689/34,370) compared with 2016-2019. The actual excess deaths in 2020 and 2021 were 3143 and 4013, respectively. The estimated total excess non–COVID-19 28-day deaths among older people in 2020 to 2021 were 1958 (95% CI 1100-2820; no time lag). Deaths on arrival (DOAs) or deaths before arrival (DBAs) increased by 33.6% (1457/4336) in 2020, while non–DOA/DBAs increased only by a moderate 4.97% (1202/24,204). In both types of deaths, the increases were higher during wave periods than in nonwave periods. Moreover, non-LTC patients saw a greater reduction in ED visits than LTC patients across all waves, by more than 10% (non-LTC: 93,896/363,879, 25.8%; LTC: 7,956/67,090, 11.9%). Most of the comorbidity subsets demonstrated an annualized reduction in visits in 2020. Renal diseases and severe liver diseases saw notable increases in deaths.

Conclusions: We demonstrated a statistical method to estimate hospital avoidance behavior during a pandemic and quantified the consequent excess 28-day mortality with a focus on older people, who had high frequencies of ED visits and deaths. This study serves as an informed alert and possible investigational guideline for health care professionals for hospital avoidance behavior and its consequences.
Introduction

The COVID-19 pandemic has posed challenges to population health beyond infection. On one hand, viral infection is a major health threat to vulnerable patients; on the other hand, among all patients, hospital non–COVID-19 mortality increased significantly. A retrospective, multicenter study in the United States reported that 30-day risk-adjusted non–COVID-19 mortality has increased by more than 20% since the pandemic [1].

Emergency departments (EDs) play an important role in the management of patients infected with COVID-19 and those with other medical emergencies. It is the first point of contact for many COVID-19 patients. EDs play an important role in diagnosis, treatment, and infection control (by isolation or hospitalization, if necessary). However, EDs manage general patients at the same time, meaning that they have to reserve capacity to manage patients with other medical emergencies.

A significant reduction in ED visits has been observed worldwide since the COVID-19 pandemic [1-4]. This reduction may be attributed to either active efforts to avoid contracting the virus in health care facilities or to passive avoidance caused by mandatory lockdown measures [3-5]. Most quantitative studies have reported excess mortality associated with reduced ED visits, although to different degrees [2], and only a few inferred the causative effect [6]. Disease-specific analysis with simpler pandemic dynamics of both excess and reduced mortality have also been reported [7,8], yet the relationships across gender, age groups, and comorbidities remain a significant knowledge gap.

Delayed medical visits and subsequent delayed diagnosis and extended symptomatic periods are most often associated with a time-dependent progression [9-11]. A meta-analysis of delayed cancer care during the pandemic involving 62 studies identified 38 different categories of delays and disruptions with impacts on treatment, diagnosis, or general health services. However, the most frequent determinants for disruptions were provider- or system-related and were caused by reductions in service availability [12-15] rather than patient-related hospital avoidance.

In our previous work, we identified a significant reduction in ED visits in the first 8 months of the COVID-19 pandemic that was associated with an increase in deaths certified in the ED and 28-day mortality in Hong Kong [16,17], despite the service in EDs never being disrupted or reduced. However, the causal effect of this observation has not been established. In this territory-wide retrospective cohort study, we measured the impact of hospital avoidance among ED patients on excess mortality using ED patient data from 2016 to 2021, a period during which Hong Kong experienced a unique COVID-19 pandemic with 4 distinct waves.

Methods

Participants and Source of Data

We performed a territory-wide retrospective cohort study using data from the Clinical Data Analysis and Reporting System (CDARS) [18], an administrative clinical database managed by the Hospital Authority of the Hong Kong Special Administrative Region, China. CDARS includes patients’ demographics, death data, diagnoses, procedures, drug prescriptions, dispensing history, and laboratory results from all public hospitals and clinics in Hong Kong. It contains inpatient and outpatient data from over 90% of the 7.47 million people served by the Hong Kong Hospital Authority [19]. The accuracy of diagnostic codes for case identification in CDARS has been validated in previous reports [20-22] with good reliability [23,24].

Full-scale emergency medicine services providing 24-hour, emergency, physician-led care are only available in 18 public hospitals under the hospital authority. In the nonpandemic years of 2016-2019, the total number of visits at these 18 EDs was 8.6 million, equivalent to an average of 287 visits per 1000 population yearly [25].

All patients attending the EDs of the 18 public hospitals in Hong Kong in the prepandemic period of January 1, 2016, to December 31, 2019, and the pandemic period of January 1, 2020, to December 31, 2021, were included. Data extraction took place on February 1, 2022, so all patients were followed up for at least 28 days.

To avoid confounding related to visits by COVID-19–positive patients, all COVID-19–positive visits and inpatient episodes were excluded from analysis. Daily COVID-19 case numbers and confirmed COVID-19 death numbers were obtained from an actively maintained online repository. Data included sex, age, long-term care home (LTC) resident status, ED visit service data, International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) codes, and treatments. Among all records, there were 3716 ED visits recorded with positive polymerase chain reaction (PCR) testing results for COVID-19, and these records were excluded from the analysis.

Ethical Considerations

All patient record entries are anonymized. The institutional review board of the University of Hong Kong/Hospital Authority West Cluster approved the study (UW 20-112) and granted a waiver of participant consent.

Visit Reduction and 28-Day Mortality

Deaths within 28 days of the last ED visit are defined as 28-day mortality. This was imputed by death registration minus visit
date, which must be less than or equal to 28 days. Daily 28-day mortality counts were tallied by the deceased patients’ last visit dates. As visit reduction was hypothesized to take place prior to subsequent excess mortality, counting deaths by visit dates (instead of simply deaths by dates) is preferable. The percentage change in ED visits was analyzed for fair comparison across age and sex strata in each COVID-19 wave and after-wave period.

**Excess 28-Day Mortality Estimation by Causal Inference**

In this study, we used the 2-stage least squares (2SLS) method [26] to estimate the daily excess 28-day mortality from daily reduced visits. The 2SLS is a common tool for causal inference. Others have characterized the extent of excess deaths by regression [27], difference-in-difference [28], and propensity matching [29]. Yet these methods cannot infer causation between attendance and death in a population. The 2SLS model is visualized as follows (Multimedia Appendix 1, Figure S1 contains further details):

Five binary instrumental variables (IV) or Z were introduced to model the effect of COVID-19 waves on visit reduction: after-wave and wave 1 to wave 4. After-wave IV is 1 for dates after each wave and excludes all COVID-19 waves; otherwise it is 0. IV for waves 1 to 4 are 1 for dates within a COVID-19 wave; otherwise they are 0. Waves 1, 2, 3, and 4 were designated with reference to government actions (Multimedia Appendix 1, Table S1), which were usually implemented at the onset and recession of COVID-19 waves; hence, these act as pivotal timestamps of pandemic severity.

On validity of the wave periods as IVs, calendar time has been reported to be a valid IV [6,7] when dramatic changes in practice occur in a relatively short period of time. As calendar time has been used in COVID-19 literature as an IV [8-10], we believe that government announcements, policy changes, and surges in COVID-19 case numbers from nonwave to wave periods in Hong Kong can also be regarded as drastic changes and are not seasonal (ie, have no L/U-Z association), making the wave periods a valid IV. We also believe that by excluding COVID-19–positive patients from the study population, the association between COVID-19 and 28-day death numbers (ie, Z-Y) has been minimized.

Age and sex strata with mean daily 28-day mortality from 2016 to 2021 less than or equal to 1 were excluded from the causal inference analysis due to model instability. The strata were the age groups 0-17, 18-34, and 35-44 years and both sexes (male and female).

We used the ivreg package [11,30] of R (R Foundation for Statistical Computing) to implement 2SLS. First, the exposure (daily number of ED visits) was regressed on the 5 binary IVs: \( \beta_1 \) to \( \beta_5 \). Then, we regressed ead (death, i), that is, ED 28-day mortality, with \( i \) lagged days on the predicted exposure, (ie, attendance), which yielded the local average treatment effect (LATE) among the compliers of each age and gender stratum. In both stages, we added 4 terms for seasonality adjustment: year (2016 was 0), \( t \) (number of days since the first day of a year), squared \( t \), and cubic \( t \).

Time lag \( i \) was also introduced to investigate the lagging effect of visit reduction on future 28-day deaths. For example, the excess death coefficient, \( \theta_1 \), can be interpreted as follows: if \( \theta_1 \) is \(-0.02\) for a population at a time lag of 5 days, there is a reduction of 100 ED visits on a certain day that caused 2 excess deaths 5 days away. Multimedia Appendix 1, Figures S2A and 2B show the dynamics of visits and deaths estimated by 2SLS models in tandem with COVID-19 waves.

To establish the validity of using COVID-19 waves as instrumental variables, a partial \( F \) statistic test was conducted between instruments and exposure [31] (visit with no time lag).

**Individual-Level Longitudinal Analysis of the Incidence Rate of Deaths on Arrival or Deaths Before Arrival Among Older People**

Deaths on arrival (DOAs) or deaths before arrival (DBAs) among 2 groups of people (COVID-19 and pre–COVID-19) aged 65 years or older were identified by patient IDs and filtered by those who visited at least twice in their respective control periods. The COVID-19 DOA/DBA group of older people visited EDs from between July 1, 2020, and July 1, 2021. Changes in their individual incidence rates (daily ED visits) between January 1, 2019, and January 24, 2020, (the control period) and between January 25, 2020, (the pandemic start), and June 30, 2020 (the treatment period), were calculated. The pre–COVID-19 DOA/DBA group of older people visited EDs between July 1, 2018, and July 1, 2019. Changes in their individual incidence rates between January 1, 2017, and June 30, 2017 (the control period), and January 1, 2018, and June 30, 2018 (the treatment period), were calculated.

**DOA/DBAs and Comorbidities Among Older People**

To further investigate clinical attributes of the excess 28-day mortality among older patients, we divided patient mortality in EDs into DOA/DBAs and non-DOA/DBAs.

Among DOA/DBAs, most had no ICD-9-CM diagnosis code or were simply diagnosed as, for example, cardiac arrest, so their comorbidities cannot be inferred meaningfully. For non-DOA/DBAs, their diagnostic codes were mapped to Deyo comorbidities using the R package icd [32]. Episode ED admissions and 28-day mortality were counted for each selected comorbidity.

**Results**

We examined a total of 11,966,786 ED visit records from January 1, 2016, to December 31, 2021, among which there were 212,288 (1.8%) patient deaths within 28 days of their last visit to the ED. We found that 28-day ED mortality was 43,335 in 2020 and 44,205 in 2021, compared to the 2016-2019 average of 40,192 (Table 1).
Table 1. Yearly changes in absolute numbers of and ratios between total 28-day emergency department mortalities and registered all-cause deaths in Hong Kong government censuses; the values include the 2016-2019 average and values for 2020 and 2021.

Visit Reductions and 28-Day Mortality

Compared with the average in 2016-2019, there was a reduction in total ED visits in 2020 of 25.4% (548,116/2,142,609). Total ED visits were 1,594,493 in 2020 and 1,812,703 in 2021, compared to the 2016-2019 average of 2,142,609 (Multimedia Appendix 1, Table S2). During the same period, the 28-day mortality of non–COVID-19 ED deaths increased by 7.82% (3143/40,192) compared with 2016-2019 (Table 1). The COVID-19 pandemic progressed in Hong Kong through 4 distinct waves, with the fourth wave lasting until February 18, 2021, resulting in 149 COVID-19 deaths in 2020 and 64 in 2021. ED visits in 2016-2019 was roughly stable throughout the year, while in 2020 and 2021 they fluctuated and mostly showed noticeable decreases at the start of each wave and subsequent resurgences (Figures 1A and 1B). These decreases in ED visits in 2020 and 2021 generally correspond to an increase in excess ED deaths, particularly during the first and fourth waves (Figures 1E and 1F).

The number of ED visits and the 28-day mortality of ED patients in 2016-2019 and in 2020 and 2021 are shown in Figures 1C to 1F. Compared with the 2016-2019 average value in Figure 1C, the number of visits in 2020 and 2021 demonstrated an observable reduction, to between 3000 and 4000 daily, during each wave of COVID-19, followed by a gradual rebound to a higher visit number until the next wave. With relatively improved infection control in 2021, the number of visits reached
close to prepandemic levels in late 2021 (Figure 1E). The 28-day mortality in 2020 roughly followed the pattern of the 2016-2019 average until the fourth wave, during which the mortality reached its peak throughout the study period (Figure 1D and 1F). The median ED waiting time from entry to reaching a cubicle in 2020 displayed similar dynamics as the ED visit curve (Multimedia Appendix 1, Figure S3).

**Excess 28-day Mortality Estimation by Causal Inference**

Next, the reduced ED visits and 28-day excess mortality across age and sex groups were characterized. Visits in each wave period were adjusted to same-period 2016-2019 data, while after-wave period data across 2020 and 2021 were summed and adjusted. In all adult groups, female patients saw a larger reduction in annualized visits than male patients of the same age in every wave (Figure 2A). However, it is also notable that in the 55-to-64 and ≥65-year age groups, the patients were less affected by further waves with time. ED visits and excess 28-day deaths across age strata with percentage changes from the 2016-2019 average and 2020 and 2021 are shown in Figure 2B. The reduction of ED visits was attenuated in 2021 when compared with 2020, but it was not restored to the 2016-2019 average.

**Figure 2.** Seasonally adjusted changes in Hong Kong public hospital emergency department visits and 28-day mortality, segmented by age and sex, from 2016 to 2019 and in 2020 and 2021, per wave period and yearly. (A) Line plots of seasonally adjusted visit change percentage among age and sex groups across waves, with after-wave periods shown by dashed lines (see Methods). The seasonally adjusted visit change percentage is calculated as the same-period change percentage against the 2016 to 2019 average. (B) Emergency department visits and excess 28-day deaths across age strata with percentage changes between 2020 and the 2016 to 2019 average, as well as 2021 vs the 2016 to 2019 average. Numerical values are percentage changes from the 2016 to 2019 average to the annual sum of each year (2020 and 2021). (C) Line plots of excess 28-day mortality per 100 reduced emergency department visits among 45-54, 55-64, and ≥65 year age groups and sex groups (95% CIs are shown by the shaded areas) across 0-to-14-day delays. This was estimated by instrumental variable analysis, with wave and after-wave periods as instrument variables, emergency department attendance as exposure, and emergency department 28-day deaths as outcome.

Although the ≥65-year age group had the highest absolute numbers of ED visits in the study period (3,849,923 episodes; Multimedia Appendix 1, Table S1), the 0-to-17-year age group had by far the largest reduction in ED visits in 2020 and 2021 from the 2016-2019 average (range −49.4% to −59.3%, n=−65,232/132,330; −102,411/172,781; Figure 2B and Multimedia Appendix 1, Table S3).

Apart from being the largest contributor to the total number of ED visits, the older group also saw the largest excess 28-day mortality in 2020 and 2021 (Figure 2C). Older male patients had a similar excess 28-day mortality rate (with a 95% CI greater than 0) to female patients, with an immediate (no time lag) excess 28-day death rate of 0.953 (95% CI 0.382-1.52) per 100 reduced ED visits among male patients and 1.15 (95% CI 0.382-1.52) per 100 reduced ED visits among female patients and 1.15 (95% CI 0.382-1.52).
0.763-1.54) among female patients (Multimedia Appendix 1, Table S4). All partial $F$ statistics had a $P$ value <.05.

Multimedia Appendix 1, Table S5 provides estimates of older male and female total excess deaths by visit reduction in 2020 and 2021. The estimated total excess non–COVID-19 28-day deaths due to reduced ED visits among older people throughout 2020 and 2021 was 1958 (95% CI 1100-2820; no time lag). The actual excess deaths in 2020 and 2021 were 3143 and 4013, respectively, with the 2016-2019 average in the census [33,34] as the benchmark.

**Individual-Level, Longitudinal Analysis of Incidence Rate of DOA/DBAs Among Older People**

The ED excess 28-day mortality of older patients can be categorized as DOA/DBAs and non-DOA/DBAs. DOA/DBAs increased by 1457 or 35.1% in 2020, while non-DOA/DBA mortalities increased by only a moderate 1202 or 4.65% (Multimedia Appendix 1, Table S6). Table 2 provides a breakdown of the changes in both DOA/DBAs and non-DOA/DBAs; the increases were higher during wave periods than in nonwave periods. The corresponding results in 2021 generally follow the same trends as the ones in 2020.

Results in Table 3 show that there were more DOA/DBAs among older people without ED visits or who reduced their visits in the COVID-19 group when compared to their number of ED visits at least twice in prior months. Moreover, non-LTC patients saw a greater reduction in ED visits than LTC patients across all waves by more than 10% (non-LTC: 93,896/363,879, 25.8%; LTC: 7956/67,090, 11.9%) (Figure 3). We further broke down DOA/DBA and non-DOA/DBA mortalities among older people by their LTC residence status (Table 4). In 2020, DOA/DBAs among non-LTC residents increased by 42.4% (1284/3026), which is a more than 7-fold greater increase compared to that among LTC residents (173/1310, +13.2%). In 2021, the trends were similar, apart from a smaller LTC death increase. Taken together, these results show that non-LTC patients had a much higher rate of DOA/DBA excess ED deaths during the COVID-19 pandemic (when normalized against 2016-2019).

**Table 2.** Excess emergency department 28-day deaths in the ≥65-year age group, broken down by deaths on arrival or deaths before arrival (DOA/DBA) status; wave and nonwave periods in 2020 and 2021, as defined in Multimedia Appendix 1, Table S1; and same-period 2016-2019 average deaths.

DOA/DBAs and Comorbidities Among Older People
Most of the comorbidity subsets demonstrated an annualized reduction in visits in 2020, as shown in Figure 4. Patients diagnosed with renal diseases and severe liver diseases saw a notable increase in deaths.

Figure 4. Seasonally adjusted change in episode admission among people aged ≥65 years by comorbidity and 28-day all-cause mortality, as well as absolute yearly change in 28-day mortality, vs the 2016-2019 average in 2020 wave and nonwave periods. The blue line is the 1:1 visit and death change line, on which high mortality-rate situations like cardiac arrest and sudden death normally fall. Deaths on arrival/deaths before arrival were excluded. Comorbidities were defined by the Charlson comorbidities. CHF: congestive heart failure; DM: diabetes mellitus; MI: myocardial infarction; PUD: peptic ulcer disease; PVD: peripheral vascular disease.

Discussion

Principal Findings
This study used 2SLS modeling to quantify hospital avoidance behavior and resulting excess mortality in the COVID-19 pandemic across sex, age groups, and comorbidities. Through causal inference, we discovered a higher prevalence of hospital avoidance behavior in female patients, children, and adolescents during the study period. Although surges of COVID-19 patients may overwhelm health systems and increase excess 28-day deaths [35], the waiting time in EDs in 2020 did not vastly differ from the 2016-2019 average in Hong Kong (Multimedia Appendix 1, Figure S3) [36]. Thus, the capacity of ED service was not severely impacted in 2016-2021 and we can exclude the effect of ED capacity on excess death.

The association between COVID-19 waves and hospital avoidance was observed among all age and sex groups. However, the extent of reduction varied in each age group. Lange et al [37] reported a similarly greater age-related reduction in ED use under the National Syndromic Surveillance Program for patients with selected comorbidities. On the other hand, Hung et al [38] did not discover any statistically significant differences in hospital avoidance among different age groups in their survey.

Stratified by sex, we found that women avoided hospitals more than men. This concurs with the literature on hospital avoidance behavior during the pandemic [36-40].

The largest relative reduction in ED visits in this study was found in children and adolescents (Figure 2A, Multimedia Appendix 1, Table S2), which is consistent with previous reports. Parents or caretakers may weight infection risk more heavily than the risk of delayed illness management. They might resort to visiting clinics rather than the ED or even adopt home care, given that children and adolescents are the healthiest of all age groups.

At a population level, there was a statistically significant excess death rate among older people associated with reduced ED visits. The results in Table 3 show that at the individual level, there was a significant difference in hospital avoidance behavior among older people during the pandemic compared to the prepandemic period. These observations imply that in Hong Kong, excess deaths among older people confirmed by the ED were more often due to the individual’s decision to avoid hospitals and stay home despite being severely ill rather than because of worsened hospital treatment received during the pandemic. Further breakdown of the results (Multimedia Appendix 1, Tables S6 and S7) by LTC status shows that there was a significant decrease in non-LTC ED visits during the pandemic, and there were nearly half the number of non-LTC ED DOA/DBAs among older people (n=280) compared to their
Conclusion

We demonstrated a statistical method to estimate hospital avoidance behavior during a pandemic and quantified the consequent excess 28-day mortality with a focus on older people, who have a high frequency of ED visits and deaths. This study serves as an informed alert and possible investigational guideline for health care professionals on hospital avoidance behavior and its toll.

Abstract

Background: The World Health Organization emphasizes the importance of completely voluntary blood donation to maintain safe and sustainable blood supplies. However, the benefits of blood donation for donors, such as reducing the risk of disease, remain a topic of debate due to the existence of the healthy donor effect (HDE). This effect arises because of inherent health differences between blood donors and the general population, and it is also considered a methodological issue.

Objective: This study aims to generate a more detailed health profile of blood donors from a donor cohort study to mitigate and quantify the HDE and properly interpret the association between blood donation and disease outcomes among blood donors.

Methods: A retrospective cohort study was conducted between January 2012 and December 2018 among donors before their first donation. One-to-one propensity score matching was conducted through a random selection of individuals without any history of blood donation, as reported from their electronic health records. We conducted a Poisson regression between blood donors and non–blood donors before the first donation to estimate the adjusted incidence rate ratio (AIRR) of selected blood donation–related diseases, as defined by 13 categories of International Classification of Diseases, Tenth Revision (ICD-10) codes.

Results: Of the 0.6 million blood donors, 15,115 had an inpatient record before their first donation, whereas 17,356 non–blood donors had an inpatient record. For the comparison between blood donors and the matched non–blood donors, the HDE (the disease incidence rate ratio between non–blood donors and blood donors) was an AIRR of 1.152 (95% CI 1.127-1.178; \( P<.001 \)). Among disease categories not recommended for blood donation in China, the strongest HDE was observed in the ICD-10 D50-D89 codes, which pertain to diseases of the blood and blood-forming organs as well as certain disorders involving the immune mechanism (AIRR 3.225, 95% CI 2.402-4.330; \( P<.001 \)). After age stratification, we found that people who had their first blood donation between 46-55 years old had the strongest HDE (AIRR 1.816, 95% CI 1.707-1.932; \( P<.001 \)). Both male and female donors had significant HDE (AIRR 1.082, 95% CI 1.05-1.116; \( P=.003 \); and AIRR 1.236, 95% CI 1.196-1.277; \( P<.001 \), respectively) compared with matched non–blood donors.
**Conclusions:** Our research findings suggest that the HDE is present among blood donors, particularly among female donors and those who first donated blood between the ages of 46 and 55 years.

**Introduction**

The World Health Organization (WHO) promotes voluntary blood donation as the safest and most effective means to maintain an adequate supply of safe blood and blood products for transfusion. To ensure the safety and sustainability of blood supplies, the WHO advocates for completely voluntary blood donation without compensation. Despite the collection of approximately 118.54 million blood donations worldwide [1], the benefits of blood donation for donors are still a matter of debate, as some studies suggest the existence of the healthy donor effect (HDE).

The HDE refers to the observation that blood donors exhibit lower disease morbidity and mortality compared with the general population. This phenomenon can be attributed to the fact that blood donors are typically selected from a healthier subset of the population, due to both donor selection procedures and self-selection factors [2,3]. The HDE has been examined in numerous past studies by comparing the health status of blood donors to that of non–blood donors [3-8]. Although some studies have failed to reveal any significant effects on health status resulting from blood donation [4,6,7], others found substantial differences such as decreased cancer incidence [5] and better cardiovascular status in blood donors compared with the general population [9]. The findings regarding the HDE have been largely inconclusive and sometimes contradictory, mainly because researchers were not able to deal with inevitable selection bias, that is, the fact that donors have better healthier status due to the donation policy requirements. In practice, it is nearly impossible to determine whether a beneficial health status observed in blood donors reflects the inherent healthier status of donors or the actual health gains due to blood donation [8]. Thus, it is important to mitigate and quantify the HDE to properly interpret the association between blood donation and disease outcomes.

Multiple methods have been used to address the HDE in various studies. The main strategy is to apply an exposure window or qualification period to potentially mitigate the HDE [10]. It mainly involves using 1 qualification period (ie, all donors must donate for at least 5 or 10 years to be eligible for the study) to adjust for the HDE [11-13]. However, this effort to reduce the HDE is conducted after blood donation. In addition, some studies reduce selection bias by analyzing only healthier groups; comparing differences within blood donors; and dealing with mixed bias, including the HDE, through ANOVA or some form of regression analysis [14-17]. However, adjusting age, sex, and demographic factors to reduce the HDE through some form of statistical strategy will affect the probability of subsequent exposure, and adjusting for confounding factors is not enough to address the HDE sufficiently [15,16]. To avoid the possible bias, another method is to compare or restrict the study within the active donor population, which still cannot exclude the existence of the residual HDE from most observational studies [14,17,18]. Currently, there is no evidence to certify the existence of the HDE prior to donation. The major weakness is that the potential HDE is not quantified and is usually estimated by researchers [10].

The first step to reduce the HDE is to accurately estimate it. The precise assessment of the HDE can be retrospectively obtained during the predonation period. Leveraging our large blood donor cohort, which is among the largest in the world, we are able to match non–blood donors and thus overcome the major limitations of previous studies on the HDE. This would allow us to obtain unprecedented insights into the health status of blood donors and non–blood donors and to quantify the HDE in a more accurate manner. Our study was conducted as a retrospective cohort study, wherein the health status of blood donors and non–blood donors were compared by one-to-one propensity score matching (PSM). Our main objective is to confirm the existence of the HDE in the population while also assessing the impacts of age and sex on the HDE. Through this comprehensive analysis, we aim to generate a more detailed health profile of blood donors to certify the HDE and better understand the underlying factors that contribute to it.

**Methods**

**Data Source**

We extracted the disease information from blood donors in Shaanxi Province, which is located in Northwest China. The Shaanxi Blood Donation Database is a computerized, combined donation and transfusion register from 3.4 million individuals who donated blood voluntarily between 1998-2018, and their relevant blood information was collected in the Shaanxi Blood Donor Database by linking with province-wide Shaanxi electronic health records (EHRs) and centralized hospital medical records. From this linkage, all the inpatient records of the donors can be searched. This database also tracks the disease information of participants without any history of blood donation. We have provided detail information for this cohort in our previous publication [19]. The disease burden of blood donors and non–blood donors was demonstrated. This natural and representative population cohort could be used to describe the health profiles of blood donors and investigate the potential HDE for selected clinically diagnosed diseases (as listed below) for donors, compared with non–blood donors, before the first donation date.
We initially included 3,389,981 donors in the cohort, and 1,907,146 had health records from January 1, 2012, to December 31, 2018. We excluded 1,063,418 participants with disease records before 2012, resulting in 641,523 qualified EHR records of eligible donors. Based on this information, we established a control group with the same criteria by using one-to-one matching to the donor group. Our study recognized the substantial impact of factors such as population aging, sex disparities, environmental issues, and rural-urban differences on individual health [20-23]. Thus, to provide a more accurate assessment of the HDE, we used a PSM analysis. This approach allowed us to match non–blood donors to blood donors with identical demographic characteristics (sex, age, and residence) from the EHRs and investigate the occurrence of a wide range of inpatient diseases defined by International Classification of Diseases, Tenth Revision (ICD-10) codes prior to the first donation date. The number of disease records was calculated during 2012-2018 and was extracted from the inpatient record, which is automatically uploaded from the hospital system. The matching was conducted by random sampling without the replacement of individuals without any history of blood donation from the EHR. We only extracted the disease information related to the blood donation criteria, resulting in the blood donor data set and non–blood donor data set having 58,235 and 57,002 inpatient records, respectively. Then, we further restricted the disease records to before the donation period, resulting in 15,115 donor records and 17,356 nondonor records, respectively (Figure 1).

Figure 1. Study flowchart of the longitudinal study.

Selection of Diseases
According to the national guidelines for blood donation requirements [24], only specific diseases that are related to blood donation were selected for study. Thus, diseases corresponding to injury, poisoning, pregnancy, childbirth and the puerperium, and others were excluded. We only collected disease information for 13 categories—certain infectious and parasitic diseases (A00-B99); neoplasms (C00-D48); diseases of the blood and blood-forming organs and certain disorders involving the immune mechanism (D50-D89); endocrine, nutritional, and metabolic diseases (E00-E90); mental and behavioral disorders (F00-F99); diseases of the nervous system (G00-G99); diseases of the circulatory system (I00-I99); diseases of the respiratory system (J00-J99); diseases of the skin and subcutaneous tissue (L00-L99); diseases of the genitourinary system (N00-N99); external causes of morbidity and mortality (V01-Y98); and factors influencing health status and contact with health services (Z00-Z99)—to conduct the comparison between blood donors and non–blood donors before donation.

Inclusion and Exclusion Criteria
In this cohort, we only included (1) blood donors who gave their first donation between 2012 and 2018 and (2) blood donors who have EHR records between 2012 and 2018 in Shaanxi Province. We excluded (1) blood donors without a blood donation date; (2) blood donors with a disease record before 2012 or who left Shaanxi Province; and (3) blood donors with incomplete demographic information. For the control group of
non–blood donors, identical inclusion and exclusion criteria were implemented, with the exception of content specific to blood donation. This standardized approach ensures comparability between the blood donor and non–blood donor cohorts, establishing a robust foundation for our comprehensive investigation into the HDE.

Assessing the HDE

We then specifically collected the disease information of these blood donors between baseline and the date of their first blood donation. Similarly, we also extracted the disease information of the matching non–blood donors during the same time and compared the disease rates to quantify the HDE. For example, we collected the number of certain infectious and parasitic diseases (A00-B99) diagnosed among donors and nondonors during the study period, which was used as the numerator, whereas the total observed number of donors and nondonors (it is the same number in this study; n=641,523) was used as the denominator (Figure 2). Then, we further estimated the incidence rate ratio between these 2 groups.

According to the Chinese blood donation guidelines, we set the age criteria for entering the cohort as 18-55 years, and we stratified age into 4 groups (18-25, 26-35, 36-45, and 46-55 years). The age when the participants entered the cohort was used. The model compared all the disease rates among male and female donors and nondonors among the 4 age groups. Poisson regression models were built to identify donors’ and nondonors’ health status in the respective exposure windows. The observed period was defined as from 2012 to the first donation date, and the non–blood donors used the same cutoff point accordingly (Figure 2).

Figure 2. Study schematic of the longitudinal study.

Statistical Analysis

Poisson regression is often used for count data where the outcome variable represents the number of events that occur in a fixed interval of time or space. It is also appropriate for rare events [25]. This methodology has been widely used in HDE studies [3,26]. We used Poisson regression to compare the likelihood of becoming hospitalized between blood donors and non–blood donors prior to the first blood donation. The adjusted incidence rate ratio (AIRR) was used as an estimate of the ratio of the incident risks for an event for the non–blood donors to the risks for the blood donors during the study period; that is, the reference group is blood donors. The model was adjusted by occupation, education, and marital status. The waiting period between hospital discharge and first blood donation was calculated for each age group in each disease category. Descriptive and inferential statistical analyses were conducted as part of our methodology. Mean and SD were used to summarize age and donation counts, whereas median and IQR were used to summarize the duration in days between discharge and the first donation. For categorical variables, we described them using frequencies and percentages. In the context of inferential statistical tests, we used both multivariate regression analyses and sensitive analysis to evaluate model assumptions and validate the suitability of our chosen analytical techniques. All statistical analyses and data handling were conducted with computer software (SAS version 9.4; SAS Institute).

Ethical Considerations

Ethical approval for the study was obtained from the institutional review board of the People’s Hospital of Shaanxi Province (No: 2020-R002). The study was preregistered at China National Medical Research Register (MR-61-21-011750) and Chinese Clinical Trial Registry (ChiCTR2200055983). Since our study is a secondary analysis using existing data with primary consent, where the original consent or institutional review board approval covers secondary analysis, no additional consent was needed for this study. The data have been deidentified and can only be accessed by the researcher group for this study.

Results

Baseline Characteristics

This study included 641,523 blood donors and 641,523 non–blood donors, which were matched by age, sex, and region. There were 396,681 male donors and 244,842 female donors in the study, and a total of 3,396,992 person-years (PYs) were observed. The mean age was 30.4 (SD 9.3) years, with most of them (253,045/641,523, 39.4% for both groups) being aged 18-25 years. The majority (429,421/641,523, 66.9%) of the blood donors came from Central Shaanxi, 26.6% (170,274/641,523) came from South Shaanxi, and 6.5% (41,828/641,523) came from North Shaanxi. Age, sex, and region distributions of the non–blood donors were the same as
those of blood donors. Regarding education, 59.2% (379,592/641,523) of the blood donors and 56.9% (365,294/641,523) of non–blood donors had received an education of junior high school or below. Regarding occupation, 65.3% (418,757/641,523) of the blood donors and 61.2% (392,540/641,523) of the non–blood donors were farmers. Regarding marriage status, 71.4% (458,070/641,523) of the blood donors and 70.5% (452,156/641,523) of the non–blood donors were married. Baseline characteristics of the participants are displayed in Table 1.

\(^{a}\)Chi-square test.

### Disease Burden Among Donors

Among the blood donors, 15,115 participants had inpatient records during the observed period, with a median follow-up duration of 1061 (IQR 510-1803) days. The disease incidence consistently showed an upward trend with age: it increased from 26.69 per 10,000 PYs for the 18-25 years age group to 86.98 per 10,000 PYs for the 46-55 years age group. Diseases of the digestive system (K00-K93) were most reported diseases among blood donors with 3240 records, which was followed by diseases of the circulatory system (I00-I99; n=2856) and diseases of the genitourinary system (N00-N99; n=2519). Diseases of the circulatory system (I00-I99) were the most reported diseases with an incidence rate of 30.30 per 10,000 PYs in the 46-55 years age group.

### Disease Burden Among Non–Blood Donors

Among non–blood donors, 17,356 participants had inpatient records during the observed period. The disease incidence increased with age: it ranged from 34.63 per 10,000 PYs for the 18-25 years age group to 149.51 per 10,000 PYs for the 46-55 years age group. There were 3462 patients who had...
diseases of the digestive system (K00-K93), which was the most reported disease, followed by diseases of the circulatory system (I00-I99; n=3042) and diseases of the genitourinary system (N00-N99; n=2533). The highest incidence of 44.36 per 10,000 PYs was found among diseases of the circulatory system (I00-I99) in the 46-55 years age group.

**HDE on the Overall Population**

Overall, the risk of reporting ICD-10 diseases in nondonors was generally higher than that from donors before the first blood donation (AIRR 1.152, 95% CI 1.127-1.178; \(P<.001\)), which was defined as the existence of HDE. The top 3 diseases with the strongest HDE were observed in diseases of the blood and blood-forming organs and certain disorders involving the immune mechanism (D50-D89; AIRR 3.225, 95% CI 2.402-4.330; \(P<.001\)); certain infectious and parasitic diseases (A00-B99; AIRR 1.995, 95% CI 1.812-2.196; \(P<.001\)); and factors influencing health status and contact with health services (Z00-Z99; AIRR 1.980, 95% CI 1.796-2.184; \(P<.001\)). When considering the specific diseases, non–blood donors had a lower risk in relation to diseases of the nervous system (G00-G99; AIRR 0.939, 95% CI 0.841-1.049; \(P=.13\)); diseases of the respiratory system (J00-J99; AIRR 0.933, 95% CI 0.882-1.135; \(P=.29\)); diseases of the skin and subcutaneous tissue (L00-L99; AIRR 1.101, 95% CI 0.946-1.281; \(P=.21\)); and diseases of the genitourinary system (N00-N99; AIRR 1.006, 95% CI 0.952-1.064; \(P=.32\); Figure 3 and Table S1 in Multimedia Appendix 1).

**Figure 3.** Adjusted incidence rate ratio (AIRR) in comparing blood donation–related diseases between donors and nondonors: the healthy donor effect. ICD-10: International Classification of Diseases, Tenth Revision.

**HDE by Sex Differences**

Our study found that male and female individuals both have significant HDE, but it was stronger in female individuals (AIRR 1.236, 95% CI 1.196-1.277; \(P<.001\)) than male individuals (AIRR 1.082, 95% CI 1.050-1.116; \(P=.003\)). The most substantial difference was found in the risk of having factors influencing health status and contact with health services (Z00-Z99), as female non–blood donors in all age groups had a higher risk than blood donors, but only male non–blood donors aged 46-55 years had a higher risk (AIRR 2.273, 95% CI 1.205-4.289; \(P<.001\)). For diseases, the most significant difference was observed in the risk of diseases of the blood and blood-forming organs and certain disorders involving the immune mechanism (D50-D89); the HDE of female donors was stronger than that of male donors (female: AIRR 4.294, 95% CI 2.887-6.388; \(P<.001\) vs male: AIRR 2.042, 95% CI 1.299-3.210; \(P<.001\)). After age stratification, male donors who had their first donation between 46-55 years old had the strongest HDE among all age groups (AIRR 2.193, 95% CI 2.011-2.392; \(P<.001\)), whereas female donors who first donated between 18-25 years old had the strongest HDE (AIRR 1.571, 95% CI 1.465-1.685; \(P<.001\); Figure 4 and Tables S2-3 in Multimedia Appendix 1).
HDE by Age Groups

In terms of age groups, among non–blood donors, the 46-55 years age group showed the highest risk (AIRR 1.816, 95% CI 1.707-1.932; P < .001), followed by the 18-25 years age group (AIRR 1.302, 95% CI 1.245-1.362; P < .001). Conversely, the 26-35 and 36-45 years age groups did not show significant differences between donors and nondonors (AIRR 0.979, 95% CI 0.936-1.023; P = .21 and AIRR 0.988, 95% CI 0.951-1.025; P = .32, respectively). Notably, donors who initiated donation after the age of 46 years had a consistently better health status compared with non–blood donors. It was shown that non–blood donors had a 5-times higher risk than donors in diseases of the blood and blood-forming organs and certain disorders involving the immune mechanism (D50-D89; AIRR 5.181, 95% CI 1.968-13.636; P < .001) and a 3-times higher risk in endocrine, nutritional, and metabolic diseases (E00-E90; AIRR 3.384, 95% CI 2.612-4.383; P < .001) and certain infectious and parasitic diseases (A00-B99; AIRR 3.181, 95% CI 2.183-4.635; P < .001). Non–blood donors in all age classes were associated with higher risks for certain infectious and parasitic diseases (A00-B99); diseases of the blood and blood-forming organs and certain disorders involving the immune mechanism (D50-D89); endocrine, nutritional, and metabolic diseases (E00-E90); mental and behavioral disorders (F00-F99); and factors influencing health status and contact with health services (Z00-Z99) compared with donors (Figure 3 and Table S1 in Multimedia Appendix 1).

Sensitive Analysis

Upon conducting a comparative analysis, we made necessary adjustments to the overall findings by excluding the disease categories of external causes of morbidity and mortality (V01-Y98) and factors influencing health status and contact with health services (Z00-Z99). Subsequently, our results demonstrated a consistent increase in the risk of HDE among both blood donors and non–blood donors, with an AIRR of 1.117 (95% CI 1.092-1.143).

Gaps Between Hospital Discharge and First Blood Donation

The overall median waiting period between inpatients being discharged from the hospital and the first blood donation was 534 (IQR 241-960) days. This duration showed a declining trend with respect to age groups. The longest waiting period was found in the 18-25 years age group (median 592, IQR 267-1027 days). The shortest waiting period was found in the 46-55 years age group (median 439, IQR 204-813 days). In the 26-35 years age group, the gap was a median of 531 (IQR 240-970) days, whereas in the 36-45 years age group, the gap was a median of 521 (IQR 239-942) days. The longest gap was observed among those who had the disease category of neoplasms (C00-D48; median 673, IQR 358-1137 days).
followed by factors influencing health status and contact with health services (Z00-Z99; median 660, IQR 373-1109 days), and certain infectious and parasitic diseases (A00-B99; median 654, IQR 298-1154 days). The shortest gap was found in those with the disease category of endocrine, nutritional, and metabolic diseases (E00-E90; median 456, IQR 152-877 days).

Regarding the overall trend, the waiting period showed a descending trend, with the gap changing from a median of 592 (IQR 267-1027) days in 18-25 years age group to a median of 439 (IQR 204-813) days in the 46-55 years age group (Table 2).

**Discussion**

The findings of our study provide robust evidence of the existence of the HDE among blood donors in China. In line with the blood donation guidelines of the country, the overall health status of blood donors was found to be superior to that of non–blood donors, as evidenced by a reduced risk of developing selected diseases. In particular, individuals who had their first blood donation at or after the age of 46 years exhibited a significantly lower risk of developing diseases across all categories compared with non–blood donors. The results of our study highlight a marked disparity in the HDE by sex, with concerns that donating blood may negatively impact the health of participants with these conditions. Although previous research has aimed to disprove the HDE, our study is the first to both confirm its presence and quantify its magnitude.

Although blood donors generally exhibit a better health status than non–blood donors during the predonation period, our findings indicate that non–blood donors are superior in certain disease age groups. The disparity in health status between blood donors and non–blood donors could be attributed to several factors. First, our data revealed that blood donors with a higher disease rate than non–blood donors were all younger than the age of 45 years. This observation suggests that older donors may be more conscientious of their health and well-being [27,28]. Second, certain diseases, although they may require hospitalization, do not necessarily prohibit patients from donating blood. For instance, our data revealed that the majority of blood donors with inpatient records for respiratory diseases had contracted influenza or pneumonia (J09-J18). As the risk of transmitting these diseases directly through blood or blood products is extremely low, individuals who have recovered from these conditions and are free from clinical symptoms may still be eligible to donate blood [29]. Third, previous studies have shown that appropriate blood donation can help reduce the risk of certain diseases. Blood donation has been found to increase the concentrations of high-density lipoprotein and apolipoprotein A while also lowering the potential for oxidation of low-density lipoprotein (LDL) particles. Lower levels of LDL peroxidation may have a protective effect against certain diseases [30]. Additionally, blood donation has been associated with a reduced risk of circulatory diseases and tumors [31,32], possibly due to the reduction of iron concentrations in the body through blood loss therapy. However, some studies suggest that iron loss through blood donation may also be associated with certain diseases [6,33,34].
This study demonstrated that female individuals exhibited a stronger HDE than male individuals. This difference can be attributed to social and physiological factors, as well as the different incidence of common diseases in male and female individuals [35]. Furthermore, female individuals demonstrated a strong HDE in relation to oncology and digestive diseases, which may be related to life circumstances, work stress, and lifestyle factors such as smoking and alcohol consumption [36,37]. Interestingly, the results of age stratification indicated that the strength of the HDE differs between age categories. Specifically, female individuals between the ages of 18-45 years exhibited a stronger HDE than their male counterparts, whereas male individuals aged 46-55 years exhibited a stronger HDE compared to female individuals in the same age group. These results may be explained by the overall physiological differences that exist between male and female individuals in their reproductive stages, such as the menstrual cycle and pregnancy, which could lead to female donors paying more attention to their health and neonatal health and following the donation guidelines more closely, resulting in an increased HDE compared to male individuals [38]. Importantly, it is worth noting that the strength of HDE was no longer accentuated in female individuals after the age of 46 years, as they have entered the nonreproductive phase and the aforementioned reproductive factors have disappeared, resulting in a stronger HDE in male individuals compared to female individuals. These results highlight the importance of considering sex effects in the expression of the HDE.

We also found that the average time interval between participants donating blood and being discharged from hospital was almost 2 years. Given the shortage of blood storage, it is recommended that restrictions on donation requirements be discussed, similar to other countries [39], such as allowing inpatients with cured diseases to donate blood after a certain period. This is especially important during the COVID-19 outbreak, where blood supply shortages have been reported [40], and China has updated guidelines stating that patients with COVID-19 can donate blood after 7 days of seroconversion [41]. We are the first to demonstrate that older people have a shorter interval between discharge and blood donation than younger people, which may be due to 2 reasons. First, as the age limit for blood donation is ≤55 years, donors must donate blood before this age limit. Many countries have a higher age limit than China, and considering that life expectancy has increased in China, the age limit for blood donation may also need to be increased. Furthermore, China encourages donors to donate blood by allowing the donor or a family member to receive an equal volume of the donated blood with priority.

Older adults may have been more reluctant to donate blood previously but have become more accepting after this promotion policy was enacted. Consistent with this policy, donors aged 46-55 years have increased from 11.7% in 2012 to 19.6% in 2018 in Shaanxi Province, whereas donors aged 18-25 years have decreased from 36.7% in 2012 to 30.3% in 2018 [42]. However, it is crucial to ensure the safety of blood transfusions, particularly for donors with hospitalization records. To address this, we recommend that blood centers link donors’ identification with their EHRs, allowing health care staff to access their previous disease history and determine their eligibility for blood donation. In China, the National Health Commission has been promoting the establishment of EHRs with various policies and financial support since 2010 [43]. The health system can be effectively used to inform donors about their medical history, and only healthy individuals with eligible medical histories could be qualified to donate blood or blood components.

Some limitations should be noted in this study. First, as a retrospective study, the records were extracted from the EHR, and the number of people who left the province was not recorded, which may have influenced the hospitalization rate. However, based on the current data, the proportion of immigrants from Shaanxi Province is approximately 10%, and this is unlikely to significantly affect the results. Second, environmental factors and family medical history, both of which may have an impact on respiratory diseases and tumors, were not taken into account in the study. Third, blood routine and liver function data were not readily available for non–blood donors, so we cannot include these factors in the PSM process at baseline. Given that blood routine and liver function tests involve multiple indicators, participants with abnormal data in these tests may potentially have asymptomatic diseases that have not yet been diagnosed. This limitation introduces a potential source of confounding bias in our investigation of related diseases. Finally, the duration of hospitalization may have been influenced by the economic and health care quality factors of the admitting hospitals, which could not be considered in the analysis. Despite these limitations, this study is the first and largest population-based study to provide comprehensive evidence of the existence of the HDE, especially for the female donors and donors who donate over the age of 46 years. We highlighted the substantial differences in blood-related diseases between blood donors and non–blood donors prior to donation. Consequently, this has the potential to introduce bias in comparing donor effects between the 2 groups. Future studies should aim to develop more accurate methods to calculate donor effects and eliminate this bias.

Abstract

Background: In Italy, it has been difficult to accurately quantify hospital admissions of patients with a COVID-19 diagnosis using the Hospital Information System (HIS), mainly due to the heterogeneity of codes used in the hospital discharge records during different waves of the COVID-19 pandemic.

Objective: The objective of this study was to define a specific combination of codes to identify the COVID-19 hospitalizations within the HIS and to investigate the risk factors associated with mortality due to COVID-19 among patients admitted to Italian hospitals in 2020.

Methods: A retrospective study was conducted using the hospital discharge records, provided by more than 1300 public and private Italian hospitals. Inpatient hospitalizations were detected by implementing an algorithm based on specific International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) code combinations. Hospitalizations were analyzed by different clinical presentations associated with COVID-19 diagnoses. In addition, 2 multivariable Cox regression models were performed among patients hospitalized “due to COVID-19” from January 1 to December 31, 2020, to investigate potential risk factors associated with 30-day death and the temporal changes over the course of the pandemic; in particular, the 30-day death rates during the first and the second waves were analyzed across 3 main geographical areas (North, Center, and South and Islands) and by discharge wards (ordinary and intensive care).

Results: We identified a total of 325,810 hospitalizations with COVID-19–related diagnosis codes. Among these, 73.4% (n=239,114) were classified as “due to COVID-19,” 14.5% (n=47,416) as “SARS-CoV-2 positive, but not due to COVID-19,” and 12.1% (n=39,280) as “suspected COVID-19” hospitalizations. The cohort of patients hospitalized “due to COVID-19” included 205,048 patients, with a median age of 72 years and a higher prevalence of male patients (n=124,181, 60.6%). The overall 30-day death rate among hospitalized patients due to COVID-19 was 9.9 per 1000 person-days. Mortality was lower for women (hazard ratio [HR]=0.83; P<.001) and for patients coming from high migration pressure countries, especially Northern Africans (HR=0.65; P<.001) and Central and Eastern Europeans (HR=0.66; P<.001), compared to patients coming from Italy and high-income countries. In the southern regions and the Islands, mortality was higher compared to the northern regions (HR=1.17; P<.001), especially during the second wave of COVID-19 among patients with a transfer to intensive care units (HR=2.52; P<.001).

Conclusions: To our knowledge, the algorithm is the first attempt to define, at a national level, selection criteria for identifying COVID-19 hospitalizations within the HIS. The implemented algorithm will be used to monitor the pandemic over time, and the patients selected in 2020 will be followed up in the next years to assess the long-term effects of COVID-19.
Annex 1 of the Ministerial Decree and the guidelines issued on specific only with the Ministerial Decree of October 28, 2020 [14], by adapting unspecific codes already existing in the homogeneity in the criteria and methods of HDR coding (MoH) published the first guidelines to ensure the needed therefore, on March 20, 2020, the Italian Ministry of Health currently used in Italy for coding in the HDRs.

Indeed, with the beginning of the COVID-19 pandemic, the importance of human genetics in the onset and course of severity of the disease [6-8], evidence is arising about the association with a greater risk of death from COVID-19 [5]. Although environmental, clinical, and social characteristics have a role as risk factors for SARS-CoV-2 infection and the severity of the disease [6-8], evidence is arising about the importance of human genetics in the onset and course of COVID-19 [9,10].

In Italy, despite early data provided by the COVID-19 Integrated Surveillance System [11], it has been difficult to accurately quantify hospital admissions of patients with a COVID-19 diagnosis using the Hospital Information System (HIS), mainly due to the heterogeneity of codes used in the hospital discharge records (HDRs) during different waves of the COVID-19 pandemic.

Indeed, with the beginning of the COVID-19 pandemic, the World Health Organization provided, in response to member state requests, codes and instructions for COVID-19 coding in the International Classification of Diseases, 10th Revision (ICD-10) and International Classification of Diseases, 11th Revision (ICD-11) [12], but not in the International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM), which is the international classification of diseases currently used in Italy for coding in the HDRs.

Therefore, on March 20, 2020, the Italian Ministry of Health (MoH) published the first guidelines to ensure the needed homogeneity in the criteria and methods of HDR coding throughout the country [13]. Such guidelines provide instructions to identify COVID-19 and related clinical conditions by adapting unspecific codes already existing in the ICD-9-CM. Only with the Ministerial Decree of October 28, 2020 [14], specific ICD-9-CM codes were introduced for COVID-19.

February 19, 2021, provided new instructions for both the principal and secondary diagnoses, aiming to overcome differences in coding among different Italian regions. However, the harmonization of COVID-19 information on HDRs has been gradual in different Italian regions, and sometimes, it was done retrospectively by updating and changing codes in HDRs.

The algorithm presented in this paper, based on the COVID-19 codes included in different MoH guidelines, the ICD-9-CM SARS codes, and the codes that reported a dramatic increase in 2020, has made it possible to quantify patients with COVID-19–related diagnoses admitted to Italian hospitals. Moreover, the algorithm made it possible to classify hospitalizations as “due to COVID-19,” “SARS-CoV-2 positive, but not due to COVID-19,” and “suspected COVID-19,” and investigate the risk factors associated with mortality “due to COVID-19” among patients admitted to Italian hospitals in 2020.

Moreover, the algorithm is important because other researchers could use it for potential investigations on specific issues related to the pandemic.

Methods

Source

A nationwide retrospective study was conducted using the HDRs on health care services in 2020, provided by more than 1300 public and private Italian hospitals. Hospital discharge data are routinely collected by the Italian MoH and contain patient demographic information (eg, gender and age), admission and discharge dates, up to 6 discharge diagnoses (ICD-9-CM), up to 11 medical procedures or surgical interventions, and status at discharge (eg, alive, deceased, or transferred to another hospital). In addition, the National Tax Registry was used to determine vital status or death following hospitalization. HDRs were linked with National Tax Registry records using deterministic record linkage.

Ethical Considerations

This study is conducted in accordance with the Ministerial Decree, “Evaluation in terms of quality, safety and appropriateness of activities provided for accreditation and contractual agreements with health facilities,” released on December 19, 2022, Article 4 [15]. This decree grants a mandate, inter alia, to the Italian National Agency for Regional Healthcare Services to monitor hospital activity and publish reports based on anonymized Italian hospitalizations. We did not include any identifiable data of patients’ personal information, including name, identity information, address, and telephone number; therefore, ethics approval was not required.
Algorithm to Identify COVID-19 Hospitalizations

Inpatient hospitalizations were detected by implementing an algorithm based on specific ICD-9-CM code combinations. This was carried out through the integration of 2 distinct approaches. One approach, deductive (ie, from the general rule to practical use), was based on the ICD-9-CM codes reported in the official documents of the MoH for COVID-19 case identifications. In addition, we used codes referring to SARS (though not specifically due to SARS-CoV-2), assuming that these codes, mainly at the beginning of the pandemic and before the MoH guidelines publication, were used to indicate COVID-19 hospitalizations. These codes are presented in Table 1.

<sup>a</sup>MoH: Ministry of Health.  
<sup>b</sup>ICD-9-CM: International Classification of Diseases, Ninth Revision, Clinical Modification.

The other approach, inductive (ie, from an empirical observation to a general rule) was used to confirm and integrate the algorithm. In detail, comparing the number of hospitalizations between 2019 and 2020, a dramatic increase was found in the principal diagnosis with the ICD-9-CM code 484.8 for “pneumonia in other infectious diseases classified elsewhere.” This code was presumed to be associated with COVID-19 and was integrated into the algorithm.

The hospitalizations were then grouped into clinical profiles according to a hierarchical approach based on 3 main criteria, as follows:

- The main reason for hospitalization: admissions categorized as “due to COVID-19” (codes identifying COVID-19 in the principal diagnosis) or “SARS-CoV-2 positive, but not due to COVID-19” (codes identifying COVID-19 only in secondary diagnosis).
- Degree of certainty: diagnosis confirmed or categorized as “suspected COVID-19”; the latter included hospitalizations with nonspecific diagnoses or V codes (exposure to SARS-CoV-2, observation, or isolation), for which it is difficult to ascertain if they refer to COVID-19 cases.
- Clinical presentation: pneumonia or acute respiratory distress syndrome, other acute respiratory infections, full-blown COVID-19 without respiratory symptoms, and asymptomatic or pauci/asymptomatic COVID-19.

All diagnosis codes and their combined use (algorithm) in the principal and secondary diagnoses used to select and classify COVID-19 hospitalizations are shown in Table S1 in Multimedia Appendix 1.

Statistical Analysis

Hospitalizations were analyzed with respect to the distribution of different clinical presentations associated with diagnoses of COVID-19.

A further analysis was performed only among patients hospitalized “due to COVID-19” from January 1 to December 31, 2020, to investigate potential risk factors associated with 30-day mortality. The cohort included all patients with at least 1 “due to COVID-19” hospitalization, excluding repeated admissions due to transfers to other hospitals or readmissions. Time-to-event techniques were used to analyze survival. The follow-up of patients began from the hospital admission date until either the ascertainment of death (outcome) or up to 30 days after admission (censoring).

The 30-day death rate was calculated as the total number of all-cause deaths up to 30 days after admission divided by the total follow-up days of hospitalized patients in the cohort and was reported per 1000 patient-days. To investigate the association of one or more risk factors with the 30-day death rate among patients hospitalized “due to COVID-19,” a multivariable Cox proportional-hazards regression model (Cox, 1972) was used, after having checked the proportional hazard assumption.

https://publichealth.jmir.org/2024/1/e44062
Sociodemographic data (eg, age, gender, area of residence, or nationality) were considered in the analysis. Patients were classified according to the following geographic areas of nationality: Italy or other high-income countries; migrants from high migration pressure countries (HMPC), which include Central and Eastern European countries (including those belonging to the European Union) and Malta; Northern African countries; other African countries; Central and South American countries, Asian countries (excluding Japan, Israel, and South Korea); and Oceania (excluding Australia and New Zealand) [16].

The transfer to ICU has been used as a proxy for the clinical severity of the disease.

The Charlson Comorbidity Index (CCI) [17,18] was used to account for current comorbidities or comorbidities over the previous 4 years in patients that could affect the death rate. To calculate the CCI, 17 medical conditions were considered [19,20]. The CCI was categorized into the following scores: CCI=0, CCI=1 or 2, and CCI³3.

To detect differences in the 30-day death rate during the year 2020, three pandemic periods were considered, as follows:

- First wave, including the Italian lockdown (January 1 to May 5, 2020)
- Postlockdown period (May 6 to October 7, 2020)
- Second wave (October 8 to December 31, 2020)

Two further multivariable Cox regression models were performed to assess temporal changes over the course of the pandemic; in particular, the 30-day death rates during the first and second waves were analyzed across 3 main geographical areas (ie, North, Center, and South and Islands) and by discharge wards (ie, ordinary and intensive care).

The selection of patients and hospital admissions was performed using SAS Studio (version 3.81; SAS Institute; Enterprise edition). The Cox proportional-hazards regression was performed using STATA (version 14.0; StataCorp). Tests were 2-sided, and statistical significance was set at \( P<.05 \).

Results

COVID-19 Hospitalizations Analysis

We identified a total of 325,810 hospitalizations with COVID-19-related diagnosis codes within the public and private accredited Italian hospitals throughout the year 2020 (Table 2).

A total of 239,114 (73.4%) out of the initial HDR selection were classified as “due to COVID-19” hospitalizations (in most cases, with a diagnosis of pneumonia and acute respiratory distress syndrome), and 47,416 (14.5%) were classified as “SARS-CoV-2 positive, but not due to COVID-19” hospitalizations, mainly in association with diseases of the circulatory system, injuries, chronic diseases of respiratory system, and complication of pregnancy, childbirth, and the puerperium.

The remaining 12.1% (n=39,280) were “suspected COVID-19 hospitalizations.” A high proportion of such hospitalizations (n=29,327, 9%) were also found in association with other pathological conditions reported in principal diagnosis.

There was a significant increase in the length of ICU stay out of the overall length of hospital stay (calculated in days), compared with the prepandemic period (1,031,037/54,170,360, 1.9% in 2019 vs 1,204,216/46,113,945, 2.6% in 2020; \( P<.001 \)).

In addition, this proportion was 2.6% (33,509/1,295,932) in 2020 for the “SARS-CoV-2 positive, but not due to COVID-19” and “suspected COVID-19” hospitalizations, while it increased to 8.4% (281,783/3,355,386) among the “due to COVID-19” hospitalizations (data are not shown in the Tables).

“Due to COVID-19” Patients Analysis

Table 3 shows the baseline demographic and clinical characteristics of patients hospitalized “due to COVID-19.”

The cohort included 205,048 patients, with a median age of 72 years. Of these patients, 147,266 (71.8%) were older than 60 years, and there was a higher prevalence of male patients (n=124,181, 60.6%). Additionally, 6.1% (n=12,364) were HMPC citizens coming from Central and Eastern Europe (n=3721, 1.8%), Asia (n=2842, 1.4%), Central and South America (n=2637, 1.3%), Northern Africa (n=1786, 0.9%), and other African countries (n=1378, 0.7%). More than two-thirds of patients resided in the northern Italian regions, while 31.5% (n=64,491) were in Central and Southern Italy. Over the 3 periods of analysis, 39.4% (n=80,843) of patients were hospitalized in the first wave, 53.9% (n=110,446) were hospitalized in the second wave, and only 6.7% (n=13,759) were hospitalized in the postlockdown period. A total of 199,283 (97.2%) patients reported a Charlson Comorbidity Index score lower than or equal to 2.

The overall 30-day death rate in patients hospitalized “due to COVID-19” was 9.9 per 1000 person-days. After adjustment, mortality was lower for women (HR=0.83; P<.001) and for patients coming from HMPC. Among the latter, North African patients (HR=0.65; P<.001) and patients from Central and Eastern Europe (HR=0.66; P<.001) were around 35% less likely to die within 30 days, compared to patients coming from Italy and other high-income countries; Asian patients as well as Central and Southern American patients were 17% less likely to die within 30 days.

aN/A: not applicable.
bMedian age was 72 years.
cThe North includes Valle d’Aosta, Piemonte, Liguria, Lombardia, Trentino-Alto Adige, Friuli-Venezia Giulia, Veneto, and Emilia-Romagna regions. The Center includes Toscana, Umbria, Marche, and Lazio regions. The South and Islands include Abruzzo, Molise, Campania, Puglia, Basilicata, Calabria, Sicilia, and Sardegna regions.

In addition, we found a higher 30-day survival in the central regions compared with the northern regions, which were the most affected by COVID-19 (HR=0.90; P<.001), while the southern regions and the Islands showed a higher risk of 30-day mortality (HR=1.17; P<.001).

Transfers to ICUs involved 13.8% (28,247/205,048) of hospitalized patients.

Patients referred to ICUs were two and a half times more likely to die within 30 days, compared to patients hospitalized in ordinary wards (HR=2.55; P<.001).
Table 4 shows the survival analysis by geographic area and wards during 2 pandemic waves.

Over the first wave, among patients in ordinary wards, we found a higher 30-day death rate in the northern regions (10.9 per 1000) compared to the central (7.7 per 1000) and southern islands regions (5.6 per 1000). On the contrary, among patients with a transfer to ICUs, the southern regions and the Islands showed a higher 30-day death rate (28.4 per 1000) compared to the northern regions (15.2 per 1000).

Table 4. Survival analysis of patients in hospitals due to COVID-19 during the first and the second waves of the pandemic by geographic area and wards of discharge in Italy in 2020.

Discussion

Principal Findings

In Italian hospitals, due to the lack of COVID-19 codes in the ICD-9-CM system, multiple codes were used for COVID-19 patient admissions throughout the pandemic outbreak; this made it difficult to identify COVID-19 hospitalizations. This study enabled the definition of a specific combination of codes to identify COVID-19 hospitalizations at the national level within the HIS. Additionally, it facilitated the investigation of risk factors associated with mortality due to COVID-19 among patients admitted to Italian hospitals in 2020. The selection algorithm made it possible to identify 239,114 hospitalizations “due to COVID-19” from HDR. This number is very similar to the data on hospital admissions gathered from the COVID-19 Integrated Surveillance System, which amounted to 240,542 [11]. The monthly trend (data are not shown in Tables) is also very similar in the 2 data sources. Only in a few regions, the number of cases derived from HDRs is lower than the number obtained from the Surveillance System, especially in the first wave of the pandemic, likely due to a miscoding of data at the beginning of the epidemiological crisis. Nevertheless, the use of HDR data for COVID-19 impact analyses remains preferable to Surveillance System data for several reasons. The Surveillance System is based on data provided by the regions to monitor the evolution of the pandemic with timely data. Nevertheless, HDR data, although less timely, have higher quality, as they are collected following criteria and rules established by national legislation and guidelines, which guarantee greater homogeneity and comparability across different periods and territories. Moreover, HDR contains more information than the Surveillance System, especially on comorbidities, and allows comparisons with non–COVID-19 hospitalizations as well.

Throughout the second wave, among patients in ordinary wards, there was a significant decrease in 30-day death rates in the northern regions (8.7 per 1000), whereas such rates increased up to 7.4 per 1000 person-days in the southern regions and the Islands. On the other hand, among patients with a transfer to ICUs, the 30-day death rate increased in all geographic areas, particularly in the southern regions and the Islands, where the number of ICU patients more than tripled from the first to the second wave; this resulted in a significantly higher mortality risk in the southern regions and the Islands compared to the northern ones (HR=2.52; P<0.001).

Overall, we observed a decrease in the 30-day death rate among patients hospitalized “due to COVID-19” between the 2 waves of the pandemic. This cannot be explained by the introduction of new pharmacological therapies [21]; however, it could be due to a better use of existing therapies associated with gained experience in managing the disease by health care providers and a more effective preparedness of the health care system, including reorganization of hospitals and increasing number of ICU beds for patients with COVID-19 [22].

In particular, in the second wave, mortality was reduced in the northern regions among patients treated in ordinary wards, with a lower proportion of cases referred to ICUs (from 9144/65,993, 13.9% to 7990/67,406, 11.9%); this may have led to a higher concentration of patients with severe symptoms in ICUs, consistent with a small increase in 30-day death rates (from 15.2 to 17.0 per 1000 person-days). On the contrary, in the southern regions and the Islands, mortality increased between the 2 waves, both in the ordinary wards and in the ICUs, and
this might be due to a higher burden on hospital care compared to the first wave, which had affected Southern Italy to a lesser extent. Furthermore, the South reported a decrease in non–COVID-19 hospitalizations, which was greater than the national mean [23], a sign indicating that the hospital system was struggling.

Our study also highlighted the lower 30-day death rate for women compared to men, regardless of age. The observed disparity may be attributed to sex-based differences in immunological responses, comorbidities prevalence, or differences in behaviours [24,25]. Consistent with several studies, this analysis showed that critically ill older patients were at high risk of disease severity and mortality [26,27]. Some studies also highlighted important post–COVID-19 sequelae in patients with cancer, which adversely affect survival and oncological outcomes after recovery [28].

Finally, our findings, consistent with the findings of a study carried out in the city of Milan [29], confirmed that mortality among migrants in hospitals due to COVID-19 was lower than that of Italians and people coming from high-income countries. The lower 30-day death rate observed among HMPC migrants can be explained as the effect of specific selection processes (especially in the early and late stages of the migration path), which tend to maintain the overall health status of the foreign population high. One of them is the so-called “healthy migrant effect,” a dynamic for which only people in good health tend to emigrate [30]. Another selection dynamic, known as the “salmon effect,” is due to the habit of older migrants, especially if ill, to go back to their country of origin [31].

Moreover, an Italian study on data retrieved from the COVID-19 Integrated Surveillance System found an interaction between nationality and the epidemic phases; the analysis stratified by year showed that compared to Italians, mortality and other severe clinical outcomes in non-Italian nationals slightly increased from the last months of 2020 through 2021. The authors hypothesize that reduced access to vaccination by the immigrated population could partly explain such an increase [32], as a high risk of missed vaccination was observed among non–Italian-born people living in Italy, both overall and for individuals ≥50 years of age [33].

Limitations
This study has several limitations. First, results may be affected by the information quality of the HDR or by missing or incorrect coding of some diagnoses, leading to possible underestimation of comorbidities. Therefore, to minimize the effect of underreporting bias, comorbidities over the previous 4 years were also retrieved.

Second, the study is based on the HDR, which collects administrative data and does not contain clinical information of patients, which is useful to better characterize COVID-19 severity. For this reason, the transfer to the ICU has been used in this study as a proxy for the clinical severity of the disease.

Third, due to the lack of specified COVID-19 codes from the onset of the pandemic, the overall hospitalizations detected through the algorithm might be underestimated.

Finally, the issue of patients hospitalized due to “suspected COVID-19,” which cannot be defined as COVID-19 cases, remains unsolved.

Conclusions
To our knowledge, the algorithm represents the first attempt to define, at the national level, selection criteria for identifying COVID-19 hospitalizations within the HIS. While awaiting the adoption of more updated International Classification of Diseases coding systems for hospital diagnoses and procedures in Italy, consistent with the World Health Organization recommendations, the implemented algorithm will be used to monitor the pandemic over time, and the patients selected in 2020 will be followed up in the subsequent years to assess the long-term effects of COVID-19.

Further analyses will be useful to assess the impact of the anti–COVID-19 vaccination campaign on the severity and mortality of the disease and to investigate possible inequalities between population subgroups.

Acknowledgments
We would like to thank Roberto Blaco for his technical support about the COVID-19 coding, Stella Lanzi for the Italian-to-English translation, Simona Gorietti for reference editing, and Elisa Guglielmi for organizational and administrative support. These individuals were not compensated for their role in the study.

This research received no external funding.

Data availability

Abstract

Background: The question of the utility of face masks in preventing acute respiratory infections has received renewed attention during the COVID-19 pandemic. However, given the inconclusive evidence from existing randomized controlled trials, evidence based on real-world data with high external validity is missing.

Objective: To add real-world evidence, this study aims to examine whether mask mandates in 51 countries and mask recommendations in 10 countries increased self-reported face mask use and reduced SARS-CoV-2 reproduction numbers and COVID-19 case growth rates.

Methods: We applied an event study approach to data pooled from four sources: (1) country-level information on self-reported mask use was obtained from the COVID-19 Trends and Impact Survey, (2) data from the Oxford COVID-19 Government Response Tracker provided information on face mask mandates and recommendations and any other nonpharmacological interventions implemented, (3) mobility indicators from Google’s Community Mobility Reports were also included, and (4) SARS-CoV-2 reproduction numbers and COVID-19 case growth rates were retrieved from the Our World in Data—COVID-19 data set.

Results: Mandates increased mask use by 8.81 percentage points ($P=.006$) on average, and SARS-CoV-2 reproduction numbers declined on average by $-0.31$ units ($P=.008$). Although no significant average effect of mask mandates was observed for growth rates of COVID-19 cases ($-0.98$ percentage points; $P=.56$), the results indicate incremental effects on days 26 ($-1.76$ percentage points; $P=.04$), 27 ($-1.89$ percentage points; $P=.05$), 29 ($-1.78$ percentage points; $P=.04$), and 30 ($-2.14$ percentage points; $P=.02$) after mandate implementation. For self-reported face mask use and reproduction numbers, incremental effects are seen 6 and 13 days after mandate implementation. Both incremental effects persist for $>30$ days. Furthermore, mask recommendations increased self-reported mask use on average ($5.84$ percentage points; $P<.001$). However, there were no effects of recommendations on SARS-CoV-2 reproduction numbers or COVID-19 case growth rates ($-0.06$ units; $P=.70$ and $-2.45$ percentage points; $P=.59$). Single incremental effects on self-reported mask use were observed on days 11 (3.96 percentage points; $P=.04$) and 25 to 27 (4.20 percentage points; $P=.048$ and 5.91 percentage points; $P=.01$) after recommendation. Recommendations also affected reproduction numbers on days 0 ($-0.07$ units; $P=.03$) and 1 ($-0.07$ units; $P=.03$) and between days 21 ($-0.09$ units; $P=.04$) and 28 ($-0.11$ units; $P=.05$) and case growth rates between days 1 and 4 ($-1.60$ percentage points; $P=.03$ and $-2.19$ percentage points; $P=.03$) and on day 23 ($-2.83$ percentage points; $P=.05$) after publication.
Conclusions: Contrary to recommendations, mask mandates can be used as an effective measure to reduce SARS-CoV-2 reproduction numbers. However, mandates alone are not sufficient to reduce growth rates of COVID-19 cases. Our study adds external validity to the existing randomized controlled trials on the effectiveness of face masks to reduce the spread of SARS-CoV-2.

Introduction

Background

Viral and bacterial acute respiratory infections (ARIs) are among the leading causes of death worldwide. With a total of 3.8%, ARIs contributed the fourth largest share to the global burden of disease in 2019 [1]. Thus, ARIs pose a significant threat to global health. A measure to prevent ARI, which has also been discussed extensively in the context of the COVID-19 pandemic, is the wearing of face masks. At the heart of this discussion are the following 2 considerations: first, a large proportion of COVID-19 infections are transmitted by asymptomatic individuals [2,3], and second, masks worn by infected individuals are thought to reduce transmission risks. Therefore, in the face of a potentially large number of undetected cases, it has been argued that wearing masks could contribute to a sustained decrease in the spread of COVID-19 [4]. In contrast, a recently updated Cochrane review did not reach a clear conclusion regarding the preventive efficacy of face masks for viral respiratory infections [5]. On the basis of 78 randomized controlled trials (RCTs) conducted during influenza seasons as well as during the H1N1 influenza and COVID-19 pandemics, the authors conclude that masks alone are not sufficient to reduce the spread of respiratory viruses. However, given the results, it should be noted that interpretation is complicated by the fact that adherence was low, and outcome measures varied across a large proportion of RCTs. Furthermore, the observations of Jefferson et al [5] are at odds with clinical trials demonstrating the efficacy of masks in protecting uninfected individuals from COVID-19 [6,7]. Clinical trials have also shown that masks reduce the risk of transmission of influenza or SARS-CoV-2 from previously infected individuals [8].

A key advantage of studies that are based on real-world data is their high external validity. As such, they can significantly complement the evidence from RCTs on the efficacy of face masks in protecting against ARIs. ARIs can be most effectively prevented at the population level when masks are worn by both susceptible and infectious individuals [8,9]. Following this line of reasoning, the World Health Organization issued a recommendation to publicly wear face masks to contain the spread of SARS-CoV-2 [10]. This recommendation has been adopted by countries around the world by implementing face mask mandates in 2020. As some countries and regions did not introduce any face mask policies, 3 studies used this fact to identify the causal effect of mandates on SARS-CoV-2 infections. Lyu and Wehby [11] conducted a natural experiment with real-world data to show that mandates in 15 states of the United States and Washington, District of Columbia, resulted in reductions in COVID-19 growth rates of up to 19%. Another study using real-world data from the Global COVID-19 Trends and Impact Survey (CTIS) found mask mandates in the United States to be related to decreases in daily new cases, daily new deaths, daily new hospital admissions, and increases in population shares wearing masks [12]. These findings are corroborated by Mitze et al [13], who, using a synthetic control design, found a 47% reduction in daily COVID-19 case growth rates attributable to a local mask mandate in Jena, Germany. In addition, 2 other population-level studies found evidence for a direct association between wearing face masks and COVID-19 outcomes. Controlling for time-constant unobserved heterogeneity, Rader et al [14] report decreasing growth rates of COVID-19 cases with increasing state-specific proportions of face mask wearers at the US state level. Leffler et al [15] use a cross-sectional design across 196 countries and observe that longer durations of face mask use are inversely associated with COVID-19 mortality.

Objectives

To our knowledge, no real-world studies have been conducted to compare the effects of face mask mandates on SARS-CoV-2 infections internationally. Our study provides missing evidence. A prerequisite for mask mandates to be effective is that they encourage populations to wear masks [5,16]. Therefore, we exploited longitudinal variations in outcomes to first evaluate the hypothesis that mask mandates increase mask use in 51 countries worldwide. We then used the same design to test the hypothesis that mask mandates lead to a decrease in SARS-CoV-2 reproduction numbers and growth rates in COVID-19–related cases. In planning future nonpharmacological interventions, it is also important to be able to assess whether mandates are necessary to achieve the desired effect on health outcomes or whether recommendations are sufficient. Thus, the hypothesis that recommendations for face masks would lead to an increase in self-reported face mask use and a reduction in SARS-CoV-2 reproduction numbers and COVID-19 case growth rates was also evaluated. COVID-19 is a specific type of ARI. Except for rhinovirus infections, ARIs are comparable in terms of their transmission routes. Therefore, the results of our study not only provide an indication of the effectiveness of face mask interventions in the context of the COVID-19 pandemic but may also be indicative of how future ARI outbreak scenarios could potentially be addressed.
**Methods**

**Measures**

We gathered information on the proportions of face mask wearers in 105 countries from the CTIS, which is administered by the Carnegie Mellon University and the University of Maryland in partnership with Meta [17]. The CTIS uses an administrative region-stratified random sample that was drawn daily from Facebook’s active user base. Via Facebook’s news feed, the drawn individuals were invited to participate in the survey. After obtaining informed consent, users were provided with a link to a web-based questionnaire on COVID-19–related attitudes, symptoms, and behaviors. Daily population shares of self-reported face mask users were calculated from the responses of survey participants who stated that they had worn a face mask always or most of the time when in public. Before aggregation, the individual-level observations were reweighted by means of survey weights provided by Meta. Although no information collected by the survey is shared with Meta, Meta itself calculated weights that adjust for nonresponse and sampling frame mismatches with country-specific populations based on age, gender, and administrative regions [18]. Weights were made available to researchers without disclosing any user-related content.

To allow for linear model specifications, we chose 2 country-specific COVID-19 outcome measures: SARS-CoV-2 reproduction numbers and 3-day growth rates of COVID-19–associated cases per 100,000 inhabitants. To obtain information on the progression of reproduction numbers over time, we used the Our World in Data—COVID-19 data set [19]. The daily effective reproduction numbers included in the data set were derived using Kalman filter estimates of weekly case growth rates, as described by Arroyo-Marioli et al [20].

Data on nonpharmacological interventions were obtained from the Oxford COVID-19 Government Response Tracker (OxCGRT) [21]. Between January 1, 2020, and December 31, 2022, the tracker collected the start and end dates of COVID-19–related policy interventions in 186 countries. The OxCGRT data set also includes a measure that captures the scope of face mask–related policies on an ordinal scale from 1 to 4. On this scale, 1 designates official face mask recommendations. Mandates are indicated by values ranging from 2 to 4. Using this scale, we defined the levels of mandates according to the extent to which exemptions from the obligation to wear face masks in public were made. Corresponding to a value of 2, level 1 applies to all mandates that required face masks to be worn in some public places where other people were present or where social distancing was not possible, such as certain shops or public transport. Level 2 is equivalent to a value of 3, which corresponds to mandates that were more restrictive and generally required people to wear face masks in public places where other people were present or where social distancing was not possible. Level-2 mandates only allowed people not to wear masks in places such as less crowded streets or parks. Level 3 corresponds to a value of 4 and means that face masks had to be worn outdoors at all times, regardless of location or the presence of other people. We created dummy variables for each mandate level to indicate whether the mandates at a particular level were enacted at a particular time. The OxCGRT data further include an item that differentiates between policies targeted at subgroups or entire populations. A control variable for country-specific face mask mandates that applied only to subgroups was generated from this item and the indicators for level-1 face mask mandates. The variable takes the value 1 at dates when the corresponding subgroup mandates were active; otherwise, it takes the value 0. This allows for the inclusion of all subgroup mandates. None of the included countries implemented subgroup mandates at a level higher than level 1. Furthermore, we added date-specific indicators of the following additional nonpharmacological interventions: school closures, bans on events and gatherings, international travel restrictions, curfews, and measures to protect older adults. Measures to protect older adults include recommendations or restrictions on the number of visitors and hygiene practices in nursing homes. At a given time, indicators for additional nonpharmacological interventions indicate whether the intervention is recommended or mandatory, as opposed to not recommended or mandatory. Country-level mobility indicators are also included in the analyses. The mobility indicator is calculated by Google from aggregated location data that users have agreed to share through their devices. The metric indicates the daily relative changes in mobility as compared with the baseline period between January 3 and February 6, 2020 [22].

**Observational Sample**

For the analyses, we constructed a longitudinal data set by merging daily repeated cross-sections of the CTIS with the OxCGRT, Our World in Data, and Google mobility data sets. Beginning on April 23, 2020, when the first CTIS data became available, the observation period was restricted to October 31, 2020, yielding a total of 192 observation dates in calendar time. In total, 102 countries with national-level policy interventions targeted at general populations are commonly represented in all 3 data sets. Of these, 78.4% (80/102) enacted national mandates on the use of face masks in public. As the recording of the CTIS data commenced only after the interventions, the effects of face mask policies could not be identified for 43% (34/80) of the mandate countries. These countries were excluded from the analysis. Another 4% (3/80) of the mandate countries were excluded because information on SARS-CoV-2 reproduction numbers was not available at the time when mask mandates became effective.

The CTIS data and information on SARS-CoV-2 reproduction numbers and COVID-19 case growth rates were available for 100% (8/8) of the countries that did not enact any face mask policies throughout the observation period. These countries served as the control group. As can be inferred from Table 1 [17,21], this resulted in a total of 51 observed countries worldwide, out of which 84% (43/51) countries implemented level-1 face mask interventions. The countries included were Albania, Azerbaijan, Belgium, Bangladesh, Belarus, Bolivia, Costa Rica, Germany, Denmark, Egypt, Finland, France, Ghana, Greece, Honduras, Croatia, Hungary, Ireland, Jordan, Japan, Kazakhstan, South Korea, Kuwait, Libya, Sri Lanka, Moldova, Myanmar, Nigeria, Nicaragua, the Netherlands, Nepal, New Zealand, Oman, Panama, the Philippines, Portugal, Paraguay,

Empirical Strategy

To evaluate face mask mandates, we follow the recommendations of Lison et al [23] for effectiveness assessments of nonpharmacological interventions. A test of our hypotheses is provided by the following potential outcomes framework: Let $y_{1,ct}$ denote a potential outcome of interest in country $c=1, 2, ..., C$ at calendar time $t=1, 2, ..., T$ if a mandate is implemented, $y_{0,ct}$ designates the potential outcome of interest in the same country if no mandate has been implemented. The average treatment effect on the outcome of interest in countries treated with mandates (average treatment effect on the treated [ATT]) is then defined as

$$\beta = \frac{E[y_{1,ct} - y_{0,ct}|D_{ct}=1]}{P(D_{ct}=1)}$$ (1)

where $D_{ct}=(0, 1)$ is a mandate indicator switching on during mandate period $s=1, 2, ..., S; S<T$. As any given country is only observed for either $D_{ct}=1$ or $D_{ct}=0$, the observed outcomes of interest $y_{ct}$ can be written

$$y_{ct} = y_{0,ct} + (y_{1,ct} - y_{0,ct}) \times D_{ct}$$ (2)

When fitted to real-world data such as those generated with the CTIS, models require additional identifying assumptions to provide causal interpretations of $\beta$. A first assumption that is being made is that, in the absence of any mandates, outcomes would exhibit parallel trends for intervention and nonintervention countries. The parallel trends assumption ensures that the estimates of the mandate effect are not biased by unobserved time-varying heterogeneity. The identification of the average treatment effect on countries with face mask mandates, $\beta$, further requires that country populations do not demonstrate any self-reported anticipatory uptake of face masks or decreases in SARS-CoV-2 reproduction numbers and COVID-19 case growth rates before mandate introduction. In terms of Granger causality, a causal interpretation can be given to estimate $\beta$ only if the mandate effects are observed after the intervention. In addition, we assume face mask mandates to homogeneously affect all intervention countries in all periods.

It must also be noted that the estimates $\beta$ are unbiased only under the strict exogeneity of $D_{ct}$. Furthermore, our empirical strategy aims to estimate changes in the levels of self-reported face mask use, SARS-CoV-2 reproduction numbers, and COVID-19 case growth rates. Countries with large differences in outcome baseline levels can therefore be included in the analysis without violating the underlying assumptions regarding the functional form of the model specifications, shown below in equation 3. On the basis of the preceding assumptions, we estimate the average mandate effects on the treated countries $\beta$ by

$$z_{ct} = \lambda_c + \phi_c + \beta_{ct} D_{ct} + \gamma X_{ct} + \epsilon_{ct}$$ (3)

whereby $y_{1,ct} = \exp(z_{ct})$ / 1+$\exp(z_{ct})$ designates the expected share of self-reported face mask users or $y_{ct}=z_{ct}$ indicates Sars-CoV-2 reproduction numbers or case growth rates, respectively. Within this specification strategy, country and calendar time fixed effects $\lambda_c$ and $\phi_c$ provide full nonparametric control for any unobserved time–constant and country-constant heterogeneity [24]. $X_{ct}$ represents a row vector of covariates containing subgroup treatment and treatment-level indicators. Measures of COVID-19 outcomes depend on country-specific testing rates [25]. Therefore, $X_{ct}$ also contains the number of country-specific COVID-19 tests per 100,000 inhabitants. Moreover, nonpharmacological interventions other than mask mandates as well as domestic mobility are a possible source of heterogeneity in SARS-CoV-2 reproduction numbers and COVID-19 case growth rates during the observation period. This may lead to biased estimates of the mandate effects. For SARS-CoV-2 reproduction numbers and COVID-19 case growth rates, $X_{ct}$ thus includes indicators for both country-level mobility and nonpharmacological interventions other than mask mandates. $\gamma$ is a column vector designating the corresponding parameters of interest. Assuming a quasi-binomial distribution of country proportions of self-reported face mask wearers, an error is given by $\epsilon_{ct} \sim \text{Logistic}(\mu, \phi)$, with mean $\mu$ and dispersion parameter $\phi$. $\epsilon_{ct} \sim (0, \sigma^2)$ is assumed for linear models of SARS-CoV-2 reproduction numbers and COVID-19 case growth rates. By specifying $r=0$, $T_0$ leads and lags of the mandate effect, with $T_0<0$ being the lowest and $T_0 \geq 0$ the highest number of leads and lags considered, we use a design that incorporates incremental mandate effects. This specification provides a test for the previously outlined assumption of no anticipatory events. As countries imposed face mask mandates at different calendar dates, using already treated countries as control groups for yet-to-be treated countries is likely to induce heterogeneities of policy effects across treated units. Therefore, estimating equation 3 with conventional two-way fixed effects methods would result in biased estimates $\beta$. Hence, to relax the treatment homogeneity assumption made in the preceding section, we group countries into cohorts depending on the calendar dates.
of mandates becoming effective, as suggested by Sun and Abraham [26]. Countries without any face mask mandates during the entire observation period are combined into a single control group. Cohort outcomes at \( r = -1 \), that is, the period before mandate implementation, are used as baseline outcomes. Estimates of average treatment effects are obtained by weighing the aggregated cohort-specific effects by cohort size.

**Ethical Considerations**

Only publicly available data aggregated at the country level have been analyzed. This eliminates any reidentification risks for individuals. The study did not require any direct or indirect interaction with humans. This means that the regulatory requirements for research involving humans are not met. Therefore, this study is exempt from institutional review board approval.

**Results**

**Descriptive Results**

Figure 1 [17,18,21] illustrates the daily average evolution of self-reported face mask use, SARS-CoV-2 reproduction numbers, and COVID-19 case growth rates in countries with mask mandates. Visual inspection of panel A reveals a substantial increase in self-reported face mask wearers around the time the regulations came into effect in these countries. As further shown in the panels B and C, no clear trends are visible for average SARS-CoV-2 reproduction numbers or growth rates of COVID-19 cases.

The timing of the introduction of face mask mandates in each country during the observation period is presented in Figure 2 [21]. There is a range of 186 days between the dates when mandates were introduced: although in Egypt and Qatar the wearing of masks in public was compulsory from 4 days after the start of the observation period, that is, from April 26, 2020, in Libya, it was only compulsory from October 29, 2020, that is, 3 days before the end of the observation period.

Effects of Face Mask Mandates

We first estimated equation 3 for proportions of self-reported face mask users, SARS-CoV-2 reproduction numbers, and growth rates of COVID-19–related cases. All postmandate period effects were aggregated to the total ATT of face mask mandates. As shown in Table 2 [17,19,21,22], the results indicate that—on average—mandates are followed by an increase in self-reported face mask wearers of 8.81 percentage points ($P = .006$).

Similarly, an average decrease of $-0.31$ units ($P = .008$) was observed for SARS-CoV-2 reproduction numbers after face mask mandates became effective. No reduction in the growth rates of COVID-19 cases was observed after mask mandates became effective ($-0.98$ percentage points; $P = .56$).

The incremental effects of pre- and postmandate implementation periods according to the event study specification of equation 3 are presented in Figure 3 [17,19,21,22,26]. As can be seen, the incremental effects of face mask mandates are demonstrated in an increase in the proportion of self-reported mask wearers at 6 days and decreases in reproduction numbers at 13 days after mandate implementation. For self-reported face mask use and reproduction numbers, the effects continuously persist for $>30$ days. Furthermore, our estimations yield single mandate effects on case growth rates on days $26$ ($-1.76$ percentage points; $P = .04$), $27$ ($-1.89$ percentage points; $P = .05$), $29$ ($-1.78$ percentage points; $P = .04$), and $30$ ($-2.14$ percentage points; $P = .02$) after mandates were enacted. We observe pretrends in self-reported face mask use on up to 4 days and on day 4 in case growth rates before the beginning of the mandate periods. Our identifying assumption of no anticipatory events is supported for a period of at least 4 days before the beginning of mandates for all outcomes.
Table 2. Event study regressions of self-reported face mask use, SARS-CoV-2 reproduction numbers, and growth rates of COVID-19 cases on face mask mandates. Percentage point changes are shown for self-reported face mask use and growth rates of COVID-19 cases, and unit changes are shown for SARS-CoV-2 reproduction numbers. Data sources: COVID-19 Trends and Impact Survey, Oxford COVID-19 Government Response Tracker, Our World in Data—COVID-19 data set, and Google COVID-19 Community Mobility Reports.

Sensitivity Analyses

To assess the parsimony of the models of SARS-CoV-2 reproduction numbers and COVID-19 case growth rates, equation 3 was re-estimated by restricting the parameters of mobility and containment measures other than mask mandates to jointly equal 0. Restricted models yielded a lower mandate ATT for SARS-CoV-2 reproduction numbers (−0.32 units; P=0.01). In line with the original specification, the results do not demonstrate any relationship between mask mandates and growth rates of COVID-19 cases (−1.22 percentage points; P=0.43). In postmandate periods, the restricted specification also reveals no changes regarding incremental decreases in SARS-CoV-2 reproduction numbers, and our findings demonstrate a negative effect of mask mandates on reproduction numbers at 12 days after mandate beginning. The observed incremental effects last >30 days. A single incremental effect of mandates on COVID-19 case growth rates is observed on day 30 after mandate implementation (−1.84 percentage points; P=0.03). A Wald test was used to test the null hypothesis that the parameters of mobility and containment measures other than mask mandates jointly equal 0. The null hypothesis was rejected.
for both models of mask mandate effects on reproduction numbers (2.67; P=.01) and case growth rates (6.13; P<.001). Therefore, we retained the initial model specification including indicators of mobility and nonpharmaceutical interventions other than mask mandates.

Equation 3 was also re-estimated with counterfactual linear trends to evaluate the robustness of the initial results. Compared with the baseline specification, the observed mandate ATTs are lower for self-reported face mask use (8.66 percentage points; P=.01) and remain unchanged for SARS-CoV-2 reproduction numbers (−0.31 units; P=.01). As in the original specification, no ATT is found for the growth rates of COVID-19–related cases (−0.97 percentage points; P=.56). The incremental increases in self-reported mask use are observed on day 6 after mandate implementation. In addition, the incremental decreases in COVID-19 reproduction numbers are demonstrated on day 12. The incremental effects persist for >30 days for both models. Both results are consistent with the original specification. Significant incremental effects of mandates on COVID-19 case growth rates are found between days 26 and 30 (−1.76 percentage points; P=.04 and −2.13 percentage points; P=.02) after the mandates take effect.

As a final sensitivity check, we have considered that the selection of mandate policies must be strictly exogenous for our specification to yield unbiased estimates of mandate effects. However, the possibility that countries enacted mask mandates depending on the course of the pandemic cannot be ruled out. To rule out bias, the mandate indicators DAt were regressed on SARS-CoV-2 reproduction numbers and growth rates of COVID-19 cases, controlling for country-specific fixed effects. No significant effects were observed. In conclusion, the results of the sensitivity analyses confirm the baseline estimation results. An overview of all results from the sensitivity analyses mentioned in the preceding section is presented in Multimedia Appendix 1 [17,19,21,22,26].

**Effects of Face Mask Recommendations**

The mask mandates evaluated required the populations of the countries under study to wear masks. However, in 25 (24.5%) of the 102 countries represented in the data underlying our analysis, recommendations for voluntary mask use were issued first. Therefore, the final step was to investigate whether these recommendations might have been sufficient to prevent COVID-19 transmission. Accordingly, the baseline specification of equation 3 was re-estimated, with cohorts defined depending on the calendar dates of recommendations becoming effective. Information on self-reported mask use, SARS-CoV-2 reproduction numbers, and COVID-19 case growth rates were available for 60% (15/25) of the countries at the time of face mask recommendations. A total of 11.8% (12/102) of countries were excluded from the evaluation because they demonstrated nonparallel outcome trends in the preliminary analyses. This resulted in a total of 40% (10/25) countries with face mask recommendation being included in the analyses, yielding an analysis sample incorporating 78.4% (80/102) of the countries. The control group consisted of 88% (70/80) of the countries, of which 4% (3/70) of the countries did not implement any face mask policies, whereas 96% (67/70) of the countries enacted mask mandates only.

As presented in Table 3 [17,19,21,22], no significant ATTs of mask recommendations were found for SARS-CoV-2 reproduction numbers and COVID-19 case growth rates (−0.06 units; P=.70 and −2.45 percentage points; P=.59).

However, an ATT of 5.84 percentage points (P<.001) was shown for mask use. In addition, increases in mask use by 11.70 percentage points (P=.04) and 13.60 percentage points (P=0.02) are observed for mask mandates and subgroup mandates, respectively. Our findings also demonstrate mandate effects on reproduction numbers (−0.19 units; P=.04).

Figure 4 [17,19,21,22,26] presents the effects of face mask recommendations in 10 countries. As can be inferred, recommendations had an isolated incremental effect on self-reported use of face masks on days 11 (3.96 percentage points; P=.04), 13 (3.77 percentage points; P=.04), and 25 to 27 (4.20 percentage points; P=.048 and 5.91 percentage points; P=.01) after publication. Single incremental effects of mask recommendations are also observed for reproduction numbers on days 0 (−0.07 units; P=.03) and 1 (−0.07 units; P=.03) and between days 21 (−0.09 units; P=.04) and 28 (−0.11 units; P=.05) after publication. Case growth rates decrease incrementally between days 1 and 4 (−1.60 percentage points; P=.03 and −2.19 percentage points; P=.03) and on day 23 (−2.83 percentage points; P=.05) after recommendations were published. Pretrends are shown for >10 days and on day 9 before the recommendation for self-reported face mask use, on days 9, 5, and 4 for SARS-CoV-2 reproduction numbers, and on days 10 and 9 for growth rates of COVID-19–related cases. These findings support the assumption of no anticipatory events for at least 3 days before face mask recommendations.

Discussion

Principal Findings

According to the results presented in the preceding section, the introduction of face mask mandates was associated with an increase in self-reported face mask use and a decrease in SARS-CoV-2 reproduction numbers. The sustainability of face mask mandates is demonstrated by the fact that the observed effects persist for >30 days after the mandates come into effect.

Our results are robust to different sensitivity analyses. Thus, during our observation period, face mask mandates proved to be an effective nonpharmacological measure to reduce SARS-CoV-2 reproduction numbers.

The effectiveness of mask use has occasionally been questioned in public debate [9]. This is particularly true in light of the inconclusive findings of Jefferson et al [5]. According to the authors, a key problem with the existing RCTs is that they have a wide variation in outcome measures, making it difficult to
compare results. Using real-world data, our study allows a comparison of SARS-CoV-2 reproduction numbers and COVID-19 case growth rates across 51 countries. This increases the external validity of previous findings, which are largely based on RCTs. Furthermore, our results support the findings of Ueki et al [27] and Cheng et al [28]. On the basis of aerosol and droplet transmission models, both papers show that face masks are effective in reducing the risk of transmission in low virus load environments such as public spaces.

In addition, our observations suggest inconclusive evidence on the effect of mask mandates on the growth rates of COVID-19 cases. Although Chernozhukov et al [29] demonstrate that mask mandates have contributed to a reduction in case growth rates at the US state level, we found no differences in COVID-19 cases between mandate and nonmandate countries. The lack of mask mandate effects in our study may be, at least in part, owing to the high infectiousness of the SARS-CoV-2 virus. With such high infectiousness, the implementation of mask mandates may not be sufficient to prevent clusters of COVID-19 cases in the most susceptible populations, such as older adults or those who are immunosuppressed. This may be particularly true for facilities such as older people’s care homes, where most cases occurred. Inadequate compliance with mask mandates or improper use of face masks by infected individuals in contact with these populations is hardly always avoidable. Therefore, the occurrence of such clusters is difficult to prevent. Additional strict containment measures may have been required to protect the most susceptible populations.

For masks to have a preventive effect, they must be worn by the public. Accordingly, Jefferson et al [5] discuss the lack of mask adherence as a possible cause of the inconclusive results of RCTs on the effectiveness of face masks in preventing ARIs. To increase the willingness to wear masks, public health authorities used social media to educate the public during the COVID-19 pandemic [30] or distributed masks free of charge [31]. In addition to these interventions, governments have introduced more drastic initiatives, such as mandatory masks, which penalize people who do not wear masks. Adding to the existing evidence from RCTs, our study shows that the self-reported use of masks is significantly increased because of such regulations. Although this is consistent with a previous study that found high compliance with mandatory mask use [12], our results further indicate that mandates, rather than recommendations, are required to ensure self-reported mask adherence.

**Limitations**

It cannot be completely ruled out that the estimates of self-reported face mask use are biased because of the sampling method used. First, the data on self-reported face mask use are obtained from country-specific samples of Facebook users. The distribution of these samples may not reflect the composition of each country’s population. The survey weights calculated by Meta, which are based on population- and region-specific gender and age distributions, may only partially compensate for such biases. Another possible limitation is that it can be assumed that the course of infection is determined by individual behavior. No microlevel data were available for this study that would have allowed us to test this assumption and accurately estimate behavioral effects on the effectiveness of mask mandates. A third complication is that the available data do not allow to distinguish between the type of mask worn (surgical mask vs N95 mask). Depending on mask type, the effects of mandates on reproduction numbers may differ. Such differences cannot be estimated within the framework of this study.

**Conclusions**

Our results suggest that mask mandates encourage self-reported mask use and reduce SARS-CoV-2 reproduction numbers. They may be a simple measure in a nonpharmacological strategy to control epidemics caused by respiratory-transmissible pathogens. When implementing mask mandates, special care should be taken to ensure compliance with respect to the most susceptible individuals. Given the lack of mandate effects on the growth rates of COVID-19 cases, additional containment measures may be required to ensure the adequate protection of the most susceptible populations.

Abstract

Background: Asthma has become one of the most common chronic conditions worldwide, especially among children. Recent findings show that the prevalence of childhood asthma has increased by 12.6% over the past 30 years, with >262 million people currently affected globally. The reasons for the growing asthma epidemic remain complex and multifactorial.

Objective: This study aims to provide an up-to-date analysis of the changing global and regional asthma prevalence, mortality, disability, and risk factors among children aged <20 years by leveraging the latest data from the Global Burden of Disease Study 2019. Findings from this study can help inform priority areas for intervention to alleviate the rising burden of childhood asthma globally.

Methods: The study used data from the Global Burden of Disease Study 2019, concentrating on children aged 0 to 14 years with asthma. We conducted an in-depth analysis of asthma, including its age-standardized prevalence, incidence, mortality, and disability-adjusted life years (DALYs), across diverse demographics, such as region, age, sex, and sociodemographic index, spanning 1990 to 2019. We also projected the future burden of the disease.

Results: Overall, in the Western Pacific Region, the age-standardized prevalence rate of asthma among children increased slightly, from 3898.4 cases per 100,000 people in 1990 to 3924 per 100,000 in 2019. The age-standardized incidence rate of asthma also increased slightly, from 979.2 to 994.9 per 100,000. In contrast, the age-standardized death rate of asthma decreased from 0.9 to 0.4 per 100,000 and the age-standardized DALY rate decreased from 234.9 to 189.7 per 100,000. At the country level, Japan experienced a considerable decrease in the age-standardized prevalence rate of asthma among children, from 6669.1 per 100,000 in 1990 to 5071.5 per 100,000 in 2019. Regarding DALYs, Japan exhibited a notable reduction, from 300.6 to 207.6 per 100,000. Malaysia also experienced a DALY rate reduction, from 188.4 to 163.3 per 100,000 between 1990 and 2019. We project that the burden of disease in countries other than Japan and the Philippines will remain relatively stable up to 2045.

Conclusions: The study indicates an increase in the prevalence and incidence of pediatric asthma, coupled with a decrease in mortality and DALYs in the Western Pacific Region between 1990 and 2019. These intricate phenomena appear to result from a combination of lifestyle shifts, environmental influences, and barriers to health care access. The findings highlight that nations such as Japan have achieved notable success in managing asthma. Overall, the study identified areas of improvement in view of persistent disease burden, underscoring the need for comprehensive collaborative efforts to mitigate the impact of pediatric asthma throughout the region.
Introduction

Asthma, which affects >14% of children globally, is one of the most common chronic respiratory diseases and poses significant public health challenges [1]. Childhood asthma often starts early in life and persists throughout life, frequently continuing into adulthood [2]. Asthma symptoms manifest as wheezing, chest tightness, and coughing that disrupt daily functioning [3]. This disease leads to impaired quality of life, loss of school days, poor sleep, and increased healthcare use and costs [4]. The global burden and impact of childhood asthma continue to increase. Recent findings from the Global Burden of Disease (GBD) Study 2019 show that over the past 30 years, the prevalence of childhood asthma has increased by 12.6%, with >262 million people currently affected worldwide [5]. The reasons for the growing asthma epidemic remain complex and multifactorial and are linked to rising air pollution, urbanization, tobacco smoke exposure, genetics, overuse of antibiotics, and other modern lifestyle factors [6,7]. Careful analysis of recent global and regional trends in childhood asthma prevalence, morbidity, mortality, and projections can inform priority areas for intervention to alleviate this rising disease burden.

The Western Pacific Region (WPR), 1 of the 6 regions classified by the World Health Organization, comprises approximately one-fourth of the world’s population and faces a substantial pediatric disease burden owing to respiratory conditions. Previous analyses of global data reflect increasing asthma prevalence and mortality rates in the WPR from 1990 to 2015, with high rates among boys [8,9]. Recent WPR data on the burden of chronic respiratory diseases also suggest an increasing prevalence of asthma, although mortality rates may be declining [10,11]. Recent global data on pediatric asthma are limited, with most large-scale studies only presenting analyses up to 2015. Adding the latest available disease estimates from 2016 to 2019 provides a contemporary 30-year perspective that is critical to uncovering current trends. Moreover, forecasting future patterns up to 2045 based on recent data can help anticipate trajectory changes and inform priority setting for pediatric asthma care in the WPR over the next 2 decades.

In this study, we leveraged the extensive global disease data within the GBD Study 2019 to analyze past trends from 1990 to 2019 and project estimates up to 2045 for key childhood asthma outcomes in the WPR. The findings can highlight success and gaps in managing this disease, whereas the future projections may guide strategic priorities for improving diagnosis, treatment access, and risk factor reduction to curb the rising prevalence of pediatric asthma across the region.

Methods

Data Source and Definitions

Our study used data from the GBD Study 2019 [12]. This extensive data set encompasses information about 369 diseases and injuries and 87 risk factors across 204 countries and territories, as described in a publication [13]. In the context of the GBD Study 2019, asthma was categorized based on the International Classification of Disease codes. Consistent with the most recent criteria set by the World Bank, countries within the WPR were categorized into 3 economic tiers: high income, upper middle income, and lower middle income. In each economic category, we selected 2 countries for our analysis, intentionally omitting islands or relatively isolated nations owing to their unique health care systems and health technology factors that might skew asthma burden data. For the high-income category, Japan and Singapore were chosen. China and Malaysia represent the upper-middle-income tier, and Vietnam and the Philippines were the choices for the lower-middle-income group.

We focused our analysis on the impact of asthma among children by dividing the patient data into 3 distinct age groups: <5 years, between 5 and 9 years, and between 10 and 14 years. We used linear regression methods to calculate the estimated annual percentage change (EAPC), providing an in-depth view of the changing trends. EAPC is commonly used in epidemiological studies to examine time-related changes in age-standardized rates (ASRs) of diseases. In this model, y represents ln (ASR) and x represents the calendar years. The EAPC, along with its 95% CI, was ascertained through the subsequent linear regression model [14]:

\[ y = \alpha + \beta x + \epsilon \]

\[ \text{EAPC} = 100 \times (\exp[\beta] - 1) \]

To understand the ASR trend, we examined the EAPC and its 95% CI. An upward trend in the ASR is inferred when both the EAPC and the lower bound of the 95% CI are positive. In contrast, a downward trend is indicated when both the EAPC and the upper bound of the 95% CI are negative [14].

Age-Period Cohort Analysis

In our study, we implemented the age-period cohort (APC) model, a highly esteemed statistical framework prevalent in health and social science disciplines. This model was instrumental in our analysis of disease prevalence across various time frames, with a particular emphasis on age, period, and birth cohort [15]. The APC model’s widespread use is especially notable in the study of noncommunicable diseases within the field of epidemiology. In this context, the age effect denotes the varying risk levels across different age groups. The period effect reflects the variations in disease incidence over time, affecting all age groups. Finally, the cohort effect pertains to the shifts in ratios among groups born in the same year, thereby affecting successive age groups over different periods. This nuanced approach enables a comprehensive understanding of disease dynamics across demographic, sociological, and epidemiological perspectives. Our approach involved using asthma data and applying the APC model to understand patterns and trends. To ensure precise analysis, we aligned 5-year age intervals with 5-year periods, spanning from 1990 to 2019.

The APC model provides a refined method for examining disease burden, revealing both broad temporal trends and age-specific nuances in the disease data. The model identifies the general temporal trend or “net drift” as the annual percentage change in the disease burden. This reflects the combined impact of time progression and successive birth cohorts. In contrast, the “local drift” or age-specific temporal trend is the annual percentage change within each age group.

Even a small drift value, when expressed as a yearly percentage change, can indicate significant changes in disease prevalence over a 30-year period. We used a Wald chi-square test to evaluate the statistical significance of these trends. In the APC framework, age effects are observed through age-specific rates over different birth cohorts, adjusted for period influences. Period and cohort effects are shown as relative risks of the disease burden, comparing age-specific rates across different periods or cohorts with a selected reference point. This reference choice is arbitrary and does not alter the interpretability of the findings.

Measurement of Health Inequalities

Total disability-adjusted life years (DALYs) and their ASRs were collected for assessing inequality. The analysis was conducted using the slope index of inequality and the concentration index. These are established measures for assessing absolute and relative gradient inequalities, respectively [16]. The slope index of inequality was calculated by performing a regression analysis on country-level, age-standardized, years of life lost rates owing to asthma among children against an income-based, social position scale. This scale was defined using the midpoint of cumulative population intervals, ranked by per capita gross domestic product. To address variations in the data and the diminishing marginal utility reflected in the data, we used a weighted regression model and applied logarithmic transformation to the relative social position values.

The health inequality concentration index was determined by plotting a Lorenz concentration curve. This curve represented the cumulative relative distribution of the population, ordered by income, against the years of life lost owing to asthma. We then quantified the inequality by numerically integrating the area beneath this curve. When the Lorenz curve is positioned above the line of equality, it indicates that the health burden predominantly affects low-income countries, a scenario reflected by a negative concentration index. It is proposed that an absolute value within the range of 0.2 to 0.3 signifies a considerably high degree of relative inequality.

This approach provided a nuanced understanding of the disparity in asthma burden among children across different income levels in the WPR [17]. The APC analysis was performed with the apc_ie package in Stata (version 17.0; StataCorp).

Future Burden

To forecast the burden from 1990 to 2045, we used a log-linear APC model, which is adept at tempering exponential growth and confining linear trend extrapolation [18]. This makes it particularly effective for aligning with recent trends. The implementation of this model was conducted using the Nordpred package in R (R Foundation for Statistical Computing) [19], which has demonstrated effective empirical performance in forecasting future trends [20]. This method facilitates a more controlled and realistic projection of future trends, using past and present data.

Ethical Considerations

The original GBD study obtained informed consent from the study participants or was granted exemptions by the institutional review board of the University of Washington. As this was a secondary analysis of existing data, no additional human participant research ethics review or informed consent was required. The data used in our study were thoroughly anonymized and deidentified to safeguard participant privacy and confidentiality. Furthermore, our analysis adheres to the established Guidelines on Accurate and Transparent Health Estimate Reporting [21-23]. All participants in this study consented to publication of the results.

Results

Temporal Trends in Pediatric Asthma Prevalence, Incidence, Deaths, and DALYs in the WPR

Overall, in the WPR, the age-standardized prevalence rate (ASPR) of asthma among children increased slightly from 3898.4 cases per 100,000 people in 1990 to 3924 per 100,000 in 2019. The age-standardized incidence rate (ASIR) of asthma also increased slightly from 979.2 to 994.9 per 100,000. In contrast, the age-standardized death rate (ASDR) of asthma decreased from 0.9 to 0.4 per 100,000, and the age-standardized DALYs rate decreased from 234.9 to 189.7 per 100,000 (Table 1; Figure 1).

At the country level, Australia had the highest ASPR of asthma in 1990 at 14,769.1 per 100,000, but it decreased to 10,974.9 per 100,000 in 2019. The age-standardized incidence rate (ASIR) of asthma also increased slightly from 979.2 to 994.9 per 100,000. In contrast, the age-standardized death rate (ASDR) of asthma decreased from 0.9 to 0.4 per 100,000, and the age-standardized DALYs rate decreased from 234.9 to 189.7 per 100,000 (Table 1: Figure 1).
Table 1. Temporal trends in pediatric asthma prevalence, incidence, deaths, and disability-adjusted life years (DALYs) in the Western Pacific Region (1990-2019).

JMIR Public Health Surveill 2024 | vol. 10 | e55327 | p.1502
(page number not for citation purposes)


New Zealand had the highest ASIR of asthma in 1990 at 2086.4 per 100,000. By 2019, the incidence in New Zealand decreased to 1785.4 per 100,000 (EAPC = 0.31, 95% CI: −0.08 to 0.7). The countries with the lowest ASIR of asthma in 2019 were the Lao People’s Democratic Republic at 692 per 100,000 and Mongolia at 723.7 per 100,000.

Papua New Guinea had the highest ASDR of asthma in 2019 at 2.8 per 100,000. By 2019, the ASDR of asthma in the Lao People’s Democratic Republic decreased from 13.6 per 100,000 to 2 per 100,000 (EAPC = −6.35, 95% CI: −6.49 to −6.21). In terms of DALYs owing to asthma, there was a significant overall decrease among children in the WPR. The figures decreased from 234.9 per 100,000 in 1990 to 189.7 per 100,000 in 2019, indicating an EAPC of −0.46, with the 95% CI ranging from −0.92 to 0. This trend mirrors the mortality patterns, with Japan exhibiting a notable reduction in pediatric asthma DALYs during this period. In Japan, the rate decreased from 300.6 to 207.6 per 100,000 (EAPC = −2.27, 95% CI: −2.75 to −1.79). Malaysia also experienced a reduction, from 188.4 to 163.3 per 100,000, between 1990 and 2019 (EAPC = −0.37, 95% CI: −0.60 to −0.15), as shown in Table 1 and Figure 1.

<sup>a</sup>Num_1990: number in 1990.
<sup>b</sup>UI: uncertainty interval.
<sup>c</sup>ASR_1990: age-standardized rate in 1990.
<sup>d</sup>Num_2019: number in 2019.
<sup>e</sup>ASR_2019: age-standardized rate in 2019.
<sup>f</sup>EAPC: estimated annual percentage change.
Figure 1. Temporal trends in pediatric asthma prevalence, incidence, deaths, and disability-adjusted life years (DALYs) in the Western Pacific Region (1990-2019). ASIR: age-standardized incidence rate; ASPR: age-standardized prevalence rate.

Trends in Asthma Burden Among Children Across the Sociodemographic Index Quintiles in the WPR

Over the 3 decades under study, the WPR experienced significant changes in the ASPR, ASIR, and ASDR for asthma burden among children across all countries categorized by the sociodemographic index (SDI) level (Figure 2). We found that as the SDI increased, the ASPR and ASIR gradually increased, whereas the ASDR gradually decreased.
Temporal Trends in Asthma Burden Among Children Across Age Groups

The annual percentage change in asthma prevalence for each age group, that is, the local trends in prevalence calculated using the APC model, is presented in Figure S1 in Multimedia Appendix 1. In the WPR, asthma prevalence decreased in the 0-to-4 year and 10-to-14 year age groups. The upper middle-income group (China and Malaysia) showed the same trend. Japan and Singapore also showed favorable changes, with Japan showing a gradual downward trend and Singapore maintaining a stable trend, with no significant upward trend. In Vietnam, asthma prevalence demonstrated decreasing trends in the 0-to-4 year and 5-to-9-year age groups and showed a flat trend in the 5-to-9-year and 10-to-14-year age groups. The local trends in prevalence are shown in Multimedia Appendix 2.

Temporal changes in the age distribution of asthma prevalence are illustrated in Figure S2 in Multimedia Appendix 1. The distribution of age around the world and across the WPR has remained relatively stable over the past 30 years.

Age, Period, and Birth Cohort Effects on Asthma Prevalence Across Different Age Groups

The age, period, and birth cohort effects on asthma prevalence derived from the APC model are illustrated in Figure 3, Multimedia Appendix 3, and Multimedia Appendix 4, respectively. Overall, the pattern of age effects was similar across the selected regions or countries, with the lowest risk among those aged between 0 and 4 years and the risk increasing, decreasing, and then increasing with age. In addition, we found that, in all the regions, the prevalence was higher among men than among women. Overall, period effects presented an initially decreasing and then increasing risk of prevalence across different regions or countries, except in Vietnam. The Vietnam region had generally low period risks over the study period, whereas others had more unfavorable period risks most of the time. Compared with individuals in the reference period from 2000 to 2004, the relative period risk for individuals in the 2015 to 2019 period ranged from 1.25 (95% CI 1.19-1.31) in the WPR to 0.84 (95% CI 0.82-0.86) in Japan and 1.47 (95% CI 1.36-1.58) in China (Multimedia Appendix 5). Regarding birth cohort effects, there was an initially decreasing and then increasing risk of prevalence in successive birth cohorts in the WPR (Multimedia Appendix 4). Japan and Singapore (high-income countries) had favorable prevalence improvements in successive birth cohorts, whereas China, Malaysia, and Vietnam had progressive prevalence deteriorations (Multimedia Appendix 4). Compared with individuals born in the reference cohort from 1990 to 1999, the relative cohort risk for individuals born in the 2010 to 2019 cohort ranged from 1.12 (95% CI 1.06-1.20) in the WPR to 1.35 (95% CI 1.22-1.50) in China (Multimedia Appendix 6).
Health Inequality and Future Burden

The slope index of inequality was $-294$ and $-56$ DALYs per 100,000 in 1990 and 2019, respectively, showing a negative association between the age-standardized DALY rate and gross domestic product per capita. This reduction indicates that the inequality in the age-standardized burden of asthma among children between high-income and low-income countries narrowed during this time (Figure 4). In contrast, a relative inequality analysis showed that the concentration index has increased by 0.06 over 30 years, showing disproportionate concentration of the burden among the richer half of the population (Figure 5).

The projected ASPR and ASIR of childhood asthma for specific representative countries suggest an ongoing increase in both the Philippines and Japan. In contrast, the rates in other selected countries are expected to remain comparatively stable (as illustrated in Multimedia Appendices 7 and 8). In addition, DALYs associated with childhood asthma are anticipated to maintain a relatively steady trend in the future, as shown in Multimedia Appendix 9.
Figure 4. Slope index of inequality in pediatric asthma, presented using regression lines (1990 vs 2019). Regression of age-standardized disability-adjusted life year (DALY) rate on the relative rank by per capita gross domestic product. The slope index of inequality, shown as the slope of the regression line, represents the absolute difference in blindness and vision loss burden between countries or territories with the highest and lowest incomes. Dots represent countries or territories, with different sizes representing the population sizes (1990 in blue and 2019 in red). SDI: sociodemographic index.

Figure 5. Concentration index in pediatric asthma, presented using concentration curves (1990 vs 2019). Concentration curves (Lorenz curves) graphed by plotting the cumulative fraction of population ranked by national per capita gross domestic product (x-axis) against the cumulative fraction of pediatric asthma burden ranked by age-standardized disability-adjusted life year (DALY; y-axis). The concentration index, calculated as twice the area between the 45° diagonal line and the Lorenz curve, represents the relative extent to which the pediatric asthma burden is concentrated among the poor (negative value) or the rich (positive value). Dots represent country or territories, with sizes representing population sizes (1990 in blue and 2019 in red). Trendline (in green) of the hollow rhombi demonstrates the trend in concentration index from 1990 to 2019. SDI: sociodemographic index.
Discussion

Principal Findings

Our study used comprehensive data from the GBD Study 2019 to examine the trends in crucial childhood asthma outcomes across countries in the WPR from 1990 to 2019 and to project future patterns up to 2045. The study revealed increases in both the ASPR and ASIR, alongside decreases in mortality rates and DALYs related to childhood asthma in the WPR over the past 3 decades. This pattern persisted across nations with varying income levels, hinting at universal contributing factors. Notably, Japan showed a significant reduction in pediatric asthma DALYs, reflecting effective management strategies. According to our projections, both the Philippines and Japan might experience continued increases in the ASPR and ASIR. In summary, although the WPR is making progress in reducing fatal asthma outcomes, it continues to face increasing instances of the condition. Focusing on risk factors and ensuring equal access to health care could be key in altering these projected trends.

The gradual upward trend in the ASPR likely results from complex interactions among genetic predisposition, lifestyle changes, and environmental exposure. Key factors influencing the increasing pediatric asthma risk across nations in the WPR include increasing air pollution and urbanization, which promotes triggers such as vehicle emissions, industrial fumes, and household air pollution [24,25]; reduced rates of protective elements such as breastfeeding, which bolsters immune maturation [26]; overseuse of antibiotics, linked to microbiome disruption and heightened immune reactions [27]; limited exposure to microbial diversity, particularly in urban versus rural areas [15]; and unhealthy modern lifestyles marked by poor diets, minimal exercise, and increasing obesity [26]. In addition, dietary shifts, sedentary lifestyles, and increasing obesity may contribute [28]. Hereditary factors also increase the susceptibility in Asian populations. Meanwhile, the increase in the ASIR could arise from superior diagnostic capabilities and awareness over time. Hence, although part of the escalating incidence is because of new-onset disease, improved case identification may also play a role.

Our study indicates that from 1990 to 2019, the ASPR and ASIR for pediatric asthma in countries in the WPR have notably increased, whereas the ASDR has decreased. This trend suggests that although the prevalence and incidence of asthma among children are increasing, efforts to reduce mortality after intervention measurement have been successful. These findings are consistent with those of previous studies of long-term asthma patterns. For example, a global data analysis from 1990 to 2015 showed an increase in asthma prevalence in countries in the WPR, despite a decrease in mortality rates [4]. Moreover, in Organisation for Economic Co-operation and Development countries, there has been a surge in asthma prevalence in recent decades, but child mortality rates have decreased [1]. Thus, advancements in asthma management appear to be effective in reducing fatalities among patients who have been diagnosed. However, the continual increase in asthma cases across nations points to the existing limitations in disease prevention.

This study’s per-country data offer additional insights into pediatric asthma patterns in different WPR settings. From 1990 to 2019, Australia exhibited a reduction in the ASPR while still retaining the highest ASPR, signaling scope for further progress. The substantial reduction in childhood asthma mortality and DALYs in Japan is likely owing to its cutting-edge health care system centered on universal coverage, easy access, technology integration, and personalized care [29]. This facilitates early diagnosis and evidence-based treatment. In addition, nationwide asthma control initiatives in Japan, such as the Practical Asthma Management Guideline, offer standardized diagnostic approaches and globally recognized therapies [30]. Malaysia witnessed a marginal reduction in the DALY rate; however, its burden remains higher than those of neighboring countries with comparable income levels. Thus, Malaysia may glean best practices from Japan’s robust asthma care models to enhance outcomes.

The gradual increase in the SDI has been accompanied by a corresponding increase in both the ASPR and ASIR for pediatric asthma over this study’s time frame. The SDI is indicative of socioeconomic development with factors such as income, education, and fertility rates [31,32]. It appears that pediatric populations in the WPR are still witnessing a growing burden of the disease alongside developmental indexes. Implementing targeted prevention strategies to reduce these avoidable risk factors could help in altering this trend for different socioeconomic groups.

Our age-specific analysis in the WPR reveals a decrease in asthma prevalence across various age groups, starting from ≤5 years and extending to older age groups. This trend can be attributed to the natural maturation of the respiratory and immune systems in very young children, with approximately 75% of early-onset asthma cases resolving by midchildhood [33]. However, for those with moderate to severe asthma persisting beyond the age of 10 years, there is an increased risk of impaired lung function later in life [34]. Therefore, although prevalence decreases with age, the subset struggling with ongoing asthma beyond childhood needs adequate control and follow-up to prevent long-term pulmonary deficits.

In terms of temporal trends, the age distributions within the WPR have remained fairly stable, yet we observed fluctuating asthma risks across the decades. Following an initial reduction, there has been a recent increase in risk. This fluctuation suggests that time-related factors significantly influence asthma risk among different pediatric age groups in the region. Environmental factors are likely the primary drivers of these varying period effects. The successive birth cohorts between 2000 and 2009 exhibited escalating asthma risks compared with the preceding generation. Rapidly evolving environmental and lifestyle changes appear to influence disease susceptibility over generations differently. For example, factors such as shifting microbiome composition, increased exposure to antibiotics, and reduced number of older siblings may contribute to risk amplification in more recent cohorts [35]. In contrast, favorable cohort effects in Japan and Singapore reflect the strengths of those health systems. However, overarching regional trends highlight the need for ready-to-implement pediatric asthma strategies to break the intergenerational risk acceleration.
Our inequality assessment revealed that absolute socioeconomic disparities in childhood asthma DALYs have reduced slightly, but relative inequality persists. Low-income nations in the WPR still disproportionately face asthma burden compared with high-income economies. Barriers related to health awareness, low access to quality care, unaffordable therapies, and high out-of-pocket costs may underpin inequities. Cross-regional cooperation and localized health policy initiatives aimed at marginalized pediatric groups are required to tackle these demands.

Recent global data about pediatric asthma are limited, with most large-scale studies only presenting analyses up to 2015. Adding the latest estimates from 2016 to 2019 provides an up-to-date, 30-year perspective that is critical to capturing the current trends and trajectory changes. Forecasting future patterns up to 2045 based on recent data rather than old estimates can help anticipate potential increases or decreases in childhood asthma morbidity. This long-range projection up to 2045 is key for priority setting, resource planning, and targeted interventions by western Pacific health systems aimed at managing pediatric asthma over the next 2 decades. Specifically, updating the data up to 2019 revealed a reversal from the previous decreasing trends in some nations. These emerging increases signal to policy makers that renewed efforts are needed against pediatric asthma amid the possibly worsening patterns. The value of the 2045 projections lies in helping countries pre-empt potential resurgences and proactively formulate control strategies tailored to local risk factors. From a resource allocation perspective, the expected trajectories can direct preventive efforts and capacity building, where the impacts of pediatric asthma are likely to escalate. Overall, augmenting the data scope offers granular insights to strategically mitigate the barriers confronting children with asthma across the western Pacific area based on where the disease burdens are headed.

Limitations
Our study had some limitations. First, it is vital to recognize the inherent constraints of GBD research. The validity and accuracy of our findings depend on the quality of the population and disease data collected, which may lead to discrepancies between our results and the actual conditions across regions. Second, the lack of comprehensive registry systems for recording mortality in many countries is another limitation. This deficiency often leads to the underestimation of actual figures. Finally, despite the multiple methodologies used in GBD studies for calculations, rectifying the disease classification errors, and reclassifying ambiguous codes, the potential inaccuracies within the data cannot be disregarded. These inherent inaccuracies can affect the reliability of our findings.

Conclusions
Our study offers a comprehensive 30-year analysis of pediatric asthma trends in the WPR. It highlights an increase in disease prevalence alongside a decrease in mortality, amid moderate advancements in development. These trends reflect a dynamic interplay of lifestyle changes, generational transitions, obstacles in accessing health care, and demographic challenges. Addressing these issues requires focused strategies for enhancing awareness, improving prevention, ensuring equitable diagnosis and treatment, and minimizing risks. Ultimately, fostering overall population health and mitigating the risk factors are key to altering the projected trend shifts. Insights from the regional achievements in effective care models can guide future strategies.

Data Availability
The data sets generated during and analyzed during this study are available from the Global Health Data Exchange query tool on the web [12].

Authors’ Contributions
RHZ and HG designed the study. CHY, XYL, MJH, RHZ, JJL, and HG drafted and revised the paper. JJL and CF collected and cleaned the data. JJL checked the accuracy of the data and prepared the tables. CHY, XYL, and CF performed the statistical analysis. All authors reviewed the paper. CHY, XYL, and JJL are credited as co–first authors for their significant contributions, whereas RHZ, CF, and HG are recognized as co–corresponding authors.

Abstract

Background: Live attenuated vaccines may be used to prevent nontargeted diseases such as lower respiratory tract infections (LRTIs) due to their nonspecific effects (NSEs).

Objective: We aimed to analyze the NSEs of the Japanese encephalitis vaccine on pediatric LRTIs in children aged 25 months to 35 months.

Methods: A retrospective cohort study was conducted by using a population-based electronic health record database in Zhejiang, China. Enrolled participants were children born from January 1, 2017, to December 31, 2017, and who were inoculated with the live-attenuated Japanese encephalitis vaccine (JE-L) or inactivated Japanese encephalitis vaccine (JE-I) as the most recent vaccine at 24 months of age. The study was carried out between January 1, 2019, and December 31, 2019. All inpatient and outpatient hospital visits for LRTIs among children aged 25 months to 35 months were recorded. The Andersen-Gill model was used to assess the NSEs of JE-L against LRTIs in children and compared with those of JE-I as the most recent vaccine.

Results: A total of 810 children born in 2017 were enrolled, of whom 585 received JE-L (JE-L cohort) and 225 received JE-I (JE-I cohort) as their last vaccine. The JE-L cohort showed a reduced risk of LRTIs (adjusted hazard ratio [aHR] 0.537, 95% CI 0.416-0.693), including pneumonia (aHR 0.501, 95% CI 0.393-0.638) and acute bronchitis (aHR 0.525, 95% CI 0.396-0.698) at 25 months to 35 months of age. The NSEs provided by JE-L were especially pronounced in female children (aHR 0.305, 95% CI 0.198-0.469) and children without chronic diseases (aHR 0.553, 95% CI 0.420-0.729), without siblings (aHR 0.361, 95% CI 0.255-0.511), with more than 30 inpatient and outpatient hospital visits prior to 24 months of age (aHR 0.163, 95% CI 0.091-0.290), or with 5 to 10 inpatient and outpatient hospital visits due to infectious diseases prior to 24 months old (aHR 0.058, 95% CI 0.017-0.202).

Conclusions: Compared with JE-I, receiving JE-L as the most recent vaccine was associated with lower risk of inpatient and outpatient hospital visits for LRTIs among children aged 25 months to 35 months. The nature of NSEs induced by JE-L should be considered for policymakers and physicians when recommending JE vaccines to those at high risk of infection from the Japanese encephalitis virus.

nonspecific effect of vaccines; Japanese encephalitis vaccine; Anderson Gill model

Introduction

Vaccination is widely recognized as one of the most effective measures to prevent infectious diseases and has been listed as the top priority for public health precautions by governments worldwide. According to estimates provided by the World Health Organization, 2-3 million children younger than 5 years old could be saved through vaccination against target diseases [1].

Recently, several observational studies and randomized controlled trials have suggested that, in addition to their specific effects, vaccines may have nonspecific effects (NSE) against nontargeted diseases [2]. Live vaccines such as the bacillus Calmette-Guérin (BCG) vaccine [3]; measles, mumps, and rubella (MMR) vaccine [4]; and oral polio vaccine (OPV) [5] have been observed to decrease all-cause mortality and nontargeted infectious disease hospitalizations in children, while inactivated vaccines such as the inactivated polio vaccine (IPV) [5] and diphtheria, tetanus, and pertussis (DTaP) vaccine [6] have been associated with a possible increase in all-cause mortality, on average [7,8]. Consequently, it could be extrapolated that the nature of NSEs produced by a vaccine may be associated with the type of vaccine (ie, NSEs may be more likely to be produced by a live vaccine rather than an inactivated vaccine). However, the conclusions of these previous studies are drawn from studies with a high risk of bias [6] and must be treated with caution. A high risk of bias includes selection bias and information bias arising from, for example, misclassification of vaccination status, confounding at baseline, and selective reporting (and nonreporting) of results. Currently, the immunological mechanisms underlying this phenomenon are unclear but may be related to the trained immunity generated by live vaccines, which is defined as the induction of innate immunity to generate immune memory while clearing pathogens by innate immune cells [9].

In addition, the NSEs of a live vaccine are affected by the sequence of vaccinations. Sørup et al [4] reported that receiving the inactivated DTaP-IPV-Haemophilus influenzae type b (Hib) vaccine as the most recent vaccine (the type of the last vaccine administered to the child) could increase the risk of hospital admissions by 62% during the first 11 months to 24 months after vaccination, while the risk decreased by 14% if MMR was the most recent vaccine. In the United States, Bardenheier et al [10] replicated the study by Sørup et al [4] and demonstrated that receiving a live vaccine as the most recent vaccine was associated with a lower risk of hospitalization for nontargeted infectious diseases from 16 months through 24 months of age compared with an inactivated vaccine (hazard ratio [HR] 0.83, 95% CI 0.72-0.94) as well as concurrent receipt compared with inactivated vaccine (HR 0.91, 95% CI 0.72-0.94).

Japanese encephalitis (JE) vaccines have been included in China’s National Immunization Program (NIP) since 2008. According to the vaccination schedule, children need be inoculated with 2 doses of the live-attenuated JE vaccine (JE-L) at 8 months and 24 months of age or with 4 doses of the inactivated JE vaccine (JE-I) at 8 months, 8 months (7-10 days after the previous dose), 24 months, and 72 months of age [11]. In China, all school-aged children who have reached the age at which they should be vaccinated are vaccinated in accordance with the current NIP vaccination procedures. The type of vaccine (attenuated or inactivated) can be chosen by the child's guardians. Otherwise, the local health authority randomly replenishes JE vaccines, and the providers administer one after another. In Hangzhou, for example, failure to receive immunization vaccines affects children’s enrollment in day care and school. In contrast, children in the United States are administered only the JE-I due to safety considerations [12]. Based on the conclusions of previous studies, we hypothesized that JE-L might also have NSEs. Therefore, in this study, we aimed to evaluate whether the risk of inpatient and outpatient hospital visits for a lower respiratory tract infection (LRTI) differed among children who received the JE-L as their most recent vaccination in comparison with the JE-I.

Methods

Data Source and Participants

Yinzhou is an urban district of Ningbo located in the southeast coastal region of China with an estimated area of 812.40 km² and 1.61 million permanent residents in 2020. A previous study [13] conducted a comprehensive surveillance of JE in Ningbo and showed that the dominant mosquito species in Ningbo was Culex tritaeniorhynchus and that neither JE virus nor dengue virus was detected in mosquitoes throughout the year, suggesting that the rate of local mosquito vectors carrying the virus was relatively low. In addition, another study [14,15] found the vaccine coverage against JE for children aged 1 year to 3 years in Yinzhou District in 2015 was 99.66%.

In 2005, the Yinzhou District Center for Disease Control and Prevention (CDC) developed a population-based electronic health record (EHR) database that collects information from hospitals and community health service centers in the region. This database includes general demographic characteristics, health care information, inpatient and outpatient electronic medical records, health insurance information, disease surveillance, vaccination information, management information, and death certificates [16,17]. As of 2015, it contained the health records of 1.19 million people [18].

We performed this analysis using the aforementioned database as our source of data from 2017 to 2019. Children born in Yinzhou between January 1, 2017, and December 31, 2017, who had received the second dose of JE-L or the third dose of JE-I at 24 months of age as their most recent vaccine were enrolled in this study.
Data Collection
We collected information on demographic characteristics, vaccination (type of vaccine, vaccine name, vaccine dose, and vaccination date), inpatient and outpatient visits (visit time, admission time, discharge time), and disease diagnosis for all included participants. Data pertaining to other variables including maternal parity, birth weight, chronic diseases (including malformations of the respiratory system, other conditions associated with respiratory symptoms, neuromuscular disease, congenital diseases of the heart and urinary system, chromosomal abnormalities, and acquired chronic conditions; see Table S1 in Multimedia Appendix 1 for the specific chronic disease types and International Statistical Classification of Diseases, Tenth Revision [ICD-10] codes), and the number of inpatient and outpatient visits for infectious diseases or for all causes (see Table S2 in Multimedia Appendix 1) prior to 24 months of age were also obtained.

Outcomes
From January 1, 2019, to December 31, 2019, we recorded the primary or secondary discharge diagnosis of LRTIs including influenza, pneumonia, pertussis, acute bronchitis, and others encoded under the diseases of the respiratory system by the ICD-10 as the outcomes of interest (see Table S3 in Multimedia Appendix 1).

Design
Children who had received vaccines other than JE-L or JE-I at the age of 25 months to 35 months were excluded from this study to limit the possibility of bias due to other vaccines. Further, participants with any incomplete or missing information were also excluded. The remaining participants were divided into two groups by the type of JE vaccines received at 24 months of age. Children who received JE-L as their most recent vaccine were included in the JE-L cohort, while those who received JE-I as their most recent vaccine were included in the JE-I cohort. Participants in both groups were followed from the date of administration of JE-L or JE-I to 35 months of age, death, or migration.

We calculated the incidence density of LRTIs and constructed a model to estimate the HR between the JE-L cohort and JE-I cohort.

Statistical Analysis
We used mean (SD) or frequencies with constituent ratios to report the distribution of the children’s age, sex, chronic diseases, maternal parity, and other variables. The chi-square test and Fisher exact test were used to compare baseline characteristics between the 2 cohorts.

Since a child could have had recurring hospital visits due to an LRTI, all hospital visits needed to be involved in the analysis. We calculated the incidence density of LRTIs by using the sum of the number of inpatient and outpatient visits at 25 months to 35 months of age and divided this by the number of person-years of observation. At the same time, we assessed the average length of hospital stay by using the total number of days of hospitalization divided by the number of patients.

The Cox regression hazards model is primarily applied to a single outcome. Therefore, we decided to construct an Andersen-Gill model to assess the HRs and 95% CIs. This model is used for recurrent data and allows every participant to be presented only once and not be compared with him or herself [4]. Schoenfeld residuals were evaluated to assume the proportionality of hazards. If violations were detected, the normal Andersen-Gill model was changed to a time-dependent Andersen-Gill model. We used gender, age group, chronic diseases, birth weight, and the number of outpatient visits with or without infectious diseases prior to 24 months of age as potential covariates in the adjusted analyses. In addition, the results were stratified by sex and other variables.

Statistical analyses for this study were performed using SAS 9.4 (SAS Institute Inc). All tests were 2-sided, and P<.05 was considered significant.

Sensitivity Analyses
Given that the JE-L needs to be administered in 2 doses and JE-I needs to be administered in 4 doses, sequential immunization may be undertaken in clinical practice. Meanwhile, studies have shown that the NSEs of live vaccines might be influenced by the concurrent or successive administration of inactivated vaccines. Consequently, to limit the bias caused by receiving 2 types of JE vaccine by a single child, we repeated our analyses by dividing the children into 4 groups according to the immunization course, as follows: (1) children who received JE-L only, (2) children who received JE-I after JE-L, (3) children who received JE-L after JE-I, and (4) children who received JE-I only. We calculated the incidence density of LRTIs in all 4 groups. At the same time, the Andersen-Gill model was constructed to estimate the HR for the cohort that received JE-L only compared with the cohort that received only JE-I. As per previous reports, if JE-L has NSE, the HR should be <1 [2,10].

Ethical Considerations
The protocol for this study was approved by Zhejiang Chinese Medical University Ethics Committee (No. 20200515-1).

Results
Population
The study initially included 8447 children born in Yinzhou in 2017, of whom 1 child lacked vaccination records and 405 had missing weight information. Further, 7075 children who received vaccines other than those for JE at 25 months to 35 months of age were also excluded. Among the remaining children, 156 were excluded because JE was not administered as their most recent vaccine. The JE-L cohort included the 585 remaining children were administered JE-L as the most recent vaccine, and the JE-I cohort included the 225 children who were administered JE-I as the most recent vaccine, for a total of 810 participants (Figure 1).

Of the 810 children included in the final analysis, 53.1% (430/810) were male, 22.5% (182/810) had a birth weight <3000 g, 5.2% (42/810) had chronic diseases, 63.5% (514/810) had a mother with 1 parity, 30% (243/810) had visited the hospital...
more than 15 times prior to 24 months of age, and 6.5% (53/810) had visited the hospital more than 5 times due to infectious diseases prior to 24 months of age. Both the study cohorts were comparable in terms of sex ($P=.81$), birth weight ($P=.25$), number of hospital visits with or without infectious diseases prior to 24 months of age ($P=.38$ and $P=.79$, respectively), and chronic diseases ($P=.41$). Notably, the JE-I cohort had a higher coverage of the 13-valent pneumonia vaccine, enterovirus 71 vaccine, and rotavirus vaccine and were statistically more likely to have no siblings than the JE-L cohort (see Table S4 in Multimedia Appendix 1).

Figure 1. Flowchart of participant inclusion. JE-I: inactivated Japanese encephalitis vaccine; JE-L: live-attenuated Japanese encephalitis vaccine.

**Vaccination Status**

Among the 8041 children with complete demographic and medical records in the database, 8029 children received a JE vaccine, for a coverage of 99.85%. A total of 36.26% (2916/8041) had completed the first dose of JE-I, and 63.59% (5113/8041) had completed the first dose of JE-L. The age at vaccination administration was consistent with the recommended age in the NIP. Of the 810 children included in final analysis, 27.8% (225/810) received JE-I at an average age of 24.08 months, and 72.2% (585/810) received JE-L at an average age of 24.18 months (see Table S5 in Multimedia Appendix 1).

**Inpatient and Outpatient Hospital Visits for LRTIs**

Among the 810 children who received the JE vaccine as their most recent vaccine at 24 months of age, 85 reported LRTIs during the period of 25 months to 35 months of age, with 310 inpatient and outpatient hospital visits in total. The incidence density was 0.383 (95% CI 0.349-0.417) person-years. Of these 85 children, 73 had acute bronchitis, with an incidence density of 0.331 (95% CI 0.299-0.344) person-years; 8 experienced pneumonia, with an incidence density of 0.033 (95% CI 0.022-0.048) person-years; and 4 reported influenza, with an incidence density of 0.019 (95% CI 0.010-0.030) person-years. Due to LRTIs, 33 children were admitted only once, whereas 52 children were admitted ≥2 times between 25 months and 35 months of age, with a maximum of 28 admissions. The onset age was 29.25 (95% CI 28.70-29.80) months in the JE-I cohort and 29.24 (95% CI 28.78-29.69) months in the JE-L cohort, with no statistical difference ($P=.97$).

Of the 85 children with inpatient or outpatient hospital visits due to LRTIs, 5 were hospitalized for 33 days, with the shortest hospital stay being 5 days and the longest being 7 days. There were average lengths of hospitalization of 7 days in the JE-I cohort and 4.5 days in the JE-L cohort (see Table S6 in Multimedia Appendix 1).

**Risk of Inpatient and Outpatient Hospital Visits for LRTIs**

In the JE-I cohort, there were 128 visits attributed to LRTIs during 225 person-years, with an incidence density of 0.568 (95% CI 0.501-0.634) person-years. In the JE-L cohort, there were 182 visits attributed to LRTIs during 585 person-years, with an incidence density of 0.311 (95% CI 0.274-0.350) person-years. Further, we performed a subgroup analysis, which revealed that the incidence density of the JE-I cohort was lower than that of the JE-L cohort (Table 1).
Table 1. Incidence density and hazard ratios (HRs) of inpatient and outpatient hospital visits for lower respiratory tract infections in different cohorts (N=810): live-attenuated Japanese encephalitis vaccine (JE-L; n=585), inactivated Japanese encephalitis vaccine (JE-I; n=225).

aAndersen-Gill model adjusted for sex, birth weight, age, maternal parity, chronic diseases, number of hospital visits prior to 24 months of age, number of hospital visits prior to 24 months of age due to infectious diseases, and nonimmunization program vaccines administered before 24 months of age.

bNot applicable.
There was no violation detected between the 2 cohorts, as evaluated via Schoenfeld residuals to test the assumption of a proportional hazard. Therefore, we constructed a normal Andersen-Gill model to calculate the HR. The results showed the JE-L cohort had a lower risk of LRTIs than the JE-I cohort (adjusted HR [aHR] 0.537, 95% CI 0.416-0.693) in the adjusted analyses. Likewise, there were statistical differences within the subgroups (sex, age, chronic diseases, maternal parity), with a lower risk of LRTIs for female children (aHR 0.305, 95% CI 0.198-0.469), children aged 32 months to 35 months (aHR 0.454, 95% CI 0.336-0.612), children without chronic diseases (aHR 0.553, 95% CI 0.420-0.729), and children without siblings (aHR 0.361, 95% CI 0.255-0.511; Table 1).

### Types of LRTIs

In the adjusted analyses, the JE-L cohort had a lower risk of pneumonia (aHR 0.501, 95% CI 0.393-0.638) and acute bronchitis (aHR 0.525, 95% CI 0.396-0.698) than the JE-I cohort (Table 2).

### Association With Timing

In the adjusted analyses, no association was observed between the time elapsed after the most recent vaccine and the occurrence of LRTIs among children aged 25 months to 35 months (Table 3).

#### Table 3. Incidence density and hazard ratios (HRs) of inpatient or outpatient hospital visits according to the time elapsed since the most recent vaccine in the cohorts: live-attenuated Japanese encephalitis vaccine (JE-L; n=585), inactivated Japanese encephalitis vaccine (JE-I; n=225).

\(b\) Not applicable.
Association With the Number of Hospital Visits

In the adjusted analyses, we found that children with more hospital visits in the JE-L cohort had a lower risk of LRTIs than the children in the JE-I cohort. Prior to 24 months of age, children who visited the hospital more than 30 times (aHR 0.163, 95% CI 0.091-0.290) and those who visited the hospital 5 to 10 times owing to infectious diseases (aHR 0.058, 95% CI 0.017-0.202) had fewer hospital visits due to LRTIs (Table 4).

Sensitivity Analyses

During the entire course of JE immunization, 212 children received JE-I only, 573 children received JE-L only, 13 children received JE-I after JE-L, and 12 children received JE-L after JE-I. The incidence density of those who received JE-L only was lower than those who received JE-I only (0.316 vs 0.604 person-years), which is similar to the results of the main analysis (see Table S7 in Multimedia Appendix 1). In addition, the association between the vaccination course of JE and the risk of LRTIs was also similar to that of the main analysis. Children who received JE-L only had a lower risk of inpatient and outpatient hospital visits due to LRTIs than those who received JE-I only (aHR 0.512, 95% CI 0.396-0.662), and this effect was especially pronounced in female children (aHR 0.292, 95% CI 0.189-0.449), those aged 32 months to 35 months (aHR 0.434, 95% CI 0.321-0.587), children with no siblings (aHR 0.355, 95% CI 0.251-0.502), children without chronic diseases (aHR 0.524, 95% CI 0.397-0.692), children with >30
hospital visits prior to 24 months of age (aHR 0.163, 95% CI 0.091-0.290), and children with 5 to 10 hospital visits due to infectious diseases prior to 24 months of age (aHR 0.062, 95% CI 0.017-0.218; see Table S8 in Multimedia Appendix 1).

Discussion

Principal Findings

Most previous studies on NSEs of vaccines have been carried out in resource-limited countries, and several have been conducted in high-income countries, such as the United States [10], Denmark [4], and The Netherlands [19]. To the best of our knowledge, this is the first study to explore the NSEs of JE vaccines in China.

This retrospective cohort study was based on information derived from an integrated clinical database to explore the NSEs of JE-L and their relevant factors. Our findings show that receiving JE-L as the most recent vaccine is associated with a lower risk of hospital admission due to LRTIs (including pneumonia and acute bronchitis) among children aged 25 months to 35 months. In addition, this study also illustrated that the NSEs of JE vaccines may be influenced by sex, health status, maternal parity, number of inpatient or outpatient hospital visits prior to 24 months of age, and the absence of siblings. There was no statistical significance between the time elapsed since the last vaccination and the onset of LRTI-related hospital admissions.

We believe that our findings are reliable since the information used in this study was acquired from Yinzhou EHR databases, which have been proved to be authentic and reliable based on our previous herpes zoster study and other studies [16,18,20-23]. In addition, we had access to the complete immunization records of the children included in this study (vaccination information was obtained from the Immunization Administration Registry and the CDC Adverse Event Following Immunization Information System).

Among other studies, vaccines currently shown to have NSEs include BCG, MMR, measles, live polio, and DPT. In China, these vaccines are all NIP vaccines, which can be given to children free of charge. Some studies have reported that the vaccine coverage of NIP vaccines in China is consistently above 80% [24], and in Yinzhou, the coverage rate is even higher (96.22%) [14]. Almost all children were vaccinated. Therefore, the NSEs effect found in this study cannot be attributed to BCG, MMR, and other related vaccines.

Consistent with the findings of previous studies, our study showed that the incidence density of LRTIs at 25 months to 35 months of age among the 810 participants was much higher among male children and those with a mother with more than 1 parity. Unlike other countries, China’s one-child policy, which was in place for nearly 40 years (1979-2015), fundamentally altered the country’s demographic and social structure. The fact that most of our study participants were a single child is also influenced by the change in policy [25]. One study reported that the risk of hospital admissions for children with respiratory syncytial virus was related to maternal parity and gender of the children in the family and that children with siblings (adjusted odds ratio [OR] 1.96) and male children (adjusted OR 1.57) were at higher risk [26]. A meta-analysis also identified male sex (OR 1.23) and having siblings (OR 1.60) as risk factors for developing LRTIs [27]. Thus, having 1 child may protect against secondary LRTIs from siblings. Meanwhile, we also found that the incidence density of LRTIs was higher in children with chronic diseases and those of older age, which is in agreement with the findings by Sørup et al [4].

Several reports have shown that administration of live vaccines such as BCG [3,6,28], MMR [4,19,29], and OPV [5,30,31] as the most recent vaccine may have NSEs that decrease all-cause mortality or the risk of hospital admissions due to nontarget infectious diseases. In their study, Sørup et al [4] found that receiving MMR as the most recent vaccine, compared with DTaP-IPV-Hib, was associated with a 20% (95% CI 16%-24%) lower risk of LRTIs. In addition, Sørup et al [5] also found that OPV could reduce the risk of LRTIs by 15% (95% CI 5%-23%) compared with DTaP-IPV-Hib as the most recent vaccine. Hollm-Delgado et al [32] found that the BCG vaccine was associated with 17% to 35% risk reduction of LRTIs. A systematic review [2] also suggested that live vaccines could lower the risk of developing LRTIs. Furthermore, Bardenheier et al [10] reported that live vaccines could reduce hospitalizations due to nontarget LRTIs by 44% to 64%. Therefore, our results indicating that JE-L has NSEs on LRTIs are consistent with those of the aforementioned reports.

Although the possible biological mechanisms to support our findings have not been identified, trained immunity [9,33] can be assumed to play a major role. It is now believed that trained immunity is the result of the interaction between immunity, metabolism, and epigenetics. Alterations in the metabolism of intrinsic immune cells affect epigenetics, which can further influence metabolic pathways and cytokine production [34]. For example, the epigenetic modifications in the body after BCG vaccination led to an increase of H3K4me3 at the promoter regions of certain genes, producing protection against unrelated pathogens [35]. Further, it can be conjectured that heterologous protective immunity (cross-protection via T cells) might have a minor role in producing the NSEs of vaccines. In addition, compared with JE-I, JE-L has been reported to produce much more interferon-γ spot-forming cells and interleukin-2 spot-forming cells, both of which exert important antiviral effects [36].

Studies have also found that the NSEs of live vaccines are sex-specific to some extent and that the NSEs of BCG [37,38] and the measles vaccine [39,40] favor the female sex, whereas the NSEs of OPV [30,41] favor the male sex in all-cause mortality and hospital admissions. These results are similar to our findings showing that the NSEs of JE-L favors female children. This observation may be related to the fact that female children are more likely to have a stronger and faster innate and adaptive immune response to viruses than male children due to the higher number, activity, and inflammatory immune response of innate immune cells, including monocytes, macrophages, and dendritic cells in female children than male children [42-44]. The other possible reasons might be the hormone-mediated pro-inflammatory effects of low-dose
estradiol and anti-inflammatory effects of testosterone and progesterone in those of the female sex [2,45,46].

Notably, our results did not elicit protective effects of JE-L on those with chronic diseases, which may be related to the limited number of children with chronic diseases included in the study. Regarding the association between the NSEs of JE-L and the number of hospital visits, our study showed that more hospital visits had a greater protective effect of JE-L in children. This was in agreement with the results of the study by Sørup et al [4], which reported that the NSEs of MMR were better in children with a higher frequency of hospital admissions for infectious diseases before the age of 11 months (0 vs 1 vs 2 vs 3 times and above: HR 1.00 vs 0.96 vs 0.92 vs 0.86, respectively) and children who had been admitted before 11 months of age (0 vs 1 times and above: HR 1.00 vs 0.80). Meanwhile, similar to our findings, the study by Sørup et al [4] also reported that the NSEs of MMR are better in children with mothers with 1 parity than with mothers with 2 parities (HR 1.00 vs 1.03).

Moreover, we also performed a sensitivity analysis in our study to ensure the reliability of our results. The sensitivity analysis in this study revealed similar results to the main analysis, which further supported the finding that JE-L has NSEs on LRTIs. Additionally, it verified that the NSEs of JE-L could be diminished by JE-I.

**Limitations**

This study had several limitations. First, the limited number of participants who met the inclusion criteria resulted in a wide confidence interval for the results, which may have reduced the reliability of our study. Second, we cannot exclude some underreporting, which may bias the results toward uncorrelation. Third, due to the limitations of the database, our study failed to include potential confounders that may have influenced the results. For example, studies have demonstrated that parental smoking [4] and socioeconomic status [47] can influence hospital admissions and the highest educational level of the child’s guardian can influence vaccination choices [48]. Consequently, more studies on the NSEs of JE-L based on EHR databases with sufficient variables are needed in the future. Fourth, the low number of cases of LRTIs found in this study may be related to the vaccination of children against pneumonia [14] and influenza [49]. This may mask the NSEs of JE vaccines.

It is noteworthy that most countries recommend JE-I rather than JE-L for those with an immunocompromised status, such as patients with rheumatic diseases [50], HIV, or solid organ transplant [51,52] owing to possible safety concerns (ie, JE-L was contraindicated in immunocompromised individuals in Australia) [53]. However, inoculating healthy children with JE-L is recommended for its stronger protection [54,55] and may be associated with fewer side effects than JE-I [56,57]. According to our data, the nature of NSEs induced by JE-L should be considered by policymakers and physicians when recommending JE vaccines to those at high risk of infection from the JE virus.

Finally, as this study was conducted just prior to the COVID-19 epidemic, it would be valuable to repeat the study after COVID-19 to validate the robustness of the results in further studies, as COVID-19–related isolation and societal changes may have influenced susceptibility to LRTIs in the study cohort.

**Conclusions**

Compared with JE-I, receiving JE-L as the most recent vaccine was associated with a lower risk of hospital visits for LRTIs among children aged 25 months to 35 months.

Abstract

Background: To enhance postoperative patient survival, particularly in older adults, understanding the predictors of mortality following hip fracture becomes paramount. Air pollution, a prominent global environmental issue, has been linked to heightened morbidity and mortality across a spectrum of diseases. Nevertheless, the precise impact of air pollution on hip fracture outcomes remains elusive.

Objective: This retrospective study aims to comprehensively investigate the profound influence of a decade-long exposure to 12 diverse air pollutants on the risk of post–hip fracture mortality among older Taiwanese patients (older than 60 years). We hypothesized that enduring long-term exposure to air pollution would significantly elevate the 1-year mortality rate following hip fracture surgery.

Methods: From Taiwan’s National Health Insurance Research Database, we obtained the data of patients who underwent hip fracture surgery between July 1, 2003, and December 31, 2013. Using patients’ insurance registration data, we estimated their cumulative exposure levels to sulfur dioxide (SO₂), carbon dioxide (CO₂), carbon monoxide (CO), ozone (O₃), particulate matter having a size of <10 μm (PM₁₀), particulate matter having a size of <2.5 μm (PM₂.₅), nitrogen oxides (NOₓ), nitrogen monoxide (NO), nitrogen dioxide (NO₂), total hydrocarbons (THC), nonmethane hydrocarbons (NMHC), and methane (CH₄). We quantified the dose-response relationship between these air pollutants and the risk of mortality by calculating hazard ratios associated with a 1 SD increase in exposure levels over a decade.

Results: Long-term exposure to SO₂, CO, PM₁₀, PM₂.₅, NOₓ, NO, NO₂, THC, NMHC, and CH₄ demonstrated significant associations with heightened all-cause mortality risk within 1 year post hip fracture surgery among older adults. For older adults, each 1 SD increment in the average exposure levels of SO₂, CO, PM₁₀, PM₂.₅, NOₓ, NO, NO₂, THC, NMHC, and CH₄ corresponded to a substantial escalation in mortality risk, with increments of 14%, 49%, 18%, 12%, 41%, 33%, 38%, 20%, 9%, and 26%,
respectively. We further noted a 35% reduction in the hazard ratio for O\textsubscript{3} exposure suggesting a potential protective effect, along with a trend of potentially protective effects of CO\textsubscript{2}.

Conclusions: This comprehensive nationwide retrospective study, grounded in a population-based approach, demonstrated that long-term exposure to specific air pollutants significantly increased the risk of all-cause mortality within 1 year after hip fracture surgery in older Taiwanese adults. A reduction in the levels of SO\textsubscript{2}, CO, PM\textsubscript{10}, PM\textsubscript{2.5}, NO\textsubscript{X}, NO, NO\textsubscript{2}, THC, NMHC, and CH\textsubscript{4} may reduce the risk of mortality after hip fracture surgery. This study provides robust evidence and highlights the substantial impact of air pollution on the outcomes of hip fractures.

KEYWORDS

air pollution; hip fracture; mortality; exposure; older adult; environmental hazard; hazard; morbidity

Introduction

Hip fracture, a major concern for older adults, is associated with high mortality and morbidity as well as a high economic burden on the health care system [1,2]. Hip fracture surgery often leads to poor functional outcomes, such as reduced quality of life, substantial care demands, and limited mobility [3-9]. Several studies have reported an increased rate of mortality (12% to 40%) within 1 year after hip fracture in older adults [10-15]. Pneumonia and cardiovascular diseases are the predominant causes of mortality after hip fracture in these individuals [16-19]. Perioperative factors associated with the risk of 1-year mortality after hip fracture surgery include high baseline Charlson Comorbidity Index (CCI) scores, high American Society of Anesthesiologists grades, and prolonged surgery delay [4,20-22]. To adopt stratified care approaches, such as prioritizing geriatric patients with hip fractures at high risk of mortality for intensive care and to reduce the rate of mortality, clinicians must be aware of the relevant prognostic factors [15].

Since the 1990s, air pollution has been recognized as a major global environmental problem, which leads to increased mortality and morbidity rates [23-26]. Exposure to air pollution is associated with the risk of mortality from various conditions, such as cancer [27], critical illness [28], chronic obstructive pulmonary disease [29], COVID-19 [30], and major surgery [31-33]. However, few studies have investigated the effects of air pollution on the outcomes of hip fractures.

A recent meta-analysis revealed that high risks of osteoporosis and hip fracture were positively associated with increased exposure to air pollutants [34]. However, most studies on air pollution have focused only on bone marrow density and hip fracture incidence, but not on further prognosis or outcome. In 2022, Shi et al [35] reported that exposure to particulate matter having a size of <2.5 \mu m (PM\textsubscript{2.5}), particulate matter having a size of <10 \mu m (PM\textsubscript{10}), and nitrogen dioxide (NO\textsubscript{2}) may increase the risk of mortality within 30 days after hip fracture. Despite the limited samples of air pollutants collected and the lack of long-term evaluation, the aforementioned study may be the only one on the effects of air pollution on mortality after hip fracture surgery.

Emerging evidence underscores the need for a more detailed understanding of the relationship between air pollution and post–hip fracture mortality, particularly given the complex interplay of factors involved in the health outcomes of older adults. Beyond the direct respiratory effects, air pollution has been implicated in systemic inflammation [36-42] and oxidative stress [43-52], both of which are central to the pathophysiological processes underlying hip fracture complications and mortality [53,54]. In other words, this complex interplay might go beyond immediate respiratory implications and include the broader landscape of systemic health. Besides, the older population, particularly those with preexisting comorbidities, may be disproportionately vulnerable to the adverse effects of air pollution due to reduced physiological reserves and impaired reparative mechanisms [55]. It is essential to recognize the holistic impact of air pollution, not only as a respiratory hazard but as a systemic disruptor influencing the delicate balance of physiological processes in older adults.

Furthermore, hip fracture recovery is a complex process that involves various mechanisms that can be influenced by systemic factors. Investigations into the specific impact of long-term exposure to a comprehensive array of air pollutants on the 1-year postoperative mortality risk in this population have been limited, necessitating a deeper exploration into the biological underpinnings. As we consider the theoretical framework of hip fracture pathogenesis, we must delve into the ways air pollution may intricately contribute to the vulnerability and subsequent mortality risk in older adults following hip fracture surgery. By expanding our focus beyond the immediate postoperative period, we can unravel the enduring effects of air pollution on recovery trajectories and long-term outcomes in this vulnerable population.

Therefore, we conducted this retrospective study to investigate the effects of decade-long exposure to various air pollutants on the risk of mortality after hip fracture surgery in older Taiwanese patients. We hypothesized that long-term exposure to air pollution would have an impact on the rate of 1-year mortality after hip fracture surgery. This study investigated the effects of decade-long exposure to 12 air pollutants—sulfur dioxide (SO\textsubscript{2}), carbon dioxide (CO\textsubscript{2}), carbon monoxide (CO), ozone (O\textsubscript{3}), PM\textsubscript{10}, PM\textsubscript{2.5}, nitrogen oxides (NO\textsubscript{X}), nitrogen monoxide (NO), NO\textsubscript{2}, total hydrocarbons (THC), nonmethane hydrocarbons (NMHC), and methane (CH\textsubscript{4})—on older Taiwanese adults who underwent hip fracture surgery. This study seeks to address these critical knowledge gaps by using a population-based approach and comprehensive air pollutant exposure data.
shedding light on the intricate relationship between air pollution and post–hip fracture outcomes. This knowledge has the potential to offer evidence that may serve as a foundation for government authorities to develop strategies aimed at mitigating air pollution. Such strategies could significantly alleviate the strain on the health care system.

**Methods**

**Data Source**

In this study, we collected relevant data from Taiwan’s National Health Insurance Research Database (NHIRD), which was launched by the Taiwanese government in 1995. This database contains the comprehensive medical information of approximately 98.29% of the population of Taiwan (approximately 23 million insured individuals) [56]; these data include the patient’s sex, date of birth, employment status, inpatient and outpatient diagnoses, medical procedures, drug use, treatment duration, and medical costs [57]. We obtained the patients’ baseline information from the Longitudinal Health Insurance Database 2000, a subset of the NHIRD, containing the data of 1 million randomly selected patients.

All data generated or analyzed during this study are included in this published paper and its Multimedia Appendix files. More detailed data sets are not publicly available due to restrictions set by the Taiwan Ministry of Health and Welfare regarding the NHIRD in Taiwan. Researchers interested in accessing the data from the NHIRD must obtain approval from the Health and Welfare. For further information on data availability and access, please refer to the “Data Availability” section.

**Study Population**

Only patients with complete available data were included in this study. Patients with missing, inconsistent, or unknown records of baseline information, such as sex and birth year, were excluded from this study. The cohort included patients who underwent hip fracture surgery between January 1, 2000, and December 31, 2012. Additional exclusion criteria were as follows: unreasonable age (0 years old); younger than 60 years at baseline; with the outcome diagnosis prior to the start of the study (to prevent reverse causation bias); history of pathological fracture, open fracture, or major traffic accident before the initiation of the study; whose follow-up start date was the same as the follow-up end date. At last, participants were excluded if their survival date was before July 01, 2003, to ensure that the study population had a minimum of 10 years of exposure to air pollution. This criterion was established because the Environmental Protection Administration (EPA) data for this study was only available starting from July 1, 1993. Therefore, if a participant’s follow-up ended before July 1, 2003, their exposure to air pollution would be less than 10 years. The ICD-9 (International Classification of Diseases, Ninth Revision) codes established in the inclusion and exclusion criteria were listed in Multimedia Appendix 1.

**Exposure Data Collection**

We obtained information on the cumulative daily average levels of the aforementioned 12 air pollutants from 76 monitoring stations maintained by the Taiwan EPA, Executive Yuan. Data were collected for the period between July 1, 1993, and December 31, 2013. The cumulative daily average level of each pollutant was calculated over the 10 years before the end of follow-up. Then, the data were integrated with the patients’ residential postal codes obtained from their insurance registration data. Any change in residence during the assessment period was also considered. Specifically, changes in a patient’s place of residence during the study period were tracked by their information with insurance registration records, ensuring that any shifts in location were accounted for in the study’s data analysis to maintain accuracy and reliability.

**Outcomes and Confounders**

All-cause mortality was the major outcome of interest. We followed up on each patient until we reached the primary end point, which was determined by 2 conditions: death (withdrawal from the National Health Insurance program) or end of the study period (December 31, 2013). The survival duration was calculated in months. Several confounders were identified and adjusted for, such as age, urbanization level, insurance amount, CCI score, hip fracture procedure, comediations, antosteoporosis medication, ambient temperature, season, and lag 0–1. Patient data such as age, insurance amount, CCI score, hip fracture procedure, comediations, and antosteoporosis medication were also obtained from the NHIRD database. Specifically, the insurance amount was evaluated as an average value for the assessment period of air pollution exposure. Comorbidities were defined as those occurring before the survival date. ICD-9 codes or Anatomical Therapeutic Chemical Classification codes for the definition of hip fracture procedure, comediations, and antosteoporosis medication were detailed in Multimedia Appendix 1. Information on the meteorological factor of ambient temperature was collected from the EPA. Data on the urbanization level were recorded according to the patients’ residence at the beginning of the follow-up period in accordance with the classification proposed by Liu et al [58]. Furthermore, the season was defined on the basis of the date. We also included the 2-day moving average of current- and previous-day levels of air pollutants before the primary end point (lag 0–1) as a confounder, considering the largest effect estimate reported in the literature [59-61].

**Statistical Analysis**

To identify the patient characteristics associated with air pollution, the cohort was divided into 3 tertiles on the basis of the level of exposure to each pollutant. The tertiles were compared using the chi-square test or 1-way ANOVA. Post hoc tests were performed to estimate between-tertile differences if significance was indicated. We plotted crude cumulative incidence curves of mortality within 1 year after hip fracture surgery for the 3 tertiles; between-tertile differences were assessed through log-rank tests. Hazard ratios (HRs) for exposure at 1 SD increment for 10 years were calculated using Cox regression models to evaluate the dose-response effects between air pollutants and mortality risk. The regression models were adjusted for the aforementioned confounders. All tests were 2-sided; statistical significance was set at P<.05. All analyses were performed using the MetaTrial Research Platform (Biomedica Corp).
Ethical Considerations

The Research Ethics Committee of Taipei Medical University, Taiwan, approved this study (TMU-JIRB N202203088). Because of the anonymity of patient data in the NHIRD, the requirement of informed consent was waived.

Results

Study Population

After the inclusion of patients with complete available data (n=882,391), those who underwent hip fracture surgery during the study period were identified (n=9286). Patients who met the exclusion criteria (1349, 75, and 473 for the aforementioned 3 criteria, respectively) were further excluded from the analysis. Finally, 7426 patients were included in the analysis. Figure 1 illustrates the selection process.

CH\textsubscript{4}: methane; CO: carbon monoxide; CO\textsubscript{2}: carbon dioxide; NMHC: nonmethane hydrocarbons; NO: nitrogen monoxide; NO\textsubscript{2}: nitrogen dioxide; NO\textsubscript{X}: nitrogen oxides; O\textsubscript{3}: ozone; PM\textsubscript{10}: particulate matters having a size of <10 μm; PM\textsubscript{2.5}: particulate matters having a size of <2.5 μm; SO\textsubscript{2}: sulfur dioxide; THC: total hydrocarbons.

Characteristics and Descriptive Results

Table 1 summarizes the characteristics of the included cohort (n=7426). The incidence of mortality was 929 (12.51%). The average age of the cohort was 78.54 years, and 2926 (39.40%) patients were men. The characteristics of patients exposed to each pollutant were assessed by dividing the cohort into 3 tertiles (Multimedia Appendices 2-13). Table 2 presents the mean and distribution values of each pollutant over the 10-year exposure period.

Cumulative Mortality Incidence

Table 3 presents the incidence of mortality within 1 year after hip fracture surgery across the tertiles, as well as the corresponding P value (1-way analysis of variance and post hoc tests). The cumulative incidence curves revealed substantial differences in the direction and strength of the associations between each air pollutant and the incidence of mortality (Figures 2-13).

Dose-Response Effects Between Air Pollutants and Mortality Risk

To evaluate the dose-response effects between the levels of air pollutants and the risk of mortality, we used Cox regression models and calculated the HRs for exposure at 1 SD increment for 10 years. Table 4 presents the corresponding HRs. The findings suggest that a 1 SD increment in the average exposure levels of \( \text{SO}_2 \), \( \text{CO} \), \( \text{PM}_{10} \), \( \text{PM}_{2.5} \), \( \text{NO}_x \), \( \text{NO}, \text{NO}_2, \text{THC}, \text{NMHC}, \text{and CH}_4 \) was associated with 14\%, 49\%, 18\%, 12\%, 41\%, 33\%, 38\%, 20\%, 9\%, and 26\% significant increases in mortality risk, respectively. However, a significantly negative association was observed for \( \text{O}_3 \), with a 35\% reduction in mortality risk. \( \text{CO}_2 \) tended to exhibit only a trend but not a statistical significance to reduced mortality risk.

### Table 4. Hazard ratios for mortality associated with long-term exposure to air pollution at 1 SD increment for 10 years.

**Discussion**

**Principal Findings**

In this study, long-term exposure to \( \text{SO}_2 \), \( \text{CO} \), \( \text{PM}_{10} \), \( \text{PM}_{2.5} \), \( \text{NO}_x \), \( \text{NO}, \text{NO}_2, \text{THC}, \text{NMHC}, \text{and CH}_4 \) was associated with an increased risk of all-cause mortality within 1 year after hip fracture surgery. In older individuals, a 1 SD increment in the average exposure levels of \( \text{SO}_2 \), \( \text{CO} \), \( \text{PM}_{10} \), \( \text{PM}_{2.5} \), \( \text{NO}_x \), \( \text{NO}, \text{NO}_2, \text{THC}, \text{NMHC}, \text{and CH}_4 \) was associated with 14\%, 49\%, 18\%, 12\%, 41\%, 33\%, 38\%, 20\%, 9\%, and 26\% increases in mortality risk, respectively. By contrast, we found a significant reduction (35\%) in the HR for \( \text{O}_3 \) and a trend of potentially protective effects of \( \text{CO}_2 \).
Comparison With Prior Work

In this study, long-term exposure to SO₂, CO, PM₁₀, PM₂.₅, NOₓ, NO, NO₂, THC, NMHC, and CH₄ was consistently found to be risk factors for mortality within 1 year after hip fracture surgery. Previous studies have found an association between osteoporosis and the levels of exposure to air pollutants, including PM₂.₅, PM₁₀, CO, and NOₓ [62-65]. The same trends were observed in the risk of hip fracture associated with PM₂.₅, SO₂, NO, NO₂, and O₃ [66,67]. Shi et al [35] were the first to investigate the effects of air pollution on mortality after hip fracture. In their nationwide cohort study in the United Kingdom, the levels of specific air pollutants, such as PM₂.₅, PM₁₀, and NO₂ exhibited a moderately positive association with the increases in the incidence and 30-day mortality rates of hip fracture. Thus far, their study was the only one on the negative effects of air pollution on mortality after hip fracture. However, the focus on 30-day mortality limited the scope of the long-term prognosis assessment. Moreover, the representativeness and extrapolation of their findings were limited because of the lack of age-standardization of the incidence; the possibility of errors in air pollution assessment owing to the use of data acquired only from the hospital region; and the presence of key unadjusted confounders, such as sex, season, temperature, socioeconomic, and CCI score. The aforementioned limitations of their study and the complexity of air pollution resulted in an unclear dose-response effect. To overcome this problem, we analyzed many pollutants; the robust evidence obtained in this study may help policy makers assess the economic loss and burden associated with air pollution and devise effective prevention strategies.

Possible Mechanisms

Although the precise mechanisms underlying the association between air pollution and mortality remain unclear, we hypothesized the following mechanism: air pollution contributes to frailty in older adults, thus increasing their susceptibility to mortality after hip fracture surgery. Air pollution is an independent risk factor for mortality from respiratory and cardiac diseases [25,68]. Furthermore, air pollution modifies the aging process by interfering with biological pathways; these effects are supported by toxicological evidence indicating that air pollution enhances oxidative stress [43-52], activates systemic inflammation [36-42], and causes metabolic disorders [69-72], genetic and epigenetic alterations [73-81], and vector-mediated pathogen transmission [30]. Zanobetti and Schwartz [82] suggested that air pollution influences the frail population in the following manners: increasing the mortality rate, increasing recruitment into the frail group, and delaying recovery. This finding indicates that air pollution modifies aging through frailty. Moreover, air pollution may aggravate age-related decline and functional deterioration at the cellular, tissue, and organ levels [83], thus increasing individuals’ vulnerability to disease development and mortality incidence. Given the association of exposure to ambient air pollution with all-cause and specific morbidity and mortality, our hypothesis and the obtained significant HRs appear to be highly conceivable and concomitant.

We found a negative association between the risk of mortality after hip fracture and exposure to O₃ pollution. Various conclusions have been reported regarding the effects of O₃ exposure [84-88]. Studies reporting protective effects, which are consistent with our findings, have provided the following explanations. First, sunlight facilitates O₃ formation; O₃ is a seasonal pollutant because its level is higher in summer than in winter. Therefore, seasonal effects should be considered when analyzing the effects of O₃ on health [84,89]. In this study, season served as a confounder in our regression models for potentially adjusting for the seasonal effects. Second, O₃ appears to be associated with other air pollutants; hence, the effects of O₃ on health should be considered together with those of other pollutants. Thus, in this study, we performed a Pearson correlation analysis of air pollutants (Multimedia Appendix 1). To address the confounding impact of other pollutants and to prevent potential issues related to multicollinearity, we used potential associations among air pollutants to evaluate the impacts of multiple pollutants, selectively regulating those based on their weak correlations with other air pollutants. We defined the absolute value of correlation coefficients of <0.3 to indicate a low strength of correlation. However, the negative association between mortality and O₃ pollution persisted (Multimedia Appendix 1) in the multiple-pollutant models of the targeted pollutants; thus, the second explanation was rejected. Thus, the precise mechanisms underlying the protective effects of O₃ remain unclear. Nevertheless, other theories may provide some insights into these mechanisms, as follows: the enhanced expression levels of endothelial and inducible nitric oxide synthase [90-92], improvement of hemorheological parameters and oxygen delivery [92,93], and neuroprotective effects [92,94].

CO₂ emission exhibits a nonsignificant negative correlation with mortality after hip fracture. For the correlation between exposure to CO₂ pollution and the risk of mortality within 1 year after hip fracture surgery, the HR was 0.88 (95% CI 0.76-1.02), with a P value of .09. This finding is similar to previous findings that CO₂ emission exerted positive but nonsignificant effects on longevity [95-97]. After adjustment for the urbanization level and insurance amount, our analysis revealed a positive but nonsignificant trend in the health effects of CO₂ exposure, which is consistent with the literature. However, to the best of our knowledge, this has so far not been explained nor recognized in the literature. The need for more extensive research in the future is evident, as there remain numerous unexplored facets and complexities within this subject that warrant thorough investigation to advance our knowledge and drive progress in the field.

Strengths

Our study has several strengths. First, to the best of our knowledge, this study is the first to indicate that long-term exposure to air pollution contributes to mortality within 1 year after hip fracture surgery. Second, we analyzed many key air pollutants (n=12). Third, we assessed the mortality within 1 year of surgery, thus focusing on the long-term outcomes of hip
fracture. Finally, we adjusted for most of the major confounders, such as sex, season, temperature, socioeconomic, and CCI score, which further strengthened our findings and provided robustness for our primary conclusion.

**Limitations**

This study has some limitations. First, although smoking is a key factor influencing ambient air quality, we could not include it in the analysis because of data unavailability; this might have led to a potential bias. Second, the NHIRD does not include data on disease severity, clinical manifestations, laboratory findings, and mortality causes. Hence, we could not determine the specific causes of mortality. Third, the possibility of errors in the assessment of air pollution cannot be ignored. Fourth, because we regarded death as withdrawal from the National Health Insurance program, bias might have been introduced into our findings. Fifth, while we considered any changes in residence during the assessment period, it is worth noting that the residential postcodes may not always be updated accurately in the insurance registration data. This could result in inaccuracies when reflecting patient characteristics. Sixth, although we adjusted for several confounders, unmeasured or unknown confounders might have introduced bias into our results. Given the limitations of retrospective health insurance database cohorts, which may not encompass all potential confounding factors, the possibility of residual bias due to unmeasured variables remains. Seventh, although we aimed to analyze individual molecules separately, it is possible that we neglected the potential for nonlinear relationships or the possibility of mixed effects of other molecules. Finally, there is a potential that the current levels of air pollution may differ from the data used in our study. However, due to the availability of data, this is the most up-to-date information we can analyze. Furthermore, our paper highlights the health and societal hazards of air pollution, and we hope that our research findings can provide empirical support for air pollution control policies across various times and situations. Despite the aforementioned limitations, this study provides adequate, high-quality evidence to support our conclusion that long-term exposure to SO₂, CO, PM₁₀, PM₂.₅, NOₓ, NO, NO₂, THC, NMHC, and CH₄ is associated with an increased risk of all-cause mortality within 1 year after hip fracture surgery.

**Conclusions**

In this nationwide population-based retrospective study, we discovered that long-term exposure to SO₂, CO, PM₁₀, PM₂.₅, NOₓ, NO, NO₂, THC, NMHC, and CH₄ is correlated with an increased risk of all-cause mortality within 1 year after hip fracture surgery in Taiwanese adults older than 60 years. Furthermore, 1 SD increment in the average exposure levels of SO₂, CO, PM₁₀, PM₂.₅, NOₓ, NO, NO₂, THC, NMHC, and CH₄ was associated with 14%, 49%, 18%, 12%, 41%, 33%, 38%, 20%, 9%, and 26% increases in mortality risk, respectively. However, O₃ exposure was associated with a significant reduction (35%) in HR, whereas CO₂ exhibited a nonsignificant trend of potentially protective effects. Thus, our findings provide robust evidence that can be used by the government to devise and implement air pollution prevention strategies for reducing the burden on the health care system. Nonetheless, future studies with well-adjusted confounders are warranted to investigate the correlation between air pollution and hip fracture mortality and the underlying pathophysiologic mechanisms.

Abstract

Background: Human papillomavirus (HPV) infection causes nearly all cervical cancer cases and is a cause of anogenital and oropharyngeal cancers. The incidence of HPV-associated cancers is inequitable, with an increased burden on marginalized groups in high-income countries. Understanding how immunization status varies by material and social deprivation, health system, and geospatial factors is valuable for prioritizing and planning HPV immunization interventions.

Objective: The objective of this study was to describe school-based HPV immunization rates by individual and geospatial determinants of health in Alberta, Canada.

Methods: Health administrative data for male and female individuals born in 2004 in Alberta were used to determine HPV immunization status based on age and the number of doses administered in schools during the 2014/2015-2018/2019 school years. Immunization status and its relationship with material and social deprivation and health system factors were assessed by a logistic regression model. Geospatial clustering was assessed using Getis-Ord Gi* hot spot analysis. Mean scores of material and social deprivation and health system factors were compared between hot and cold spots without full HPV immunization using independent samples t tests. A multidisciplinary team comprising researchers and knowledge users formed a co-design team to design the study protocol and review the study results.

Results: The cohort consisted of 45,207 youths. In the adjusted model, the odds of those who did not see their general practitioner (GP) within 3 years before turning 10 years old and not being fully immunized were 1.965 times higher (95% CI 1.855-2.080) than those who did see their GP. The odds of health system users with health conditions and health system nonusers not being fully immunized were 1.092 (95% CI 1.006-1.185) and 1.831 (95% CI 1.678-1.998) times higher, respectively, than health system users without health conditions. The odds of those who lived in areas with the most material and social deprivation not being fully immunized were 1.287 (95% CI 1.200-1.381) and 1.099 (95% CI 1.029-1.174) times higher, respectively, than those who lived in areas with the least deprivation. The odds of those who lived in rural areas not being fully immunized were 1.428 times higher (95% CI 1.359-1.501) than those who lived in urban areas. Significant hot spot clusters of individuals without full HPV immunization exist in rural locations on the northern and eastern regions of Alberta. Hot spots had significantly worse mean material deprivation scores ($P=0.008$) and fewer GP visits ($P=0.001$) than cold spots.
Conclusions: Findings suggest that material and social deprivation, health system access, and rural residency impact HPV immunization. Such factors should be considered by public health professionals in other jurisdictions and will be used by the Alberta co-design team when tailoring programs to increase HPV vaccine uptake in priority populations and regions.

Introduction

Background Information
Human papillomavirus (HPV) is the most common sexually transmitted agent in Canada, with upwards of 75% of Canadians experiencing at least 1 infection in their lifetime [1]. While most infections resolve on their own, some infections cause cell abnormalities, which can lead to cancer [2]. Infection with HPV causes nearly all cases of cervical cancer and is a cause of anogenital and oropharyngeal cancers in both men and women [3]. In Canada, cervical cancer is the 13th most common cancer diagnosed in women and the third most common among women aged 20–44 years [4].

Cervical cancer tends to be a disease of inequity, with an increased burden in high-income countries observed in disadvantaged groups [1,5]. A meta-analysis of 57 studies found that the relative risk of cervical dysplasia and invasive cervical cancer increases with decreasing socioeconomic status, with the relationship strongest in low- to middle-income countries and in North America [6]. The authors postulate that these results are due to relationships between socioeconomic status, HPV exposure, and access to cervical cancer screening programs. In addition to socioeconomic status, studies from Canada and the United States have found higher cervical cancer incidence among women living in rural rather than urban areas, which could be related to health care access [7,8]. HPV-associated cancer incidence can be addressed by increasing the uptake of the HPV vaccine, a safe and effective vaccine available since 2006 [9], but there is a need to explore factors associated with the uptake of the vaccine to close the gap in the inequities of cervical cancer incidence.

In 2018, the World Health Organization announced a global call to action for the elimination of cervical cancer, with a global strategy involving improved immunization, screening, and treatment [10]. The Canadian Partnership Against Cancer (CPAC) developed a corresponding action plan, with the immunization priority targeting having 90% of 17-year-olds in Canada fully immunized with the HPV vaccine by 2025 [11]. If this target is achieved, we could expect to see a 23% reduction in cervical cancer cases and a 21% decrease in cervical cancer–related mortalities [12]. Despite the HPV vaccine being publicly available for school-aged children, HPV coverage rates across most of Canada remain below the 90% target [1]. To address this coverage gap, it is imperative that we identify individual and geospatial determinants of health associated with being underimmunized with the HPV vaccine so that public health professionals can tailor public health planning and interventions toward priority populations.

Objective
The primary objective of this study was to describe school-based HPV immunization rates by individual and geospatial determinants of health in Alberta. Factors were selected through an equity-informed lens to appropriately describe HPV immunization coverage by the determinants of health. To achieve this objective, the study had 2 aims:

1. To understand variation in HPV immunization uptake in relation to determinants of health within individual and geographic area-level analyses.
2. To identify clusters of regions with a higher percent of individuals without full HPV immunization (hot spots) and those with a lower percent of individuals (cold spots) and compare the distribution of individual determinants of health across those regions.

Methods

Setting
This study took place in Alberta, Canada, which has a fully integrated, publicly funded health care system that delivers care to nearly 4.4 million people [13]. Alberta is separated into 5 health zones based on population, geography, and the distribution of health services: Calgary, Central, Edmonton, North, and South. This study investigated Alberta’s school-based HPV immunization program, which includes HPV vaccines administered by public health in schools and in Well Child Clinics across the province [14].

In Alberta, the Gardasil vaccine was originally offered to female individuals in grade 5 in 2008 (Figure 1 [15]) [16]. The original schedule consisted of 3 doses administered over a 6-month period. In 2014, the program was extended to include grade 5 male individuals, and in 2016, the Gardasil vaccine was replaced with the Gardasil-9 vaccine. In 2018, a total of two policy changes were implemented to the school-based program: (1) administration was pushed from grade 5 to 6, and (2) the number of doses was decreased from 3 to 2 for immunocompetent individuals aged 14 years and younger. As of 2020, all residents aged 9–26 years are eligible to receive the HPV vaccine free of charge.
Participants
This was a cohort study looking at male and female individuals born in 2004 in Alberta. The index event was the date on which the individual turned 10 years old, with the assumption that they were in grade 5 during the 2014-2015 school year. Individuals who were 9 years old in September-December 2014 were also included in the cohort. The cohort was followed up for 5 years after their index date, from the 2014-2015 school year when they would have first become eligible to receive the HPV vaccine in grade 5, to the 2018-2019 school year when they would have been in grade 9 and reoffered the HPV vaccine in school if they hadn’t previously declined and were not up to date.

The exclusion criteria for this study included: (1) missing age, sex, or postal code (n=0); (2) not having valid Alberta health care coverage 3 years before index (necessary for complete covariate data), at index, or during follow-up (including deaths and emigration; n=8381); and (3) living outside of Alberta (n=144).

Outcome
The outcome of interest was whether individuals in the cohort were fully or not fully immunized with the HPV vaccine. Doses were only counted toward immunization status if they occurred during the follow-up period (2014-2015 to 2018-2019 school years). Immunization status was based on age and the number of doses administered. Individuals were assessed as fully immunized after 2 doses for those 14 years of age and younger and after 3 doses for those 15 years of age and older. Individuals were considered not fully immunized if there was no record of them being immunized over the follow-up period, or they received 1 dose at 14 years of age and younger, or 1-2 doses at 15 years of age and older (ie, partially immunized). Individuals who were partially immunized were combined with those who were not immunized during the follow-up period, as they only represented 1.65% (n=746) of the cohort, and the objective of the study was to focus on those not fully immunized to inform public health planning.

Since 2008, individuals were assessed as fully immunized after 3 doses for all individuals regardless of age; however, in September 2018, the number of doses was reduced for this group after a clinical trial found that both the 2- and 3-dose schedules produced similar vaccine efficacy [17]. Immune status was not taken into consideration for immunization status in this study, as we were not able to accurately ascertain immunocompetency or HIV status from health codes associated with the Canadian Institute for Health Information (CIHI) grouper. Immunization status for this study was classified based on post-2018 age and dose number standards throughout the entire follow-up period.

In order to achieve an optimal immune response, the first and last dose of either a 2- or 3-dose HPV vaccine series is meant to be administered over a 6-month interval [4]. The time between the first and last dose was not considered in this analysis as we deviated from the historical vaccine schedule and instead based immunization status on post-2018 age and dose number standards (ie, individuals were assessed as fully immunized at 2 doses for those 14 years of age and younger, or 3 doses for those 15 years of age and older).

Data Sources
The study cohort was created using administrative data extracted from the Alberta Health Services Enterprise Data Warehouse. The Alberta Health Care Insurance Plan (AHCIP) Provincial Registry contains population demographics for all persons in Alberta covered for basic medical and hospital insurance during a given fiscal year and was used to define our study cohort. Using a provincial health care number, the cohort was linked to other population-based data sets, including the Alberta Health Postal Code Translator File, the 2016 Pampalon Index, physician claims, the Discharge Abstract Database (DAD), and the National Ambulatory Care Reporting System (NACRS). The Alberta Health Postal Code Translator File was used to establish geographical boundaries to classify local geographic areas (LGAs), health zones, and urban and rural areas. The 2016 Pampalon Index uses Census data at the dissemination area level to present socioeconomic disparities among the population. The index is made up of material and social components, stratifying the population into 5 quintiles, with the first level being the least deprived, and the fifth being the most deprived. The material component is characterized by low income, an insecure job situation, and low education, while the social component is defined by being a single parent, being separated, divorced, or widowed, and living alone [18]. Physician claims capture data for fee-for-service and shadow-billed (ie, bills

Figure 1. Evolution of Alberta’s human papillomavirus immunization program.
submitted for reporting purposes, but practitioners compensated through alternate methods) claims by physicians and provides information on service dates, number of visits, and services provided [19]. Physician claims data cover the 3 years before index (ie, the date an individual turned 10 years old). DAD and NACRS capture acute care hospitalizations and community-based and hospital-based ambulatory care, including emergency department visits, respectively, in Alberta, and include records for demographic, diagnostic, procedural, and treatment information for each visit [20]. DAD and NACRS were used to define the CIHI grouper, which categorizes individuals into health profile groups based on the history of health services received and the presence of health conditions. Individuals from the study cohort were assigned a health profile group based on diagnoses from a variety of health sectors, including but not limited to hospitals, emergency rooms, urgent care centers, and specialist and family practice settings. A total of 226 health conditions from 16 categories (eg, minor acute, major chronic, and other mental health) were used to synthesize an individual’s clinical profile to the most complex and clinically relevant health conditions present. Youths were placed into 1 of the following 3 categories: health system nonuser, health system user without health conditions (ie, without 1 of the 226 health conditions), and health system user with health conditions (ie, with 1 of the 226 health conditions). Groups were based on data from the 2013-2014 fiscal year [20,21]. The data set was then merged with the Meditech Health Information System, which contains information on all HPV vaccines administered by public health in schools and in Well Child Clinics across the province. After merging the Meditech Health Information System data set with the AHCIP Provincial Registry and linked population-based data sources and applying the exclusion criteria, the final merged data set consisted of 45,094 observations (Figure 2).
Figure 2. Creation of the study cohort data set. The (n=2751) surplus in the initial cohort when compared to the original Alberta Health Care Insurance Plan (AHCIP) Provincial Registry and linked data sources study cohort was due to the “did not have Alberta coverage at index” exclusion criterion being pre-applied to the AHCIP Provincial Registry but not the Meditech data set. This surplus is removed in the next exclusion step. HPV: Human Papillomavirus.

Individual postal code was geocoded using the Alberta Health Postal Code Translator File and estimates of percent of individuals without full HPV immunization were aggregated at the LGA. The LGAs were chosen for this spatial analysis as they are the smallest geographic area that Alberta Health Services and Alberta Health use as official geographies [22], and they determine how health services are distributed across Alberta. In Alberta, there are 132 LGAs of varying sizes divided across the 5 health zones.

Analysis
Variation in HPV immunization status and its relationship with determinants of health were assessed by analytical, data visualization, and geospatial techniques. Variables for inclusion in this analysis were selected a priori based on our conceptual framework (Figure 3; adapted from Dahlgren and Whitehead [23]) and data availability. Our conceptual framework was based on determinants of health documented in the literature (for example [5,24-28]) that impact student HPV immunization coverage.
Characteristics were summarized by HPV immunization status using counts and percentages. The use of mean and SD was determined based on the distribution of the data. Before their inclusion in the logistic regression analysis, correlations between covariates were checked using chi-square and Spearman rank-order correlation tests, where appropriate. A logistic regression model was used to estimate the odds ratios (ORs) comparing not fully immunized with fully immunized status for the characteristics of interest. ORs, adjusted odds ratios (aORs), and 95% CIs are reported. Observations were excluded from the logistic regression if they had missing covariate values (n=1694). No variables had more than 5% missing observations.

Global Moran’s $I$ was used to detect whether spatial autocorrelation exists, meaning that individuals without full HPV immunization are spatially clustered in Alberta. Moran’s $I$ ranges from +1 to −1 with positive values indicating spatial autocorrelation (ie, clustering of similar rates), while negative values indicate similar rates are located far away from each other (ie, dispersion). A $P$ value that is smaller than .05 means we can reject the null hypothesis of complete spatial randomness and accept that spatial autocorrelation exists and there is clustering [29].

To detect the location and magnitude of spatial clustering, we used local Getis-Ord Gi* optimized hot-spot analysis. Getis-Ord Gi* hot-spot analysis was used to identify areas of statistically significant clusters of LGAs with high rates of individuals without full HPV immunization are spatially clustered in Alberta. Moran’s $I$ ranges from +1 to −1 with positive values indicating spatial autocorrelation (ie, clustering of similar rates), while negative values indicate similar rates are located far away from each other (ie, dispersion). A $P$ value that is smaller than .05 means we can reject the null hypothesis of complete spatial randomness and accept that spatial autocorrelation exists and there is clustering [29].

Ethical Considerations
This study received ethics approval by the Health Research Ethics Board of Alberta (HREBA.CC-20-0425).

Co-Design Team
A multidisciplinary team based in Alberta formed a co-design team comprising experts in cancer prevention, epidemiology, immunization programming, biostatistics, public health planning, and communicable disease control to collaborate on this study. Co-design, or collaborative design, involves the active engagement of stakeholders involved with an issue who work together to design solutions to address the problem [30,31]. By drawing on the collective perspectives, experiences, and strengths of the group, there can be improved idea generation, better interventions, and enhanced outcomes [30]. The co-design team designed the study protocol, reviewed the study results, and will use the findings to identify priority populations and regions that should be engaged when designing interventions to improve HPV immunization coverage across Alberta. This collaboration facilitated the creation of relevant questions,
appropriate methods, and how the results could be used for public health planning.

**Results**

**Descriptive Statistics**

Descriptive statistics summarizing characteristics by HPV immunization status are displayed in Table 1. While the majority of youths who were fully immunized received their doses in grade 5, nearly 10% (2750/31,388) of youths received all of their doses in grade 9. A lesser proportion of youths who were fully immunized were from the Central, North, and South zones, compared to those in the Calgary and Edmonton zones. Those who were fully immunized tended to live in urban rather than rural areas. Youths who were not fully immunized tended to live in areas with more material and social deprivation than those who were fully immunized. Youths who were fully immunized were more likely to have had a GP visit in the 3 years before the index and tended to have a higher number of GP visits compared with youths who were not fully immunized. Those who were not fully immunized were more likely to be health system nonusers or health system users with health conditions.

Logistic Regression

A logistic regression model was fitted to estimate the aORs of not being fully HPV immunized, compared to being fully immunized according to study characteristics (Table 2). The odds of those who did not see their GP in the 3 years before index not being fully immunized were 1.965 (95% CI 1.855-2.080) times higher than those who did see their GP. The odds of health system users with health conditions and health system nonusers not being fully immunized were 1.092 (95% CI 1.006-1.185) and 1.831 (95% CI 1.678-1.998) times higher than health system users without health conditions. The odds of those who lived in areas with the most material and social deprivation not being fully immunized were 1.287 (95% CI 1.200-1.381) and 1.099 (95% CI 1.029-1.174) times higher than those who live in areas with the least deprivation. The odds of those who lived in rural areas not being fully immunized were 1.428 (95% CI 1.359-1.501) times higher than those who lived in urban areas.

Geospatial Analysis

Spatial autocorrelation of individuals without full HPV immunization at the LGA level was detected using Global Moran’s \(I\). With a Moran’s \(I\) index value of 0.051, a \(z\)-score of 3.74, and \(P<.001\), the null hypothesis was rejected, and it was concluded that there was more than a 99% probability that the distribution of individuals without full HPV immunization formed a clustered pattern by LGA in Alberta, Canada.

Getis-Ord \(Gi^*\) hot-spot analysis was used to determine the location and magnitude of the spatial autocorrelation. Results from Figure 4 indicate that there were 48 statistically significant hot or cold spots of individuals who were not fully immunized with the HPV vaccine. There were 2 clusters of hot spots in the North zone (High Level LGA) and on the eastern side of Alberta.
that cross the North and Central zones (St. Paul, Two Hills County, and Vegreville/Minburn County LGAs). There were also 2 large statistically significant cold spots within the Edmonton and Calgary zones. Nonsignificant data are presented in yellow. Due to small sample sizes (ie, under 20 individuals making up the estimate), data in 16 LGAs were suppressed—these areas are presented in white.

Independent samples t tests were used to determine if determinants of health vary between hot spots of individuals without full HPV immunization and cold spots (Table 3). Individuals living in hot spots were more likely to have a higher mean material deprivation score than those living in cold spots. Individuals living in hot spots had a statistically lower mean number of GP visits compared to those living in cold spots.

**Figure 4.** Areas of statistically significant clusters of local geographic areas with high (ie, hot spots) and low (ie, cold spots) rates of male and female individuals born in 2004 without full human papillomavirus immunization in Alberta, Canada.
Experiencing more material and social deprivation appears to impact vaccine acceptance, uptake, and series completion [33-39]. In school, which has been shown to influence vaccine hesitancy, but further research is needed to dissect the relationship between vaccine hesitancy and immunization behaviors at the community level [48].

**Strengths and Limitations**
This study has several methodological strengths. Large population-based sample sizes have high internal validity, and findings could be generalized to jurisdictions similar to Alberta. In addition, the HPV immunization data were sourced from the Meditech Health Information System, an administrative database, which is significantly more reliable than self-reporting, which is susceptible to recall bias. Furthermore, by solely focusing on doses administered by public health, recommendations for improvement can focus on school-based programs.

In the past, it has taken an average of 17 years for research evidence to move into practice and implementation [49]. To circumvent this issue, it is critical for researchers to partake in integrated knowledge translation, wherein knowledge users (eg, policy makers, practitioners, and administrators) are collaborators throughout the entire research process [50]. By

### Discussion

**Principal Results**
This population-based cohort study analyzed material and social deprivation, health system, and geospatial factors to describe school-based HPV immunization rates in Alberta. Overall, 69% (31,388/45,207) of the cohort was fully immunized with the HPV vaccine, and 31% (13,819/45,207) were not fully immunized. One interesting finding was that while most fully immunized youths in Alberta received their doses in grade 5, the grade 9 catch-up program caught almost an additional 10% (2750/31,388). While the majority of Canadian provinces and territories implemented catch-up programs for girls when the HPV vaccine was initiated in the respective jurisdiction, only 2 other provinces implemented such a program for boys [32]. Alberta continues to rescreen youths in grade 9 to determine whether they are missing one or more doses of their HPV vaccine. Considering the proportion of youths who were immunized by this catch-up program, it is an initiative that other jurisdictions could consider implementing to increase HPV vaccine uptake.

The results indicate that a lack of health system use may be an important indicator of HPV vaccine uptake. Individuals who do not visit their GP are less likely to be recommended the HPV vaccine by a health care provider, which has been demonstrated to impact vaccine acceptance, uptake, and series completion [33-39]. In urban areas, this may be more of a matter of taking advantage of missed opportunities for education when children and their parents or guardians visit their health care provider. In rural areas, it may be more of an issue of access to a health care provider [1,40]. On the other hand, the parents or guardians of health system nonusers may have lower trust in public institutions, which may impact their willingness to consent to the HPV vaccine for their child. For example, direct or intergenerational trauma associated with colonization or previous negative experience in health care, such as racism or discrimination, has discouraged trust in government-provided health care for some Indigenous Peoples of Canada, causing some individuals to avoid or delay seeking care [41]. One way we can improve the current system is by adopting an approach to cultural safety, which involves practitioners self-reflecting on their assumptions, challenging inequalities, and improving health care access by shifting the power from the practitioner to the patient [41,42].

Experiencing more material and social deprivation appears to be associated with not being fully immunized with the HPV vaccine. Other studies in Canada have found that living in areas of high material and social deprivation was associated with lower HPV vaccine refusal [43], those living in areas of high material deprivation were more likely to complete the HPV vaccine series [44], and those living in areas of high social deprivation had lower HPV vaccine coverage [45]. These results indicate that social and material deprivation as it relates to HPV vaccine uptake is complex, and individual-level associations may be difficult to discern using area-level information. Further analysis of individual-level factors should be an area of further research.

The results indicate that living in rural areas may be associated with not being fully immunized with the HPV vaccine. This is reflected in coverage variation by health zone, as a lesser proportion of youths who were not fully immunized were from the Central, North, and South health zones, with clustering occurring in the North and Central zones, which comprise more rural communities than the Calgary and Edmonton zones. With rural Canadian communities experiencing a shortage of family doctors [46], rural youths and their parents or guardians may not be receiving a recommendation to receive the HPV vaccine in school, which has been shown to influence vaccine acceptance, uptake, and series completion [33-39]. There is also an imbalance between the supply of nurses working in rural and remote areas in Alberta (12% in 2015) and the portion of the population residing there (18.5% in 2015) [47]. This discrepancy could lead to rural and remote public health nurses having less capacity to complete vaccine series for school-aged children. Parents and guardians in rural communities may also be declining the HPV vaccine for their child due to increased levels of vaccine hesitancy, but further research is needed to dissect the relationship between vaccine hesitancy and immunization behaviors at the community level [48].

focusing on questions that are relevant to practice and working with partners who are capable of implementing identified recommendations, integrated knowledge translation can effectively promote the uptake and use of research findings [50-52]. The key strength of this study was the use of a co-design team to enable an integrated knowledge translation approach. By using an integrated knowledge translation approach, the co-design team strives to shorten the typical 17-year research evidence-to-innovation gap, integrating study findings into public health planning to reach the 90% immunization target by 2025. Notably, these results will be supplemented with information on barriers and facilitators of the school-based HPV immunization program from the perspective of parents and guardians, as well as program leaders and front-line providers, through a CPAC-funded study being conducted by members of the co-design team [15].

There are several methodological limitations that should be noted, as they will impact the generalizability of the findings. First, HPV coverage was determined by applying current immunization standards to all follow-up years, despite the policy change that occurred in 2018, and immune status was not considered when determining immunization status. While this may overestimate the number of individuals fully immunized for HPV in the pre-2018 period, the objectives of this study center around determining the characteristics associated with being underimmunized in order to inform improvements to the current school-based immunization program, including who and where to target improvements, rather than solely determining coverage rates.

Second, the cohort denominator is population-based rather than school-based due to a lack of school list availability. Consequently, the AHCIP Provincial Registry needed to be used as a proxy denominator, which could result in underestimated coverage rates.

Third, the outcome variable of not being fully immunized may not necessarily mean that the individual was not fully immunized in certain situations. Immunization data were gathered from the Meditech Health Information System, thus only allowing us to classify those HPV doses administered by Alberta public health. Children may have received immunization at a local pharmacy, family doctor, or out of province, and consequently would have been misclassified as not being fully immunized.

Fourth, the exclusion criterion of removing those who did not have valid Alberta health care coverage over the full study period represented more than 5% (8381/53,588) of the original cohort. These individuals were excluded due to incomplete data, either for covariate data before index or immunization data at index or during follow-up. Due to incomplete data, it cannot be determined if these individuals would have a different propensity to be fully immunized if they had had access to the school-based HPV immunization program throughout the entire study period; thus, these individuals were excluded to avoid bias in the results.

Fifth, attributing area-level information to individuals, as was the case for the Pampalon Index and comparisons of the hot and cold spots, assumes area-level data can be attributed to all individuals in that geographic location, which is an ecological fallacy. Research has also shown that such inferences can attenuate true relationships between the factor and the outcome (ie, immunization status) [53]. These results will have to be interpreted with caution to ensure appropriate conclusions are drawn.

Lastly, LGA was used as the boundary for our geographic mapping. This boundary can help identify areas of the province to prioritize for intervention, but LGAs are based on population patterns of health system access (ie, use of hospital services) and may not capture the similarities in HPV immunization outcomes across these boundaries. Further research could explore the use of other geographic boundaries that might provide additional context into HPV immunization rates, such as school districts. Despite this limitation, LGA is currently the smallest official geographic unit used by Alberta Health Services and Alberta Health [22], provides sufficient sample size to allow for accurate and precise estimates in most LGAs, and has been used in other geospatial studies of health outcomes in Alberta [54-56]. Furthermore, in 16 LGAs, there were fewer than 20 cases, making up the estimates for the geospatial analysis. While conducting hot-spot analysis on small sample sizes is possible, it limits the reliability of the estimates over time. Therefore, we chose to suppress the findings from these 16 LGAs, which limits the information available in those specific areas but was necessary to avoid reporting hot spots based on potentially unstable estimates.

Conclusions
This study highlighted how HPV immunization status varies by individual and geospatial determinants of health. Those who were not fully immunized with the HPV vaccine tended to be health system nonusers, less likely to visit their GP, live in rural areas, and experience higher levels of material and social deprivation. In Alberta, there were 2 statistically significant hot spots of individuals not fully immunized with the HPV vaccine, located on the north and east sides of the province, with individuals living in hot spots being more likely to have a higher mean material deprivation score and less likely to visit a GP than those living in cold spots.

Study results will enable the co-design team to make evidence-informed decisions when tailoring the school-based HPV immunization program for priority populations and regions. Public health professionals in other jurisdictions should consider these determinants of health when designing interventions to increase HPV immunization coverage.

Acknowledgments
We would like to acknowledge the members of the school-based human papillomavirus (HPV) immunization project co-design team for their support throughout this project. We would like to thank Howie Thomson for the creation of Figures 1-3. Data extraction and linkage support were provided by the Alberta Strategy for Patient Oriented Research Data and Research Services.
This research was funded by the Urban Public Health Network in partnership with the Canadian Partnership Against Cancer (CPAC), which is funded by Health Canada, as well as Cancer Prevention and Screening Innovation in partnership with Alberta Health. The provision of funding by Alberta Health does not signify that this project represents the policies or views of Alberta Health. CPAC and Alberta Health had no role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Timely Pulmonary Tuberculosis Diagnosis Based on the Epidemiological Disease Spectrum: Population-Based Prospective Cohort Study in the Republic of Korea

Yousang Ko, MD, PhD; Jae Seuk Park, MD, PhD; Jinsoo Min, MPH, MD; Hyung Woo Kim, MD; Hyeon-Kyoung Koo, MD; Jeeyoun Oh, MD; Yun-Jeong Jeong, MD; Eunhye Lee, MD; Bumhee Yang, MD; Ju Sang Kim, MD; Sung-Soon Lee, MD, PhD; Yunhyung Kwon, PhD; Jiyeon Yang, RN, MSN; Jieyoun Han, PhD; You Jin Jang, MS; Jinseob Kim, MD, MPH

Abstract

Background: Timely pulmonary tuberculosis (PTB) diagnosis is a global health priority for interrupting transmission and optimizing treatment outcomes. The traditional dichotomous time-divided approach for addressing time delays in diagnosis has limited clinical application because the time delay significantly varies depending on each community in question.

Objective: We aimed to reevaluate the diagnosis time delay based on the PTB disease spectrum using a novel scoring system that was applied at the national level in the Republic of Korea.

Methods: The Pulmonary Tuberculosis Spectrum Score (PTBSS) was developed based on previously published proposals related to the disease spectrum, and its validity was assessed by examining both all-cause and PTB-related mortality. In our analysis, we integrated the PTBSS into the Korea Tuberculosis Cohort Registry. We evaluated various time delays, including patient, health care, and overall delays, and their system-associated variables in line with each PTBSS. Furthermore, we reclassified...
the scores into distinct categories of mild (PTBSS=0-1), moderate (PTBSS=2-3), and severe (PTBSS=4-6) using a multivariate regression approach.

**Results:** Among the 14,031 Korean patients with active PTB whose data were analyzed from 2018 to 2020, 37% (n=5191), 38% (n=5328), and 25% (n=3512) were classified as having a mild, moderate, and severe disease status, respectively, according to the PTBSS. This classification can therefore reflect the disease spectrum of PTB by considering the correlation of the score with mortality. The time delay patterns differed according to the PTBSS. In health care delays according to the PTBSS, greater PTB disease progression was associated with a shorter diagnosis period, since the condition is microbiologically easy to diagnose. However, with respect to patient delays, the change in elapsed time showed a U-shaped pattern as PTB progressed. This means that a remarkable patient delay in the real-world setting might occur at both apical ends of the spectrum (ie, in both mild and severe cases of PTB). Independent risk factors for a severe PTB pattern were age (adjusted odds ratio 1.014) and male sex (adjusted odds ratio 1.422), whereas no significant risk factor was found for mild PTB.

**Conclusions:** Timely PTB diagnosis should be accomplished. This can be improved with use of the PTBSS, a simple and intuitive scoring system, which can be more helpful in clinical and public health applications compared to the traditional dichotomous time-only approach.

### Introduction

In 2020, an estimated 10 million cases of tuberculosis (TB) were reported worldwide [1]. In the Republic of Korea (ROK), the number of notified TB cases had long remained stable without a decrease [2,3]; however, the number of notified TB cases has decreased significantly in the last decade following continuous nationwide efforts [4,5]. Specifically, in 2021, the overall notification rate for incident TB cases (n=18,335) was 35.7/100,000 persons, which constituted a 53.6% decrease in the number of cases compared with those notified in 2011 (39,557 incident TB cases; notification rate 78.9/100,000 persons) [3]. As a low-TB-burden country, it is now an appropriate time to take the next step toward the goal of TB elimination in the ROK.

Timely TB diagnosis plays a crucial role in TB elimination by reducing the disease burden and preventing further community-based infections [6,7]. Numerous studies in various countries have focused on estimating the time delay for early TB diagnosis and treatment while identifying associated risk factors [7-19]. Previously, we also conducted research at the national level in the ROK, following a similar approach and drawing on references from previous studies [20]. However, we concluded that the binary time approach used in previous studies from other countries did not offer significant assistance in the context of the ROK. This is because the absolute value of the diagnostic delay time in the ROK was shorter than that observed in other countries. Therefore, we considered the clinical usefulness of this conventional dichotomous time-divided approach as limited for our context and attempted to approach the delayed diagnosis issue from a new perspective by focusing on the pulmonary TB (PTB) disease spectrum.

The “iceberg concept” has been applied to describe TB infection [21], illustrating that TB infection exists in varying quantities within the population. Furthermore, this concept helps to elucidate the disease spectrum, ranging from latent TB to clinical disease. According to the iceberg concept, two directions of effort are necessary to eliminate TB: the first involves moving from the bottom to the top of the iceberg in preventing progression from latent TB to active TB infection, whereas the second involves moving from the top to the bottom of the iceberg, reflecting the fact that early diagnosis and prompt treatment of active disease are crucial in preventing further community-based transmission of the infection.

In the ROK, active TB screening, including the progression from latent TB infection (LTBI) to clinical TB infection, especially in schools and military services, helped to significantly decrease the TB incidence among younger individuals in their 10s to 20s [4]. Active TB contact investigation and highly recommended treatment for LTBI are needed. Therefore, the remaining areas of early diagnosis of active TB at a national level are needed to assess and help establish TB control policies, while informing where efforts should be focused.

In this study, we investigated the diagnostic delay in timely PTB diagnosis; quantified the time-consuming processes contributing to patient, health care, and overall delays in access to TB treatment in the ROK based on the PTB disease spectrum; and compared demographic characteristics between cases diagnosed with mild versus severe disease. These data could reveal the epidemiological characteristics of PTB in the ROK, thereby informing the development of a real-world approach to PTB diagnosis that could provide important insights into the nature of the process wherein a patient develops symptoms and is finally diagnosed with PTB.

### Methods

**Korea TB Cohort and Recruitment**

The Korea TB Cohort (KTBC) is a nationwide, prospective, and observational cohort comprising active TB cases from 172 public-private mix (PPM)–participating hospitals in 21 districts (>70% of all patients with TB in the ROK were treated in these
PPM hospitals) since July 2018 [22]. Each patient with TB was notified, treated, and followed up every month until the completion of anti-TB treatment based on the national TB program. An investigation of the detailed data of the characteristics of active TB cases was planned to enable the establishment of a long-term plan in the future that shared the aim of an advanced National TB Elimination Project, which is operated by the Korean Academy of Tuberculosis and Respiratory Diseases under supervision of the Korea Disease Control and Prevention Agency (KDCA). The inclusion criteria for the KTBC include notified TB cases in all participating hospitals by the Korea National TB Surveillance System.

After enrollment of the KTBC, specialist TB nurses from each hospital conducted detailed interviews with patients with TB and completed standardized case-level forms. This process includes comprehensive investigations into patient information, including comorbidities, height, body weight, economic status, employment status, social status, education level, and symptoms. Additionally, data related to the program were gathered, including details about treatment initiation, discontinuation, termination, and adverse effects, along with mortality. The collected data were checked by regional and central data managers. Following a regional and central audit, a central statistical team analyzed and organized the data every quarter.

Data collected from July 1, 2018, to December 31, 2020, were obtained from the KTBC. We included all PTB cases and excluded those with only extrapulmonary TB (EPTB) because the disease spectrum of EPTB could not be clearly determined. Furthermore, we excluded patients with rifampicin-resistant PTB to reduce heterogeneity when validating the developed Pulmonary Tuberculosis Spectrum Score (PTBSS) in comparing the disease spectrum of TB with outcomes (Figure 1).

**Figure 1.** Flow diagram of the study design. EPTB: extrapulmonary tuberculosis; KTBC: Korea Tuberculosis Cohort; PTB: pulmonary tuberculosis.

---

**Definitions of Time Delays in the Diagnostic Pathway**

We divided the PTB time interval into patient, health care, and overall delays [7]. A patient delay was defined as the duration between the onset of PTB-related symptoms and the first hospital visit. A health care delay was defined as the duration between the first hospital visit and initiation of anti-PTB treatment after a confirmed diagnosis of PTB. The overall delay was defined as the sum of the patient and health care delays.

**Determination of the PTBSS Based on the PTB Disease Spectrum**

The PTBSS was designed based on previously published proposals for the PTB disease spectrum (Figure 2) [23-28]. Due to the lack of a true reference value that can accurately reflect the PTB disease spectrum, we identified factors that are commonly used in the diagnosis of PTB and can assess disease severity based on the epidemiological concept of PTB. We calculated the PTBSS according to six important variables: presence of symptoms, positive sputum in TB-polymerase chain reaction (PCR), positive sputum in an acid-fast bacilli (AFB) smear, sputum culture-positive *Mycobacterium tuberculosis*, cavitation detected on chest x-ray, and bilateral lung involvement of PTB on chest x-ray. However, since these six factors we identified and set were not weighted through statistical analysis, it may be challenging to view them as equally important. In addition, asymmetry can occur as the frequency of the manifestation of each factor can differ depending on the stage in the PTB disease spectrum. Therefore, for analysis, we proceeded by grouping in the following manner. Depending on the score assigned from 0 to 6 points, scores of 0-1, 2-3, and 4-6 were classified as mild, moderate, and severe disease, respectively.
Figure 2. Determination of the Pulmonary Tuberculosis Spectrum Score (PTBSS). The PTBSS was calculated and distributed from 0 to 6 according to the presence of six clinical variables: symptoms, positive sputum in tuberculosis polymerase chain reaction (TBPCR), positive sputum in the acid-fast bacilli (AFB) smear test, sputum culture-positive Mycobacterium tuberculosis (MTB), cavitation on chest x-ray, and bilateral lung involvement of pulmonary tuberculosis (PTB) on chest x-ray scanning.

Validation of the PTBSS

While the PTBSS was designed based on a consensus around the disease spectrum, as supported by existing scientific evidence, it is necessary to validate the PTBSS within appropriate clinical and public health contexts. However, effective and specific biomarkers that are applicable in real-world settings have not been used, and these biomarkers cannot be implemented within the framework of the KTBC, which consists of clinical practice data from a real-world setting. Therefore, we sought to validate our results by comparing mortality rates according to the PTBSS. In accordance with the iceberg concept, disease progression could ultimately result in death. Hence, higher mortality could be associated with a longer disease duration. If the group with a high PTB score exhibits a high mortality rate, this group may have a longer disease period, which can be interpreted as the time elapsed from disease onset to diagnosis.

Statistical Analysis

Categorical data are described as numbers and percentages, which were compared using the \( \chi^2 \) or Fisher exact test. Continuous variables are expressed as mean (SD) or median (IQR) for normal or skewed distributions, respectively, and were compared using the \( t \) test or Mann-Whitney \( U \) test. The Kaplan-Meier method was used to estimate the cumulative survival rates of active PTB according to the PTBSS during anti-TB treatment. To determine intergroup differences, survival curves were compared by means of log-rank tests, and hazard ratios with 95% CIs were estimated using Cox regression analysis. A multivariate logistic regression analysis by binary classification was used to identify independent risk factors for each mild and severe disease condition at the time of diagnosis, based on the PTBSS, as measured by the estimated odds ratio with 95% CI, including variables with \( P < 0.20 \) on univariate analysis [29]. All analyses were two-sided and statistical significance was set at \( P < 0.05 \). Statistical analyses were performed using R version 4.2.0 (R Foundation for Statistical Computing) and GraphPad Prism 9.4.

Ethical Considerations

The Institutional Review Board of Hallym University Kangdong Sacred Heart Hospital approved the study protocol (approval number 2022-08-003-001) and waived the requirement for written informed consent from the participants because of the purely observational, noninterventional study design and analysis of anonymized patient data. The data are stored by the KDCA with authority to use as surveillance data for public health and research purposes.

Results

Participants

The flowchart in Figure 1 shows the recruitment of the study population after the exclusion of patients according to the above-described criteria. The distributions of these 14,031 patients with PTB according to the PTBSS are shown in Table 1.
The largest proportion of active cases of PTB were diagnosed as grades II to III (22.2% and 21.1%, respectively, according to a PTBSS of 1-2) and the smallest proportion of cases were diagnosed as grade VII (3.0% according to a PTBSS of 6). After the reclassification of severity based on the PTBSS, 37.0%, 38.0%, and 25.0% of patients with PTB were diagnosed with mild, moderate, and severe forms, respectively (Table 2). The detailed clinical characteristics of the enrolled 14,031 patients with PTB according to the PTBSS and reclassification of severity are presented in Table S1 in Multimedia Appendix 1.

Validation of the PTBSS Based on Survival Analysis

We evaluated the cumulative survival rate of KTBC patients with respect to both all-cause and PTB-related mortality, according to both the PTBSS itself and reclassified disease severity based on the PTBSS. With regard to all-cause mortality (Figure 3, Table S2 in Multimedia Appendix 1), survival rates were higher in patients with a low PTBSS and mild disease than in those with high scores and moderate-to-severe disease (Kaplan-Meier analysis, log-rank test P<.001). The overall cumulative mortality rates during anti-TB treatment for active PTB were 4.9% (grade I, score of 0), 8.0% (grade II, score of 1), 11.0% (grade III, score of 2), 14.3% (grade IV, score of 3), 14.6% (grade V, score of 4), 15.6% (grade VI, score of 5), and 14.6% (grade VII, score of 6). The overall cumulative mortality rates during anti-TB treatment for active PTB were 6.8% (mild disease), 12.4% (moderate disease), and 14.9% (severe disease).

With respect to PTB-related mortality (Figure 4, Table S3 in Multimedia Appendix 1), survival rates were higher in patients with a low PTBSS and mild disease compared with those in the high score and moderate-to-severe disease groups (P<.001). The PTB-related cumulative mortality rates during anti-TB
treatment for active PTB were 0.4% (grade I), 0.8% (grade I),
1.5% (grade III), 2.7% (grade IV), 4.2% (grade V), 7.3% (grade
VI), and 8.1% (grade VII). The overall cumulative mortality
rates during anti-TB treatment for active PTB were 0.7% (mild
disease), 2.0% (moderate disease), and 5.7% (severe disease).
Considering the correlation between the PTBSS and mortality,
the PTBSS can be considered to reflect the natural course of
PTB.

**Figure 3.** Kaplan-Meier survival probability curves of all-cause mortality for patients with active pulmonary tuberculosis (PTB) according to the Pulmonary Tuberculosis Spectrum Score (PTBSS; left curve, seven groups) and disease severity classified based on the PTBSS (right curve, three groups).

**Figure 4.** Kaplan-Meier survival probability curves of pulmonary tuberculosis (PTB)-related mortality according to the Pulmonary Tuberculosis Spectrum Score (PTBSS; left curve, seven groups) and disease severity classified based on the PTBSS (right curve, three groups).

**Time Delays According to the PTBSS in the Diagnostic Pathway**

After evaluating whether the PTBSS reflects the natural course of PTB, we checked all possible types of time delays according to the scores (Figure 5). As the PTBSS increased, the health care delay gradually decreased. However, the patient delay decreased with an increase in the PTBSS from 1 to 3 and then increased again from a score of 4 and above. The overall delay, as the sum of the health care and patient delays, gradually increased as the PTBSS increased. When including time delays in the diagnostic pathway and classifying them on a spectrum from mild to severe disease, health care and overall delays increased with increased disease severity. However, the patient delay exhibited a U-shaped pattern (Figure 5). This means that different patient-related time delays in the real-world setting, ranging from symptom onset of PTB to the first hospital visit, appeared at both extremes (ie, in the mild and severe forms) of PTB. This further means that two different approaches are required to reduce the patient delay.

Furthermore, we conducted comparative analyses to verify the impact of each factor included in the construction of the PTBSS on patient delay, health care delay, and overall delay. The results are presented in Table 3. Patients without symptoms exhibited differences in health care delay, likely indicating that symptomatic patients receive expedited testing in hospitals. Both sputum TB PCR positivity and AFB smear positivity were associated with differences in both patient and health care delays. In contrast, a positive *Mycobacterium tuberculosis* (MTB) culture in sputum did not exhibit any significant difference in either the patient or health care delay. The presence of cavitation on chest x-rays appeared to affect both patient and health care delays similarly. However, while bilateral lung involvement seemed to reduce the health care delay, it did not show a significant impact on the patient delay.
Figure 5. Patient, health care, and overall delays according to the PTBSS (top) and disease severity classified according to the PTBSS. Patient, health care, and overall time delays are presented as the median with IQR. PTB: pulmonary tuberculosis; PTBSS: Pulmonary Tuberculosis Spectrum Score.

**Risk Factors for a Diagnosis of Mild or Severe Disease Based on the PTBSS**

The independent risk factors associated with mild or severe disease at the time of diagnosis were investigated (Table 4). In the multivariate analysis adjusted for potential confounding factors, age and male sex were independently associated with severe PTB in patient delay. The significant difference in symptoms such as cough and/or sputum, dyspnea, and hemoptysis may be attributed to the progression of PTB itself and may be unrelated to the late patient delay of severe PTB. However, no factor was significantly associated with patient delay for mild PTB.

Discussion

Principal Results

The time elapsed from the onset of PTB to diagnosis could be heterogeneous depending on personal, cultural, and health system situations. For effective TB control, the best solution needs to be identified according to each situation. We have previously recognized that a time-only approach is insufficient for the timely diagnosis of active PTB. In this study, we developed a new approach based on the disease spectrum of PTB, deviating from the perspective that has been studied based on the time delay itself.

The main findings of this study are as follows. First, the PTBSS could reflect the disease spectrum of PTB by considering the correlation of the score with mortality. Second, the pattern of time delays differed according to the PTBSS. In health care delays according to the PTBSS, greater PTB progression was associated with a shorter diagnosis period, because the condition is microbiologically easy to diagnose. However, with respect to patient delays, the change in elapsed time showed a U-shaped pattern as PTB progressed. This means that a remarkable patient delay in the real-world setting might occur at both apical ends of the spectrum (ie, in mild and severe PTB). This further means that two different approaches are required to reduce the patient delay. Third, the independent risk factors of a late visit to a medical institution as patient delay factors were age and male sex in the severe form of PTB. In contrast, there were no significant risk factors for mild PTB. Considering the natural course of PTB infection within the population, our approach could be helpful for a diagnostic strategy of active PTB involving passive case finding for the severe form and active case finding for mild forms [26] (Figure 5).

Comparison With Prior Work

A diagnostic approach for the timely diagnosis and subsequent treatment of PTB is essential to reduce ongoing transmission in the community and PTB-related morbidity and mortality [30,31]. This approach is composed of two different types of time delays: patient and health care delays [7]. Both patient and health care delays have different medical and public health implications. Patient delay is the major determining time period for the total duration of the PTB diagnostic pathway, and is associated with infectiousness due to long-term exposure to...
others in the community and poor outcomes due to disease progression [11,20]. In contrast, the health care delay is the period immediately preceding the diagnosis of PTB, which is characterized by the highest infectious state in the disease course of PTB and is associated with in-hospital transmission to health care workers or other patients [32]. To date, studies have investigated timely diagnosis and related risk factors according to the time dichotomy [8,9,11,12,14,20,33]. However, this approach has inherent limitations for general application because the time delay and risk factors can vary greatly depending on the environments within each country [7,9,10,12,13,15,19,33]. Among the types of time delays, the patient delay is greatly influenced by the culture of each country, such as the perception of disease, personal circumstances, and medical policy. Health care delay will be affected by the specialty of the health care provider and the medical resources of each country. Therefore, it was difficult to identify consistent risk factors in previous studies.

PTB can be presented as a dynamic spectrum along with pathophysiology resulting from bacterial progression and associated changes in the host response, which is distinct from the binary simple classification of active and latent TB infection [25,27]. To reach the goal of TB elimination, a promising approach that possesses the above-mentioned characteristics is essential for a timely diagnosis of PTB and includes recognizing the development of subclinical PTB from an LTBI state, early detection of active PTB from subclinical PTB, and timely differential diagnosis of severe PTB from mild PTB [24,27,28,34]. The insights and perspectives on PTB as a spectrum in a disease state are becoming increasingly accepted, leading to new diagnostic approaches for different stages of the disease spectrum. However, in clinical practice, in a real-world setting, this is considerably more complicated than what is usually expected because of the limited evidence on predictive biomarkers for disease progression within active PTB [24]. Therefore, a simple and accessible approach is needed from both clinical and public health perspectives. Thus, we attempted to design the PTBSS for clinical and public use, which is expected to be easily applied in clinical and public health practice, as the PTBSS consists of variables that are widely used in real-world settings.

We aimed to validate this proposed and devised scoring system by examining the correlation of the PTBSS and the mortality rate during the treatment of PTB. The results revealed that for all-cause mortality, there was no significant difference in the Kaplan-Meier curve and hazard ratio between high-grade scores (eg, grade IV to VII), while clear distinctions were observed when grouping into mild, moderate, and severe disease categories. Conversely, for PTB-related mortality, significant differences were observed either when considering each PTBSS grade or when classifying patients into three distinct groups. We believe that the PTBSS, as an operational definition to predict the disease spectrum of PTB, reflects PTB-related mortality relatively better than all-cause mortality, which indirectly might demonstrate its excellence in reflecting the disease spectrum of PTB. Among 1538 deaths (10.9%) recorded after a confirmed diagnosis and treatment initiation in the KTBC, 342 (2.4%) were related to PTB, while 1196 (8.5%) were due to other causes. Most PTB-related deaths were a result of respiratory failure (n=324, 94.7%), with secondary ischemic heart disease accounting for 20 deaths (5.4%) and death from massive hemoptysis for 5 cases (1.5%).

As shown in Table 3, we conducted comparative analyses to assess the impact of various factors on each delay in PTBSS construction. Asymptomatic patients experienced health care delays, suggesting that hospitals may expedite testing for those with symptoms. A positive sputum TB PCR result was linked to both patient and health care delays; health care providers might quickly decide on treatment for TB PCR–positive patients, thereby reducing health care delays. However, TB PCR positivity may also lead to longer patient delays due to late hospital visits after symptom onset. AFB smear positivity of sputum also affected both delays, likely for similar reasons. Conversely, positive MTB cultures in sputum did not influence either delay, possibly because treatment typically starts when PTB is suspected clinically rather than waiting for culture results. Cavitation on chest x-rays was associated with delays in a similar way to TB PCR and AFB smear positivity. Bilateral lung involvement seemed to shorten the health care delay but not patient delay, as health care providers might act quickly in such cases, while the patient’s perception of the disease onset—whether unilateral or bilateral—might not affect their decision to seek care. With this novel approach, we determined at what level of severity, the degree of patient delay, and the degree of health care delay that cases of PTB are diagnosed in the ROK based on the severity of PTB. This new perspective will help to change the classic perspective of active PTB and establish a more specific and realistic PTB elimination policy. We confirmed that the patient delay of PTB in the ROK was not linearly correlated, such as an increase in time with PTB progression.

The definition of patient delay, which refers to the time taken by a patient to visit a health care facility after the onset of symptoms, can lead to discrepancies in the measured period and the associated risk factors due to the inherent inaccuracy of a patient’s subjective symptom onset. Because of these limitations, numerous studies have shown that while the health care delay remains somewhat consistent, the patient delay significantly varies depending on each country in question. Factors such as each society’s medical infrastructure, economic conditions, perspectives on the disease, and language barriers are complexly intertwined, suggesting that an integrated approach that a society can employ is necessary. From this standpoint, we believe that using objective factors, rather than just relying on a patient’s subjective symptom onset, and employing the PTBSS, which can reflect the natural progression of PTB, could be helpful in understanding the factors causing TB diagnostic delays in each society.

According to our study, older individuals with PTB were more likely to be diagnosed with advanced disease, possibly because they were unaware of TB-related symptoms because of their preexisting comorbidities or because they considered the possibility of diseases other than PTB. Thus, older adults were probably more likely to visit medical facilities late after symptom onset. Moreover, even if older people visit a medical institution, the diagnosis of PTB can be delayed because of the
possibility of other diseases. Furthermore, male patients are likely to be diagnosed with advanced disease. This is consistent or inconsistent with the results of previous observational studies conducted in different countries [8,11,12,14]. Thus, more research is needed.

**Limitations**

This study has some limitations. First, this study was performed in the ROK, a country with a high level of medical resources, the highest rate of health care use among the Organisation for Economic Co-operation and Development (OECD) countries, an aging population, and a low prevalence of HIV. Therefore, our analysis may have overestimated or underestimated the prevalence of PTB. Second, the patient delay could be affected by recall bias because this factor is determined by the patient’s own symptom description. Third, we only evaluated the disease spectrum using clinical variables, without specific immunological or bacteriological data, due to a lack of laboratory-based information. Fourth, the timing data for patient delay may vary between passive and active case-finding. Active case-finding might result in a shorter patient delay compared to passive case-finding. Nevertheless, we believe that a patient delay would primarily occur in symptomatic patients in the ROK, where a nationwide health insurance system enables citizens to access medical services despite economic constraints. Koreans are more likely to seek medical care at facilities compared to citizens from other OECD countries due to the ease of accessibility to medical services. However, we acknowledge that despite these favorable circumstances, there could be instances where some symptomatic patients might not seek medical attention due to personal reasons. To gain a deeper understanding of these diagnostic situations, the KTBC made the decision, in March 2022 during a meeting with the KDCA, to investigate the reasons for hospital visits. As a result, we plan to consider these factors and incorporate relevant analyses in our future follow-up studies.

**Conclusions**

A diagnostic approach for the timely diagnosis of PTB would be improved if based on the disease spectrum rather than the traditional dichotomous time-only approach. The PTBSS, as a simple and intuitive scoring system, could facilitate clinical and public approaches for TB detection and elimination specific to the context of each country.

Abstract

Background: Maternal preeclampsia is associated with a risk of autism spectrum disorders (ASD) in offspring. However, it is unknown whether the increased ASD risk associated with preeclampsia is due to preeclampsia onset or clinical management of preeclampsia after onset, as clinical expectant management of preeclampsia allows pregnant women with this complication to remain pregnant for potentially weeks depending on the onset and severity. Identifying the risk associated with preeclampsia onset and exposure provides evidence to support the care of high-risk pregnancies and reduce adverse effects on offspring.

Objective: This study aimed to fill the knowledge gap by assessing the ASD risk in children associated with the gestational age of preeclampsia onset and the number of days from preeclampsia onset to delivery.

Methods: This retrospective population-based clinical cohort study included 364,588 mother-child pairs of singleton births between 2001 and 2014 in a large integrated health care system in Southern California. Maternal social demographic and pregnancy health data, as well as ASD diagnosis in children by the age of 5 years, were extracted from electronic medical records. Cox regression models were used to assess hazard ratios (HRs) of ASD risk in children associated with gestational age of the first occurrence of preeclampsia and the number of days from preeclampsia onset to delivery.

Results: Preeclampsia occurred in 16,205 (4.4%) out of 364,588 pregnancies; among the 16,205 pregnancies, 2727 (16.8%) first occurred at <34 weeks gestation, 4466 (27.6%) first occurred between 34 and 37 weeks, and 9012 (55.6%) first occurred at ≥37 weeks. Median days from preeclampsia onset to delivery were 4 (IQR 2,16) days, 1 (IQR 1,3) day, and 1 (IQR 0,1) day for those first occurring at <34, 34-37, and ≥37 weeks, respectively. Early preeclampsia onset was associated with greater ASD risk (P=.003); HRs were 1.62 (95% CI 1.33-1.98), 1.43 (95% CI 1.20-1.69), and 1.23 (95% CI 1.08-1.41), respectively, for onset at <34, 34-37, and ≥37 weeks, relative to the unexposed group. Within the preeclampsia group, the number of days from preeclampsia onset to delivery was not associated with ASD risk in children; the HR was 0.995 (95% CI 0.986-1.004) after adjusting for gestational age of preeclampsia onset.

Conclusions: Preeclampsia during pregnancy was associated with ASD risk in children, and the risk was greater with earlier onset. However, the number of days from first preeclampsia onset to delivery was not associated with ASD risk in children. Our study suggests that ASD risk in children associated with preeclampsia is not increased by expectant management of preeclampsia in standard clinical practice. Our results emphasize the need to identify effective approaches to preventing the onset of preeclampsia, especially during early pregnancy. Further research is needed to confirm if this finding applies across different populations and clinical settings.

**Introduction**

Autism spectrum disorder (ASD) is a neurodevelopmental condition characterized by repetitive behaviors and difficulties in communication, social behavior, and sensory processing [1]. ASD is typically diagnosed in early childhood [2], with prevalence rising [3]. In 2020, it was estimated that 2.8% of children in the United States had an ASD diagnosis at 8 years old, an increase from 0.7% in 2000 and 2.3% in 2018, with rates varying by sex, race, and ethnicity [3]. ASD is characterized by a range of symptoms, behaviors, and severity; children with autistic disorders, Asperger syndrome, or pervasive developmental disorder not otherwise specified can be diagnosed with ASD [4]. The etiology of ASD is multifactorial, and genetic factors only explain a small proportion [5]. Early life exposures, including adverse maternal health conditions during pregnancy, such as obesity and diabetes, and environmental pollutants, such as near-roadway air pollution and particulate matter 2.5, are all shown to be associated with the development of ASD [5-9].

One common pregnancy complication is preeclampsia, a hypertensive condition defined by placental vascular deterioration and maternal liver or kidney dysfunction [10]. As preeclampsia is an inflammatory condition complicating 2% to 8% of pregnancies worldwide each year [11], it is important to understand its effect on offspring’s development and long-term health. Previous studies have reported associations between maternal hypertensive disorders and an increased risk of ASD in children [12-15]. Hypertensive disorders of pregnancy, which include preeclampsia, were shown to be associated with adverse childhood neurodevelopment [16,17] and a 2-fold increase in ASD risk in childhood [15]. A meta-analysis reported a higher risk of ASD in the offspring of mothers with preeclampsia than those with gestational hypertension [18]. Previous studies also reported that preeclampsia is associated with an increased risk of ASD [6,19], as well as with preterm birth, which is a risk factor for ASD [20]. However, it is unknown whether the increased ASD risk associated with preeclampsia is due to preeclampsia onset or clinical management of preeclampsia after the onset. Identifying the risk associated with preeclampsia onset and exposure is important to provide evidence supporting the care of high-risk pregnancies and to reduce adverse effects on offspring.

Evidence suggests that preeclampsia results from impaired vascularization of the placenta, with inadequate diastolic uterine arteries causing insufficient blood flow to the placenta and increased systemic maternal inflammation [21]. The primary treatment for preeclampsia is delivering the baby or managing the condition until the best time to deliver the baby [22-24]. Depending on the severity, health care providers will closely monitor symptoms, including blood pressure, platelet count, and fetal growth, as well as renal and hepatic function, and hypertensive medications can be added to control blood pressure [24]. Current preeclampsia treatment guidelines advise expectant management for preeclampsia symptoms until 34 or 37 weeks gestation [24], depending on the severity of symptoms, such that preeclampsia occurring early could be expected to continue for several weeks before delivery.

The purpose of this study is to fill the knowledge gap by examining whether the number of days from preeclampsia onset to delivery in clinical standard practice is associated with an increased risk of ASD in offspring, considering the gestational age of preeclampsia onset. This study will provide important information concerning clinical guidelines for the management of preeclampsia and the effort to minimize the impact on offspring. Data are derived from a large, representative clinical birth cohort with comprehensive electronic medical records (EMR).

**Methods**

**Study Population**

This population-based retrospective birth cohort study used mother-child pairs of singleton births at Kaiser Permanente Southern California (KPSC) hospitals between January 1, 2001, and December 31, 2014. Of 414,463 mother-child pairs, 49,875 were excluded for lack of Kaiser Permanente membership by the age of 1 year or death of the child by the age of 1 year. The final cohort for this study was 364,588 mother-child pairs. Children were followed through KPSC EMR from birth until age 5 years. The KPSC health care system includes a diverse population of 4.5 million members throughout Southern California, and member demographic data reflect that of local census tracts [25]. Maternal social demographic and pregnancy health data, as well as the child’s ASD diagnosis, were extracted from KPSC’s integrated EMR.

**Outcome: ASD Diagnosis in Children at or Before the Age of 5 Years**

The outcome of this study was whether a child had an ASD diagnosis before or at the age of 5 years and the age of the initial diagnosis in KPSC EMR. We chose the follow-up of children up to the age of 5 years because the majority of ASD cases were diagnosed by the age of 5 years, and prenatal exposure is likely to manifest its adverse effect on early developmental disorders. The diagnosis of ASD is recorded in EMR using the International Classification of Diseases (ICD) codes developed by the World Health Organization. KPSC transitioned from ICD-9 codes to ICD-10 on October 1, 2015. In EMR records dated before October 1, 2015, ASD diagnoses were identified by ICD-9 codes 299.0, 299.1, 299.8, and 299.9. After that date, ASD diagnosis was identified by ICD-10 codes F84.0, F84.3, F84.5, F84.8, and F84.9. The diagnostic codes included autistic disorders, Asperger syndrome, and pervasive developmental disorder not otherwise specified but excluded Rett syndrome or childhood disintegrative disorder. ASD diagnosis was
determined if codes were present in the EMR at 2 or more separate health visits. This method was previously validated by an expert chart review with a positive predictive value of 88% [8,26-28].

**Exposure: Maternal Preeclampsia During Pregnancy**

Maternal preeclampsia during pregnancy was identified by ICD-9 codes 642.50-642.54, 642.60-642.64, and 642.40-642.44 and included eclampsia and hemolysis, elevated liver enzymes, low platelet count (HELLP) syndrome, a serious form of preeclampsia characterized by a low platelet count and elevated liver enzymes [29]. Preeclampsia is diagnosed when blood pressure measurements are >140 systolic or 90 diastolic and when a urine test reports >0.3 g of protein in 24 hours [24,30]. Severe cases involve blood pressure >160 systolic or 110 diastolic and 1 or more of the following: persistent headache, vision changes, thrombocytopenia (platelet count <100,000/mcL), impaired liver function, progressive renal insufficiency (serum creatinine >1.1 mg/dL or doubling of serum creatinine not explained by other known renal disease), and pulmonary edema [24,30]. The date of first occurrence (ie, onset defined for this study) of preeclampsia during pregnancy was extracted, and the corresponding gestational week of preeclampsia onset was calculated by subtracting the date of last menstrual period (LMP) from the date of first occurrence recorded in the EMR. Preeclampsia onset was categorized into the following three groups: (1) <34 weeks (diagnosis between 24 weeks 0 days and 33 weeks 6 days); (2) 34-37 weeks (34 weeks 0 days to 36 weeks 6 days); and (3) ≥37 weeks (≥37 weeks 0 days). This categorization reflected known gestational ages for fetal viability at birth and clinical management guidance for preeclampsia. The duration of 24 weeks has been reported to be the lower boundary for infant survival [31,32], and expectant management guidelines aim to maintain pregnancies until 34 or 37 weeks, depending on the timing of preeclampsia onset and the severity of symptoms [30]. Expectant management duration was calculated as the number of days between the date of preeclampsia onset and the date of delivery.

**Covariates**

Covariates selected to adjust for potential confounding were maternal age, self-reported race, ethnicity, and education; prepregnancy obesity, diabetes, and smoking during pregnancy; history of comorbidity (≥1 diagnosis of heart, lung, kidney, liver disease, or cancer); offspring sex; and census tract–level household income at child’s first birthday. These covariates were potential risk factors associated with child’s ASD risk, as shown in previous studies [21,24]. The birth year was also included as a covariate to account for trends of increasing ASD prevalence over the study period [8]. Maternal obesity was defined as a prepregnancy BMI ≥30 kg/m². Maternal prepregnancy BMI was calculated using maternal height and weight recorded in EMR from the date closest to LMP, with a window of 6 months before and 3 months after LMP [33]. Diabetes during pregnancy included preexisting type 1 or type 2 diabetes and gestational diabetes mellitus diagnosed before 26 weeks, as these were previously associated with ASD risk in this study sample [26,27].

**Statistical Analyses**

Outcome variables were child’s ASD diagnosis by the age of 5 years and the age of ASD diagnosis. Exposure variables of interest were the gestational age of preeclampsia onset and days from preeclampsia onset to delivery. The gestational age of preeclampsia onset was analyzed as a continuous variable as well as a categorical variable categorized as <34 weeks, 34-37 weeks, and ≥37 weeks. Duration from preeclampsia onset to delivery was analyzed both as a continuous variable and a categorical variable, using the median number of days between onset and delivery for each onset group as the cutoff. Maternal and child characteristics by preeclampsia exposure status were reported as median and IQR for continuous variables and total number (n) and proportion (%) for categorical variables. Wilcoxon rank-sum tests and chi-square tests were used to assess differences in maternal and child characteristics between preeclampsia exposures.

Associations between preeclampsia exposure and child’s ASD risk were assessed using Cox regression models. Robust standard errors were used to correct for potential correlation between siblings born to the same mothers. Associations were quantified as hazard ratios (HRs) with 95% CI. We first assessed the risk of ASD associated with preeclampsia exposure (yes vs no), followed by assessing ASD risk associated with gestational age of onset within the preeclampsia group and comparing the risk of ASD in the <34 weeks, 34-37 weeks, and ≥37 weeks onset groups relative to the unexposed. We then examined ASD risk associated with duration from onset to delivery among those with preeclampsia exposure, adjusting for gestational weeks of the first occurrence of preeclampsia. All models adjusted for birth year, maternal age, self-reported race and ethnicity, educational qualifications, prepregnancy obesity, diabetes, smoking during pregnancy, census tract–level household income at child’s first birthday, and child’s sex. Birth year was modeled as a penalized spline to account for the nonlinear relationship between birth year and outcomes. We also assessed the roles of gestational age at delivery and birth weight as pathways to risk associated with early onset of preeclampsia and duration from onset to delivery by further adjusting these 2 variables.

Statistical significance was set at P<.05. All statistical analyses were performed in R software (version 3.6; R Foundation for Statistical Computing).

**Ethical Considerations**

This study was approved by KPSC Institutional Review Boards (review #12075), with individual participant consent waived. All data analyzed were deidentified. No compensation was offered to individual participants. There was no community involvement in the study.

**Results**

Table 1 presents cohort characteristics by maternal preeclampsia status. Of the 364,588 children included in this study, 16,205 (4.4%) were exposed to preeclampsia in utero (Table 1). The preeclampsia group had more nulliparous women than the non-preeclampsia group (8238/16,205, 50.8% vs 124,405/348,383, 35.7%). Maternal age at delivery, race,
ethnicity, and educational qualifications, as well as census-tract household income and smoking behavior during pregnancy, did not differ between the 2 groups. Larger proportions of women with preeclampsia had diabetes preexisting or diagnosed at ≤26 weeks gestation (2194/16,204, 13.5% vs 20,147/348,383, 5.8%), obesity (4242/16,205, 26% vs 53,210/348,383, 15%), and histories of comorbidities (2694/16,205, 16.6% vs 45,291/348,383, 13%) than women who did not have preeclampsia. Sex was comparable among children of mothers with and without preeclampsia. Both median gestational age at delivery (38 weeks vs 39 weeks) and median birth weight (3005 g vs 3390 g) were lower in children of mothers with preeclampsia than in children of mothers without preeclampsia.

Table 1. Cohort characteristics by preeclampsia exposure. Tests for differences in each characteristic between the 2 groups were statistically significant at *P* <.001.

*a* Maternal diabetes includes preexisting type 1 diabetes (T1D) and type 2 diabetes (T2D) and gestational diabetes mellitus (GDM) diagnosed at ≤26 weeks (no preeclampsia—T1D: 574, 0.2%; T2D: 9150, 2.6%; GDM ≤26 weeks: 10,423, 3%; preeclampsia—T1D: 137, 0.8%; T2D: 1128, 7%; GDM ≤26 weeks: 929, 5.7%)

*b* Height and weight at each clinical visit were not recorded in Kaiser Permanente Southern California electronic medical records until late 2006; therefore, maternal obesity data were missing for children born between 2001 and 2006. Maternal prepregnancy BMI was categorized as obese (BMI ≥30 kg/m²), nonobese (BMI <30 kg/m²), and unknown (including mothers with unavailable BMI information). Maternal obesity proportion excludes women with missing BMI data (no preeclampsia: missing BMI sample size=135,139; preeclampsia=6229)

*c* Maternal comorbidity was defined as ≥1 diagnosis of heart, lung, kidney, liver disease, or cancer.

Of the 16,205 pregnancies with preeclampsia, 2727 (16.8%) first occurred at <34 weeks, 4466 (27.6%) first occurred between 34 and 37 weeks, and 9012 (55.6%) first occurred at ≥37 weeks. When assessing days from first occurrence to delivery, expectedly, mothers with onset at <34 weeks had the greatest number of days from first occurrence to delivery, with 31.6% (863/2727) having ≥10 days between onset to delivery in this group. For first onset at ≥37 weeks, 78.8% (7104/9012) delivered in ≤1 day. Median days from preeclampsia onset to delivery were 4 (IQR 2,16) days, 1 (IQR 1.3) day, and 1 (IQR 0,1) day for onset at <34, 34-37, and ≥37 weeks, respectively. A total of 7194 (2.1%) of the 348,383 children were diagnosed with ASD by the age of 5 years: 2.9% (465/16,205) in the preeclampsia exposed and 1.9% (6729/348,383) in the
unexposed groups, with an HR of 1.36 (95% CI 1.23-1.49) of ASD risk for exposed versus unexposed after adjusting for birth year, maternal age, race, ethnicity, education, history of comorbidity, prepregnancy obesity, diabetes, smoking during pregnancy, offspring sex, and census-tract household income (Table 2). When considering preeclampsia exposure by gestational week of first onset, earlier preeclampsia onset was associated with greater ASD risk ($P=0.003$ for testing ASD association with gestational age of preeclampsia onset among the preeclampsia group). The HRs were 1.62 (95% CI 1.33-1.98), 1.43 (95% CI 1.20-1.69), and 1.23 (95% CI 1.08-1.41) for onset at <34, 34-37 weeks, and ≥37 weeks, respectively, relative to the unexposed group (Table 2).

### Table 2. Hazard ratios (95% CI) of child’s ASD risk associated with preeclampsia exposure and diagnosis at different gestational weeks, relative to unexposed. Adjusted for birth year, maternal age, race, ethnicity, education, comorbidities, prepregnancy obesity, diabetes, smoking during pregnancy, offspring sex, and census-tract household income (per US $10,000).

Among those exposed to preeclampsia, the number of days from first onset to delivery was not associated with ASD risk. When analyzed as a continuous variable adjusting for preeclampsia onset, the HR of ASD risk associated with days from onset to delivery was 0.995 (95% CI 0.986-1.004; Table 3). When analyzed as a categorical variable cut at median days stratified by gestational week of preeclampsia onset, the HR associated with days above the median relative to at or below the median days for each onset group were 1.16 (95% CI 0.74-1.82) for onset at <34 weeks; 1.11 (95% CI 0.74-1.65) for onset between 34 and 37 weeks; and 1.23 (95% CI 0.85-1.78) for onset at ≥37 weeks (Table 3).

### Table 3. Hazard ratios (HRs; 95% CI) of child’s ASD risk associated with the number of days from preeclampsia diagnosis to delivery among those exposed to preeclampsia. Adjusted for birth year, maternal age, race, ethnicity, education, comorbidities, prepregnancy obesity, diabetes, smoking during pregnancy, offspring sex, and census-tract household income (per US $10,000).

a Adjusted for gestational age at preeclampsia diagnosis in weeks, as a continuous variable.

b The hazard ratio represents the risk associated with days from diagnosis to delivery above the median relative to equal or below the median distribution within each group (<34 weeks: median 4, IQR 2.16 days); (34-37 weeks: median 1, IQR 1.3 day); (≥37 weeks: median 1, IQR 0.1 day).

Early preeclampsia diagnosis was positively correlated with early gestational age at delivery ($r=0.90$) and lower birth weight ($r=-0.70$), but the number of days from onset to delivery was not correlated with gestational age at delivery ($r=-0.01$) or birth weight ($r=-0.005$). Further adjusting for gestational age at delivery and birth weight reduced HRs to 1.19 (95% CI 0.97-1.48) for onset at <34 weeks and 1.27 (1.07-1.50) for onset between 34 and 37 weeks but did not change the HR for preeclampsia onset ≥37 weeks (1.24, 95% CI 1.08-1.41). The number of days from onset to delivery remained unassociated with ASD risk in offspring after adjustment for gestational age at delivery and birth weight.

### Discussion

#### Overview

In this large sample and multiethnic clinical cohort study, children exposed to preeclampsia in utero were at higher risk of ASD than children who were not exposed, with a greater risk for children exposed to preeclampsia earlier in pregnancy. However, among children exposed to preeclampsia, there were no significant associations of risk of ASD with the number of days from first onset to delivery. This was analyzed both as a continuous variable adjusting for gestational age of preeclampsia first onset and as a categorical variable cut at the median number of days and stratified by gestational age of preeclampsia first occurrence. These results suggest that a child’s risk of ASD associated with preeclampsia is not increased by expectant management of preeclampsia in standard clinical practice.

https://publichealth.jmir.org/2024/1/e47396
To our knowledge, this study is the first to assess whether the reported ASD risk associated with maternal preeclampsia was due to preeclampsia onset or clinical management of preeclampsia during pregnancy. Current clinical management of preeclampsia advises maintenance of pregnancies until 34 or 37 weeks gestation, depending on the week of diagnosis and preeclampsia severity [24]. Expectant management of preeclampsia requires balancing maternal medical needs with intrapartum developmental requirements and reduction of infant comorbidities associated with preterm birth [34,35]. Planned preterm delivery of pregnancies complicated by preeclampsia improves maternal outcomes but increases the risk of neonatal admissions for prematurity [36]. Expectant management of moderate preeclampsia before 37 weeks gestation has been reported to extend pregnancies without increasing neonatal comorbidities; however, studies have reported the risk of stillbirth [37] and neonatal mortality [38] associated with expectant management for severe preeclampsia diagnosed before 34 weeks gestation. The results presented in our study demonstrate that early onset of preeclampsia is associated with a greater risk of ASD in offspring; however, clinical management for preeclampsia does not add additional risk, potentially eliminating one comorbidity of concern associated with preeclampsia exposure and expectant management.

Prenatal preeclampsia may affect child neurodevelopment by altering the maternal environment during fetal maturation. Preeclampsia has been observed to influence maternal immune activation [39], increasing circulation of maternal proinflammatory cytokines, and contributing to higher levels of oxidative stress, which have been associated with divergent neurodevelopment in children [40]. Studies have reported differences in the etiology of early and late-onset preeclampsia [41,42], as well as varying risks of adverse outcomes associated with the timing of exposure [43,44]. Early-onset preeclampsia may be driven by placental dysfunction [45], which occurs when a placental abnormality restricts blood flow, potentially due to suppression of estrogen-related receptor-gamma leading to vascular abnormalities [46]. Late-onset preeclampsia could be primarily a maternal hypertensive condition [45]. Placental inflammation and vascular dysfunction have been linked to an increased risk of ASD in children [47,48]. Therefore, differences in ASD risk by gestational week of onset may be explained by the influence of preeclampsia on specific stages of fetal neurodevelopment [19].

In our study, earlier onset of preeclampsia had larger HRs than onset in later pregnancy, which is consistent with results from a study of ASD risk and preeclampsia, which reported an increased risk of ASD in children exposed to preeclampsia earlier in pregnancy [19]. Adjustment for gestational age at delivery and birth weight attenuated the risk of ASD after early preeclampsia in our study, suggesting that there may be different mechanisms underlying the risk of ASD by the timing of preeclampsia exposure. Exposure to preeclampsia has been reported to be associated with an increased risk of ASD in offspring [49]. Preeclampsia is also associated with preterm birth, another risk factor for ASD [20]. Our results are consistent with previous results that prematurity and low birth weight are risk factors for ASD [6,20] and extend them to show that early preeclampsia is one of the root causes for prematurity, low birth weight, and associated ASD risk.

Our results concerning the increased risk of ASD associated with maternal preeclampsia during pregnancy are consistent with previous findings. However, the novel finding in our study is that the number of days between preeclampsia’s first occurrence and delivery was not associated with ASD risk in offspring after taking the gestational age of preeclampsia onset into account. Thus, the results of our study suggest that clinical expectant management of preeclampsia after diagnosis does not increase the risk of ASD in offspring. As this is the first study to report these results, future research is needed to determine whether this finding is consistent in other populations and to assess whether these associations vary by type of preeclampsia treatment or severity of illness. Our results provide evidence demonstrating the need to identify effective approaches to prevent the onset of preeclampsia, especially during early pregnancy, to mitigate risk not only to mothers but also to offspring.

**Strengths and Limitations**

A strength of this study is its large, clinical, and longitudinal birth cohort with characteristics reflecting census tract–level social and demographic information of Southern California. Comprehensive EMR data with detailed pregnancy history and dates allowed us to assess preeclampsia by gestational week of diagnosis and duration from diagnosis to delivery, and to adjust for relevant covariates. The continuity of care at KPSC minimizes the risk of ascertainment bias in exposures and outcomes. We think the assessment of expectant management of preeclampsia on ASD risk is novel.

This observational study has some limitations. The results presented here do not establish a causal link between preeclampsia exposure and ASD risk. The severity of preeclampsia was not explicitly considered due to the lack of a clear definition of severity in EMR. However, diagnosis to delivery periods allowed some inference about severity, as severe cases were likely to be delivered more quickly than moderate cases [24]. Genetic information was unavailable; therefore, we were unable to control for genetic contributions to ASD risk. There may be other perinatal risk factors or postnatal environmental exposures not adjusted for in these analyses.

**Conclusion**

In this population-based retrospective clinical birth cohort study, exposure to preeclampsia in utero was associated with an increased risk of ASD in offspring, with a greater risk for children of mothers with preeclampsia occurring earlier during pregnancy. However, among children of mothers with preeclampsia, the number of days between preeclampsia diagnosis and delivery was not associated with increased ASD risk. Our study suggests that clinical management of pregnancies with preeclampsia does not increase the risk of ASD in offspring. Future research into the prevention of preeclampsia is still needed.

Abstract

Background: The first 1000 days of life, encompassing pregnancy and the first 2 years after birth, represent a critical period for human health development. Despite this significance, there has been limited research into the associations between mixed exposure to air pollutants during this period and the development of asthma/wheezing in children. Furthermore, the finer sensitivity window of exposure during this crucial developmental phase remains unclear.

Objective: This study aims to assess the relationships between prenatal and postnatal exposures to various ambient air pollutants (particulate matter 2.5 [PM\textsubscript{2.5}], carbon monoxide [CO], sulfur dioxide [SO\textsubscript{2}], nitrogen dioxide [NO\textsubscript{2}], and ozone [O\textsubscript{3}]) and the incidence of childhood asthma/wheezing. In addition, we aimed to pinpoint the potential sensitivity window during which air pollution exerts its effects.

Methods: We conducted a prospective birth cohort study wherein pregnant women were recruited during early pregnancy and followed up along with their children. Information regarding maternal and child characteristics was collected through questionnaires during each round of investigation. Diagnosis of asthma/wheezing was obtained from children’s medical records. In addition, maternal and child exposures to air pollutants (PM\textsubscript{2.5}, CO, SO\textsubscript{2}, NO\textsubscript{2}, and O\textsubscript{3}) were evaluated using a spatiotemporal land use regression model. To estimate the mutual associations of exposure to mixed air pollutants with the risk of asthma/wheezing in children, we used the quantile g-computation model.

Results: In our study cohort of 3725 children, 392 (10.52\%) were diagnosed with asthma/wheezing. After the follow-up period, the mean age of the children was 3.2 (SD 0.8) years, and a total of 14,982 person-years were successfully followed up for all study participants. We found that each quartile increase in exposure to mixed air pollutants (PM\textsubscript{2.5}, CO, SO\textsubscript{2}, NO\textsubscript{2}, and O\textsubscript{3}) during the second trimester of pregnancy was associated with an adjusted hazard ratio (HR) of 1.24 (95\% CI 1.04-1.47). Notably, CO made the largest positive contribution (64.28\%) to the mutual effect. After categorizing the exposure according to the embryonic respiratory development stages, we observed that each additional quartile of mixed exposure to air pollutants during the pseudoglandular and canalicular stages was associated with HRs of 1.24 (95\% CI 1.03-1.51) and 1.23 (95\% CI 1.01-1.51), respectively. Moreover, for the first year and first 2 years after birth, each quartile increment of exposure to mixed air pollutants...
was associated with HRs of 1.65 (95% CI 1.30-2.10) and 2.53 (95% CI 2.16-2.97), respectively. Notably, SO2 made the largest positive contribution in both phases, accounting for 50.30% and 74.70% of the association, respectively.

**Conclusions:** Exposure to elevated levels of mixed air pollutants during the first 1000 days of life appears to elevate the risk of childhood asthma/wheezing. Specifically, the second trimester, especially during the pseudoglandular and canalicular stages, and the initial 2 years after birth emerge as crucial susceptibility windows.

### Introduction

Asthma is one of the major respiratory diseases. It is also the most common noncommunicable disease in children and imposes a huge economic and disease burden worldwide [1]. Asthma is estimated to affect around 14% of children worldwide, with its prevalence reported to be on the rise [2]. It is well-known that childhood asthma increases the burden on society in terms of disruption to children’s lives, reduced physical ability, increased caregiver strain, and various direct medical costs. Wheezing during early childhood is frequently regarded as the primary symptom linked to asthma later in life [3]. Research has shown that the intricate interplay of environmental exposures and genetic susceptibility can contribute to the onset of wheezing and asthma [4].

The first 1000 days of life, encompassing pregnancy and the initial 2 years after birth, represent a crucial period for human health development and interventions [5]. Lung and airway development commences between the 4th and 7th weeks of pregnancy, reaching the alveolar stage by 36 weeks. During pregnancy, fetal cells exhibit more rapid replication and differentiation compared with mature cells, making them highly responsive to external signals [6]. Consequently, they are particularly susceptible to external exposure events. Air pollution, for instance, can disrupt alveolarization, leading to compromised lung development and function postnatally [7,8].

The lungs undergo growth from conception through early adulthood, with the prenatal and early postnatal phases being particularly critical [9]. There is evidence suggesting that exposure to air pollution during early life can trigger the onset of asthma or wheezing and exacerbate preexisting conditions [5,10,11]. A review, which has consolidated the link between exposure to air pollutants throughout the first 1000 days of life and the onset of childhood asthma/wheezing, was associated with HRs of 1.65 (95% CI 1.30-2.10) and 2.53 (95% CI 2.16-2.97), respectively. Notably, SO2 made the largest positive contribution in both phases, accounting for 50.30% and 74.70% of the association, respectively.

**Conclusions:** Exposure to elevated levels of mixed air pollutants during the first 1000 days of life appears to elevate the risk of childhood asthma/wheezing. Specifically, the second trimester, especially during the pseudoglandular and canalicular stages, and the initial 2 years after birth emerge as crucial susceptibility windows.

### Methods

**Study Settings and Participants**
All participant data were sourced from the Prenatal Environments and Offspring Health (PEOH) cohort study.
conducted at Panyu Central Hospital in Guangzhou, China. Detailed descriptions of this cohort study have been provided in previous publications [15,17,18]. Further information regarding the population within the hospital’s catchment area, along with some basic demographic details concerning the broader populations of Guangzhou and China, can be found in Multimedia Appendix 1. Pregnant women were enrolled in the study at the antenatal care unit, adhering to the following inclusion criteria: (1) gestational age <13 weeks; (2) between 18 and 50 years of age; and (3) absence of significant medical conditions, including hyperthyroidism, hypertension, chronic kidney disease, tuberculosis, and mental illness. All eligible women underwent face-to-face interviews to collect baseline information, and they were subsequently followed up during hospital delivery. Furthermore, we administered follow-up surveys on the children during their hospital visits. Throughout the follow-up period, we excluded cases involving multiple pregnancies and study participants with missing key variables. Recruitment for our study commenced in January 2016 and continued until July 31, 2020, when the follow-up concluded.

**Baseline Investigation**

The baseline survey for the study was initiated in January 2016 and concluded in December 2017. A total of 4928 pregnant women were successfully recruited and their personal profiles were established. The collected information encompassed their demographic characteristics, lifestyle behaviors, changes in home address, living environment at home, work environment, activity patterns, medical history, diet during pregnancy, and antenatal care records.

**Follow-Up Investigation**

As illustrated in Figure 1, of the 4928 pregnant women enrolled in the baseline survey, 4279 were effectively followed up during their hospitalization for delivery. Throughout this period, maternal information was gathered via a follow-up questionnaire, while neonatal birth records were extracted from maternal medical records. Following the exclusion of cases involving multiple births (n=79) and those with missing key variables (n=10), a total of 4190 mother-child pairs were included in the follow-up. All children who attended child health clinics, pediatric outpatient clinics, or emergency departments were tracked for follow-up. Clinical symptoms, diagnostic disorders, and anthropometric data were extracted from their medical records, and questionnaires were administered to their parents or accompanying individuals. Throughout the follow-up process, a total of 465 infants were not successfully followed up. The final follow-up survey was concluded by July 31, 2020, with a total of 3725 children enrolled in the study (Figure 1).

**Figure 1.** Flow chart of the progress of the research topic.

Major Health Outcomes

The health outcomes in this study were delineated in accordance with the 10th edition of the International Classification of Diseases (ICD-10), encompassing asthma (J45) and wheezing (R06). Asthma was characterized by recurrent and variable clinical manifestations, such as wheezing, chest tightness, persistent cough, shortness of breath, and restricted expiratory airflow. Our health outcomes also incorporated wheezing because of the challenges in diagnosing early childhood asthma, which led to a relatively low number of children diagnosed with asthma (n=17). Conversely, early childhood wheezing is frequently regarded as the primary symptom linked to asthma in later life and holds significant prognostic value for the early detection of asthma. Consequently, we ultimately delineated the health outcome as the first admission to the hospital for wheezing.
asthma or wheezing, using the time of initial occurrence of asthma/wheezing as the onset time. For cases where asthma or wheezing did not manifest, the follow-up continued until July 31, 2020. Eventually, to enhance statistical power, we combined asthma and wheezing (n=392) as a unified outcome.

**Ethical Considerations**

The PEOH study received approval from the Ethics Committee of the Guangdong Center for Disease Control and Prevention under the reference number W96027E-2015001. Furthermore, it was registered in the Chinese Clinical Trial Registry with the registration number ChiCTR-ROC-17013496. This analysis was approved by the Ethics Committee of the Faculty of Medicine of Jinan University under the approval number JNUKY-2023-0075. During the establishment of the original cohort, comprehensive details about the study were provided to the recruited women, and informed consent was obtained from them through signed documents under conditions of autonomy. When accessing the data set for this research, it was entirely deidentified, and there was no feasible way to link the data to the women, either through a key in the coding system or otherwise. Stringent measures have been implemented to safeguard the personal information of the women.

**Exposure Assessment of Air Pollution**

In this study, we incorporated 5 major ambient air pollutants (PM$_{2.5}$, SO$_2$, NO$_2$, CO, and O$_3$). To evaluate each individual’s weekly exposure to these air pollutants, we used a spatiotemporal land use regression (ST-LUR) model, which has been extensively described in our team’s previous publications [18-20]. In particular, we collected spatiotemporal data from air quality monitoring stations located throughout Guangdong Province to establish the ST-LUR model. We used an inverse distance weighting method to extract the weekly visibility of each address. This method relied on the latitude and longitude information to calculate the proximity between each participant’s home and work addresses and the air quality monitoring stations. Population density, road length, and land use–type data were obtained for each air quality monitoring station address within a radius of 1300 m. Predictor variables for both residential and work addresses of each participant were incorporated into the model. Subsequently, we used these variables to predict the weekly average concentrations of air pollutants at each address throughout the pregnancy period. To evaluate mothers’ exposure to air pollutants during pregnancy, we forecasted weekly pollutant concentrations at their individual residences and workplaces. Subsequently, we multiplied these concentrations at the home address for children aged 0-2 years. To identify sensitive exposure time windows during childhood, considering the considerable changes in children’s activity patterns as they grow, we calculated air pollutant concentrations for 2 distinct periods: from birth to 12 months (the first year of life) and from birth to 24 months (the first 2 years of life) [25].

**Covariates**

Upon reviewing the literature, the following variables were identified as covariates: ambient temperature, maternal age, parity, gravidity, maternal occupation, annual per capita income, passive smoking, history of asthma, preterm birth, gestational diabetes, season of conception, and maternal diet (Multimedia Appendix 2). We used variance inflation factors (VIFs) to detect collinearity among covariates both between individual pollutants and among covariates themselves. A maximum VIF exceeding 10 often suggests that multiple correlations significantly influence least squares estimates. The findings revealed that when all covariates, including temperature, were incorporated, the VIF for PM$_{2.5}$ exceeded 10 in all 3 trimesters, as well as during the saccular and alveolar stages. However, when temperature was excluded from the covariates, all VIFs for PM$_{2.5}$ were below 10 except for the third trimester (Multimedia Appendices 3-5).

**Statistical Analysis**

We conducted a comparison of characteristics between the case and control groups using a chi-square test. Pearson correlation was applied to examine correlations between air pollutants and temperature (Multimedia Appendix 4). The mutual effects of air pollution mixtures on asthma/wheezing in children were analyzed using the quantile g-computation (QG-comp) model. QG-comp is used for the impact analysis of exposure mixtures, where it evaluates the exposure as a whole rather than as individual components in its calculations. The QG-comp model combines the simplicity of weighted quantile sum regression inference with the flexibility of the g-calculation method for causal effect estimation. Unlike traditional methods, QG-comp does not necessitate that the direction of the effect is consistent between the exposure variable and the outcome. Moreover, it can capture the effects of all pollutant exposures, 1 quartile increase at a time [26]. The model used the Cox proportional hazards model as the base model and established quartiles of...
simultaneous increases in all air pollutant concentrations. Hazard ratios (HRs) along with 95% CIs were reported. In addition, the positive or negative weight of each pollutant was documented in each QG-comp model.

In the sensitivity analyses, we narrowed our focus to children with clear information on the feeding method. Furthermore, we adjusted for children’s feeding methods in both prenatal and postnatal QG-comp models for this subgroup to mitigate the potential confounding effect of the feeding method on childhood asthma/wheezing. To assess whether the COVID-19 outbreak in early 2020 and subsequent public health interventions targeting COVID-19 might introduce confounding factors, we conducted sensitivity analyses by limiting the data to the period before the COVID-19 outbreak. In addition, in our sensitivity analyses, we adjusted for air pollutants in the preceding periods in the model for that specific period. This adjustment was made to account for the cumulative effects of early developmental exposure.

All analyses were performed using R 4.2.2 (R Development Core Team 2019 [27]). All statistical tests were conducted using a 2-sided approach.

Results

Characteristics of Study Participants

Of the 3725 children included in this study, 392 (10.52%) were diagnosed with asthma/wheezing, with a mean age of onset of 1.48 (SD 0.89) years. At the conclusion of the follow-up period, the mean age of the children was 3.2 (SD 0.8) years, and a total of 14,982 person-years were successfully followed up for all study participants. These included 1984 (53.26%) boys and 1741 (46.74%) girls, with a prevalence of asthma/wheezing of 13.16% (261/1984) in boys compared with 7.52% (131/1741) in girls. The majority of mothers were engaged in commercial activities (2008/3725, 53.91%). Demographic information, the number of asthma cases, and prevalence rates stratified by covariates are presented in Table 1.

## Associations Between Maternal Ambient Pollutant Exposure and Childhood Wheezing Risk

Table 2 displays the risk of asthma/wheezing in children exposed to mixed air pollutants during pregnancy. In the adjustment model, each quartile increase in exposure to mixed air pollutants during the second trimester was linked to an adjusted HR of 1.24 (95% CI 1.04-1.47), with CO contributing the most positively (64.28%) to the joint effect (Figure 2). Following staging by lung development, each additional quartile of exposure to mixed air pollutants during the pseudoglandular and canalicular stages was associated with HRs of 1.24 (95% CI 1.03-1.51) and 1.23 (95% CI 1.01-1.51), respectively. During the pseudoglandular stage, PM$_{2.5}$ (50.98%) and CO (48.92%) made the greatest positive contributions, while CO made the largest positive contribution during the canalicular stage (65.50%; Figure 2).

**Associations Between Child Ambient Pollutants Exposure and Childhood Wheezing Risk**

The adjusted HRs for childhood asthma and wheezing were 1.24 (95% CI 1.30-2.10) and 1.23 (95% CI 2.16-2.97), respectively, for each quartile increase in air pollutants during the first year and first 2 years of childhood. Notably, SO\textsubscript{2} made the largest positive contribution in both periods, accounting for 50.30% and 74.70%, respectively. Another significant contributor is NO\textsubscript{2}, accounting for 36.8% and 25.3% in the first year and first 2 years of childhood, respectively (Figures 2 and 3).

Sensitivity Analyses
We conducted sensitivity analyses in a subgroup of children with clear information on the feeding method and restricted the data to the period before the COVID-19 outbreak. Adjusting for the feeding method and the COVID-19 outbreak did not substantially alter the associations of prenatal and postnatal exposure to a mixture of air pollutants with the risk of childhood wheezing (Table 3). Similarly, the relationship between air pollutants and childhood asthma/wheezing did not change significantly after adjusting for air pollutants in the preceding periods in the model for that specific period (Table 4).

Several epidemiological studies have also reported associations between exposure to mixed air pollutants and the incidence of asthma/wheezing in children. The study was conducted in 3 northern Chinese cities (Urumqi, Beijing, and Taiyuan) and 4 southern cities (Nanjing, Shanghai, Chongqing, and Changsha). However, the 3 northern cities typically experience lower temperatures compared with Guangzhou. Nevertheless, both studies reached similar conclusions to our study, despite significant differences in terms of the number of years studied, air temperature, and air pollutant concentrations between the 2 studies and this study.

HR: hazard ratio.

We adjusted the pollutants for the period preceding each period based on model 1. For example, air pollutants from the first trimester were included as covariates in the model for the second trimester, and air pollutants from both the first and second trimesters were included as covariates in the model for the third trimester. Air pollutants from the embryonic stage were added to the covariates in the model for the pseudoglandular stage, while contaminants from both the embryonic and pseudoglandular stages were added to the covariates in the model for the canalicular stage to adjust the model. Contaminants from the previous 3 periods were added to the covariates in the saccular stage model to adjust the model, and contaminants from the previous 4 periods were added to the covariates in the model for the alveolar stage to adjust the model. Contaminants for the period preceding each period were added to the covariates in the model for adjustment. The adjusted covariates do not include temperature.

dN/A: not applicable.

eAdjusted for temperature, maternal age, gravidity, parity, maternal occupation, yearly income per capita, passive smoking, maternal diet, history of asthma, gestational diabetes mellitus, premature, and season of conception.

Discussion

Principal Findings

In this prospective cohort study, we assessed the effects of exposure to 5 mixed air pollutants, including PM$_{2.5}$, SO$_2$, NO$_2$, CO, and O$_3$, during the first 1000 days of life on the incidence of asthma/wheezing in children. We observed positive associations between exposure to mixed air pollutants and the incidence of asthma/wheezing. Furthermore, exposure to mixed air pollutants during the second trimester, particularly during the pseudoglandular and canalicular stages, as well as in the first 2 years of life, may have a greater impact on the risk of childhood asthma/wheezing. These findings suggest potential critical exposure windows for air pollution. They extend our understanding of the adverse effects of air pollution exposure during early life on children’s respiratory health and provide suggestive information for implementing protective measures to mitigate the adverse effects of air pollution on children’s health.

Several epidemiological studies have also reported associations between maternal exposure to single or multiple air pollutants during pregnancy and the risk of childhood asthma, which aligns with our findings. For instance, a Canadian birth cohort study investigated the impact of perinatal air pollution exposure on asthma exacerbation in children, revealing that early-life exposure to higher concentrations of CO, NO$_2$, PM$_{10}$, and SO$_2$ elevates the risk of asthma in preschool children [28]. However, the aforementioned study took place earlier than this study and involved a city with lower temperatures and air pollutant concentrations compared with Guangzhou. Another cohort study from China demonstrated that each interquartile range increment of maternal exposure to NO$_2$ during pregnancy was positively associated with childhood asthma [29]. The study was conducted in 3 northern Chinese cities (Urumqi, Beijing, and Taiyuan) and 4 southern cities (Nanjing, Shanghai, Chongqing, and Changsha). However, the 3 northern cities typically experience lower temperatures compared with Guangzhou. Nevertheless, both studies reached similar conclusions to our study, despite significant differences in terms of the number of years studied, air temperature, and air pollutant concentrations between the 2 studies and this study.

Subgroup analyses indicated that the second trimester, specifically the pseudoglandular stage and the canalicular stage, may represent critical exposure windows for mixed air pollution–induced asthma in children. This finding is consistent with previous studies [21,30,31]. The Asthma Coalition for...
Community, Environmental, and Social Stress (ACCESS) project in the United States discovered that maternal exposure to higher PM\textsubscript{2.5} concentrations can elevate the risk of asthma attacks in offspring at 6 years of age, with the gestational period between 16 and 25 weeks potentially holding particular significance [21]. Another cohort study from Canada similarly demonstrated a significant association between maternal midgestational exposure to PM\textsubscript{2.5} and NO\textsubscript{2} and the incidence of asthma in children [30].

During the pseudoglandular stage, which occurs during GWs 6-16, all potentially conducting airways are formed, and the emergence of alveolar contours occurs. This stage is characterized by the significant development of fine bronchial structures. By GW 17, the major components of the lung are mostly formed, with the exception of the gas exchange component. During the canalicular stage, which spans GWs 16-24, early development of the lung parenchyma occurs. This stage is characterized by the expansion of the lumen of the bronchi and terminal fine bronchioles, as well as the initiation of thin-walled terminal vesicle formation at the ends of the respiratory fine bronchioles [22,32]. By the end of the canalicular stage, all conducting airways have emerged, allowing respiration and gas exchange to commence [33]. This indicates that during the pseudoglandular and canalicular stages, the developing lungs may be more susceptible to inhaled air pollutants, potentially leading to the development of asthma in childhood.

We also observed that exposure to mixed air pollutants during the first 2 years of life significantly elevated the risk of asthma/wheezing, suggesting that this period may represent another important window. This finding aligns with previous studies, such as the one [10] that investigated the association between air pollution and asthma development in all children born between 1999 and 2000 in southwestern British Columbia, Canada. The study assessed air pollution exposure in quartiles and discovered that children exhibited an increased odds ratio for asthma when exposed to higher quartiles of CO, NO, NO\textsubscript{2}, PM\textsubscript{10}, and SO\textsubscript{2} in the first year of life [10]. Furthermore, a prospective cohort study from Copenhagen identified air pollution as being associated with wheezing symptoms in children. They found a significant effect of NO\textsubscript{2} on asthma symptoms in infants 3 years after birth and also noted a significant correlation between PM\textsubscript{10}, CO concentrations, and wheezing symptoms in infants (0-1-year olds) [34]. A study conducted in Changsha, China, similarly demonstrated that postnatal exposure to outdoor industrial and traffic air pollutants, including PM\textsubscript{10}, SO\textsubscript{2}, and NO\textsubscript{2}, was significantly associated with an increased risk of asthma in children [35].

Studies have indicated that infants are particularly vulnerable to the effects of air pollutants due to their incomplete development of respiratory and immune systems [36]. Furthermore, alveolarization primarily occurs after birth, with approximately 85% of alveoli developing postnatally. Lung volume doubles by 6 months of age and triples by 1 year of age [37]. Collectively, these findings suggest that children’s respiratory systems continue to rapidly develop after birth, potentially rendering their lungs more sensitive to inhaled air pollutants.

In addition, our weighted analyses revealed that air pollutants at various stages may exert distinct impacts on the development of asthma in children. During the second trimester and the canalicular period, CO emerged as the largest contributor to the development of asthma/wheezing in children. Equally significant contributors during the pseudoglandular stage were CO and PM\textsubscript{2.5}. In childhood, the air pollutants contributing the most were SO\textsubscript{2} and NO\textsubscript{2}.

Many previous studies investigating the relationship between air pollutants and respiratory diseases have placed particular emphasis on PM\textsubscript{2.5} [38,39]. These studies suggest that the pathogenic mechanism of PM\textsubscript{2.5} is primarily associated with oxidative stress. This stress can either cross the placental barrier and directly affect the fetus or induce systemic inflammation in the mother, leading to a reduction in the supply of nutrients and oxygen to the fetus, thereby affecting fetal lung function [16]. However, our study proposes that CO may be a more significant contributor to air pollutants affecting lung development in pregnant children than PM\textsubscript{2.5}.

CO is a highly soluble, nonirritant gas that easily enters the bloodstream through the alveoli, capillaries, and placental barrier. Once in the bloodstream, it competes with oxygen and binds to hemoglobin, resulting in tissue hypoxia [40]. Hypoxia in maternal tissues can decrease the amount of gases carried by the fetus, potentially affecting the development of fetal lung function and possibly leading to the development of childhood asthma. However, there has been relatively less focus on its association with the development of asthma in children in developing countries, and the results of the few studies conducted have been inconsistent [41]. Therefore, it is recommended that future research on the relationship between CO and childhood asthma should be intensified to further clarify the association and the pathogenesis of the disease.

SO\textsubscript{2} is primarily released into the atmosphere through the combustion of fossil fuels and is highly soluble in water. Its effects are primarily harmful to the upper respiratory tract. SO\textsubscript{2} can cause severe airway constriction, which may be related to its pathogenic mechanism [41]. Andersson et al [42] reported an HR of 5.8 (95% CI 2.6-13) for asthma among individuals reporting inhalation of SO\textsubscript{2} gas compared with unexposed individuals following a survey of sulfite mill workers. In addition, several studies have demonstrated a connection between SO\textsubscript{2} and the development of asthma in children [43,44]. NO\textsubscript{2} is among the main components of TRAP. Similarly, the association between NO\textsubscript{2} and asthma has been affirmed by several studies [33,45,46]. Health Canada has also proposed a causal relationship between exposure to current levels of ambient NO\textsubscript{2} and increased asthma-related morbidity [47]. NO\textsubscript{2} is insoluble in water; it dissolves in the most distal airways and directly affect the fetus or induce systemic inflammation. This stress can either cross the placental barrier and directly affect the fetus or induce systemic inflammation in the mother, leading to a reduction in the supply of nutrients and oxygen to the fetus, thereby affecting fetal lung function [16]. However, our study proposes that CO may be a more significant contributor to air pollutants affecting lung development in pregnant children than PM\textsubscript{2.5}.

The association and the pathogenesis of the disease.
Limitations

There are several limitations that need to be acknowledged. First, due to the challenges associated with early diagnosis of asthma, there may be cases that do not present to the hospital after the onset of the disease, leading to missed diagnoses. In addition, some of the wheezing cases observed may not have been asthma, potentially resulting in misclassification of outcome measures. By contrast, the small number of diagnosed cases of asthma led us to combine asthma and wheezing into a single outcome. This approach prevented us from accurately estimating the effects of outdoor air pollution exposure on asthma incidence. Third, our study participants were sourced from only 1 hospital, and the administrative area covered by the hospital’s services (Panyu District, Guangzhou) differs somewhat from the demographic composition of the entire city of Guangzhou and of China (Multimedia Appendix 1). This aspect also imposes limitations on the generalizability of our results. Finally, we conducted a passive survey of children during their visits to a pediatric clinic, pediatric outpatient department, or emergency department. Children who did not attend the hospital were lost to follow-up, potentially leading to an underestimation of the effect of air pollutants.

Conclusion

This prospective cohort study offers new evidence suggesting a potential association between exposure to ambient mixed air pollutants during the first 1000 days of life and childhood asthma/wheezing. The second trimester, particularly the pseudoglandular stage and the canalicular stage, as well as the first 2 years after birth, may represent critical susceptibility periods for this exposure window. Our study is a cohort study, and therefore, firm causal inferences cannot be made. However, by incorporating findings from previous studies, our research contributes to a broader understanding of the adverse respiratory effects of outdoor air pollution exposure. This knowledge can empower clinicians and pregnant women to take proactive measures to reduce air pollution exposure, particularly during vulnerable windows of susceptibility. Such preventive measures are crucial for the prevention of childhood asthma.

Abstract

Background: There have been over 772 million confirmed cases of COVID-19 worldwide. A significant portion of these infections will lead to long COVID (post–COVID-19 condition) and its attendant morbidities and costs. Numerous life-altering complications have already been associated with the development of long COVID, including chronic fatigue, brain fog, and dangerous heart rhythms.

Objective: We aim to derive an actionable long COVID case definition consisting of significantly increased signs, symptoms, and diagnoses to support pandemic-related clinical, public health, research, and policy initiatives.

Methods: This research employs a case-crossover population-based study using International Classification of Diseases, 10th Revision, Clinical Modification (ICD-10-CM) data generated at Veterans Affairs medical centers nationwide between January 1, 2020, and August 18, 2022. In total, 367,148 individuals with ICD-10-CM data both before and after a positive COVID-19 test were selected for analysis. We compared ICD-10-CM codes assigned 1 to 7 months following each patient’s positive test with those assigned up to 6 months prior. Further, 350,315 patients had novel codes assigned during this window of time. We defined signs, symptoms, and diagnoses as being associated with long COVID if they had a novel case frequency of ≥1:1000, and they significantly increased in our entire cohort after a positive test. We present odds ratios with CIs for long COVID signs, symptoms, and diagnoses, organized by ICD-10-CM functional groups and medical specialty. We used our definition to assess long COVID risk based on a patient’s demographics, Elixhauser score, vaccination status, and COVID-19 disease severity.

Results: We developed a long COVID definition consisting of 323 ICD-10-CM diagnosis codes grouped into 143 ICD-10-CM functional groups that were significantly increased in our 367,148 patient post–COVID-19 population. We defined 17 medical-specialty long COVID subtypes such as cardiology long COVID. Patients who were COVID-19–positive developed signs, symptoms, or diagnoses included in our long COVID definition at a proportion of at least 59.7% (268,320/449,450, based on a denominator of all patients who were COVID-19–positive). The long COVID cohort was 8 years older with more comorbidities (2-year Elixhauser score 7.97 in the patients with long COVID vs 4.21 in the patients with non–long COVID). Patients who had a more severe bout of COVID-19, as judged by their minimum oxygen saturation level, were also more likely to develop long COVID.

Conclusions: An actionable, data-driven definition of long COVID can help clinicians screen for and diagnose long COVID, allowing identified patients to be admitted into appropriate monitoring and treatment programs. This long COVID definition can also support public health, research, and policy initiatives. Patients with COVID-19 who are older or have low oxygen saturation levels during their bout of COVID-19, or those who have multiple comorbidities should be preferentially watched for the development of long COVID.

KEYWORDS
long COVID; PASC; postacute sequelae of COVID-19; public health; policy initiatives; pandemic; diagnosis; COVID-19 treatment; long COVID cause; health care support; public safety; COVID-19; Veterans Affairs; United States; COVID-19 testing; clinician; mobile phone

Introduction
Numerous symptoms are cited as long-term sequelae of COVID-19. “The symptoms may affect a number of organ systems, occur in diverse patterns, and frequently get worse after physical or mental activity” [1]. Early studies found that the most common long-term symptoms were fatigue, dyspnea, joint pain, and chest pain [2]. Others reported gastrointestinal tract disorders correlated with gut microbiome shifts after COVID-19 infection [3,4]. Cognitive dysfunction, often referred to as brain fog, is another commonly reported long-term symptom [5]. Cognitive dysfunction is particularly concerning given evidence that COVID-19 can alter brain structure [6]. The most common self-reported symptoms documented via a smartphone app were fatigue, headache, dyspnea, and anosmia [7,8].

More recent studies have added to the knowledge base concerning symptoms of long COVID (post–COVID-19 condition). For example, a study observing cohorts in 4 Chinese cities showed that fatigue, cough, sore throat, difficulty in concentrating, feeling of anxiety, myalgia, and arthralgia were common severe long COVID symptoms. While there is considerable overlap, there is still value in new studies as they help validate previous studies and add new insights, such as identifying a previously underappreciated increase in anxiety among those who had COVID-19 [9].

Recent reviews have analyzed and integrated long COVID research to date [10]. Reviews like these contribute knowledge (eg, that over 200 symptoms have been identified, affecting multiple organ systems while proposing potential mechanisms). They also point out where our knowledge base is lacking. For example, Davis et al [10] observed a study stating that postural tachycardia syndrome can be a potential complication [11] but research has recently shown that long COVID can also greatly increase the likelihood of complications such as atrial fibrillation [12]. Such contributions are why continued research is critically important to combat the detrimental effects of long COVID.

Concerningly high long COVID frequencies have been reported since near the start of the pandemic. A cohort study from the Netherlands found that approximately 1 in 8 patients with COVID-19 developed long-term somatic symptoms [13]. Another study showed that approximately 30% of their cohort reported persistent symptoms, with many experiencing worse health-related quality of life compared with baseline and negative impacts on at least one activity of daily living [14]. More recent studies confirm these alarming statistics, indicating that 1 in 7 adults in the United States have reported symptoms of long COVID [15]. Furthermore, long COVID’s impacts extend beyond individual morbidity to include the health care system and economic consequences. Cutler [16] noted long COVID resulted in reduced workforce participation (eg, 44% out of the workforce), direct earning losses, and worker shortages in service jobs. This is likely directly related to the fatigue associated with long COVID, which has now been linked to muscular abnormalities and overall dysfunction of mitochondria within these tissues [17].

The widespread occurrence of lingering ailments and their impacts on individuals and society make clear the need for a long COVID definition. US public health officials note that we must balance our need for an accurate long COVID definition that includes all afflicted individuals against our need for interim long COVID definitions to expedite immediate action and mobilization [18]. In particular, a working definition of long COVID based on routinely collected coded data could support the identification of at-risk or undiagnosed patients for monitoring, referral, or therapeutic interventions. In this study, we empirically derive an actionable broad-based long COVID definition to support current clinical, public health, research, and policy initiatives related to the pandemic.

Methods
Overview
We selected veterans who had laboratory-confirmed positive COVID-19 tests. We examined the veterans’ electronic health records for novel International Classification of Diseases, 10th Revision, Clinical Modification (ICD-10-CM) codes between 1 and 7 months after a positive COVID-19 test. We grouped codes with a novel frequency of 1/1000 or greater by diagnosis type creating ICD-10-CM functional groups and performed χ² testing with Bonferroni correction to compare diagnosis frequencies before and after a positive COVID-19 test. We defined ICD-10-CM functional groups that significantly increased in frequency as “upregulated” (see Figure 1). We then manually aggregated upregulated ICD-10-CM functional groups into medical specialties to organize our empiric definition of long COVID.
Population Definition and Data Extraction

We selected patients with laboratory-confirmed positive COVID-19 studies and followed them for 13 months (6 months before the COVID-19 test result and 7 months after COVID-19) to create a long COVID definition. We used the electronic health records of all the patients who tested positive for COVID-19 at Veterans Affairs (VA) medical facilities nationally between January 1, 2020, and August 18, 2022. In total, 2,377,720 patients were tested for COVID-19 during this time period.

We applied SQL queries to VA Informatics and Computing Infrastructure, Corporate Data Warehouse data tables [19] to generate 2 diagnosis files for analysis. The first file (“before”) contains a row of retrospectively collected information for each patient and each ICD-10-CM diagnosis assigned to them in the 6-month control window before their COVID-19 test. The row includes the ICD-10-CM code and its description, a unique patient identifier, the COVID-19 test date, and the calculated number of months between ICD-10-CM code entry and COVID-19 testing. This “before” file contained 14,980,288 observations across 426,970 patients.

We followed the patients for 7 months. The second file (“after”) was created 7 months after the last patient was included. The after file contained ICD-10-CM codes assigned during the 7 months following COVID-19 testing and similar related information as the “before” file. This “after” file contained 15,493,587 observations across 389,677 patients.

We limited the analysis to the 367,148 patients that appeared in both the “before” and “after” files to ensure that we had a diagnostic history for each patient and eliminated acute findings by removing all ICD-10-CM codes documented less than a month after the positive COVID-19 test (Figure 1). We used the date of the first positive COVID-19 test for patients with multiple positive tests. Multiple repeating ICD-10-CM codes for a single patient were counted once. We wrote R (R Development Core Team) and Python (Python Software Foundation) programs to remove all data concerning patients who tested negative for COVID-19, ICD-10-CM codes that were documented less than a month after the positive COVID-19 test, and patients who were not present in both the “before” and “after” files. The methodology used to generate the patient cohort is depicted in Figure 2.

We collected additional data to examine the association of demographics, comorbidities, vaccination status, and COVID-19 case severity with the incidence of long COVID. Demographic data collected included age, sex, race, and ethnicity. Comorbidities were evaluated using 2-year Elixhauser Comorbidity Indices Scores. Patients who were vaccinated were defined as having at least one COVID-19 vaccine dose recorded for at least two weeks and no more than 9 months before their positive COVID-19 test. We defined 2 classes of severe COVID-19 based on the minimum recorded oxygen saturation. The first class, severe COVID-19, was defined by a minimum oxygen saturation of <94% [20]. The second class, severe COVID-19 with severe desaturation, was defined by a minimum oxygen saturation of <88% [21].
Figure 2. Patient selection flowchart for this study. The first step excludes all patients that test negative for COVID-19. The second step excludes all patients that are not in both the “before” and “after” files, indicating either a lack of diagnosis history or a lack of follow-up, respectively. The final step excludes any patient that does not have a novel diagnosis 1 to 7 months after their positive test. A diagnosis is novel if it was not observed in the “before” file but was observed during this time. The “before” file consists of data concerning every ICD-10-CM code assigned to each patient who was COVID-19 positive in our cohort for up to 6-months before their test. The “after” file consists of data concerning every ICD-10-CM code assigned to each COVID-19 positive patient in our cohort for up to 7-months after their test. ICD-10-CM: International Classification of Diseases, 10th Revision, Clinical Modification.

Ethical Considerations
An institutional review board protocol was developed and approved for this research by the Department of Veterans Affairs (number 1580090). It uses electronic health care records data for patients of VA hospitals across the country. These data are protected health care data and are only used outside of the VA system in a summarized, deidentified format. The original informed consent from patients allows these analyses without additional consent. No additional compensation was given. A HIPAA (Health Insurance Portability and Accountability Act) waiver was approved (00004461).

Data Analysis
We chose 6 months “before” and “after” COVID-19 test control and case windows to allow patients to serve as their own controls. The 6 month “after” case window began 1 month after the positive COVID-19 test. We defined “novel” ICD-10-CM codes as those that appeared in a patient’s “after” file but not in the “before” file. We calculated the frequency of each novel ICD-10-CM code as the percentage of this study’s cohort assigned with the code. We excluded novel codes with a frequency of <1:1000 from further analysis. We defined codes as upregulated when the frequency of that code in the after file was significantly increased as compared to the frequency in the before file, if it had a $\chi^2$ with a Bonferroni corrected $P<.00006$. We limited the long COVID ICD-10-CM code functional groups to those that were significantly increased in frequency. We used “before” and “after” frequencies to calculate odds ratios and CIs for each novel ICD-10-CM functional group. We calculated odds ratios from frequency data.

ICD-10-CM Functional and Medical Specialty Groupings
We grouped ICD-10-CM codes in 3 steps. We first combined ICD-10-CM codes that had the same initial 3 characters. We then grouped ICD-10-CM codes with different initial characters if the diagnoses were functionally similar to create our ICD-10-CM functional groups. For example, we grouped I47.1 (supraventricular tachycardia), I47.2 (ventricular tachycardia), and R00.0 (tachycardia, unspecified) as tachycardia. Finally,
we manually curated each of these *ICD-10-CM* functional groups into medical specialties for organizational purposes.

**Long COVID Definition**

We included in our long COVID definition each *ICD-10-CM* code with an incidence over 6 months ($T_0 + 1M - T_0 + 7M$) >1:1000 (M: months; $T_0$: date of positive COVID-19 test) and a significant overall frequency increase. Patients with long COVID were defined as having any of the 323 upregulated *ICD-10-CM* codes between 2 and 7 months after their positive COVID-19 diagnosis, but not in their pre–COVID-19 diagnoses.

**Risk Factors for Long COVID**

The multivariate regression models were done for each risk factor one including age, gender, race, ethnicity, and 2-year Elixhauser score; a second with age, gender, race, ethnicity, 2-year Elixhauser score, and $O_2$ saturation <94%; and a third with age, gender, race, ethnicity, 2-year Elixhauser score, and COVID-19 vaccination status. We present the univariate rates as well as the results of the regression analysis using R (version 4.1.2) and RStudio.

**Results**

**Long COVID Definition**

We extracted *ICD-10-CM* diagnosis codes assigned to 367,148 patients who underwent a positive COVID-19 test at VA. A total of 268,320 patients had one or more novel COVID-19–related diagnoses. The remaining 98,828 patients had no novel long COVID *ICD-10-CM* diagnoses in their post–COVID-19 period when compared to their pre–COVID-19 period. Table 1 contains the demographic characteristics of this study’s cohort. Men were significantly older than women on average, 60.29 years (95% CI 60.24-60.35) versus 47.85 years (95% CI 47.73-47.97), respectively.

We developed a definition of long COVID consisting of 323 *ICD-10-CM* diagnosis codes grouped into 143 *ICD-10-CM* functional groups that were significantly increased in our 367,148 patient post–COVID-19 population. We define 17 medical specialty long COVID subtypes including cardiology long COVID, neurology long COVID, and pulmonary long COVID. Multimedia Appendix 1 shows the *ICD-10-CM* functional groups and medical specialties. Within each field, the *ICD-10-CM* code groups are sorted in descending order by their odds ratios. Combined odds ratios were calculated for each medical specialty category in Table S2 in Multimedia Appendix 2. Additional information about specific codes can be found in Table S3 in Multimedia Appendix 3.

Figures 3-6 show the signs, symptoms, and diagnoses with significantly increased relative risks in the post–COVID-19 period with their respective 95% CIs sorted by medical specialty. The data used to create these figures can be found in Table S4 in Multimedia Appendix 4.

Case counts were greatest for the specialties of cardiology (196,632), neurology (159,358), ophthalmology (149,817), and pulmonary (138,470). The lowest case counts were for oncology (7256), rheumatology (10,543), and dermatology (13,233; see Table 2 for more details).

Patients who were COVID-19 positive were assigned novel signs, symptoms, or diagnoses included in our definition of long COVID at a rate of between 59.7% (268,320/449,450, the percentage is based on patients who were COVID-19 positive and tested at the VA) and 76.6% (268,320/350,315, the percentage is based on all patients who were COVID-19 positive with a diagnostic history and follow-up diagnoses 1 to 7 months after test).

Most patients with long COVID were documented with at least one *ICD-10-CM* code found in our long COVID definition within 3 months of their positive COVID-19 test (168,194/268,320, 62.7%). The percentage of patients documented with their first long COVID *ICD-10-CM* code decreased with each subsequent month.

Risk Factors for Long COVID

We presented in Table 1 a comparison of demographic characteristics and Elixhauser comorbidity scores of patients with long COVID and patients with non–long COVID. The long COVID cohort was older with more comorbidities. The long COVID cohort also had higher percentages of White and Black individuals and non-Hispanic and non-Latino ethnicities. The patients with a 2-year Elixhauser score of greater than 21 had a much higher proportion to develop long COVID ($P<.001$, Pearson $\chi^2$; see Table 3).

Our data did not indicate that vaccination was protective against the development of long COVID. However, vaccination resulted in significantly lower rates of novel acute respiratory distress syndrome in the post–COVID-19 period (13.2%, 95% CI

10.4%-16.9%) as compared with the unvaccinated population (19.6%, 95% CI 18.1%-21.2%; \(P<.001\)). Patients with minimum \(O_2\) saturations constituting severe COVID-19 and severe COVID-19 with severe desaturation were significantly more likely to develop long COVID (both had \(P<.001\), Pearson \(\chi^2\); see Table 4).

The multivariate regression models all confirmed that patients with COVID-19 during the Omicron variant predominant period were at a slightly higher risk of developing long COVID at \(P<.001\).

### Discussion

#### Conclusions

Numerous reports document specialty-specific signs, symptoms, and diagnoses correlated with long COVID. We present a novel analysis based on a large national data set and the full multispecialty breadth of ICD-10-CM diagnosis codes to create a holistic long COVID definition that confirms and extends previous reports.

We allowed patients to be their own controls and used the entire cohort before and after COVID-19 infection to determine the relative risk of signs, symptoms, and disorders. This ensured that the signal was both novel and upregulated. We found patients who were COVID-19 positive developed signs, symptoms, or diagnoses included in our long COVID definition at a proportion of between 59.7% (268,320/449,450, the percentage is based on a denominator of all patients who were COVID-19 positive and tested at the VA) and 76.6% (268,320/350,315, the percentage is based on a denominator of all patients who were COVID-19 positive with a diagnostic history and follow-up diagnoses 1 to 7 months after test). More than three-fourths of patients with long COVID met our long COVID definition within 4 months of their positive COVID-19 test.

We found long COVID frequency differences based on race and ethnicity. These differences may be related to socioeconomic status, which is directly correlated with the presence of comorbidities [22-24]. The long COVID cohort was 8 years older with more comorbidities (2-year Elixhauser score 7.97 in the patients with long COVID vs 4.21 in the patients with non–long COVID). In our cohort, the men were significantly older than the women on average, 60.29 years (95% CI 60.24-60.35) versus 47.85 years (95% CI 47.73-47.97), respectively. We found that long COVID frequency was increased in patients who were more severely ill before infection and patients who had a more severe bout of COVID-19 as judged by their minimum oxygen saturation.

We found 143 upregulated diagnostic groups, with odds ratios as high as 23. We also found 17 upregulated medical specialty groupings containing between 3 and 21 signs, symptoms, or diagnoses. This provides strong evidence for a broad definition of long COVID.

Carfi et al [2] found that the most common long-term symptoms were fatigue, dyspnea, joint pain, and chest pain. Each except joint pain is represented in our long COVID definition. However, joint pain may be related to findings in our definition such as difficulty walking and an overall decrease in mobility. COVID-19 is known to cause lung abnormalities, especially in

https://publichealth.jmir.org/2024/1/e49841
cases with pneumonia [25]. We found that the likelihood of developing pneumonia after COVID-19 infection is significantly upregulated, potentially interconnected with the numerous findings in our pulmonary long COVID definition. Autopsy evaluation of COVID-19 victims’ lung tissue demonstrated diffuse alveolar damage with perivascular T-cell infiltration and severe endothelial injury [26]. Patients with long COVID have been found to have abnormal 133Xe magnetic resonance imaging gas exchange and computed tomography vascular density measurements, which we postulate could be related to the pulmonary fibrosis (J84.10) or emphysema (J43.9) diagnoses identified in our definition [27].

Our definition shows that the long-term effects of COVID-19 are associated with damage to numerous body systems including the kidneys, heart, eyes, and nervous system. Our results are corroborated by other studies. Cognitive dysfunction (brain fog) is often associated with long COVID and can be difficult to diagnose and treat [5]. COVID-19 infection is far more likely to cause cardiac complications than vaccination [28]. The gastrointestinal codes we observed reflect previous literature [29] and may relate to reported alterations to the gastrointestinal tract after COVID-19 [3,4]. Finally, previous studies have noted that COVID-19 can alter ocular physiology, supporting our ophthalmology-related findings [30].

Patients with more severe cases of COVID-19, as manifested by low oxygen saturations, should be watched carefully for the development of long COVID as they are significantly more likely to develop long COVID. Sicker patients with higher 2-year Elixhauser scores were significantly more likely to develop long COVID. Patients with multiple comorbidities should be made aware of this risk and participate in active surveillance for the development of signs and symptoms of long COVID.

The American Medical Association notes there are 3 categories of patients with long COVID: those who do not recover completely and have ongoing symptoms, those with symptoms related to chronic hospitalization, and those who develop new symptoms after recovery [31]. In our study, we did not differentiate by these subtypes and instead leave that to future research. It is possible that some of these signs and symptoms may have occurred during the first month and may be the persistent subtype. It is possible that some of the upregulated codes may be found with other serious illnesses, though only 9.1% (33,314/367,148) of our cohort had severe COVID-19 based on oxygen saturation <94%. We are not able to distinguish conditions that represent an acceleration of pre-existing disease from those that represent de novo COVID-19–related conditions. For example, is the increased incidence of nonsore throat elevation myocardial infarction (I21.4) related to the general stress of acute illness impacting pre-existing coronary artery disease or to an underlying de novo long COVID–related condition? A better understanding will require additional research. In any event, whether causal or associative, de novo disease or exacerbation of chronic disease and new or persistent clinical problems require assessment, treatment, and monitoring.

Limitations include that the cohort study population is 84% men, reflective of the overall patient population of VA which is between 87% and 95% men (depending upon data source and whether gender has been self-reported) [32,33]. Additionally, the male veteran population who use the VA health care system is older than the population of female veterans who use the VA. Our study did not include home testing for COVID-19 that went unreported to the VA health care system. Patients who tested positive during the omicron dominant time period were slightly more likely to develop long COVID when compared to the earlier strains (66,643/87,522, 76%; 201,677/279,626, 72%; P<.001). The reality of emerging viral variants emphasizes the need for a well-defined and well-maintained definition of long COVID over time and with variant-specific derivation. This study was not powered to show the independence of the individual risk factors for long COVID.

We hope that our empirically defined long COVID definition will lead to more consistent identification of long COVID and its medical specialty subtypes and support of a variety of COVID-19–related initiatives. Our definition is actionable as individuals who have multiple comorbidities and more severe bouts of COVID-19 should be followed more closely for the development of long COVID signs or symptoms. Our definition can also inform screening questions for high-risk patients. For example, helping clinicians identify patients with enhanced long COVID risk who may benefit from monitoring programs or patients with previously undiagnosed long COVID for whom it may be appropriate to create a referral to a long COVID clinic. We also anticipate that our long COVID definition will support the standardization of future subspecialty-specific long COVID research.

Future research should look at health outcomes for each long COVID-19 medical specialty subtype to identify those at greatest risk of developing severe morbidity. Predictive analytics should be used to help refer these individuals earlier to monitoring and treatment programs.

As of December 17, 2023, there have been over 772 million confirmed cases of COVID-19 worldwide [34]. Case counts are ever-increasing. As Levine [18] notes, immediately useful long COVID definitions are needed as are ultimately more fully inclusive definitions. We offer our long COVID definition as a public health contribution to our pandemic response.

Abstract

Background: As income and health are closely related, retirement is considered undesirable for health. Many studies have shown the association between pension and health, but no research has considered the association between contribution-based public pensions or their types and health.

Objective: This study investigates the association between the type of contributory public pension and depressive symptoms among older adults.

Methods: We analyzed the data of 4541 older adults who participated in the South Korea Welfare Panel Study (2014-2020). Depressive symptoms were measured using the 11-item Center for Epidemiologic Studies Depression scale. Public pensions in South Korea are classified into specific corporate pensions and national pensions. For subgroup analyses, pensioners were categorized according to the amount of pension received and the proportion of public pension over gross income. Analyses using generalized estimating equations were conducted for longitudinal data.

Results: Individuals receiving public pension, regardless of the pension type, demonstrated significantly decreased depressive symptoms (national pension: \( \beta = -0.734; P < .001 \); specific corporate pension: \( \beta = -0.775; P = .02 \)). For both pension types, the higher the amount of benefits, the lower were the depression scores. However, this association was absent for those who received the smaller amount among the specific corporate pensioners. In low-income households, the decrease in the depressive symptoms based on the amount of public pension benefits was greater (fourth quartile of national pension: \( \beta = -1.472; P < .001 \); second and third quartiles of specific corporate pension: \( \beta = -3.646; P < .001 \)).

Conclusions: Our study shows that contributory public pension is significantly associated with lower depressive symptoms, and this association is prominent in low-income households. Thus, contributory public pensions may be good income sources for improving the mental health of older adults after retirement.

Introduction
Depression in older adults decreases successful aging, adversely affecting not only the health-related quality of life of individuals but also of families and communities [1]. Older adults are more likely to be exposed to depression because they experience a series of adversities such as death, retirement, and health problems [2,3]. In old age, depression is a risk factor for nonsuicidal mortality, and both major and minor depression have been associated with suicide [4].

The prevalence of depression in South Korea (hereafter referred to as Korea) was 2.09% in 2019, which was lower than that reported in Japan (2.10%) and in the United States (4.38%) [5]. However, the prevalence of depression tends to increase with age, reaching 13.9% in those in their 60s and 70s and 18.4% in those in their 80s or older [6]. The proportion of older adults with depression reached 14% in 2018, and Korea is expected to become a superaged society by 2025, when the older adult population reaches 20.3% of the total population in Korea [7]. Therefore, a better understanding of depression in old age is of paramount importance from a clinical and public health perspective.

Income and health are closely related; to some extent, the more money people make, the better is their health [8]. This makes retirement, where a certain income for a person ceases, undesirable for health. In other words, old age income is important for health and other aspects [9]. Low economic status often leads to adjustment disorders accompanied by a depressed mood [10]. In Korea, the disposable income of older adults is less than 70% of the economy-wide average, which is the lowest among the Organization for Economic Co-operation and Development countries [11]. Moreover, Korea has a relative poverty rate of 45% among adults over 65 years, which is the highest among the Organization for Economic Co-operation and Development countries. Relative poverty is defined as an income below half the national median equivalized household income.

As in many countries, Korea’s retirement income security system has a multilayered structure. First, the National Basic Livelihood Security System and the noncontributory basic old age pension are positioned as safety nets for the low-income class. Second, public pension, which provides pension benefits based on the subscribers, plays the most important role in guaranteeing retirement income [12]. The types of public pensions vary depending on the country, but in Korea, they are divided into (1) specific corporate pension for special workers such as public officials, private school faculty members, and military personnel, and (2) national pension for the general public [13,14]. Lastly, individuals can prepare additional retirement income by choosing to subscribe to a private pension operated by a company rather than the government. Among these multilayered income security systems, public pensions play a role in dispersing the risk of poverty that may occur among citizens. Furthermore, they allow the entire society to bear the costs evenly, without the double burden of paying for other people’s retirement living expenses on income-earning people due to those who are guaranteed a minimum living by relying on the public assistance system.

The relationship between health and pension, which guarantees income for the aged population, is debatable [15-18]. Unlike noncontributory pensions, which are paid only if income requirements are met (even if there is no certain contribution), few studies have been conducted on how contribution-based pensions (guaranteed for their contributions) affect the mental health of older adults [19]. When public pensions are divided into national pensions and specific corporate pensions, as in Korea, and there is a large difference in the amount received based on the type of pension (assuming that the contribution is different), the association of depression may differ depending on the type and amount of public pension received.

We hypothesized that a contribution-based pension would help the mental health of the older population and that larger public pension benefits would be more beneficial to mental health. It was also assumed that as the characteristics of the 2 pillars of Korea’s public pension are different, the degree of impact on mental health will also be different. Therefore, this study examines whether public pensions are associated with depressive symptoms, depending on the type and amount of receipt, among older adults over 65 years.

Methods

Study Population and Data
Data from the Korea Welfare Panel Study (KoWePS) conducted by the Korea Institute for Health and Social Affairs and Seoul National University were analyzed in this study. The KoWePS was a large-scale, annual, longitudinal panel survey conducted from 2006 (wave 1) to 2020 (wave 15). We used samples extracted from wave 9 (2014) to wave 15 (2020), as the 11-item Center for Epidemiologic Studies-Depression (CESD-11) scale measures depressive symptoms. The study participants were also limited to those who were 65 years or older and who did not have a history of depression in wave 9 in order to evaluate the association between pension benefits and depressive symptoms. After excluding participants with missing data, the CESD-11 score (n=254), 4541 respondents were included in the final sample of the baseline study year.

Depressive Symptoms
The primary outcome was depressive symptoms, which were evaluated based on the 11-item version of the CESD scale. The CESD-11 is a well-validated self-reported screening tool and is a shorter version of the original 20-item instrument [20]. It is designed to evaluate 11 depressive symptoms for 1 week on a 4-point scale (0-3). The respondents reported symptoms for each year of the study period. The total score was multiplied by a 4-point scale (0-3). The respondents reported symptoms for each year of the study period. The total score was multiplied
analyses were performed to investigate whether the annual variables in contrast to the fixed effects model [24]. Subgroup analyses can predict the coefficients of time-dependent average response for every 1-unit increase in a covariate across study design [23]. The GEE model assesses the change in the association between type of public pension and depressive symptoms, we used the generalized estimating equation (GEE) design was used to select households, including multiple household members, household income, highest level of education, and employment status. Health-related factors included smoking status, alcohol consumption, and chronic diseases. Income-related factors were realized property income, including interest or rental income; public transfer income, including basic old age pension, a noncontributory social pension in Korea; private transfer income, including income from the adult children and private pension; and household debt.

Covariates
This study includes demographics, socioeconomic characteristics, health-related factors, and income-related factors as covariates, which reflected the results obtained for each wave. Demographic variables included sex, age, and region. Socioeconomic variables included marital status, number of household members, household income, highest level of education, and employment status. Health-related factors included smoking status, alcohol consumption, and chronic diseases. Income-related factors were realized property income, including interest or rental income; public transfer income, including basic old age pension, a noncontributory social pension in Korea; private transfer income, including income from the adult children and private pension; and household debt.

Statistical Analyses
The distribution of general characteristics was calculated at baseline. Two-sided t tests, analysis of variance, and univariate linear regression were used to analyze the differences in the CESD-11 scores. The KoWePS data used in this study were hierarchically structured, and a stratified multistage probability design was used to select households, including multiple individuals from the same household [22]. For estimating the association between type of public pension and depressive symptoms, we used the generalized estimating equation (GEE) model, which can explain the time variations and correlations among the repeated measurements observed in the longitudinal study design [23]. The GEE model assesses the change in the average response for every 1-unit increase in a covariate across the population and can predict the coefficients of time-dependent variables in contrast to the fixed effects model [24]. Subgroup analyses were performed to investigate whether the annual amount of pension benefit was associated with depressive symptoms by using the GEE model. Furthermore, this study assessed the relationship between the proportion of public pension income in gross income and depressive symptoms. Finally, stratified analysis was performed by stratifying low- and high-income households by defining less than 60% of the equalized median income as low-income households [25]. All calculated P values were 2-sided; P values <.05 were considered significant. All analyses were performed using SAS software (version 9.4; SAS Institute). This study follows the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines for observational studies [26].

Ethics Approval
This study was approved by the institutional review board of Severance Hospital at Yonsei University College of Medicine (approval 4-2021-0310). Informed consent was waived by the institutional review board, as the data of KoWePS are open to the public and do not contain any personally identifiable information.

Results
Characteristics of the Study Participants
The study participants were more likely to be older than the excluded individuals, live with their family, have higher incomes, and be unemployed (Table S1 of Multimedia Appendix 1). Table 1 describes the participants’ general characteristics in the baseline year (2014). A total of 4541 participants were included, and the mean CESD-11 score was 6.13 (SD 5.41); 3128 (68.9%) participants did not receive public pension, 1225 (26.9%) received national pension, and 188 (4.1%) received
specific corporate pension. Their mean CESD-11 scores were 6.72 (SD 5.55), 5.03 (SD 4.89), and 3.61 (SD 4.42), respectively. Table S2 of Multimedia Appendix 2 demonstrates the demographic characteristics of the study participants in 2014 according to pension type. The rate of not receiving public pensions among women was higher than that among men and among those aged 80 years or older. Furthermore, the lower the level of education and the lower the income, the higher was the rate of not being enrolled in public pensions.

Table 2 presents the results of the GEE model, which shows that the scores of CESD-11 were lower among those who received public pensions. After adjusting all covariates, including income-related factors, individuals receiving public pension, regardless of pension type, tended to have lower CESD-11 scores than those who did not receive public pension (national: \( \beta = -0.734; P < 0.001 \); specific: \( \beta = -0.775; P = 0.02 \)). The results also showed that a higher realized property income was correlated with lower CESD-11 scores (\( \beta = -0.283; P < 0.001 \)). However, public or private transfer income were not associated with depressive symptoms.

Table 3 shows the results of the GEE model for the subgroup analyses of the associations among amount of pension benefit, proportion of public pension income, and depressive symptoms. After adjusting for all the covariates, older adults who received more than the fourth quartile among the specific corporate pension recipients reported the lowest depression score (\( \beta = -1.221; P = 0.001 \)). For both national pension and specific corporate pension recipients, the CESD-11 scores tended to decrease as the amount of pension benefits increased. The CESD-11 score was significantly lowered when the proportion of national pension income over gross income was 75% or less (\( P < 0.001 \)), but no statistical significance was found when it exceeded 75%. Meanwhile, when the proportion of specific corporate pension income over gross income exceeded 25%, the depression score decreased significantly (\( P < 0.05 \)).

Table 4 shows the results of the analyses, which present the associations of public pension with depressive symptoms stratified by household income. In low-income households with less than 60% of equalized gross income, there was a clear relationship among public pension benefits, amount of benefits, and lower CESD-11 scores. Moreover, the CESD-11 score was significantly lowered even if the proportion of national pension income over gross income exceeded 75% (\( \beta = -2.783; P < 0.001 \)).

the association between these circumstances, we evaluated the association between public pensions and mental health, as each country has different forms and types of pensions. Many European countries have studied the association between disability pensions and health outcomes [29]. Research in Europe has shown that receiving a disability pension can have a more negative impact on mental health than not receiving it. It is presumed that this phenomenon is due to the psychosocial stress experienced by beneficiaries in obtaining eligibility for disability pension. Additionally, claims stigma can have a negative impact on mental health [30].

Contrary to the findings in the aforementioned reports, our findings show a positive relationship between public pension as a means of maintaining income in old age and mental health. Recently, many studies in China have found that China’s new rural pension scheme reduces depressive symptoms and lowers the prevalence of depression [9,31,32]. The findings of a Japanese study on the relationship between contribution-based public pensions and happiness were also similar to our study results [19]. Furthermore, the results of a study analyzing the relationship between aged pension schemes and mental health conducted in New Zealand reported that material hardship can cause health inequities, including mental health [33]. These studies suggest that older adults can benefit their mental health by reducing labor supply and spending more leisure time with friends and family through the pension income. Additionally, pensions can reduce depressive symptoms by strengthening the financial capacity of beneficiaries and their families. However, there are limitations in that the existing studies [9,31,32] examined the effects of pension systems that were implemented in rural areas or had cross-sectional research designs. Under these circumstances, we evaluated the association between contributory public pensions and mental health after adjusting for each individual’s pension income type, considering the multilayered Korean pension system.

In this study, among older adults without a history of diagnosed depression, those receiving contribution-based public pensions, regardless of pension type, were less likely to experience depressive symptoms than those who did not receive public pensions. Additionally, in subgroup analyses, we observed that the CESD-11 scores tended to decrease as the amount of pension benefits increased for both national pension and specific corporate pension recipients. These results imply that the policy of guaranteeing old age income through public pensions was associated with a lower depressive score and that the larger the amount of public pension benefits, the better was the mental health.

Several studies have evaluated that pensions could affect mental health through the following pathways: first, through changes in lifestyle habits such as independent living and leisure time; second, by enabling healthy life choices such as with nutrition and medical treatment; and third, by reducing economic stress [9,34,35]. In addition to the 3 pathways mentioned above, the relation between contribution-based public pension receipt and alleviation of depressive symptoms can be explained by the following mechanisms. In the case of a contribution-based public pension, the result of one’s labor is returned later. Therefore, there is a possibility that even a small amount of money may make one feel satisfied, believing that the pension is a reward for one’s effort [36]. In particular, given the hedonic adaptation hypothesis, according to which the pleasure of economic benefits gradually disappears after receiving a noncontributory pension [37], the contribution-based pension has a different mechanism in relieving depressive symptoms in that it reflects the results of previous labor. Another possibility is that public pension recipients were economically active and stable when they were young, since they earned income from work or self-employment for at least 10 years or more, contributing to the pension. This may have lowered their likelihood of experiencing depressive symptoms. In addition, the experience of working long-term at a company or being self-employed to contribute to public pensions may have affected their social networks, which may ultimately influence their mental health [38]. However, no association with lower depressive symptoms was observed when the pension amount among national pension recipients was 75% or more of the gross income, although the CESD-11 score tended to decrease. Considering our research showing that the top 25% of national pension recipients receive only US $2790 per year (US $232.50 per month), there is a possible limitation to improving depressive symptoms merely if older adults receive public pension, requiring them to live with fewer pension benefits. This phenomenon is in line with the results of this study and previous studies, which indicate that receiving a low

### Discussion

#### Principal Results

This longitudinal study investigates whether receiving public pension, which plays a major role in the old age income security policy in Korea, was associated with depressive symptoms in older adults. In particular, we distinguished between national and specific corporate pensions, which are the 2 pillars of public pension in Korea and evaluated whether the 2 types of pensions could improve depressive symptoms. We found that the depression scores decreased as the amount of benefits increased for both public pensions. Regardless of the type, the association between public pension benefits and decreased depressive symptoms was pronounced in low-income households. The results of our study imply that financial resources provided through public pensions can improve the mental health of older people.

Conflicting findings have been reported regarding the relationship between pension income and health [27,28]. However, care must be taken when interpreting the relationship between pensions and health, as each country has different forms and types of pensions. Many European countries have studied the association between disability pensions and health outcomes [29]. Research in Europe has shown that receiving a disability pension can have a more negative impact on mental health than not receiving it. It is presumed that this phenomenon is due to the psychosocial stress experienced by beneficiaries in obtaining eligibility for disability pension. Additionally, claims stigma can have a negative impact on mental health [30].

Contrary to the findings in the aforementioned reports, our findings show a positive relationship between public pension as a means of maintaining income in old age and mental health. Recently, many studies in China have found that China’s new rural pension scheme reduces depressive symptoms and lowers the prevalence of depression [9,31,32]. The findings of a Japanese study on the relationship between contribution-based public pensions and happiness were also similar to our study results [19]. Furthermore, the results of a study analyzing the relationship between aged pension schemes and mental health conducted in New Zealand reported that material hardship can cause health inequities, including mental health [33]. These studies suggest that older adults can benefit their mental health by reducing labor supply and spending more leisure time with friends and family through the pension income. Additionally, pensions can reduce depressive symptoms by strengthening the financial capacity of beneficiaries and their families. However, there are limitations in that the existing studies [9,31,32] examined the effects of pension systems that were implemented in rural areas or had cross-sectional research designs. Under these circumstances, we evaluated the association between contributory public pensions and mental health after adjusting for each individual’s pension income type, considering the multilayered Korean pension system.

In this study, among older adults without a history of diagnosed depression, those receiving contribution-based public pensions, regardless of pension type, were less likely to experience depressive symptoms than those who did not receive public pensions. Additionally, in subgroup analyses, we observed that the CESD-11 scores tended to decrease as the amount of pension benefits increased for both national pension and specific corporate pension recipients. These results imply that the policy of guaranteeing old age income through public pensions was associated with a lower depressive score and that the larger the amount of public pension benefits, the better was the mental health.

Several studies have evaluated that pensions could affect mental health through the following pathways: first, through changes in lifestyle habits such as independent living and leisure time; second, by enabling healthy life choices such as with nutrition and medical treatment; and third, by reducing economic stress [9,34,35]. In addition to the 3 pathways mentioned above, the relation between contribution-based public pension receipt and alleviation of depressive symptoms can be explained by the following mechanisms. In the case of a contribution-based public pension, the result of one’s labor is returned later. Therefore, there is a possibility that even a small amount of money may make one feel satisfied, believing that the pension is a reward for one’s effort [36]. In particular, given the hedonic adaptation hypothesis, according to which the pleasure of economic benefits gradually disappears after receiving a noncontributory pension [37], the contribution-based pension has a different mechanism in relieving depressive symptoms in that it reflects the results of previous labor. Another possibility is that public pension recipients were economically active and stable when they were young, since they earned income from work or self-employment for at least 10 years or more, contributing to the pension. This may have lowered their likelihood of experiencing depressive symptoms. In addition, the experience of working long-term at a company or being self-employed to contribute to public pensions may have affected their social networks, which may ultimately influence their mental health [38]. However, no association with lower depressive symptoms was observed when the pension amount among national pension recipients was 75% or more of the gross income, although the CESD-11 score tended to decrease. Considering our research showing that the top 25% of national pension recipients receive only US $2790 per year (US $232.50 per month), there is a possible limitation to improving depressive symptoms merely if older adults receive public pension, requiring them to live with fewer pension benefits. amount of noncontributing basic old age pension was not associated with decreased depressive symptoms [39]. Nevertheless, among low-income people, public pensions were associated with low CESD-11 scores, even for low amounts. These results suggest that for low-income people, even a small amount of national pension can improve their depressive symptoms and that the level of income should be considered when formulating a pension policy.

In our study, even for a specific corporate pensioner whose pension benefit amount was higher than that of the national pensioner, pension receipt was not associated with alleviation of depressive symptoms for individuals whose pension amount was in the bottom 25% or less than 25% of the gross income among specific corporate pensioners. Depressive symptoms may not decrease for those with low specific corporate pension benefits because they must earn income through other means. In Korea, the corporate pension amount is higher than the national pension amount. Thus, specific corporate pension beneficiaries do not have to worry about their postretirement income. Our results suggest that it is necessary to consider the types of public pensions and their implications for beneficiaries in addition to the pension receipt or amount, when studying the effects of public pensions on mental health.

The state’s finances are limited; thus, tax-based noncontributory pensions cannot be increased indefinitely. Moreover, it is almost impossible to expand noncontributory pensions, especially in low-income countries, which are forced to spend a considerable share of the state’s finances on economic development. Therefore, the few financial policies that can be used to improve the mental health of older adults are contribution-based pensions. The objective of the public pension policy is to guarantee a certain amount of benefits to individuals so that they do not experience economic difficulties when they become older. This can be achieved, for example, by increasing contributions or by extending the period of contributions when people are young.

Taken together, our findings may provide several important implications not only for the Korean society but also for countries planning and revising pension policies. First, our findings justify a wide range of policy interventions that promote public health based on retirement income security policies such as public pensions. Second, these findings suggest that mental health can be effectively improved with economic resources. Third, the best way to use economic resources to improve mental health is to ensure an income that is economically sufficient. However, creating this condition without contributions can be difficult. Fourth, for low-income countries that cannot afford to preserve older adults’ income, a contribution-based public pension system may be an important policy in order to maintain the mental health of older adults after retirement.

Limitations
This study has several limitations. First, the exact causal relationship between public pension benefit and depressive symptoms could not be confirmed, although this study used longitudinal data with repeated observations at the individual level over a specific period [40]. Second, residual confounding may exist because of income-related factors. Finally, since the economic and cultural basis that determines the pension policy and the direction of policy in each country may differ, direct application of the results of this study may be limited [41]. Longitudinal studies in more countries and based on larger numbers of public pension recipients are needed to confirm causal relationships.

Conclusions
This study evaluates both the national and specific corporate pensions, which are the 2 pillars of public pensions, and their association with lower prevalence of depressive symptoms in Korea. The depression scores decreased as the amount of benefits increased for both public pensions. However, for beneficiaries of specific corporate pensions with lower benefits, the association with depressive symptoms was absent. Regardless of the pension type, the association between public pension benefits and decreased depressive symptoms was pronounced in low-income households. For low-income countries that cannot afford to preserve older adults’ income, the contribution-based public pension system may be an important policy to maintain the mental health of older adults after retirement.

Abstract

Background: The number of cancer survivors who develop subsequent primary cancers (SPCs) is expected to increase.

Objective: We evaluated the overall and cancer type–specific risks of SPCs among adult-onset cancer survivors by first primary cancer (FPC) types considering sex and age.

Methods: We conducted a retrospective cohort study using the Health Insurance Review and Assessment database of South Korea including 5-year cancer survivors diagnosed with an FPC in 2009 to 2010 and followed them until December 31, 2019. We measured the SPC incidence per 10,000 person-years and the standardized incidence ratio (SIR) compared with the incidence expected in the general population.

Results: Among 266,241 survivors (mean age at FPC: 55.7 years; 149,352/266,241, 56.1% women), 7348 SPCs occurred during 1,003,008 person-years of follow-up (median 4.3 years), representing a 26% lower risk of developing SPCs (SIR 0.74, 95% CI 0.72-0.76). Overall, men with 14 of the 20 FPC types had a significantly lower risk of developing any SPCs; women with 7 of the 21 FPC types had a significantly lower risk of developing any SPCs. The risk of developing any SPC type differed by age; the risk was 28% higher in young (<40 years) cancer survivors (SIR 1.28, 95% CI 1.16-1.42; incidence: 30 per 10,000 person-years) and 27% lower in middle-aged and older (≥40 years) cancer survivors (SIR 0.73, 95% CI 0.71-0.74; incidence: 80 per 10,000 person-years) compared with the age-corresponding general population. The most common types of FPCs were mainly observed as SPCs in cancer survivors, with lung (21.6%) and prostate (15.2%) cancers in men and breast (18.9%) and lung (12.2%) cancers in women. The risks of brain cancer in colorectal cancer survivors, lung cancer in laryngeal cancer survivors, and both kidney cancer and leukemia in thyroid cancer survivors were significantly higher for both sexes. Other high-risk SPCs varied by FPC type and sex. Strong positive associations among smoking-related cancers, such as laryngeal, head and neck, lung, and esophageal cancers, were observed. Substantial variation existed in the associations between specific types of FPC and specific types of SPC risk, which may be linked to hereditary cancer syndrome: for women, the risks of ovarian cancer for breast cancer survivors and uterus cancers for colorectal cancer survivors, and for men, the risk of pancreas cancer for kidney cancer survivors.

Conclusions: The varying risk for SPCs by age, sex, and FPC types in cancer survivors implies the necessity for tailored prevention and screening programs targeting cancer survivors. Lifestyle modifications, such as smoking cessation, are essential to reduce the risk of SPCs in cancer survivors. In addition, genetic testing, along with proactive cancer screening and prevention strategies, should be implemented for young cancer survivors because of their elevated risk of developing SPCs.

**Introduction**

The number of cancer survivors is on the rise due to population growth, an aging population, and improved survival rates resulting from early diagnosis and advanced cancer treatment strategies [1]. As of 2019, there were approximately 16.9 million and 2 million cancer survivors in the United States and South Korea, respectively [2]. Managing the health of cancer survivors is critical because they face unique physical, psychosocial, and medical conditions, with the more serious being subsequent primary cancers (SPCs) [1,3]. Identifying the associations between the types of SPC and first primary cancer (FPC) is crucial, as cancer survivors continue to live in similar environments to where their FPC developed and the genetic risk persists. Identification of and preemptive intervention for these associations provide opportunities for risk reduction and early detection through tailored prevention and cancer screening programs.

A comprehensive study investigating SPCs among 5-year cancer survivors using the Surveillance, Epidemiology, and End Results (SEER) Program reported a higher risk of SPCs with several types of FPCs [4]. However, the SEER study had a predominantly White population (>80%), and over 40% of male and female participants were prostate and breast cancer survivors, respectively. In Korea, previous studies have mainly focused on specific types of FPCs, rather than comprehensively addressing cancer survivors in general [5-8]. Therefore, given the differences in ethnicity and cancer incidence between the United States and South Korea, a comprehensive epidemiological investigation is necessary to provide new insight on developing SPCs in cancer survivors with diverse socioenvironmental and different ethnic-genetic interactions.

The occurrence of cancers is influenced by environmental and hereditary factors, as well as random mutations [9]. Hereditary factors are linked to young-onset and multiple cancers [10-12]. Consequently, young cancer survivors may be at a higher risk of developing SPCs than their older counterparts and may exhibit unique combinations of FPCs and SPCs that are influenced by genetic susceptibility. Thus, age should be taken into consideration when investigating the association between FPCs and SPCs; however, this aspect has not been assessed in previous studies.

In this study, we assessed the relationships between FPCs and SPCs by analyzing data obtained from the South Korea Health Insurance Review and Assessment (HIRA) database, which covers nearly the entire Korean population.

**Methods**

**Data Source and Study Population**

The study was a nationwide, population-based, cohort study that analyzed data obtained from the HIRA database of South Korea between January 1, 2008, and December 31, 2019, which includes over 50 million Koreans. The study population included patients diagnosed with cancer between January 1, 2009, and December 31, 2010, and newly diagnosed cancer cases during this period were identified by excluding patients diagnosed with cancer in 2008. Cancers were classified into 23 types (20 types for men and 21 types for women) using the 10th revision of the International Classification of Diseases (ICD) code, and the Korean Individual Co-payment Beneficiaries Program (ICBP) data in the HIRA were used to define each cancer type. The ICBP was established for rare and intractable diseases, including cancers, in 2008, and patients in this program pay only 5% to 10% of their medical costs for 5 years from the day of registration. Therefore, the most affected individuals are registered in ICBP, and patients who were diagnosed with cancer before 2008 were retrospectively registered in the program. We followed those cancer patients until December 31, 2019. Cancer survivors were defined as cancer patients who lived longer than 5 years without developing other cancers with no evidence of recurrence of the first diagnosed cancers. SPCs were defined as a newly diagnosed, distinct cancer type, excluding same-type cancers to minimize the bias from misclassification of FPC recurrence. Survivor follow-up began 5 years after their FPC diagnosis and continued until death; loss to follow-up; December 31, 2019; or occurrence of an SPC, whichever came first. If a patient had multiple SPCs, the first type was considered the SPC. The primary outcomes were incidence (per 10,000 person-years) and relative risk (standardized incidence ratio [SIR]) of SPCs among 5-year survivors of FPCs. The Korean National Cancer Statistics 2015 [13], the middle year of the present cohort, was used to determine the expected cancer rates.

**Statistical Analysis**

Incidence rates of SPCs among the overall sample and each group of survivors were calculated by dividing the observed number of SPCs by the corresponding total person-years and then multiplying by 10,000. To investigate the risk of SPCs among the overall sample and each group of survivors compared with the general Korean population, we calculated the age-standardized incidence ratio by type of FPCs and sex using the Korean National Cancer Statistics 2015 [13], the middle year of the cohort, as the expected cancer rates. The 95% CI of the SIR was calculated using the Poisson distribution. All estimates were calculated for overall SPCs and for type-specific SPCs. The 12 smoking-related cancers, 12 obesity-related cancers, 7 alcohol-related cancers, and 6 infection-related cancers were considered in the subgroup analyses to assess environmental factors for developing SPCs [14-16]. The incidences and SIRs were estimated to quantify the risk of developing any types of each environment factor–related SPC. A 2-sided P<.05 was considered statistically significant; multiple comparison corrections were not conducted, as the analyses were exploratory. SAS Enterprise Guide version 9.4 (SAS Institute Inc) was used for all statistical analyses.
Ethical Considerations
This study was approved by the research ethics committee of the South Korea National Health Insurance Sharing Service (M20200902739) and the institutional review board of Severance Hospital (4-2020-0155). The need for informed consent was waived owing to the use of deidentified data. Access to the HIRA data is restricted to authorized individuals and is only permissible from designated computers.

Results
A total of 266,241 (71.7%) 5-year cancer survivors were identified among 371,181 patients who were diagnosed with FPCs between 2009 and 2010, accruing 1,003,008 person-years of follow-up 5 years after their FPCs (mean 3.8 years; median 4.3 years; Figure 1 and Table 1). Among 371,181 patients who were diagnosed with an FPC between January 2009 and December 2010 in South Korea, there were 266,241 (71.7%) 5-year cancer survivors, and among the survivors, 7348 (2.8%) patients had SPCs. The percentage of 5-year survivors varied by the type of FPC; survival was lowest with pancreatic cancer (2628/7392, 35.6%) and highest with thyroid cancer (66,087/69,211, 95.5%; Table S1 in Multimedia Appendix 1). Of the survivors, 56.1% (149,352/266,241) were female, and 12.5% (33,171/266,241) and 30.1% (80,249/266,241) were younger than 40 years and older than 65 years, respectively.

Among all survivors, 7348 SPC cases (73 per 10,000 person-years) were identified, representing a 26% lower risk of developing SPCs (SIR 0.74, 95% CI 0.72-0.76; Table 2). There were 4207 and 3141 SPC cases (99 and 54 per 10,000 person-years) in male and female survivors, respectively, which corresponded to 34% and 11% lower risks of developing SPCs compared with the risk in the general Korean population. When considering age at FPC diagnosis, the risk of developing SPCs differed by age, with a higher risk observed among young patients with FPCs (<40 years old), and the risk gradually decreased with age (Table S2 in Multimedia Appendix 1). Therefore, subgroups by age were considered for further analysis. The risk of developing SPCs was significantly higher when the patient had FPC before they reached 40 years old (men: SIR 1.43, 95% CI 1.10-1.84; women: SIR 1.26, 95% CI 1.12-1.40), while the risk was significantly lower in patients with an FPC at ≥40 years old (men: SIR 0.66, 95% CI 0.64-0.68; women: SIR 0.86, 95% CI, 0.83-0.89).

Overall, many survivor groups defined by FPC types and sex had lower-than-expected risks of developing SPCs compared with the risks in the Korean general population. Specifically, men with 14 of the 20 FPC types had a significantly lower risk of developing any SPCs, while women with 7 of the 21 FPC types had a significantly lower risk of developing any SPCs (Table 3).

</table>
Among FPC types, the risk of developing SPCs was significantly higher after laryngeal cancer in men (SIR 1.28, 95% CI 1.07-1.51; incidence: 248 per 10 000 person-years). For the 3 most common FPC types in 5-year cancer survivors, the overall SIRs in men were significantly lower for stomach, colorectal, and prostate cancers (Table 3). In women, the SIR was significantly lower for stomach cancer (SIR 0.77, 95% CI 0.69-0.86; incidence, 60 per 10 000 person-years) but not significantly lower for breast cancer and thyroid cancer.

Tables S3 and S4 in Multimedia Appendix 1 show the subgroup analyses by age (<40 and ≥40 years) for the risks of developing SPCs by FPC types in men and women. The risk of developing any type of SPC after kidney cancer (SIR 3.02, 95% CI 1.21-6.21) and thyroid cancer (SIR 1.37, 95% CI 1.18-1.58) was significantly higher in young (<40 years) men and women, respectively, than in the general population.

Figures 2 and 3 display the percentage contributions of different FPC and SPC combinations to the total incidence of SPCs, as well as the SIRs for men and women. Among all survivors, the 5 SPCs that contributed the most to the total incidence of SPCs were lung (21.6%), prostate (15.2%), stomach (12%), colorectal (9.5%), and liver (8.9%) cancers in men and breast (18.9%), lung (12.2%), stomach (10.4%), colorectal (10%), and thyroid (8.2%) cancers in women. These findings are represented in the row labeled “All FPCs” in Figure 2A and Figure 3A. In men, the 5 most significant SIRs for SPCs were observed among survivors of non-Hodgkin lymphoma for Hodgkin lymphoma (SIR 20.6), survivors of breast cancer for prostate cancer (SIR 6.07), survivors of esophageal cancer for head and neck cancer (SIR 5.62), laryngeal cancer survivors for head and neck cancer (SIR 5.19), and survivors of head and neck cancer survivors for esophageal cancer (SIR 4.27). These SIRs are shown in Figure 2B and Multimedia Appendix 2. For women, the 5 most significant SIRs for SPCs were observed among survivors of multiple myeloma for leukemia (SIR 15.11), survivors of laryngeal cancer for lung cancer (SIR 7.83), survivors of leukemia for non-Hodgkin lymphoma (SIR 7.11), survivors of non-Hodgkin lymphoma for leukemia (SIR 5.95), and survivors of colorectal cancer for uterus cancer (SIR 4.25). These findings are shown in Figure 3B and Multimedia Appendix 2. Figure 4 summarizes the heightened risk of SPCs across various FPC and SPC combinations in both men and women. Notably, the risks of brain cancer in colorectal cancer survivors, lung cancer in laryngeal cancer survivors, and both kidney cancer and leukemia in thyroid cancer survivors were significantly higher in both sexes.

The subgroup analysis to assess environmental factors for developing SPCs showed that the risks of developing each factor-related SPC were higher in young (<40 years old) patients with FPCs than older patients in general (Table S5 in Multimedia Appendix 1). Among middle-aged and older (≥40 years) survivors, some types of FPCs were associated with a higher risk of developing SPCs compared with the general population; for example, male survivors of laryngeal cancer had a higher risk of smoking-related SPCs (SIR 1.46, 95% CI 1.20-1.77), and survivors of uterus cancer had a higher risk of obesity-related SPCs (SIR 1.33, 95% CI 1.02-1.71). The results of additional subgroup analyses to assess the contribution of each FPC and SPC to the SIRs by age (<50 years and ≥50 years) in men and women are displayed in Figures S1 and S2 in Multimedia Appendix 3. Some considerable associations between the type of FPC and SPC that could be related to hereditary cancer syndromes such as hereditary breast and ovarian cancer, Lynch syndrome, and Von-Hippel-Lindau (VHL) syndrome were observed in patients with an FPC before 50 years of age (eg, uterus cancer in female breast cancer survivors, uterus cancer in female colorectal cancer survivors, pancreas cancer in male kidney cancer survivors; see Figures S1A and S2A in Multimedia Appendix 3).

*SIR: standardized incidence ratio.*
Figure 2. Risk of developing subsequent primary cancers (SPCs) among 5-year male survivors (A) calculated by dividing the observed number of SPCs of each cell by the total number of observed SPCs and the (B) standardized incidence ratios of SPCs by each first primary cancer (FPC). Statistically significant associations between the FPC and SPC are shown by bold boxes, gray cells indicate associations not tested due to a small number of observed SPCs, and blue and red colors represent lower- and higher-than-expected values, respectively, based on 195 eligible statistical tests (observed number of SPCs ≥5 or statistically significant association). GB: gallbladder.

Figure 3. Risk of developing subsequent primary cancers (SPCs) among 5-year female survivors (A) calculated by dividing the observed number of SPCs of each cell by the total number of observed SPCs and the (B) standardized incidence ratios of SPCs by each first primary cancer (FPC). Statistically significant associations between the FPC and SPC are shown by bold boxes, gray cells indicate associations not tested due to a small number of observed SPCs, and blue and red colors represent lower- and higher-than-expected values, respectively, based on 147 eligible statistical tests (observed number of SPCs ≥5 or statistically significant association). GB: gallbladder.
Discussion

Principal Findings

The results indicate that the risk of developing SPCs among adult-onset 5-year cancer survivors in South Korea is generally lower than in the general population. However, young (<40 years old) cancer survivors exhibited an increased risk of developing SPCs, and the risk of SPCs also varied according to the patient’s sex and the type of FPC. Survivors from smoking-related cancers have a significant risk of developing subsequent smoking-related cancers. These findings highlight the necessity for tailored approaches to cancer screening, prevention, and management strategies for cancer survivors.

Environmental factors such as smoking, alcohol use, exposure to ultraviolet light, and viral infections are well-known risk factors for the development of cancer [17]. In addition, an estimated 5% to 10% percent of cancers have a heritable component that is caused by genetic susceptibility [18]. Additionally, Tomasetti and Vogelstein [9,19] have suggested that “bad luck,” random mutations occurring during stem cell division, contributes to two-thirds of the adult cancer incidence; based on the results of their statistical model, there is a high correlation between the number of stem cell divisions of a given tissue and the lifetime risk of cancer in that tissue. The epidemiological results indicate a 26% lower risk of developing SPCs (SIR 0.74, 95% CI 0.72-0.76) in the overall sample of Korean cancer survivors when compared with the risk of developing cancer in the general population. This can be explained by the fact that cancer-causing mutations are stochastic in nature; therefore, the probability of “very bad luck,” the development of a SPC after an FPC in cancer survivors, is lower than “bad luck” in the general Korean population.

Although the overall risk of developing SPCs in cancer survivors is low, a high risk of developing well-known smoking-related cancers [20,21] was observed among cancer survivors with...
smoking-related cancers, including laryngeal, head and neck, and esophageal cancers in men and laryngeal and lung cancers in women. This result highlights the importance of environmental factors in the occurrence of SPCs, and primary prevention should be a priority for controlling both FPCs and SPCs, as a substantial cancer burden could be prevented through lifestyle modifications [22]. Smoking is one of the strongest carcinogens, causing various types of cancer, and quitting smoking has been shown to reduce the risk of cancer and improve survival even after a cancer diagnosis [23,24]. Therefore, it is crucial for cancer survivors to quit smoking to improve their survival and lower their risk of subsequent cancers. However, smoking cessation interventions for cancer survivors have not been successful in the past [25,26]. Clinicians need to communicate with and educate cancer survivors about the high risk of secondary cancer and guide them on smoking cessation. Collaboration between oncologists and primary physicians is essential to provide high-quality comprehensive smoking cessation interventions, as smoking cessation services are mainly provided by primary physicians [27].

The findings of this study indicate that young cancer survivors are at a higher risk of developing SPCs, implying that factors beyond “bad luck,” such as hereditary predispositions, may play a significant role in the development of SPCs in young adults. There were significant associations between specific types of SPCs and FPCs that may be linked to hereditary cancer syndrome. In men, young kidney cancer survivors were at a high risk of developing SPCs, with pancreas and brain cancers being the most common types. VHL syndrome, caused by germline mutations of the VHL gene, is characterized by tumors of the central nervous system, kidney, retina, and pancreas. Only a small number of studies have evaluated VHL syndrome in Korea; the incidence of VHL disease in patients with renal cell carcinoma was reported at 0.7%, and it was male-dominant (70%) with a median age of onset of 33 years (14-59 years) [28,29]. In women, the SIRs were significantly high among breast cancer survivors for ovarian cancer and colorectal cancer survivors for uterus cancers, possibly due to hereditary breast and ovarian cancer and Lynch syndrome harboring a germline mutation in BRCA1/2 and mismatch repair–related genes, respectively. Identifying hereditary cancer syndrome is crucial for cancer prevention and treatment, as both the individual and one-half of first-degree family members are at high risk of cancer [30]. Hereditary cancer syndromes may represent a broader clinical spectrum than previously understood [31,32]. Further genetic studies targeting young cancer survivors with a high risk of SPCs are worth conducting.

The most common types of FPCs were mainly observed as SPCs in cancer survivors, with lung cancer and prostate cancer in men being the most dominant SPCs. This suggests that cancer screening programs for cancer survivors need to focus more on these cancer types. For example, low-dose computed tomography over chest x-ray for lung cancer screening [33] in both sexes and prostate ultrasonography in addition to prostate-specific antigen tests for male cancer survivors may be worthy of consideration. Furthermore, the risk of SPCs varied by the types of FPC and sex, with young cancer survivors being more vulnerable to developing SPCs. These findings highlight the need for tailored cancer screening programs for this population. Based on these results, there is a need to develop cancer type-, age-, and sex-specific national screening programs for cancer survivors. Further studies are necessary to assess the benefits of new evidence-based tailored screening programs for this population.

An interesting association was observed in male breast cancer survivors, as they had a higher risk of developing prostate cancer as an SPC. The positive association has been reported in male patients [34,35], and 2 hypotheses have been proposed to explain it [36]. The first hypothesis is that 4% to 40% of male breast cancer patients harbor a BRCA2 germline mutation [37,38]. Since BRCA1/2 mutations are associated with both breast and prostate cancers, the increased risk of prostate cancer in male breast cancer survivors could be due to their germline susceptibility [39,40]. The second hypothesis is that most male breast cancers are estrogen receptor–positive, which makes them good candidates for hormone treatment with aromatase inhibitors [35,41]. The suppression of estrogen could cause an imbalance of estrogen and testosterone, which hypothetically increases the risk of prostate cancer [42]. This association highlights the need for germline testing and careful prostate cancer screening in male breast cancer survivors.

**Limitations**

Although this study provides novel findings on the risk of SPCs in Korean cancer survivors, several limitations need to be acknowledged. Factors such as latency, family cancer history, clinicopathologic and sociodemographic factors, and treatments for FPCs, including chemoradiation therapy, could also influence the risk of SPCs [43]. The results showed strong positive associations among non-Hodgkin lymphoma, Hodgkin lymphoma, and leukemia, which may be due to the effect of chemotherapy [44]. However, due to the unavailability of relevant data, this study did not examine their effects. Additionally, the lack of information on other known risk factors such as smoking, alcohol consumption, diet, physical activity level, excess body weight, environmental carcinogens, and cancer-associated infection status such as human papilloma virus infection, is a limitation. The incidence of SPCs at the same organ as the FPC could be underestimated as they were excluded to minimize bias due to misidentification of FPC recurrence. Furthermore, the incidence of SPCs could be underestimated in cancer survivors with FPC types associated with high mortality, such as pancreatic and lung cancers, as deceased patients within 5 years after the FPC diagnosis were not included. Heightened medical surveillance following the FPC diagnosis may have increased the chance of detecting SPCs, particularly in cases where the sites of the FPC and SPC were anatomically close (eg, thyroid and head and neck or breast and lung cancers). However, to minimize this bias, SPCs occurring within 5 years of the FPC diagnosis were excluded, as ICBP covers the medical cost for only 5 years. Some of the significant associations could be biased by multiple testing, and the statistical power was also limited, especially for the subgroup analysis in young patients with FPCs due to the small sample size. Finally, some minor malignancies that could have been related to genetic susceptibility, such as pheochromocytoma and paraganglioma syndrome [45], were excluded from the
analysis as they were classified as other cancers (other C00-96). The American Cancer Society defines cancer survivors as “anyone who has ever been diagnosed with cancer no matter where they are in the course of their disease” [46], whereas we focused on 5-year cancer survivors in this study.

**Comparison With Prior Work**

The results of this study differ significantly from those of a previous study that used SEER data [4]. In that study, the risks of SPCs in survivors of adult-onset cancers were higher in several types of primary cancer compared with the general population in the United States. Several factors could explain this difference. First, the same group conducted another study that focused on adolescent and young adult (AYA; aged 15-39 years) cancer survivors using SEER data [47], and the risk of SPCs was generally higher in AYA than in adult cancer survivors (Table S6 in Multimedia Appendix 1). Second, although the SEER study covered 9% to 13% of the US population [4], HIRA covers nearly the entire Korean population. Third, only 8.1% of the population in the SEER study Asian or Pacific Islander descent, while nearly all Koreans are Asian. Fourth, the incidences of cancer and frequent cancer types differ between Korea and the United States (Table S7 in Multimedia Appendix 1) [48]. Fifth, the mean follow-up durations were 7.3 years in the SEER study and 3.8 years in our study, and the shorter follow-up duration in this study might have led to an underestimation of the risk of developing SPCs. Last, cancer screening rates vary by cancer type and nation [49,50].

**Conclusion**

The varying risk of SPCs by age, sex, and the type of FPC in cancer survivors suggests the necessity for ongoing efforts to develop tailored prevention and screening programs for cancer survivors. Lifestyle modifications, including smoking cessation, are essential to reduce the risk of SPCs in cancer survivors. In addition, genetic testing, along with proactive cancer screening and prevention strategies, should be implemented for young cancer survivors because of their elevated risk of developing SPCs.

Abstract

Background: The metabolic score for insulin resistance (METS-IR) has emerged as a noninsulin-based index for the approximation of insulin resistance (IR), yet longitudinal evidence supporting the utility of METS-IR in the primary prevention of type 2 diabetes mellitus (T2DM) remains limited.

Objective: We aimed to investigate the longitudinal association between METS-IR, which combines fasting plasma glucose (FPG), lipid profiles, and anthropometrics that can be routinely obtained in resource-limited primary care settings, and the incidence of new-onset T2DM.

Methods: We conducted a closed-cohort analysis of a nationwide, prospective cohort of 7583 Chinese middle-aged and older adults who were free of T2DM at baseline, sampled from 28 out of 31 provinces in China. We examined the characteristics of participants stratified by elevated blood pressure (BP) at baseline and new-onset T2DM at follow-up. We performed Cox proportional hazard regression analysis to explore associations of baseline METS-IR with incident T2DM in participants overall and in participants stratified by baseline BP. We also applied net reclassification improvement and integrated discrimination improvement to examine the incremental value of METS-IR.

Results: During a mean follow-up period of 6.3 years, T2DM occurred in 527 participants, among which two-thirds (332/527, 62.9%; 95% CI 58.7%-67.1%) had baseline FPG<110 mg/dL. A SD unit increase in baseline METS-IR was associated with the first incidence of T2DM (adjusted hazard ratio [aHR] 1.33, 95% CI 1.22-1.45; P<.001) in all participants. We obtained similar results in participants with normal baseline BP (aHR 1.41, 95% CI 1.22-1.62; P<.001) and elevated baseline BP (aHR 1.29, 95% CI 1.16-1.44; P<.001). The predictive capability for incident T2DM was improved by adding METS-IR to FPG. In study participants with new-onset T2DM whose baseline FPG was <126 mg/dL and <110 mg/dL, 62.9% (332/527; 95% CI 60%-65.9%) and 58.1% (193/332; 95% CI 54.3%-61.9%) of participants had baseline METS-IR above the cutoff values, respectively.
Conclusions: METS-IR was significantly associated with new-onset T2DM, regardless of baseline BP level. Regular monitoring of METS-IR on top of routine blood glucose in clinical practice may add to the ability to enhance the early identification of primary care populations at risk for T2DM.

KEYWORDS
metabolic score for insulin resistance; type 2 diabetes mellitus; blood pressure; longitudinal study; primary care

Introduction

Type 2 diabetes mellitus (T2DM) exerts a profound impact on the health and well-being of individuals, families, and communities worldwide because of its high prevalence, concomitant increase in risks of complications and treatment costs, and reduced quality of life [1-4]. Data from the European Association for the Study of Diabetes, the American Diabetes Association, and the International Diabetes Federation consistently indicate a rising epidemic of T2DM regionally and globally [5,6]. In low- and middle-income countries, the rapid progress of urbanization, aging, lifestyle transformations, and a lack of sustainable health education have further posed significant challenges to the prevention of T2DM [6-8]. Moreover, patients at older ages with poor glycemic control may suffer from progressive pathological as well as functional decline [9]. Evidence suggests that the progression of T2DM and its complications can largely be delayed through population-based early preventive public health programs [10,11].

Insulin resistance (IR) is a common feature of prediabetes and prehypertension and also a precursor to the development of both conditions [12]. Recommendations stress that the initiation of intervention during the stage of IR, instead of after a T2DM diagnosis, is more effective in reducing treatment burden and overall health care costs [13]. The hyperinsulinemic-euglycemic clamp (HEC) has been widely considered the “gold standard” experimental method for direct determination of IR, although less popular in daily practice due to its invasiveness, expensiveness, and complex procedures [14]. The homeostatic model assessment for IR and the quantitative insulin sensitivity check index, which are both fasting insulin-based indexes [15], are also less commonly performed as part of regular checkups in low- and middle-income countries’ primary care settings.

The metabolic score for insulin resistance (METS-IR), a novel index that considers fasting plasma glucose (FPG), lipid profiles, and obesity index that can be easily obtained during routine examination, has been proposed as a simple and high-accuracy measure to assess IR in the western population [14]. Evaluation of METS-IR may reduce the cost associated with the immunoassay of insulin and the heterogeneity between different analytical methods [14,16]. The hypothesis that METS-IR is predictive of new-onset T2DM over time needs further testing in the Chinese middle-aged and older adult population, which accounts for 42.2% of the total population [17]. From a multimorbidity perspective, whether the association between METS-IR and first-incident T2DM is persistent among participants whose blood pressure (BP) falls within the normal range also remains uncertain.

We aimed to investigate the association between METS-IR at baseline and the incidence of new-onset T2DM at follow-up in a middle-aged and older adult population. We also sought to examine whether the predictive capability of METS-IR on top of routine blood glucose for incident T2DM differed between participants with and those without elevated baseline BP.

Methods

Study Design

We conducted a cohort analysis of nationally representative survey data retrieved from the China Health and Retirement Longitudinal Study between 2011 and 2018, run by Peking University in partnership with the National Natural Science Foundation of China, the National Institute on Aging, and the World Bank. The data collected during the study period are made available in the public domain. The China Health and Retirement Longitudinal Study was originally designed after the US Health and Retirement Study and other internationally developed aging-related surveys to collect high-quality data on various aspects of health and social care for middle-aged and older adults in China [18-21].

Setting and Data Source

The nationwide baseline survey commenced in 2011 (wave 1). Follow-up surveys were repeatedly conducted in 2013 (wave 2), 2015 (wave 3), and 2018 (wave 4). The details of the sampling frame and household interview procedures were described elsewhere [18,19]. In brief, multistage, region-stratified, probability proportional to size sampling was adopted for sample selection from 150 county-level districts in 28 out of a total of 31 provinces across China. The baseline participants were drawn from over 10 thousand households in 450 neighborhood- and village-level units. Information on the individual’s sociodemographics, lifestyles, and health status was collected through face-to-face computer-assisted interviews in each wave. Data on anthropometric and clinical parameters were obtained by physical examinations, including blood drawing, for subsequent laboratory tests in waves 1 and 3 [19-21].

Participants

A total of 17,708 participants were enrolled at baseline, of whom 17,314 were aged 45 years and older. We excluded individuals who had any of the following: (1) a clinical diagnosis of T2DM, FPG≥126 mg/dL (7 mmol/L), or glycated hemoglobin A1c (HbA1c) ≥6.5% (n=2414); (2) missing information on the diagnosis of T2DM (n=130); (3) unknown BP levels (n=2490); (4) incomplete data on BMI, FPG, triglycerides, and high-density lipoprotein cholesterol (HDLC) to calculate
baseline METS-IR (n=4454); and (5) nonattendance at any of the follow-ups (n=243). This yielded a total of 7583 participants who met the eligibility criteria and were included in the closed-cohort analysis (Figure S1 in Multimedia Appendix 1).

**Study Variables and Measurements**

Information on age, sex, place of residence, education level, household income, and living relationships was collected by centrally trained interviewers with an internationally comparable, validated survey instrument [19]. Self-reported lifestyles included current cigarette smoking and engagement in alcohol drinking at least once per month regularly. Anthropometric parameters were measured with participants in light clothing and without shoes, using a portable stadiometer (Seca 213 stadiometer [Seca Trading]) and a calibrated digital scale (Omron HN-286 scale [Krell Precision]) [19]. BMI was calculated as weight in kilograms divided by the square of height in meters (kg/m²). The BP of the arm with a higher value was measured in a seated position using a routinely validated automatic BP monitor (Omron HEM-7112/7200 monitor [Omron]), and the average of 3 BP readings taken at 45-second intervals was recorded [19]. A venous blood sample at fasting was collected for blood-based bioassays according to standard operating procedures [20,21]. The Hexokinase method was used for FPG measurement (mg/dL), while lipid panel profiles including total cholesterol (mg/dL) and triglycerides (mg/dL) were measured using the Oxidase method, and low-density lipoprotein cholesterol (mg/dL) and HDL-C (mg/dL) were determined using the direct method [21]. Glucose and lipid parameters, together with BMI, were taken into account in the assessment of METS-IR, which was calculated as: Ln((2xFPG)+triglyceride)×BMI/Ln(HDL-C) [14]. Elevated BP at baseline was defined as systolic BP≥120 mm Hg or diastolic BP≥80 mm Hg (or both) or the presence of physician-diagnosed hypertension [22]. This included both hypertension and high normal BP. The primary outcome of this study was the first incidence of physician-diagnosed T2DM during follow-up, which was double-verified using the information documented in the previous follow-up wave. Participants enrolled at baseline were followed until they had newly diagnosed T2DM or the recorded attendance at the most recent wave of follow-up, whichever came first.

**Statistical Analysis**

Data are presented as n (%) values for categorical variables and as mean (SD) or median (IQR; 25th to 75th percentiles) values where appropriate for continuous variables. We examined the characteristics of participants stratified by the presence of elevated BP at baseline and new-onset T2DM at follow-up. The 2-tailed 2-sample t test, the nonparametric Wilcoxon rank sum test, or the chi-square test, where appropriate, was used for between-group comparisons in participants with and those without new-onset T2DM. Participants were further divided into quartiles of METS-IR, where the lowest quartile was used as the reference group. The cumulative hazard of T2DM was determined by the Kaplan-Meier plot, and the 2-sided logrank test was used for the overall comparison of curves across METS-IR quartiles. Cox proportional hazard regression models were constructed to estimate the risk of new-onset T2DM in participants overall and in participants stratified by baseline BP after adjusting for known important covariates, including demographics, socioeconomic status, lifestyles, and anthropometric measurements. The proportional hazards assumption for model fit was tested using the scaled Schoenfeld residuals. The adjusted hazard ratios (aHR) with a 95% CI were estimated for a unit increase in METS-IR per SD and for each METS-IR quartile. We further modeled the data as restricted cubic splines with 4 knots, located at the 5th, 35th, 65th, and 95th percentiles following the Akaike information criterion [23], of METS-IR to assess the shape of the association between METS-IR and the risk of T2DM. All models were adjusted for confounders included in the Cox models.

We also assessed the predictive capability of baseline METS-IR for new-onset T2DM. We applied net reclassification improvement and integrated discrimination improvement [24] to examine whether adding METS-IR to FPG may have incremental value in improving the predictive accuracy for T2DM. Furthermore, the optimal cutoff points with the highest Youden index were derived from the receiver operating characteristic (ROC) analysis. We calculated the proportion of people with new-onset T2DM who had baseline METS-IR above the corresponding cutoff value in all participants and in the subgroup without baseline impaired fasting glucose (ie, FPG<110 mg/dL [25]).

A series of sensitivity analyses were performed to ensure the reliability of the results. We repeated the aforementioned Cox models fitted in the main analysis under 3 different scenarios. First, participants who had an incident of T2DM at the first follow-up visit were excluded to account for possible reverse causality bias. Second, participants with the presence of general obesity (ie, BMI ≥28 kg/m² according to the Working Group on Obesity in China [26]) at baseline were excluded given the strong association between obesity and incident diabetes. Third, we used laboratory test results of FPG and HbA1c, where available, to supplement the information on the occurrence of T2DM (ie, FPG≥126 mg/dL [7 mmol/L] or HbA1c≥6.5%) to ascertain whether associations between METS-IR and T2DM may vary from the main analysis. We also treated age, socioeconomic status, lifestyles, and anthropometric measurements as time-dependent variables in the Cox models built in the main analysis to take into account the potential time-varying effects of covariates. In addition, the demographic characteristics of participants included in the analysis were compared with those of participants excluded due to missing values to understand the potential selection bias and its impact on the generalizability of the findings. Analyses were conducted using SAS (version 9.4; SAS Institute Inc) and R (version 4.0.2; R Core Team). A 2-tailed P value of less than .05 was considered statistically significant.

**Ethical Considerations**

All study participants provided written consent at enrolment. Data are publicly archived by Peking University, where ethics approval was obtained (IRB00001052-11014 and IRB00001052-11015). The ethics of the present analysis were sought from the Biomedical Research Ethics Review Committee at Sun Yat-Sen University (SPH2019123). Data anonymization...
was performed by removing all participant identifiers before data analysis.

Results

Study Population and Baseline Characteristics

Data were analyzed among a total of 7583 participants free of T2DM at baseline (Figure S1 in Multimedia Appendix 1). Participants ranged in age between 45 and 96 years, with a mean age of 59.1 (SD 9.3) years, sampled from 28 out of 31 provinces. Around one-third (2502/7583) of participants had a BP<120/80 mm Hg at baseline. T2DM occurred in 527 participants (ie, 214 male participants and 313 female participants) over a mean of 6.3 years of follow-up, among which nearly two-thirds (332/527, 62.9%; 95% CI 58.7%-67.1%) had baseline FPG<110 mg/dL (6.1 mmol/L). The baseline METS-IR of participants who had T2DM at follow-up was significantly higher than that of nonincident T2DM counterparts (36.1, SD 8.4 vs 32.6, SD 6.6; P<.001 among those with normal baseline BP and 38.9, SD 8 vs 35.3, SD 7.8; P<.001 among those with elevated baseline BP; Table 1). In participants with normal baseline BP, those who developed T2DM had significantly higher levels of BMI, waist circumference, FPG, and triglyceride but lower HDL-C at baseline when compared to those free of new-onset T2DM. A similar pattern was observed in participants with elevated baseline BP (Table S1 in Multimedia Appendix 1). Relative to participants who were excluded due to missing information (METS-IR, BP, FPG, and lost to follow-up), this study sample had a greater proportion of female participants (4051/7583, 53.4% vs 3572/7317, 48.8%), rural residents (5029/7583, 66.3% vs 3948/7317, 54%), those with lower education level (5325/7583, 70.2% vs 4558/7317, 62.5%), and current smokers (2317/7583, 30.7% vs 1908/7317, 28.7%), despite similar mean age (59.1 vs 59.2 years; P=.84) and alcohol drinking profile (2522/7583, 33.3% vs 2478/7317, 34.4%; P=.15; Table S2 in Multimedia Appendix 1).

The 2-sample t test or the chi-square test, where appropriate, was used for between-group comparisons among participants with and those without new-onset T2DM (ie, T2DM at follow-up vs non-T2DM at follow-up). Normal BP was defined as systolic BP<120 mm Hg and diastolic BP<80 mm Hg. Elevated BP was defined as systolic BP≥120 mm Hg or diastolic BP≥80 mm Hg (or both) or the presence of physician-diagnosed hypertension according to the 2018 Chinese Guidelines for the Management of Hypertension.

eMETS-IR: metabolic score for insulin resistance.

The First Incidence of Physician-Diagnosed T2DM at Follow-Up

The incidence of new-onset T2DM was reached at a rate of 11 per 1000 person-years of follow-up in overall participants (ie, 7.2 and 13 per 1000 person-years for participants with normal baseline BP and elevated baseline BP, respectively; Table 2). The highest cumulative hazard of T2DM was observed at 7 years in participants with the highest quartile of baseline METS-IR (13.3%) when compared to that in those with the lowest quartile (4.1%), with a difference of 9.2 percentage points (95% CI 7.4-11; Figure 1).

<sup>a</sup>per 1000 person-years.

<sup>b</sup>HR: hazard ratio.

<sup>c</sup>aHR: adjusted hazard ratio.

<sup>d</sup>Not applicable.
Normal BP at baseline was defined as systolic BP<120 mm Hg and diastolic BP<80 mm Hg. Elevated BP at baseline was defined as systolic BP≥120 mm Hg or diastolic BP≥80 mm Hg (or both) or the presence of physician-diagnosed hypertension according to the 2018 Chinese Guidelines for the Management of Hypertension. Cox proportional hazard model adjusted for age, sex, place of residence, education level, annual household income, living relationships, cigarette smoking, alcohol drinking, BP, and waist circumference. Tests for trend are based on variables containing the median value for each quartile.

**Associations Between Baseline METS-IR and First Incident T2DM**

An SD unit increase in baseline METS-IR was associated with the first incidence of T2DM (aHR 1.32, 95% CI 1.22-1.45; \(P<.001\)) in all participants. The adjusted risk of new-onset T2DM in participants with the highest quartile of baseline METS-IR was 2.72-fold higher than that in those with the lowest quartile of METS-IR. Similar trends were obtained from both crude and adjusted models, irrespective of baseline BP levels (Table 2). The 4-knot curve demonstrated a nonlinear association between baseline METS-IR and new-onset T2DM in participants overall and in participants with elevated baseline BP (Figure 2). The same models were repeated in the sensitivity analyses with consistent results (Tables S3-S6 in Multimedia Appendix 1).
Figure 2. Restricted cubic spline estimates of the relationship between the metabolic score for insulin resistance (METS-IR) and new-onset type 2 diabetes mellitus (T2DM). BP: blood pressure; HR: hazard ratio.

Restricted cubic splines with 4 knots, located at the 5th, 35th, 65th, and 95th percentiles of METS-IR for (A) all participants, (B) participants with normal BP, and (C) participants with elevated BP. The solid black line represents the fitted curve, and the gray bands represent the 95% CI bands. The model was adjusted for age, sex, place of residence, education level, annual household income, marital relationship, cigarette smoking, alcohol drinking, BP, and waist circumference. Normal BP was defined as systolic BP<120 mm Hg and diastolic BP<80 mm Hg. Elevated BP was defined as systolic BP≥120 mm Hg or diastolic BP≥80 mm Hg (or both) or the presence of physician-diagnosed hypertension according to the 2018 Chinese Guidelines for the Management of Hypertension.

The Predictive Capability of Baseline METS-IR for New-Onset T2DM

The ROC curves based on the predicted probabilities for incident T2DM showed that the area under the curve ranged from 0.633 to 0.708 across all models. Both net reclassification improvement and integrated discrimination improvement for predicting new-onset T2DM increased by adding METS-IR to FPG, irrespective of baseline elevated BP (Table S7 in Multimedia Appendix 1). In all participants with new-onset T2DM whose baseline BP levels were <126 mg/dL (7 mmol/L) and <110 mg/dL (6.1 mmol/L), 62.9% (332/527; 95% CI 60%-65.9%) and 58.1% (193/332; 95% CI 54.3%-61.9%) had baseline METS-IR above cutoff values (ie, ≥35.3 for all participants, ≥31.7 for participants with normal BP, and ≥35.5 for participants with elevated BP), respectively. The proportion of participants with baseline METS-IR above the corresponding cutoff values was similar between participants with and those without elevated baseline BP (Figure 3).

Figure 3. Proportion of participants with new-onset type 2 diabetes mellitus (T2DM) at follow-up by blood pressure (BP) at baseline. FPG: fasting plasma glucose.
Discussion

Main Findings

We provided longitudinal evidence supporting the potential utility of METS-IR in the prediction of T2DM in a large, nationally representative sample of the Chinese middle-aged and older adult population. We demonstrated significant associations between increased baseline METS-IR and a higher incidence of T2DM, regardless of the presence of baseline elevated BP. The predictive capability for incident T2DM was improved by adding METS-IR to FPG. In participants with incident T2DM whose baseline FPG fell within the normal range, around two-thirds had baseline METS-IR above the cutoff values, implying that the use of METS-IR on top of routine blood glucose in clinical practice may add additional value to early identification of populations at risk for T2DM.

Relationship With Other Studies

The role that METS-IR plays as a complement to previously validated risk prediction models is an emerging area of research interest. As a novel noninsulin-based index for estimating insulin sensitivity, METS-IR combines fasting laboratory values and anthropometric measurements that are routinely available in primary care instead of relying on insulin-based measurements that are laborious, expensive, and of high variability due to different immunoassay techniques [16]. Recent evidence indicates a satisfactory validity of METS-IR against the adjusted whole-body glucose disposal rate (ie, M value) derived from the “gold standard” HEC and the reliability of METS-IR when compared to both fasting insulin-based indexes (eg, homeostatic model assessment for IR and quantitative insulin sensitivity check index) and noninsulin-based indexes (eg, triglyceride-glucose index, triglyceride-glucose-BMI index, and triglyceride/HDL-C ratio) for predicting T2DM in a Mexican outpatient cohort [14]. The relationship between METS-IR and the occurrence of T2DM observed in the Latin-American population was similarly documented in subsequent studies among nonobese adults recruited in the Japanese NAFld in the Gifu Area, Longitudinal Analysis cohort [27,28] and among rural adults in Henan, northern China [29]. Further to our previous cross-sectional investigation in an urbanized township in southern China [30], we extended the analysis by using a large cohort of middle-aged and older adults that are nationally representative, while taking into account the urban-rural heterogeneity in lifestyles, income, and education profiles, as well as health care disparities that are prevailing in developing countries [31]. We found a consistent relationship between increased baseline METS-IR and risks for new-onset T2DM, irrespective of BP levels, stressing that normotensive people should not be neglected in diabetes prevention.

The potential association between METS-IR and incident T2DM may have several mechanisms. METS-IR was found to be significantly correlated with visceral, intrahepatic, and intrapancreatic fat content that may contribute to pathophysiological alterations of glucose and lipid homeostasis [14,32-35]. This may translate into chronically elevated levels of glucose and fatty acids, thereby inducing toxic states in pancreatic islets and progressive worsening of beta-cell function due to glucotoxicity, lipotoxicity, and glucolipotoxicity [36]. In addition to plasma triglyceride and HDL-C that are related to insulin-mediated glucose disposal, the inclusion of BMI as a surrogate for visceral adiposity takes into account the causal relationship between adipose tissue inflammation and the development of IR and ultimately T2DM [37-39]. The nonlinear relationship we observed between baseline METS-IR and new-onset T2DM might be partly explained by the multifactorial interactions among adiposity, dysglycemia, and inflammation in metabolic pathways and vascular biologic processes [13,39-42]. Our findings echo previous literature on the nonlinear relationship between FPG and T2DM in the European population [43]. Given that splines were constructed from piecewise polynomials, the shape of the restricted cubic splines curve could be largely influenced by the location and number of knots. It is also worth noting that the cutoff values derived from the ROC analysis should not be interpreted as a rigid diagnostic threshold but rather as a reference level above which regular monitoring of METS-IR would probably yield additional value in targeted interventions despite normal blood glucose and therefore may be meaningful for risk assessment and risk communication in diabetes prevention. The use of METS-IR has also been extended to T2DM-related cardiovascular conditions in Mexican and South Korean populations [44,45], indicating the potential for wider applicability in community-based practice where a valid, easy-to-measure, and less resource-consuming prediction tool is preferable.

Strengths and Weaknesses of the Study

We examined the longitudinal relationships of baseline METS-IR and first incident T2DM in a large, nationally representative sample while evaluating potential nonlinear associations. The analyses were systematically performed using METS-IR as a continuous variable and in quartiles, with a consistent methodology adopted to deal with confounding and reverse causality. A fairly extensive range of sensitivity analyses made little difference in the estimated associations between baseline METS-IR and new-onset T2DM. A particular strength was that the size of the study allowed us to retain power while stratifying participants by the presence of baseline elevated BP and thus considering the challenge of addressing the most common modality of multimorbidity encountered in the real-world clinical setting. This study has some possible limitations that merit consideration. First, the Cox models were built on a specific cohort of population samples who were middle-aged and older adults, and thus the generalizability of our findings to a wider population, or patients in certain health care settings, should be interpreted with caution. Selection bias may occur as nearly half of participants from the source cohort were not included in the present analysis given the eligibility criteria, although comparable in population mean age and drinking profile. Second, the HEC was not available for direct assessment of insulin sensitivity due to time and budget constraints, which may inevitably affect the accuracy of the assessment. However, complex and expensive procedures for
determining insulin levels may limit implementation feasibility in large-scale studies in low-resource settings. Third, undiagnosed diabetes at baseline might have led to an underestimation of hazard ratios for new-onset T2DM. Fourth, we were not able to take account of the unmeasured confounders such as dietary regimes [46], body constitutions [47], environmental exposures, and health care usage that may exert cohort effects. We also acknowledge that time-varying confounding is impossible to fully overcome given that past exposures were not adequately captured. Fifth, we cannot rule out the possibility of random measurement errors in a large-scale multisite study, albeit with a standardized procedure for data collection. Last but not least, the blood drawing was voluntary and not performed in waves 2 and 4, and thus we were unable to cross-check the incidence of physician-diagnosed T2DM based on FPG and HbA1c. Nevertheless, the supplement use of biomedical records where available at follow-up in the sensitivity analyses yielded consistent results, suggesting the robustness of our findings.

**Implications for Research and Clinical Practice**

This study carries a clinically meaningful message for primary care physicians with a potentially greater opportunity for recognition of middle-aged and older adults early in the course of their diabetes. Physicians working in collaboration with other health care professionals can help those at-risk individuals enhance their capacity to optimize blood glucose, BP, BMI, and lipid profiles through health education paired with effective strategies such as lifestyle coaching and skill building. This is in line with recent recommendations from the United States and Europe, advocating that early and sustainable preventative efforts could spare the expense of managing T2DM and its long-term complications [48,49]. Middle-aged and older adults whose blood glucose falls within the normal range but have a higher METS-IR might remain at risk for T2DM and thus should still be monitored for disease occurrence through regular follow-up along with individualized risk assessment. This also provides an impetus for future studies to explore whether the biological underpinnings of METS-IR-T2DM may vary among individuals with different phenotypes of visceral obesity and genetic predispositions. The age of 45 years was used as a cutoff for middle age, which is in line with the eligibility criteria widely adopted in other large-scale population-based cohort studies such as the Healthy, Aging, and Retirement in Thailand Study [50], the Swedish EpiHealth Study [51], and the Canadian Longitudinal Study on Aging [52]. The Rotterdam Study, which was originally comprised of participants aged 45 years or older, has expanded the cohort that targeted participants aged 40 years or older since 2016 [53]. This echoes the shift toward earlier onset of T2DM [54,55], and thus future pragmatic trials to evaluate the use of METS-IR may be extended to the younger population. Alongside the ongoing efforts to translate team-based care into practice on a global scale [56], further steps to integrate the monitoring of METS-IR, rather than blood glucose alone, into the existing approach to diabetes prevention are especially promising. This would help inform broad public health policy and community-oriented preventive strategies that include early identification of individuals at risk of T2DM through innovative surveillance tools based on readily available routine physical examination indicators.

In conclusion, METS-IR was significantly associated with new-onset T2DM, regardless of baseline BP level. Regular monitoring of METS-IR on top of routine blood glucose in resource-limited settings may add to the ability to enhance early recognition and appropriate management of individuals at risk for T2DM in primary care.

**Acknowledgments**

We wish to acknowledge the tremendous support from the National School of Development at Peking University to ensure high-quality data collection. We also thank the Behavioral and Social Research Division of the National Institute on Aging of the National Institute of Health, the Natural Science Foundation of China, and the World Bank for their strong support of the original study. Abstract

Background: The COVID-19 pandemic has profoundly affected out-of-hospital cardiac arrest (OHCA) and disrupted the chain of survival. Even after the end of the pandemic, the risk of new variants and surges persists. Analyzing the characteristics of OHCA during the pandemic is important to prepare for the next pandemic and to avoid repeated negative outcomes. However, previous studies have yielded somewhat varied results, depending on the health care system or the specific characteristics of social structures.

Objective: We aimed to investigate and compare the incidence, outcomes, and characteristics of OHCA during the prepandemic and pandemic periods using data from a nationwide multicenter OHCA registry.

Methods: We conducted a multicenter, retrospective, observational study using data from the Korean Cardiac Arrest Resuscitation Consortium (KoCARC) registry. This study included adult patients with OHCA in South Korea across 3 distinct 1-year periods: the prepandemic period (from January to December 2019), early phase pandemic period (from July 2020 to June 2021), and late phase pandemic period (from July 2021 to June 2022). We extracted and contrasted the characteristics of patients with OHCA, prehospital time factors, and outcomes for the patients across these 3 periods. The primary outcomes were survival to hospital admission and survival to hospital discharge. The secondary outcome was good neurological outcome.

Results: From the 3 designated periods, a total of 9031 adult patients with OHCA were eligible for analysis (prepandemic: n=2728; early pandemic: n=2954; and late pandemic: n=3349). Witnessed arrest (P<.001) and arrest at home or residence (P=.001) were significantly more frequent during the pandemic period than during the prepandemic period, and automated external defibrillator use by bystanders was lower in the early phase of the pandemic than during other periods. As the pandemic advanced, the rates of the first monitored shockable rhythm (P=.10) and prehospital endotracheal intubation (P<.001) decreased significantly. Time from cardiac arrest cognition to emergency department arrival increased sequentially (prepandemic: 33 min; early pandemic: 35 min; and late pandemic: 36 min; P<.001). Both survival and neurological outcomes worsened as the pandemic progressed, with survival to discharge showing the largest statistical difference (prepandemic: 385/2728, 14.1%; early pandemic: 355/2954, 12%; and late pandemic: 392/3349, 11.7%; P=.01). Additionally, none of the outcomes differed significantly between the early and late phase pandemic periods (all P>.05).

Conclusions: During the pandemic, especially amid community COVID-19 surges, the incidence of OHCA increased while survival rates and good neurological outcome at discharge decreased. Prehospital OHCA factors, which are directly related to
OHCA prognosis, were adversely affected by the pandemic. Ongoing discussions are needed to maintain the chain of survival in the event of a new pandemic.

**Trial Registration:** ClinicalTrials.gov NCT03222999; https://classic.clinicaltrials.gov/ct2/show/NCT03222999

**Introduction**
At the end of December 2019, the outbreak of SARS-CoV-2 emerged in Wuhan, China, leading to the global pandemic of COVID-19 [1,2]. As of August 2023, more than 769 million confirmed cases and almost 7 million cumulative fatalities have been attributed to COVID-19 [3]. The emergence of SARS-CoV-2 variants and mutations has played a significant role in the pandemic’s persistence [4], and even after the end of the global pandemic, the risk of new variants and surges remains [5].

According to the current out-of-hospital cardiac arrest (OHCA) guidelines, the chain of survival (CoS) has been constantly emphasized to improve outcomes for patients with OHCA [6]. The OHCA CoS includes rapid recognition and activation of emergency response, early high-quality cardiopulmonary resuscitation (CPR) and defibrillation, and effective advanced life support interventions [6]. Each prehospital step experienced concurrent disruptions during the COVID-19 pandemic, resulting in a disruption of the OHCA CoS worldwide [7-9]. Notably, there was an increase in the incidence of OHCA, while rates of bystander CPR and automated external defibrillator (AED) use rate declined, especially during periods of heightened community transmission [10,11]. Additionally, a study using emergency medical services (EMS) data of South Korea reported that the proportion of prehospital return of spontaneous circulation (ROSC) decreased during the pandemic period [12].

During the pandemic era, outcomes of OHCA, including survival and neurological outcomes, deteriorated [9,10,13]. A previous meta-analysis reported that the ROSC rate, survival to hospital admission, and hospital discharge with good neurologic outcome (GNO) were significantly lower during the pandemic compared to the prepandemic period [10]. One recent registry-based cohort study reported that the survival rate was significantly decreased while the bystander CPR rate was stable [14]. Another study reported higher incidence of OHCA and decreased bystander CPR in regions with a high burden of pandemic [15]. A population-based nationwide study in Japan also reported that the pandemic is related to poorer neurologic outcomes and less AED use in patients with OHCA [16]. These poor outcomes could be closely related to changes in the prehospital phase during the pandemic, especially when considering the nature of OHCA.

Previous research has explored the impact of the COVID-19 pandemic on OHCA incidence, outcomes, and prehospital factors [10,17-19]. Analyzing the characteristics of OHCA during the pandemic is important to prepare for the next pandemic and to avoid repeated negative outcomes. However, previous studies have yielded somewhat varied results, depending on the health care system or the specific characteristics of social structures. Here, we aimed to investigate and compare the incidence, outcomes, and characteristics of OHCA between the prepandemic and pandemic periods, using data from a nationwide multicenter registry.

**Methods**
**Study Design**
We conducted a multicenter, retrospective, observational study using data from the Korean Cardiac Arrest Resuscitation Consortium (KoCARC) registry. This nationwide registry collates OHCA cases in South Korea in alignment with Utstein-style templates and involves a collaborative research network among multiple hospitals. The study included patients with OHCA who were transported to the emergency department (ED) by EMS and underwent resuscitation. Inclusion was limited to patients diagnosed with a medical cause identified by emergency physicians. Meanwhile, individuals with terminal illnesses, in hospice care, who are pregnant, or with a “Do Not Resuscitate” card were excluded. Patients with OHCA resulting from nonmedical causes, such as trauma, poisoning, burns, drowning, asphyxia, or hanging, were also excluded. Data were collected using a standardized registry form and uploaded to a web-based electronic database. The quality of the registry was monitored using a quality management committee to improve its reliability and integrity.

**Ethical Considerations**
The project was registered at ClinicalTrials.gov with the identifier NCT03222999 and received ethical approval from the institutional review boards of the 62 participating hospitals. Given the nature of this study, the requirement for informed consent was waived by the institutional review boards. All personal information of patients with OHCA enrolled in the registry was anonymized. There was no direct compensation for the included patients.

**Study Population**
This study included OHCA cases in South Korea registered in the KoCARC database in 3 distinct 1-year periods: the prepandemic period, early phase of the pandemic, and late phase of the pandemic. The KoCARC releases a year’s worth of data sets annually, with the period starting in July and ending in June of the following year. The prepandemic period was defined as...
the year leading up to the reporting of the first COVID-19 case (from January 1 to December 31, 2019). The early phase of the pandemic corresponds to the first data set released after the declaration of the pandemic (from July 1, 2020, to June 30, 2021). The late phase of the pandemic encompasses the most recent data set (from July 1, 2021, to June 30, 2022). Patients aged <18 years were excluded.

Data Extraction and Definition

Previously published literature has provided comprehensive details regarding the KoCARC database, including information on data elements and quality assurance [20]. We extracted the following data from the KoCARC database: (1) patient characteristics: age, sex, witnessed arrest, arrest location at home or residence, bystander response (CPR and AED), first monitored shockable rhythm, and prehospital management (defibrillation, adrenaline use, and advanced airway [supraglottic airway or endotracheal intubation]); and (2)prehospital time factors: cardiac arrest recognition to ED arrival, EMS call to EMS arrival, arrest place arrival to departure, arrest place departure to ED arrival, and cardiac arrest recognition toprehospital ROSC.

Outcome Variables

Primary outcomes were survival until hospital admission and survival to hospital discharge. We compared survival rates between the prepandemic period and the early and late pandemic periods and investigated the factors affecting survival rates. The secondary outcome was a good neurological outcome (GNO), which was defined as a Cerebral Performance Category (CPC) score of 1 or 2 at the time of hospital discharge. A CPC score of 1 denotes good cerebral performance, meaning patients are conscious, alert, and capable of functioning with only minor neurological or psychological deficits. A CPC score of 2 indicates moderate cerebral disability, with patients being conscious, possessing adequate cerebral function for independent daily activities, and having the ability to work in sheltered environments. A CPC score of 5 corresponds to mortality, specifically defined as death or brain death.

Statistical Analysis

This study used data from the KoCARC registry, which were meticulously compiled and organized using a spreadsheet application (Excel 365; Microsoft). Continuous baseline variables were presented as median and IQR, and their normal distribution was assessed using the Shapiro-Wilk test. In instances where the data deviated from the normality assumptions, the Kruskal-Wallis test was used to compare the groups and the Mann-Whitney U test was used for a post hoc test. Categorical variables were expressed as absolute counts and percentages and analyzed using the chi-square test. A significance threshold of \( P < .05 \) was adopted to establish statistical significance.

To ascertain the independent association between variables and neurological and survival outcomes, multivariate analysis was performed using logistic regression. Furthermore, to validate the calibration of the logistic model, the Hosmer-Lemeshow test was applied. The statistical software packages SPSS (version 27.0 for Windows; IBM) and MedCalc (version 17.2; MedCalc Software) were used to perform all statistical computations.

Results

From the 3 designated periods, a total of 9209 patients with OHCA were registered. After excluding patients aged <18 years, 9031 patients with OHCA were deemed eligible. The number of patients included in each period was as follows: 2728 in the prepandemic period, 2954 in the early phase of the pandemic, and 3349 in the late phase of the pandemic (Figures 1 and 2). There was a sequential increase in the incidence of OHCA at the participating hospitals throughout the pandemic.
The baseline and prehospital OHCA characteristics from the 3 periods, along with intergroup comparisons, are summarized in Table 1. Age was significantly higher in the late phase pandemic period compared to the prepandemic or early phase pandemic periods (prepandemic: 72 y; early pandemic: 72 y; and late pandemic: 73 y; \( P = .02 \)). However, there was no significant difference in the sex distribution across the periods \( (P = .55) \). Witnessed arrests \( (P < .001) \) and arrests at home or residence \( (P = .001) \) were significantly higher during the pandemic compared to the prepandemic period. Although bystander CPR was not statistically different among the 3 periods \( (P = .43) \), AED use by bystanders was lower in the early phase of the pandemic compared to the other periods. The rate of the first monitored shockable rhythm and prehospital defibrillation decreased sequentially throughout the study period. The prehospital endotracheal intubation rate significantly decreased as the pandemic progressed (prepandemic: 246/2728, 9%; early pandemic: 154/2954, 5.2%; and late pandemic: 116/3349, 3.5%; \( P < .001 \)), resulting in a significant increase in supraglottic airway use (prepandemic: 1685/2728, 61.9%; early pandemic: 2158/2954, 73.3%; and late pandemic: 2408/3349, 72.6%; \( P < .001 \)).

During the pandemic, pre–hospital phase time factors were extended compared to the prepandemic period. The time from cardiac arrest recognition to ED arrival increased sequentially (prepandemic: 33 min; early pandemic: 35 min; and late pandemic: 36 min; \( P < .001 \)). Other time-related factors also worsened during the pandemic, including EMS call to arrival, arrest place arrival to departure, and arrest place departure to ED arrival.

Primary and secondary outcomes are summarized in Table 2. As the pandemic progressed, both survival and neurological outcomes worsened. The survival-to-discharge rate exhibited the most pronounced statistical variation (prepandemic: 385/2728, 14.1%; early pandemic: 355/2954, 12%; and late pandemic: 392/3349, 11.7%; \( P = .01 \)). The survival-to–hospital admission rate was 24.3% (815/3349) in the late phase of the pandemic, which was significantly lower than that in the prepandemic period \( (P = .02) \). However, there was no statistically significant difference between the prepandemic and early phase pandemic periods \( (P = .08) \). Both the survival-to-discharge \( (P = .02 \) and \( P = .005 \), respectively) and GNO \( (both \ P = .03) \) rates were significantly lower in the early and late phase pandemic periods than in the prepandemic period. Additionally, none of the outcomes differed significantly between early and late phase pandemic periods \( (all \ P > .05) \).

- Prepandemic period: from January 2019 to December 2019.
- Early phase pandemic period: from July 2020 to June 2021.
- Late phase pandemic period: from July 2021 to June 2022.

Multivariate analyses of the factors related to survival and neurological outcomes were performed to adjust for confounders that could affect the primary outcome (Table 3). Significant independent effects on all outcomes were observed for age (P<.001), witnessed arrest (P<.001), arrest at home or residence (P<.001), first monitored shockable rhythm (P<.001), prehospital adrenaline use (P<.001 to P=.003), and supraglottic airway (P<.001). Cardiac arrest cognition at ED arrival significantly affected GNO after adjusting for confounders (adjusted odds ratio 1.001, 95% CI 1.000-1.002; P=.04). The difference in period (prepandemic, early phase, or late phase) did not independently affect any of the 3 outcomes.

Discussion

Principal Findings

In this study, we aimed to investigate changes in OHCA characteristics and outcomes during the SARS-CoV-2 pandemic using multicenter registry-based data. The incidence of OHCA increased, and neurologic and survival outcomes were worse during the pandemic era compared to the prepandemic era. Outcomes were particularly poor in the late phase when the number of SARS-CoV-2 infection cases spiked due to the spread of the Delta and Omicron variants [21].

During the pandemic, a significant increase in the global incidence of OHCA was observed compared to the prepandemic period. In cities such as New York, Detroit, and London, the number of OHCA cases increased proportionally with the number of COVID-19 cases during the initial surge [17-19]. In South Korea, the number of out-of-hospital sudden cardiac arrests increased by approximately 8%, from 60 per 100,000 population in 2019 (the year preceding the COVID-19) to 64.7 per 100,000 population in 2021 [22]. One meta-analysis that was reported early in the pandemic, which included 10 studies with a total of 35,000 participants published before October 2020, found that the incidence of OHCA increased by approximately 2.2 fold compared to the prepandemic period [10].

Globally, the outcomes of OHCA during the pandemic have consistently been reported to be less favorable than those observed before the pandemic [13]. For instance, in 2 regions of the United States, the survival-to-discharge rate decreased from 14.7% in 2019 to 7.9% in 2020 [23]. Meanwhile, in Singapore, while the incidence of OHCA increased during the pandemic, prehospital ROSC decreased [24]. In South Korea, the survival-to-discharge rate of OHCA, which had been steadily increasing for more than a decade before the pandemic, dropped from 8.7% in 2019 to 7.5% in 2020 and 7.3% in 2021. Moreover, the rate of brain function recovery at discharge reached 5.4% in 2019 but dropped to 4.9% in 2020 and 4.4% in 2021 [22]. In addition, a previous meta-analysis reported that the outcomes of OHCA were significantly poorer than before the pandemic in most of the included studies. The meta-analysis also showed a significant increase in mortality [10,25].

The characteristics of OHCA shifted during the pandemic periods in this study. Instances of witnessed OHCA and arrests at home or residence became more frequent in the pandemic era. This change has been observed in previous studies and can be attributed to the increased time spent at home during the pandemic due to quarantine and social distancing [10,26]. These results may also reflect the number of patients who progressed to OHCA due to being unable to visit a hospital in a timely manner as a result of reduced access to hospitals. Although bystander CPR decreased slightly during the pandemic, the difference was not statistically significant. This study also found that bystander use of AEDs decreased in the early phase of the pandemic but returned to prepandemic levels in the late phase of the pandemic. This is likely a reflection of bystander fears of COVID-19 transmission in the early phase of the pandemic [27]. A previous meta-analysis reported a decreased proportion of OHCAs with shockable rhythms during the pandemic [10,25]. In our research, the frequency of the first monitored shockable rhythm decreased progressively. The rise in respiratory arrests due to respiratory failure due to COVID-19 may have contributed to the diminished proportion of OHCA cases with shockable rhythms. Such cases would likely have a more unfavorable prognosis than OHCA cases of shockable rhythm with an etiology of cardiac origin [28]. Notably, the age demographic skewed older in the late phase of the pandemic, suggesting a possible increase in OHCA among older patients, who are more vulnerable to COVID-19.

Prehospital airway management has also been affected by the pandemic. An updated meta-analysis reported an increase in the use of both endotracheal intubation and supraglottic airway devices during the pandemic [25]. However, in this study, the supraglottic airway was favored, while endotracheal intubation progressively decreased during the pandemic. This is likely due to the EMS personnel’s fear of contracting COVID-19 during endotracheal intubation and the physical restrictions imposed by wearing protective clothing, face shields, and goggles. The summed rates of supraglottic airway and endotracheal intubation was higher than that before the pandemic, suggesting that more advanced resuscitation was performed in the prehospital setting.

Transport time, including the time from cardiac arrest diagnosis to ED arrival, significantly increased during the pandemic era. During the surge in patients with COVID-19, the lack of medical resources, poor access to hospitals, requirements for ambulance disinfection, and the need to wear protective equipment may have contributed to the increase in transportation time [29]. Difficulties in hospital selection led to prolonged, unnecessary prehospital treatment, and the frequency of adrenaline use increased during the pandemic. Further, prolonged transport time may have directly contributed to poorer outcomes in patients with OHCA during the pandemic. Furthermore, it emerged as an independent factor for poorer neurological outcomes in the multivariate analysis of this study. Such delays could compromise the continuity and quality of advanced life support from prehospital settings to hospitals, as underscored in the CoS, ultimately leading to suboptimal patient outcomes.

The prehospital factors consistently emphasized in the CoS, which play a key role in OHCA outcomes, were also heavily impacted by the pandemic. Maintaining a CoS in the event of future outbreaks and the emergence of new variants should be an ongoing discussion.

Limitations

This study has several limitations. First, depending on the country and region, the impact of the COVID pandemic on OHCA may vary. Our findings were derived using only patients with OHCA in South Korea, and there may be limits to extending the results globally. Second, although the KoCARC registry was prospectively collected using established protocols and methods, the aim to examine the impact of the pandemic on OHCA was not predetermined before the initiation of the registry. Third, we were unable to investigate whether SARS-CoV-2 infection was the direct cause of cardiac arrest in the enrolled patients with OHCA. However, the main contribution of this study was to investigate the impact of...
prehospital factors associated with the CoS during the pandemic. Forth, despite the comprehensive data collection employing Utstein-style templates within the registry, the potential remains for latent confounders to influence the results. Lastly, long-term prognoses were not included in this analysis due to the limited observation period.

Conclusions
The incidence of OHCA increased during the pandemic, while both the survival rate and GNO at discharge decreased, especially during community COVID-19 surges. Prehospital OHCA factors, which directly influence OHCA prognosis, were adversely affected by the pandemic. Ongoing discussions are needed to maintain the CoS in anticipation of future pandemics.

Abstract

Background: Few studies focus on the equality of pain, and the relationship between pain and death is inconclusive. Investigating the distribution of pain and potential mortality risks is crucial for ameliorating painful conditions and devising targeted intervention measures.

Objective: Our study aimed to investigate the association between inequalities in pain and all-cause mortality in China.

Methods: Longitudinal cohort data from waves 1 and 2 of the China Health and Retirement Longitudinal Study (2011-2013) were used in this study. Pain was self-reported at baseline, and death information was obtained from the 2013 follow-up survey. The concentration index and its decomposition were used to explain the inequality of pain, and the association between pain and death was analyzed with a Cox proportional risk model.

Results: A total of 16,747 participants were included, with an average age of 59.57 (SD 9.82) years. The prevalence of pain was 32.54% (8196/16,747). Among participants with pain, the main pain type was moderate pain (1973/5426, 36.36%), and the common pain locations were the waist (3232/16,747, 19.3%), legs (2476/16,747, 14.78%) and head (2250/16,747, 13.44%). We found that the prevalence of pain was concentrated in participants with low economic status (concentration index –0.066, 95% CI –0.078 to –0.054). Educational level (36.49%), location (36.87%), and economic status (25.05%) contributed significantly to the inequality of pain. In addition, Cox regression showed that pain was associated with an increased risk of all-cause mortality (hazard ratio 1.30, 95% CI 1.06-1.61).

Conclusions: The prevalence of pain in Chinese adults is concentrated among participants with low economic status, and pain increases the risk of all-cause death. Our results highlight the importance of socioeconomic factors in reducing deaths due to pain inequalities by implementing targeted interventions.

KEYWORDS
pain; equality; all-cause mortality; concentration index; decomposition

Introduction

Body pain is both a sensory and emotional experience linked to actual or potential tissue damage, incorporating physiological as well as emotional and psychological dimensions [1]. Pain is now recognized as an independent pathological condition, not merely a symptom of other diseases. The biopsychosocial framework for understanding pain emphasizes the complex and interactive relationships between biological, psychological, and social determinants. Pain creates a heavy burden of disease, with chronic pain being the predominant type [2]. According to data from the 2021 US National Health Interview Survey,
approximately 51.6 million US adults (20.9%) have chronic pain and 17.1 million (6.9%) experience high-impact chronic pain [3]. This scenario not only escalates the demand for health care resources and medical expenditures but also leads to diminished work efficiency and productivity loss, thereby exacerbating the economic burden. There is a significant correlation between pain and psychological health disorders, such as anxiety and depression, which further impacts the quality of life of patients [4]. Family members also experience additional pressures due to the caregiving responsibilities for individuals with pain. The management of pain, especially chronic pain, often involves the use of opioid medications, which increases the risk of drug dependency [5]. Notably, considering factors such as time, economic conditions, and pain perception, many middle-aged and older adults choose self-management strategies, including medication, acupuncture, and massage, to alleviate pain. Research also shows a significant rise in pain incidence in the last years of life, climbing from 26% to 46% [6].

The global trend of population aging is becoming increasingly significant. With advancing age, the issues of chronic musculoskeletal joint pain, neuropathic pain, vascular-related pain, and pain triggered by psychological factors are gradually intensifying. Research on the factors influencing pain and its treatment behavior in the older population in the northeast region of China indicates that the prevalence of physical pain is as high as 32.5% among people aged 60 years or older [7]. The Global Burden of Disease study also revealed that chronic pain ranks first among high-risk factors for nonlethal health impairments [8]. In the 2019 Global Burden of Disease study, it was further revealed that migraine ranks second among factors causing disabilities, and among women younger than 50 years, migraine becomes the leading cause of disability [9]. Each year, more than 10 million new cases of malignant tumors occur globally, with 30% to 60% of patients experiencing varying degrees of pain. In late-stage patients, the prevalence of pain can even reach up to 90%. Cancer pain, as one of the major complications of malignant tumors, not only greatly affects the quality of life of patients but also becomes one of the primary reasons for seeking medical attention. Healthy People 2030 emphasizes assisting individuals with high-impact chronic pain in managing their pain safely and reducing its effects [10]. Consequently, cancer pain control has been listed as one of the 4 key priorities in the World Health Organization’s cancer treatment planning [11].

Investigating the distribution of pain is crucial for ameliorating painful conditions and devising targeted intervention measures. Previous research has predominantly focused on the unequal distribution of pain across gender, race, and disease management. This is chiefly due to the understanding of pain as an issue intricately connected to fairness and justice, set against a societal framework marked by discrimination and structural violence [12]. However, there has been relatively scant attention given to studies investigating the distribution of pain among different socioeconomic status (SES) groups, especially in developing countries. Socioeconomic factors encompass indicators such as education, occupation, economic status, and social support. The association between socioeconomic factors and chronic diseases has been reported in numerous studies, linking lower SES to higher prevalence and severity of pain. However, results pertaining to the association between socioeconomic factors and pain are sometimes contradictory, potentially due to the variables chosen for SES, the methods used, and the procedures implemented. Macro data indicates that the prevalence of any type of pain in lower- and middle-income countries is twice that in high-income countries. Mortality rates may be influenced by pain, as evidenced by a cohort study and meta-analysis comprising over 500,000 research participants, which found that individuals with chronic widespread pain have a higher mortality rate [13]. On the other hand, some studies have arrived at opposite conclusions. A meta-analysis revealed only a moderate and nonsignificant association between chronic pain and all-cause mortality, with the degree of association being slightly stronger for widespread pain, though the combined estimate still remained nonsignificant [14].

Despite previous studies analyzing the relationship between pain and all-cause mortality, research focusing on the inequality of pain and its relation to all-cause mortality rates is scarce, particularly in developing countries. Moreover, even in large cohorts, results are not entirely consistent, necessitating further research. Therefore, we have used data from the China Health and Retirement Longitudinal Study (CHARLS) survey to quantify the association between pain in Chinese adults and all-cause mortality, and additionally, we have explored the unequal conditions of pain.

Methods

Data Sources and Study Population

The data used in this study came from CHARLS, which conducted a national baseline survey in 2011 and followed up in 2013, 2015, and 2018. The project conducted multistage sampling in 150 counties and 450 communities (villages) in 28 provinces (autonomous regions and municipalities directly under the central government), and conducted questionnaire surveys and face-to-face interviews with middle-aged and older individuals (aged ≥45 years) and their families, aiming to analyze the current situation of aging in China and promote high-quality research to solve problems related to aging. This study used baseline data from 2011 (wave 1), excluding participants with missing information on pain, economic status, and sociodemographic characteristics (n=469) and those aged <45 years (n=492); a total of 16,747 participants were included. Considering that data were available for interview status (ie, indicating that the participant was either alive or dead) and exact time of death in 2013 (wave 2), we used the 2013 data to account for all-cause deaths; a total of 394 all-cause deaths were followed. The screening flow chart is shown in Multimedia Appendix 1, Figure S1.

Pain, Economic Status, and All-Cause Mortality

Pain was the primary independent variable in this study. Pain was measured using a questionnaire that asked participants whether they had pain, as well as the severity and location of the pain. This study used the CHARLS 2011 question “Are you often troubled with any body pains?” to determine whether the
participants had pain problems and the question “How bad is your pain?” to determine the severity of pain. The response options included mild, moderate, and severe. Moreover, the study used the question “In what part of your body do you feel pain?” to determine the location of pain, including head, shoulders, arms, wrists, fingers, chest, stomach, back, waist, buttocks, legs, knees, ankles, toes, and neck. In the Constructed Expenditure, Income, and Wealth Database published by CHARLS in 2017, the indicator IM_PCE was used for economic status. All-cause death was the primary outcome of the study, and information on deaths came from the 2013 survey. There were no secondary outcome events, and follow-up was terminated when an outcome event occurred.

Covariates
We defined covariates using information collected from the baseline survey. The covariates and grouping in this study included age (45-60, 60-75, and ≥75 years), gender (male and female), education level (illiterate, primary school, secondary/high school, and university or above), marital status (never married; married; and separated, divorced, or widowed), smoking status (nonsmokers and current smokers), drinking status (never, occasionally, and regularly), BMI (<25 kg/m², 25-30 kg/m², and ≥30 kg/m²), and location (rural village or urban community). BMI was calculated by dividing weight in kilograms by the square of height in meters (kg/m²).

Statistical Analysis
This study describes the pain status and sociodemographic characteristics of the participants. Using CHARLS sampling weights (ind_weight_ad2), the data were extrapolated to estimate the percentage of Chinese adults aged ≥45 years experiencing pain. Continuous variables were represented as the mean and SD, and a 2-tailed t test was used for comparisons between groups. Categorical variables were represented as numbers and percentages, and comparisons between groups were performed using the χ² test. Logistic regression was used to describe the impact of sociodemographic characteristics on pain. Second, the concentration index was used to analyze the equality of pain, and the economic status indicator was per capita expenditure. The concentration index was defined as twice the area between the curve and the diagonal, ranging from –1 to 1. A positive concentration index value indicated that the disease distribution showed a trend to occur among groups with higher economic status, while a negative value indicated the opposite. The closer the concentration index was to 0, the more equal was the disease distribution [15]. Decomposition analysis was further used to describe the contribution of each factor to inequality. The reliability of using the concentration index and its decomposition to measure pain inequalities has been well established in previous studies [16]. Finally, a Cox proportional hazards regression model was used to explore the relationship between pain and all-cause death, and further stratified analysis was conducted based on sociodemographic characteristics. All reported P values were 2-sided, and statistical analyses were conducted with Stata (version 16.0; StataCorp).

The concentration index was calculated in detail as follows:

In the formula, R_i denotes the proportion of individuals ranked by SES, y_i denotes the prevalence of pain, and μ denotes the average prevalence of pain.

The decomposition method for the concentration index allowed decomposing the index into contributions from various influencing factors. The associated linear regression model is specified below:

In the formula, β_k denotes the regression coefficient. The concentration index was decomposed using the equation provided below:

In the formula, C_k, β_k, and indicate the concentration index, regression coefficient, and contribution, respectively.

Ethical Considerations
All practices involving human participants in this study were conducted in strict adherence to the principles of the Declaration of Helsinki. Ethical clearance for the initial CHARLS data collection was obtained from the Peking University Ethical Review Committee (IRB00001052-11015). Moreover, every participant in the CHARLS cohort willingly provided their written informed consent, ensuring ethical compliance and participant awareness. The present analysis received approval from the University of Macau’s research ethics subpanel committee (BSERE21-APP012-ICMS). All respondents signed informed consent forms, and the project was reviewed by the Institutional Review Board of Peking University.

Results
Pain Prevalence and Sociodemographic Characteristics of the Participants
A total of 16,747 participants were included in the study, with an average age of 59.57 (SD 9.82) years, of whom 48.94% (8,196/16,747) were male. A total of 31% (95% CI 29.36-32.69) of participants had pain, of whom 36.36% (1973/5426) had moderate pain. The top 3 pain locations were the waist (3232/16,747, 19.3%), legs (2476/16,747, 14.78%), and head (2250/16,747, 13.44%). There were differences in pain status among different groups by age, gender, education status, marital status, smoking, alcohol consumption, economic status, and location (Table 1). Female gender and regular drinking increased the risk of pain. Higher education, higher economic status, and living in an urban community reduced the risk of pain (Multimedia Appendix 1, Table S1).

**Concentration and Its Decomposition**

The concentration index of pain among Chinese adults was –0.066 (95% CI –0.078 to –0.054), which indicates that the prevalence of pain was higher among those with low economic status (Figure 1). Decomposition analysis found that old age, female gender, lower educational level, never being married or having another marriage status, living in a rural community, smoking, and having a lower economic status increased the inequality of pain and never or sometimes drinking and lower BMI decreased the inequality of pain. Among these factors, educational level (36.49%), location (36.87%), and economic status (25.05%) contributed significantly to the inequality of pain (Table 2). Further analysis showed that pain severity and the different parts of the body affected by pain (head, shoulders, arms, wrists, fingers, chest, stomach, back, waist, buttocks, legs, knees, ankles, toes, and neck) were concentrated in participants with low economic status, and the legs exhibited the most severe inequality (concentration index –0.121, 95% CI –0.141 to –0.101; Multimedia Appendix 1, Table S2).

Association of Pain With Risks of All-Cause Mortality

After 3 years of follow-up, 394 death events were reported, for a mortality rate of 2.35%. Participants with pain had a higher mortality rate than those without pain (log-rank test; \( P = .002 \)) (Figure 2). After adjusting for all covariates, Cox regression found that pain was associated with an increased risk of all-cause mortality (hazard ratio [HR] 1.30, 95% CI 1.06-1.61; Figure 3). Severity of pain also increased the risk of all-cause mortality (moderate: HR 1.36, 95% CI 1.02-1.83; severe: HR 1.42, 95% CI 1.07-1.87). The analysis focusing on specific types of pain showed that chest pain was significantly associated with all-cause mortality (Multimedia Appendix 1, Table S3). In addition, we performed stratified analyses according to sociodemographic characteristics, and the results for each group differed slightly from the overall results, but the different groups showed a trend that pain was associated with a higher risk of all-cause mortality across different groups (Figure 3).
**Discussion**

**Principal Results**

This study found that there was inequality in the prevalence of pain in nationally representative data from CHARLS. This inequality was concentrated in people with lower economic conditions. Education level, location, and economic status contributed significantly to this inequality. We further found that pain increased the risk of all-cause mortality. These findings outline the current inequitable status of pain and potential mortality risks in China.

**Comparison With Prior Work**

Previous studies have revealed correlations between pain and economic status. A meta-analysis found that compared to people with high SES, people with low and medium SES had an increased risk of pain [16]. We reached similar conclusions...
using the concentration index. In addition, studies on the association between SES and pain have been mainly concentrated in high-income countries, with fewer prospective studies conducted in low- and middle-income countries, and our results make up for this deficiency. In addition, we found that economic status, education level, and location were associated with greater pain inequality. All 3 variables are common indicators of SES [17-19]. Individuals with lower SES tend to report higher prevalence of pain [20,21]. Individuals with low SES often face barriers to accessing medical resources, including appropriate resources for pain management [19]. Limited access to medical resources may lead to delayed diagnosis and treatment of pain symptoms, exacerbating pain. Also, lower SES is associated with heavy physical work or a sedentary lifestyle [22,23]. These characteristics may contribute to the development of musculoskeletal pain. Chronic exposure to economic stress, including unemployment, housing instability, and food insecurity, could lead to chronic psychosocial stress. This stress is associated with the development of pain, involving the hypothalamic-pituitary-adrenal axis and neuroinflammatory status [16,24].

Pain is a sensory and emotional experience with great biological, psychological, and sociological complexity, which not only seriously affects the quality of life, but may also adversely affect longevity [1,25,26]. Song and Chung [27] used data from the Korean Longitudinal Study of Aging (2006-2016) and found there was a statistically significant relationship between pain and mortality risk, and this risk increased with the intensity of pain. Smith et al [28] also found this association in the English Longitudinal Study of Ageing. Our research led to similar conclusions. There have also been studies reporting an association between different pain sites and death. A systematic review and meta-analysis of cohort study data found that back pain was associated with increased all-cause mortality in women and people with more severe back pain [29]. Cleveland et al [30] found that knee pain was associated with increased mortality in a community-based cohort study. However, it is hard to say whether pain directly increases the risk of death. Chen et al [31], using data from the UK Biobank, found that at least half of the association between chronic musculoskeletal pain and increased all-cause mortality may be mediated by 4 factors: physical activity, smoking status, alcohol consumption, and opioid use. The effect of pain on all-cause death is a complex issue and more research is needed to further understand this association. Current evidence highlights the importance of pain management and effective pain management strategies, including comprehensive treatments and attention to the patient’s lifestyle and mental health, which may help reduce the adverse health outcomes associated with pain [32-36]. With the increase of aging in China, it is necessary to accurately understand pain and conduct policy interventions for pain.

Limitations
Our findings highlight the importance of equality-oriented policies for pain to reduce deaths associated with pain inequality. However, our study has some potential limitations. First, information about pain, its severity, and its location were self-reported, which could lead to recall bias. Second, the data for estimating pain equality in this study were from 2011, which may introduce bias relative to the current situation. Third, some studies have found that new-onset pain may significantly increase the risk of death [27], and our study did not consider the duration of pain, which led to insufficiently detailed results. Fourth, some factors, such as recent injuries, may influence the association between pain and all-cause mortality. However, CHARLS did not investigate this, potentially leading to an overestimation of the effect of pain on all-cause mortality. Finally, the study participants were aged 45 to 75 years, which limits our estimation of the equality of pain prevalence in people older than 75 years. Nevertheless, our study has important implications for highlighting the impact of pain on health.

Conclusion
The prevalence of pain in Chinese adults was concentrated among participants with low economic status, and pain increased the risk of all-cause death. Our results highlight the importance of socioeconomic factors in reducing deaths due to pain inequality by implementing targeted interventions to reduce pain inequality.

Acknowledgments
We extend our gratitude to all participants in the CHARLS study and the trial investigators. This article was crafted using research materials sourced from the Peking University Open Research Data Platform. ZZ contributed to conceptualization, formal analysis, and writing (original draft). DX contributed to formal analysis and writing (original draft). YB contributed to conceptualization, writing (review and editing), and supervision. All authors read and approved the final version of the manuscript. This study was funded by 3 research grants awarded to YB from the University of Macau (UM; MYRG2019-00044-ICMS, QRCM-IRG2022-001, and SKL-QRCM-IRG2023-032) and the UM Talent Program. This work also received funding from the Shaanxi Provincial Sports Bureau Regular Project (2023108), the Teacher Education Reform and Development Research Project of Xi’an Medical University (2023JFY-31), a school-level scientific research fund from Xi’an Medical University (2023BS21), and a Shaanxi provincial philosophy and social science research project (2024QN271). The sponsors did not play any role in study design, data collection, data analysis, data interpretation, or writing of the manuscript.

Abstract

Background: Multimorbidity is a significant public health concern, characterized by the coexistence and interaction of multiple preexisting medical conditions. This complex condition has been associated with an increased risk of COVID-19. Individuals with multimorbidity who contract COVID-19 often face a significant reduction in life expectancy. The postpandemic period has also highlighted an increase in frailty, emphasizing the importance of integrating existing multimorbidity details into epidemiological risk assessments. Managing clinical data that include medical histories presents significant challenges, particularly due to the sparsity of data arising from the rarity of multimorbidity conditions. Also, the complex enumeration of combinatorial multimorbidity features introduces challenges associated with combinatorial explosions.

Objective: This study aims to assess the severity of COVID-19 in individuals with multiple medical conditions, considering their demographic characteristics such as age and sex. We propose an evolutionary machine learning model designed to handle sparsity, analyzing preexisting multimorbidity profiles of patients hospitalized with COVID-19 based on their medical history. Our objective is to identify the optimal set of multimorbidity feature combinations strongly associated with COVID-19 severity. We also apply the Apriori algorithm to these evolutionarily derived predictive feature combinations to identify those with high support.

Methods: We used data from 3 administrative sources in Piedmont, Italy, involving 12,793 individuals aged 45-74 years who tested positive for COVID-19 between February and May 2020. From their 5-year pre–COVID-19 medical histories, we extracted multimorbidity features, including drug prescriptions, disease diagnoses, sex, and age. Focusing on COVID-19 hospitalization, we segmented the data into 4 cohorts based on age and sex. Addressing data imbalance through random resampling, we compared various machine learning algorithms to identify the optimal classification model for our evolutionary approach. Using 5-fold cross-validation, we evaluated each model’s performance. Our evolutionary algorithm, utilizing a deep learning classifier, generated prediction-based fitness scores to pinpoint multimorbidity combinations associated with COVID-19 hospitalization risk. Eventually, the Apriori algorithm was applied to identify frequent combinations with high support.

Results: We identified multimorbidity predictors associated with COVID-19 hospitalization, indicating more severe COVID-19 outcomes. Frequently occurring morbidity features in the final evolved combinations were age>53, R03BA (glucocorticoid inhalants), and N03AX (other antiepileptics) in cohort 1; A10BA (biguanide or metformin) and N02BE (anilides) in cohort 2;
N02AX (other opioids) and M04AA (preparations inhibiting uric acid production) in cohort 3; and G04CA (Alpha-adrenoreceptor antagonists) in cohort 4.

**Conclusions:** When combined with other multimorbidity features, even less prevalent medical conditions show associations with the outcome. This study provides insights beyond COVID-19, demonstrating how repurposed administrative data can be adapted and contribute to enhanced risk assessment for vulnerable populations.

**Introduction**

**Background**

COVID-19, classified as a highly infectious disease, poses a severe threat to vulnerable populations, making it a critical public health concern and a significant global epidemiological issue. The first Italian case of COVID-19 was diagnosed in the Lombardy region on February 21, 2020. The virus quickly spread across the country, leading to a nationwide lockdown and overwhelming the health care system. Italy was among the countries hardest hit by the COVID-19 pandemic, with Piedmont, a region in the northwest, experiencing a high number of cases during the first wave.

Multimorbidity refers to the presence of multiple coexisting medical conditions in a patient, which interact with each other, resulting in a complex and multidimensional health condition [1]. At the population level, it has been established that interactions between diseases can increase the severity of the overall medical condition and complicate the treatment of other diseases within the combination [2,3]. In people infected with SARS-CoV-2, multimorbidity can increase the severity of the infection [4,5]. Therefore, it is important to identify specific disease combinations that could impact the severity of COVID-19 in individuals with multimorbidity.

It is necessary to point out that having one or more of these chronic health conditions does not guarantee severe COVID-19 development, but it does increase the risk. Different diseases may affect COVID-19 outcomes differently. Therefore, identifying specific disease combinations and studying interactions between different chronic health conditions are essential for understanding the severity of COVID-19 among individuals with multimorbidity. This can help health care professionals identify those at the highest risk of severe complications and provide appropriate prevention, care, and treatment.

Studying multimorbidity using traditional methods can be labor-intensive, requiring the identification of high-dimensional combinatorial features. Also, there is no universally accepted list of medical conditions to define multimorbidity. To address these challenges, efforts must focus on identifying low-dimensional representations of multimorbidity features for effective outcome prediction. High-order input features make machine learning models more prone to overfitting, and identifying meaningful high-order combinatorial features requires extensive effort from experts with domain knowledge.

Contrary to misconceptions, the concept of combinatorial features requires extensive effort from experts with domain knowledge. Contrary to misconceptions, the concept of multimorbidity analysis in patients with COVID-19 is not outdated. Our study introduces a cutting-edge tool designed to analyze the complex interactions among diverse chronic health conditions and their collective impact, which could be valuable in situations similar to recent health crises.

Traditionally, research on multimorbidity has focused on counting the total number of chronic conditions rather than considering individual experiences and the effects of different combinations of diseases [6]. Count-based measures of multimorbidity have been utilized to predict emergency hospitalizations [7,8]. Common combinations of medical conditions have been documented to delineate patterns of multimorbidity [9,10]. Previous studies have explored multimorbidity combinations using methods such as latent class analysis [11], cluster analysis [12], network analysis [13], factor analysis [14], association rules, and tree-based analysis [13,15].

Rare features, such as diseases and drugs with low occurrence rates in the data, can pose significant challenges for both statistical and machine learning analyses. Their lower prevalence in the data can result in sparsity, which may lead to poorer predictions. Some studies using machine learning to investigate multimorbidity patterns tackled data sparsity by strategies such as removing sparsity-inducing features [16], consolidating feature categories after one-hot encoding [17], or clustering rare features [18]. However, while these methods can alleviate sparsity, they may also result in the loss of important information and impede the meaningful interpretation of multimorbidity features [19].

**Importance of the Proposed Method for Multimorbidity Research**

With the increasing prevalence of electronic health records and other large data sets, there is a rising demand for efficient and effective methods to analyze and comprehend multimorbidity. By utilizing machine learning algorithms and other advanced computational techniques, researchers can gain deeper insights into the underlying mechanisms and risk factors associated with multimorbidity. This understanding can significantly inform more effective prevention and treatment strategies.
An evolutionary algorithm coupled with deep learning–based feature scoring represents a powerful approach for analyzing multimorbidity data [20]. This method involves multiple steps aimed at identifying the most relevant features for predicting the target variable while minimizing the number of features used.

Initially, the data set undergoes preprocessing by using a feature binning approach to generate various subsets or bins of the multimorbidity features. This step aims to reduce sparsity in the data and facilitates more effective feature scoring. Subsequently, deep learning is utilized to score the features within each subset based on their relevance for predicting the target variable. The result of this process is a feature score assigned to each feature within every subset. Next, an evolutionary algorithm is applied to select the optimal subset of features based on their scores. The algorithm initiates by generating a population of candidate feature subsets and iteratively enhances this population through selection, crossover, and mutation operations [21]. The fitness of each candidate solution is assessed using a fitness function that integrates the deep learning–based feature scores derived from each subset or bin of features.

The output of the evolutionary algorithm is a subset of features that are most relevant for predicting the target variable. These features can be utilized for further analysis, such as constructing a predictive model or uncovering the underlying associations of multimorbidity patterns. In summary, using an evolutionary algorithm with deep learning–based feature scoring offers a robust approach to analyzing multimorbidity data, pinpointing the most influential features for predicting the target variable. This approach can result in enhanced model performance, faster training times, and improved interpretability in complex data sets featuring multimorbidity [22].

**Study Goal**

This study aims to identify multimorbidity patterns that may serve as predictors of COVID-19 hospitalization (as a proxy for a more severe COVID-19 outcome) using evolutionary algorithms. To assess the effectiveness of our approach, we conducted a comparative analysis to justify the use of deep learning as a classifier over other established machine learning algorithms in terms of prediction accuracy. The evolutionary model may excel not only because of its superior predictive performance but also because it effectively manages sparsity. This capability could result in better identification of key features, more stable predictions, or enhanced performance within specific subgroups of the data [23].

A logistic model might reveal multimorbidity patterns that exhibit complexity [24]. However, linear models, despite their high interpretability, may struggle in sparse data sets where effective feature selection is relevant [25]. In such cases, evolutionary algorithms, particularly genetic algorithms, excel by adeptly handling feature interactions with complexity and identifying optimal feature subsets, a task that proves challenging for linear models in sparse data scenarios [26].

The selected models are interpreted using Shapley Additive Explanations (SHAP) values [27] to understand the relationship between the multimorbidity features across different cohort data and hospitalization outcomes. The proposed method also generates a feature-engineered data set containing a specified number of outcome-associated combinations or bins of multimorbidity. Then, the best performing bins are analyzed to explore the frequency of various multimorbidity patterns across all cohorts.

This study demonstrates how our innovative tool has the potential to revolutionize traditional risk assessment approaches. By incorporating complex combinations of diseases, the tool aims to improve the accuracy of predicting severe outcomes for individuals with multiple chronic conditions. With its adaptable design, it ensures applicability even in evolving scenarios involving different communicable diseases, highlighting its ongoing relevance. This study focuses on investigating the complexities of disease interactions, demonstrating how our tool could reshape risk assessment in similar contexts.

**Methods**

**Study Design**

This retrospective cohort study is designed to exhaustively examine the presence or absence of various multimorbidities in patients over a 5-year period leading up to the onset of COVID-19. The core of our analysis is the longitudinal tracking of these multimorbidities, relevant for understanding their impact on subsequent health outcomes, particularly hospitalizations due to COVID-19. Central to the study’s design is its longitudinal nature, involving systematic analysis of patient data collected over a specified time frame to assess how individual and collective health conditions influence the risk and severity of COVID-19–related hospitalizations. The retrospective cohort framework enables the use of existing medical records, including hospital discharge summaries and drug prescription data, to construct a comprehensive picture of each patient’s health status in the years leading up to the pandemic. Through an analysis of these long-term health patterns, our aim is to understand how preexisting conditions influence the severity of COVID-19.

This study involves examining individuals’ multimorbidity history over a 5-year period, encompassing both pre– and post–COVID-19 diagnosis periods. It further investigates the relationship between multimorbidity history, COVID-19 positivity, and the subsequent severity of COVID-19. This design allows for observing participants over an extended time frame and evaluating outcomes not only before but also after the critical event of COVID-19 diagnosis.

**Multimorbidity Data Set**

Data for the multimorbidity analyses were collected from the Piedmont Longitudinal Study (PLS), a health administrative cohort comprising anonymized records linked at the individual level from various social, health, and administrative databases [5,19]. Since February 2020, the PLS has been augmented by the regional COVID-19 platform, which collects data on COVID-19 infections. From these databases, we utilized registers for (1) hospital discharges, (2) drug prescription data, and (3) COVID-19 hospitalizations of individuals diagnosed...
with SARS-CoV-2 infection for the first time between February 22, 2020, and May 31, 2020. We retrieved the 5-year medical history of patients positive for COVID-19 from these data sets. The extracted data comprises 12,793 individuals aged 45-74 years who tested positive for the first time for SARS-CoV-2 infection. Our study specifically focused on this age group to eliminate potential influences from both younger and older individuals on the results. Also, this approach helped to mitigate bias associated with patients residing in nursing homes.

As the study was integrated into the National Statistical Plan, no ethical approvals or permits were required, and the database used for the analyses contained only anonymized data. Further information regarding ethical considerations and data availability can be found in the “Ethical Considerations” section.

**Ethical Considerations**

This study is part of the PLS, a specific project within the Italian National Statistical Program, proposed by the National Statistical System (SISTAN), integrated into the National Statistical Program (Programma Statistico Nazionale [PSN]), an initiative endorsed by the National Institute of Statistics (Istituto Nazionale di Statistica [ISTAT]) in Italy. This project is annually approved by the Italian Parliament. Since 2003, a dedicated form (PIE-00001 “Monitoring of socio-economic differences in mortality and morbidity through longitudinal studies”) has been included in the PSN, currently effective for the 3-year period from 2020 to 2022 [28] and recently renewed for 2023-2025.

Ethical approval or permits from the ethics committee are not necessary for this research. Access to PLS data within the responsible institution does not require informed consent, as stipulated by the Presidential Decree published in the Official Gazette of the Italian Republic N. 122 of May 26, 2022, under the PSN [29].

Consequently, informed consent from an ethical committee is not required for this study. All analyses adhered to the principles of the World Medical Association’s Declaration of Helsinki, and to preserve privacy, the data used for analysis underwent deidentification.

**Construction of the Exposure’s Variables**

In this longitudinal cohort study, patients’ multimorbidity status over the past 5 years (2015-2019) was compared in relation to a specific outcome (hospitalization due to COVID-19). Multimorbidity was defined using records from hospital discharge and drug prescription registers. In the data sets for hospital discharges and drug prescriptions, multiple entries exist for each patient with COVID-19. The drug prescriptions data set comprises approximately 1 million records, while the hospital discharges data set includes around 19,000 entries. From the drug prescriptions data set, the Anatomical Therapeutic Chemical (ATC) classification system codes were used. All distinct ATC codes up to the 4th level (the first 5 digits of the ATC codes) were considered in this study. One-hot encoding was applied to convert categorical codes into separate feature columns with binary values (0 or 1) indicating the absence or presence of drugs in each patient’s prescription history. Similarly, from the hospital discharge data, the 9th International Classification of Diseases-Clinical Modification (ICD-9-CM) codes [30] (as diagnosis codes) were used, and one-hot encoding was applied. Following these transformations, only drug codes and diagnosis codes meeting the criterion “at least 100 patients with this code in the COVID-19-positive patients’ data” are retained. Consequently, 194 features were derived from drug codes (n=112) and diagnosis codes (n=82) as multimorbidity features from the entire data set, where the presence and absence of these features are denoted as 1 and 0, respectively. Also, 2 features—age and sex—are included, with sex coded as 1 for females and 0 for males. Subsequently, the preprocessed data were segmented into 4 data sets based on age and sex. The data set transformation steps are illustrated in Figure 1.

Subsets of various cohorts were obtained by considering the study population falling within the age criteria of “aged 45-59 years” and “aged 60-74 years.” This subdivision is made because individuals aged 60 and above are often categorized as part of the older population [5]. Median values within each age range are used as threshold values for discretizing the age feature in this study. This approach involves categorizing or binning based on median values within each specified age range. For example, to discretize the age feature into groups such as “45-59” and “60-74,” we used medians (53 for “45-59” and 68 for “60-74”) as thresholds.

In the data sets for the younger cohorts (cohorts 1 and 2), the age feature was converted into a binary variable, where 1 represents age≥53 and 0 represents age<53. The age values were derived from the 2020 COVID-19 data, and the age of 53 years was used as a threshold to divide the younger population into 2 subgroups (45-53 and 54-59 years). Similarly, the older population was divided into 2 subgroups (60-68 and 69-74 years), where the age feature was converted into a binary variable, with 1 indicating age>68 and 0 indicating age≤68. All 4 cohort data sets were treated as distinct binary classification problems. The input variables, comprising multimorbidity history and age, along with the outcome variable indicating whether a patient was hospitalized due to COVID-19, were represented as binary values.

In our study, multimorbidity features included the presence and absence of prescribed drugs and diagnosed diseases, as well as patient age and sex. However, due to the rarity of many medical conditions in the study population, the resulting data set became sparse when encoding absence as 0 values.
Data Imbalance Rectification

A significant challenge when working with clinical data is predicting rare events, which can result in an imbalance problem when the target variable has more observations in one class than in others. Therefore, it is beneficial to handle imbalanced raw data properly to prevent bias toward a particular class. All data sets used in this study exhibit imbalance, and resampling is recommended as a solution. To address this, randomly balanced samples were drawn from the unbalanced original data set to achieve class balance. Subsequently, a statistical hypothesis test, specifically the one-proportion $z$-test, was performed. This test compares the proportion of the sampled population with that of the raw data population, ensuring the representativeness.
of the randomly balanced sample data compared with the original cohort data set and mitigating potential biases.

The steps performed to obtain an unbiased balanced data set with significant features are as follows:

- Extract all minority and majority samples attributed to the outcome value from the original cohort data set.
- Randomly select samples belonging to the majority class so that they are equal in number to the minority class to achieve a balanced data set.
- Calculate the prevalence of each feature in the randomly selected samples and compare it with the prevalence in the original population.
- Perform a one-proportion $z$-test on all nonzero variables to assess whether the frequency distribution of a feature in the resampled data is representative of the same feature in the original cohort data set, using a significance level of .05.
- Evaluate the results of the one-proportion $z$-test, considering the test statistic and $P$ values, to determine the significance and eliminate nonsignificant features from the sampled data.

**Model Development**

**Machine Learning Algorithms**

To select the best model, we evaluated the performance of various supervised machine learning algorithms. Using labeled health records enables the application of supervised learning, specifically binary classification to classify a patient’s multimorbidity profile. Deep learning and other machine learning algorithms were applied to all cohort data sets, as depicted in Figure 2. Results were compared using a scoring grid with average cross-validated scores.

**Figure 2.** Selecting best ML model for each cohort data set: A streamlined process of selecting the optimal ML model for cohort data sets, using supervised algorithms for binary classification of multimorbidity profiles, with comparison based on a scoring grid featuring average cross-validated scores. AUC: area under the curve; ML: machine learning.
SHAP Analysis

SHAP values were used to elucidate the contribution of individual features in predicting hospitalization outcomes across all cohorts. These SHAP values for all features were plotted, with their positions on the y-axis indicating their impact on the model outcome. Beeswarm plots of SHAP values were used to explore the distribution of influence that each feature has on the model outcome, with features of greater importance positioned higher on the graph. Each data point for a feature corresponds to a single patient, with the position of the data point (SHAP value) on the x-axis indicating the effect of that feature on the model outcome for that specific patient. In the SHAP beeswarm plots, when multimorbidity is present (indicated by a feature value of 1 in red), a higher positive SHAP value suggests that this feature acts as a risk factor for hospitalization. Conversely, a more negative SHAP value in the presence of multimorbidity indicates that this feature acts as a protective factor against hospitalization risk for the patient. These findings are illustrated in Figure 3.

Figure 3. SHAP beeswarm plots illustrating the impact of all features on COVID-19 hospitalization for all 4 models. SHAP: Shapley Additive Explanations.
Deep Learning With Sparse Data

This study addresses a sparse health care data set that includes rare medical conditions and drugs, posing challenges for statistical and machine learning analyses due to their low prevalence [23]. To tackle this issue, the study utilizes sequential deep learning with the Adaptive Gradient Algorithm (AdaGrad), an optimization algorithm well-suited for handling sparse data [31]. AdaGrad’s adaptive scaling of the learning rate eliminates the need for manual tuning and enhances robustness compared with stochastic gradient descent. Also, the study uses early stopping functionality to improve the model’s performance.

In all deep learning models, dropout has been used as a regularization technique to mitigate overfitting during training [32]. Specifically, a dropout layer with a 20% dropout rate has been introduced after the first and second layers in the sequential model. Given the binary classification nature of the problem, the default loss function used is binary cross-entropy loss [33].

Feature Selection for Discovering the Optimal Set of Multimorbidity Features

Feature selection as a preprocessing method eliminates irrelevant and redundant information, aiding in dimensionality reduction [34]. There are 3 main methods of feature selection: filter-based, embedded, and wrapper-based methods. Filter-based methods typically generate models with reduced predictive performance compared with the other 2 methods. The embedded method performs an optimal feature subset search while constructing the model, whereas the wrapper method selects the best feature subset based on the classifier’s performance. In our study, we used a wrapper method that utilizes deep learning as the classifier algorithm and an evolutionary algorithm as the search strategy to generate feature subsets (bins). The best performing bin is determined using the area under the curve (AUC) metric and selected as the optimal subset of multimorbidity features highly associated with COVID-19 hospitalization.

Evolutionary Machine Learning

The use of evolutionary algorithms represents a promising approach for extracting a reduced set of meaningful and accurate rare associations, particularly beneficial for addressing challenges such as sparse data, epistatic associations with features, and high-dimensional representations of features. Evolutionary machine learning is a hybrid method that leverages evolutionary computation to overcome challenges encountered in various machine learning tasks [35]. Compared with traditional algorithms that rely on exhaustive search-based techniques, evolutionary algorithms offer a more robust solution.

Several key considerations arise when performing feature engineering with evolutionary algorithms: (1) a feature’s lack of prevalence does not necessarily imply irrelevance; it could still strongly influence the outcome; (2) addressing data sparsity poses a challenge for many machine learning methods, particularly concerning features with near-0 variance; and (3) evaluating combinations of features may yield greater predictive power than assessing isolated features alone, emphasizing the significance of exploring feature interactions.

We used a genetic algorithm to create an optimized feature matrix. Initially, features were randomly grouped into bins, each forming a feature matrix. These bins were then regrouped using a genetic algorithm and a wrapper-based method interacting with a classifier. The study adopted the elitism principle to preserve the best-performing bins as checkpoints. The final feature matrix represents the evolved engineering matrix after all iterations, designed to address issues of data sparsity and incorporate interactions among various multimorbidity features.

The proposed evolutionary approach in the study is an evolutionary algorithm–based wrapper method, illustrated in Figure 4. It is a modified version of an existing evolutionary algorithm known as the Relevant Association Rare-variant-bin Evolver [23]. The proposed method differs from the existing approach in several ways: it utilizes a prediction-based method with separate training and testing phases, incorporates a deep learning technique with an AdaGrad optimizer, and estimates the frequency of occurrence of specific features within the best performing feature combinations. Also, the scores produced by the deep learning model serve as fitness scores to assess the performance of multimorbidity combinations in each cycle.
**Figure 4.** Illustration of the evolutionary approach carried out in this study: The process begins by randomly initializing subsets of features. Through the execution of evolutionary computation, a final feature matrix is generated. Subsequently, frequently occurring combinations and features are identified.

**Frequent Multimorbidity Features**

The most prevalent multimorbidity combinations were identified to discern patterns among patients with COVID-19 using the Apriori algorithm. Applied to the final bins data set, which includes various multimorbidity feature combinations obtained from the evolutionary algorithm, the Apriori algorithm utilized the support measure to gauge the commonality of feature combinations across rows in the final bins. To focus on relevant feature combinations, only the most common multimorbidity patterns were analyzed. Frequent combinations of features were examined using a minimum support threshold ($s_{min}$) set at 0.5 to derive frequent itemsets.

Figure 5. Model loss plot and AUC score over epochs—validation of model efficiency for each cohort through 2 line plots: The topmost plot depicts the binary cross-entropy loss for the epochs for the training and validation data sets, and the bottommost one presents the classification performance (AUC score) over epochs. AUC: area under the curve.
In cohort 1, it is evident that the model learns the problem efficiently and rapidly, achieving an AUC score of 82% on the training data set and 80% on the test data set. The close similarity between these scores suggests that the model is neither overfitting nor underfitting. The cross-entropy loss plot showed that the model has converged, with acceptable loss values observed on both data sets. The classification performance plot further indicated convergence. The model’s performance and convergence suggested that cross-entropy loss is suitable for effectively learning this neural network problem. In cohort 2, the model achieved performance scores of 71% on the training data set and 67% on the test data set, with reasonable loss values. The minimal difference between these scores indicated that the model learned the problem satisfactorily. In cohort 3, the model achieved a training score of 74% and a test AUC score of 69%. Observing that there was no significant improvement after 30 epochs, early stopping could be implemented during model training to prevent overfitting and stabilize the validation loss.

In cohort 4, although the loss plot appeared well-converged, the model showed slightly lower classification performance compared with the models in other cohorts.

**Influence of Individual Features on COVID-19 Hospitalization: Most Prevalent Multimorbidity Features in Evolved Bins**

The accuracy scores of the evolutionarily obtained final bins have been calculated. The highest accuracy was achieved for cohort 1 using the evolutionary approach to find outcome-associated best subsets of features, reaching 71.43% (95% CI 67.31-67.97) with 64 features. For cohort 2, the accuracy was 63% (95% CI 59.43-59.75) using 69 features. Cohort 3 achieved an accuracy of 62.38% (95% CI 59.84-60.09) with 53 features, while cohort 4 achieved an accuracy of 58% (95% CI 55.42-55.63) using 61 features. These results were then compared with the accuracy score of the deep learning model that utilized all features, as illustrated in Figure 6.

**Table 4** displays the multimorbidity features that occurred most frequently in the final bins data set across all cohorts, using a minimum support (smin) measure of 0.6. It includes the prevalence of these features in the sampled data set. Detailed statistics for all other features can be found in Multimedia Appendix 3.

**Figure 6.** Maximum classification accuracy achieved by a bin versus number of features in that bin using evolutionary approach (left side) and the accuracy score achieved exclusively by the deep learning model (right side) with all the available features in the cohort.

In cohort 1, frequently occurring multimorbidity features included age>53, R03BA (glucocorticoid inhalants), and N03AX (other antiepileptics). For cohort 2, A10BA (biguanide or metformin) and N02BE (anilides) were prevalent. Cohort 3 exhibited frequent occurrences of N02AX (other opioids) and M04AA (preparations inhibiting uric acid production), while G04CA (Alpha-adrenoreceptor antagonists) was notable in cohort 4.
Table 4. Frequently occurred morbidity features in the evolutionarily obtained final bins data set with support measure with corresponding P values, and the prevalence of the features in the sampled data set utilized for the predictive analysis.

Discussion

Principal Findings

The primary findings of the study highlight prevalent multimorbidity patterns identified within the evolved data set. These patterns, characterized by specific ATC codes and ICD codes, show significant associations with hospitalization outcomes, particularly among distinct demographic groups. This analysis not only provides insights into COVID-19 but also suggests potential broader applications. Repurposing data originally collected for administrative purposes, this innovative approach shows promise for multimorbidity analysis in public health. It shows the adaptability and versatility of the methodology, capable of extracting valuable insights from existing data sets to inform effective public health strategies and interventions.

While our evolutionary machine learning model shows only marginal superiority compared with other prediction models, even slight improvements in predictive performance can hold significant value in real-world applications, particularly in critical fields such as health care where accuracy is mandatory. Moreover, we acknowledge that achieving the highest prediction performance may not be the sole objective of our study.

In the baseline method, variables are transformed into a binary format using one-hot encoding, which leads to the creation of a large, sparse matrix [26]. Evolutionary models typically excel in handling high-dimensional data compared with linear models, utilizing their enhanced ability to navigate and effectively utilize the search space [36]. Evolutionary approaches have drawbacks such as challenges in interpretability, computational efficiency, and a higher risk of overfitting [37]. However, despite the simplicity and clear interpretability of linear models, evolutionary models excel in managing complex, high-dimensional data and are proficient in handling feature interactions with complexity. This makes them particularly suitable for studies focused on detailed and complex aspects of multimorbidity patterns. Utilizing a novel evolutionary machine learning approach, we illustrate the ability to derive meaningful results even from rare events. Our model’s successful application in uncovering prevalent morbidity patterns linked to COVID-19 outcomes underscores its potential to yield valuable insights across diverse data sets, particularly where data sparsity poses challenges. While acknowledging its computational demands, we emphasize the model’s readiness and adaptability for analyzing complex medical data, highlighting its robustness as a powerful tool in medical research.

We identified prevalent morbidity patterns from the evolved data set, focusing on multimorbidity combinations or feature

Figure 8. Illustration of the features and combinations that frequently appeared in the final bins data set when configuring the support (s) between 0.7 and 1.0 as radar chart, with features presented in more than 1 cohort stacked.
subsets closely associated with the outcome. This research targets clinically significant patterns directly. Utilizing an evolutionary algorithm to identify these combinations ensures the analysis is grounded in a robust, data-driven process. Analyzing the frequency of these subsets provides a measure of their prevalence and significance in the studied population. This step helps validate the relevance of the identified combinations, ensuring that the observed patterns are not random but indicative of common trends in patient data. Focusing on the most prevalent combinations, the study aims to yield findings with practical implications for health care providers. These findings can inform clinical decision-making by helping practitioners identify patients at higher risk due to specific multimorbidity patterns, enabling them to tailor treatment approaches accordingly.

Multimorbidity features such as older age combined with specific ATC codes (N03AX and R03BA) were frequently observed in outcome-related bins, particularly among middle-aged females. Likewise, during the analysis of SHAP values in cohort 1, it was noted that the use of inhaled corticosteroid medication for asthma (R03BA) had a significantly positive impact on the likelihood of hospitalization. This observation aligns with findings from the Open SAFELY study, which identified asthma as a significant risk factor for mortality in patients with COVID-19. Specifically, it highlighted that individuals using inhaled corticosteroids face the highest risk in this context [38].

The ATC N03AX group encompasses various antiepileptic medications used in treating bipolar disorder, epilepsy, migraine, and sometimes schizophrenia. Individuals with severe mental illnesses have shown a slightly higher risk of severe clinical outcomes from COVID-19 compared with those without prior mental health conditions [39]. Also, there have been reports linking the use of antiepileptic medications with vitamin D deficiency [40]. In our study, the presence of A11CC (vitamin D and analogs) in the multimorbidity history makes middle-aged females more vulnerable to hospitalization. Conversely, for older-age females, the presence of this feature is associated with smaller SHAP values, indicating that its presence in their history is protective against hospitalization.

In a multimorbidity study of hospitalized patients with COVID-19 [41], the ATC group most closely associated with prolonged hospital stays is M04AA, which includes preparations inhibiting uric acid production. In our study, among older-age females, the combinations of M04AA and N03AX were notably frequent. M04AA also featured prominently in middle-aged males, while G04CA (alpha-adrenoreceptor antagonists), used for benign prostate hypertrophy, was notable among older-age males. Research indicates that male COVID-19 cohorts experience more unfavorable clinical outcomes compared with females [42,43]. Specifically, while patients with cancer are at an increased risk of SARS-CoV-2 infection, individuals undergoing androgen-deprivation therapy for prostate cancer appear to have some level of protection against the infection [43].

Strength and Limitations
Each row in the data set represents a comprehensive aggregation of each patient’s multimorbidity history over a 5-year period, including all relevant instances of diseases and conditions. This approach ensures a holistic view of each patient’s health status. To minimize subjectivity in the selection process, the criteria for including health records in the data set are consistent and objective. The aggregation process is governed by standardized criteria, uniformly applied across all patients. Also, aggregating multiple health records into a single patient instance helps mitigate bias that could arise from selectively choosing one entry over another.

In many clinical scenarios, understanding the implications of false positives and false negatives is a requisite beyond just disease probabilities. Although metrics such as Pietra and sBrier [44] and the average deviation about the probability threshold (ADAPT) index [45] are valuable, especially when patients seek to understand disease probabilities, we believe that traditional metrics such as AUC, accuracy, precision, recall, and $F_1$-score, along with a confusion matrix, offer a comprehensive evaluation of the prediction models in this study. The use of a confusion matrix as an evaluation tool enables us to customize model assessment to reflect different clinical priorities, which is particularly relevant when the prediction model informs treatment plans or risk assessments [46].

Evolutionary algorithms inherently favor the best performing choices available, despite their stochastic nature. These biases contribute to their improved performance. Each evolutionary cycle involves evaluating bin fitness and performing genetic operations to identify the best performing group of features. In this study, the evolutionary algorithm is used not only for feature selection in sparse data but also to indirectly assess epistatic associations between features in each evolutionary cycle. Multimorbidity features are grouped into bins and scored based on a deep learning classifier’s predictive ability for the outcome. The features within bins are regrouped iteratively after each evolutionary cycle.

Many studies using machine learning to investigate multimorbidity patterns focus on handling sparse data sets by either removing sparsity-generating features or merging feature categories to reduce sparsity. However, these methods often result in information loss and less precise interpretation of multimorbidity features [19]. Instead of relying solely on a sequential deep learning model, we aggregated all evolved bins to create a new data set. This allowed us to analyze the evolutionarily evolved bins and identify frequent multimorbidity features and combinations.

Analyzing all possible combinations of multimorbidity features in a data set can be computationally expensive, and many irrelevant combinations may not warrant further analysis. To address this, we applied an evolutionary algorithm to extract meaningful combinations, prioritizing even less prevalent features. Consequently, our focus shifted to investigating only the most common multimorbidity features found in the top bins.
Conclusions
When combined with other multimorbidity features, we identified associations with the outcome even for less prevalent medical conditions. Discovering hidden interconnections among different multimorbidity features opens new research pathways for studying multidimensional medical conditions in combination.

Using an innovative evolutionary machine learning approach, we identified prevalent morbidity patterns linked to hospitalization risk, especially among specific age and gender cohorts. Our findings highlight the adaptability of this methodology, demonstrating its ability to yield significant insights even in scenarios involving rare events. In addition to this, we repurposed administrative data for multimorbidity analysis, offering a novel path for public health research. This approach has the potential to influence future studies and interventions, encompassing areas such as polypharmacy and long COVID-19 research. By deepening our understanding of COVID-19 dynamics, this study emphasizes the broader utility of such methodologies in shaping effective public health strategies and interventions.

Data Availability
The data sets used in this study are not publicly available. As a result of ethical committee restrictions, raw data cannot be publicly or freely shared to ensure the privacy and protection of individual-level data. However, researchers may request access to aggregated data by contacting the corresponding author (DB) through a reasonable inquiry. The code utilized to derive the results in this study is accessible in Multimedia Appendix 5.

Abstract

Background: In recent years, the number and proportion of newly reported HIV/AIDS cases among older adults have increased dramatically. However, research on the pattern of temporal and spatial changes in newly reported HIV/AIDS among older adults remains limited.

Objective: This study analyzed the spatial and temporal distribution of HIV/AIDS cases and its influencing factors among older adults in Eastern China from 2004 to 2021, with the goal of improving HIV/AIDS prevention and intervention.

Methods: We extracted data on newly reported HIV/AIDS cases between 2004 and 2021 from a case-reporting system and used a Joinpoint regression model and an age-period-cohort model to analyze the temporal trends in HIV/AIDS prevalence. Spatial autocorrelation and geographically weighted regression models were used for spatial aggregation and influence factor analysis.

Results: A total of 12,376 participants with HIV/AIDS were included in the study. The newly reported HIV infections among older adults increased from 0.13 cases per 100,000 people in 2004 to 7.00 cases per 100,000 people in 2021. The average annual percent change in newly reported HIV infections was 28.0% (95% CI –21.6% to 34.8%). The results of the age-period-cohort model showed that age, period, and cohort factors affected the newly reported HIV infections among older adults. The newly reported HIV/AIDS cases among men who have sex with men (MSM) had spatial clustering, and the hotspots were mainly concentrated in Hangzhou. The disposable income of urban residents, illiteracy rate among people aged 15 years or older, and number of hospital beds per 1000 residents showed a positive association with the newly reported HIV infections among older MSM in the Zhejiang province.

Conclusions: HIV/AIDS among older adults showed an increasing trend and was influenced by age, period, and cohort effects. Older MSM with HIV/AIDS showed regional clustering and was associated with factors such as the disposable income of urban residents, the illiteracy rate among people aged 15 years or older, and the number of hospital beds per 1000 people. Targeted prevention and control measures are needed to reduce HIV infection among those at higher risk.

KEYWORDS
HIV/AIDS; men who have sex with men; newly reported infections; older adults; spatiotemporal analysis
Introduction

The first case of AIDS from HIV was reported in 1981 [1]. Since then, over 84 million individuals have been infected with HIV with over 40 million reported deaths attributed to AIDS-related illnesses. According to the Joint United Nations Programme on HIV/AIDS, approximately 38.4 million individuals are living with HIV, with 1.5 million new infections in 2021 [2]. In China, the absolute number of new HIV diagnoses has increased annually since 2005, reaching nearly 131,671 in 2020. By the end of 2020, a total of approximately 1,053,000 cases had been reported in China [3].

Initially, the epidemic was thought to affect primarily individuals aged between 15 and 49 years; however, evidence suggests that the burden of HIV/AIDS is considerable among those aged 50 years or older [4]. Epidemiological studies in China have also reported an increasing trend in the number and proportion of HIV infections among older adults [5]. A study from the Henan Province reported that the proportion of newly reported cases aged 50 years or older increased gradually from 4.5% between 1995 and 2000 to 35.5% between 2016 and 2020 through sexual transmission [6]. In China, the sexual needs of older adults are often neglected by their partners and society, often leading to high-risk sexual behavior. Unprotected sexual contact is very common among older people, which in turn increases the risk of HIV infection [4].

The generation, transmission, and distribution of HIV/AIDS are closely associated with geospatial information. Spatiotemporal analysis is commonly used in HIV/AIDS research to assess long-term trends and geographic distribution patterns [7-9]. The Joinpoint regression model can estimate long-term trends in reported HIV/AIDS incidence or infections, whereas the age-period-cohort model can estimate the effects of age, period, and cohort on HIV/AIDS annual reported incidence or infections [7]. Spatial analysis provides insights into the spatial distribution of the HIV/AIDS epidemic and risk factors associated with the geographically weighted regression (GWR) model [8]. For example, using AIDS intensity ranking maps and spatial cluster analysis, Wang et al [9] found that AIDS incidence hotspots in China in 2008 and 2011 were mainly distributed in Yunnan, Guangxi, Guizhou, Chongqing, and Sichuan.

In terms of factors influencing the AIDS epidemic, economic development is strongly positively associated with the AIDS epidemic in China; the GWR results further indicate that the impact of health care and education on the AIDS epidemic varies across regions [9]. However, the long-term trends and spatial distribution of HIV/AIDS prevalence among older adults in Eastern China have not been adequately assessed. The design and evaluation of national HIV/AIDS planning often rely on comprehensive national data, which can mask local HIV/AIDS epidemics [10]. To better control the HIV/AIDS epidemic, a more comprehensive and detailed analysis of HIV/AIDS among older adults in Eastern China is needed.

Therefore, this study assessed the changing trend and spatial distribution of newly reported HIV infections among older adults in Eastern China and aimed to clarify the temporal trends, hotspot areas, and influencing factors of the HIV/AIDS epidemic. Our findings provide novel insights into the developmental trend of the HIV/AIDS epidemic among older adults in Eastern China, help optimize resource allocation, and facilitate HIV/AIDS prevention and treatment strategies.

Methods

Ethical Considerations

This study was approved by the ethics review committee of the Center for Disease Control and Prevention of Zhejiang Province (2018-032). All of the surveillance work was completed by the local Centers for Disease Control and Prevention (CDCs). We extracted data from the Zhejiang Province database of the National Data Information System for Comprehensive HIV/AIDS Control. We did not collect extra information or specimens for this study. Therefore, our study is based on data derived from daily work and was exempt from informed consent. During data analysis, we strictly followed the requirements of the ethical review committee of the Zhejiang Provincial CDC to protect the privacy of the participants, and all data used in this study were anonymous.

Study Area

The Zhejiang Province, located on the southern flank of the Yangtze River Delta along the southeast coast of China (latitude: N 27° 02'-31° 11’ and longitude: E 118° 01'-123° 10’; Multimedia Appendix 1), has a land area of 105,500 km² with approximately 65.77 million residents as of 2022 [11]. Currently, Zhejiang Province has 11 prefecture-level cities, 37 municipal districts, 20 county-level cities, and 33 counties.

Data Sources

Since 2004, China has used a direct network reporting system called the China Infectious Disease Reporting Information System. The database was established by the Chinese CDC. Patients aged 50 years or older with newly reported HIV infection between January 1, 2004, and December 31, 2021, were screened from the Zhejiang Province database of the National Data Information System for Comprehensive HIV/AIDS Control. There were no significant differences in the data information system during the study period. In this study, patients with HIV/AIDS were diagnosed according to the HIV/AIDS diagnostic principles and China’s National HIV/AIDS Testing Technical Specifications and Standards [12]. Data on sociodemographic characteristics, transmission routes, and addresses were collected by local CDC staff in face-to-face interviews using standardized forms. Vectorized county-level geographic maps of the Zhejiang Province were derived from the National Geographic Information Public Service Platform. The area codes were determined by the Disease Control Information System.

To explore the factors influencing the newly reported HIV/AIDS cases according to geographical distribution, we collected the following variables: disposable income of urban residents, gross domestic product (GDP) per county, proportion of the illiterate population, proportion of the unmarried population, area of residence per capita, car ownership rate, number of hospital
beds per 1000 people, number of doctors per 1000 people, urbanization rate, and proportion of the older population. Data were compiled using a Microsoft Excel (version 16.0; Microsoft Corporation) spreadsheet. Data on these influencing factors were obtained from the Statistical Yearbook of Zhejiang Province due to the presence of multicollinearity between the variables. The ordinary least squares (OLS) method was used to exclude redundant variables (variance inflation factor >7.5) and those that did not pass the significance test.

Statistical Analysis

Temporal Analysis

The temporal analysis used the crude rate of newly reported HIV/AIDS for each year. The new reporting rate is calculated by dividing the total number of incidents in the year by the number of people in the corresponding year and multiplied by 100,000.

The annual percent change (APC) and average APC (AAPC) of each component were estimated using a Joinpoint regression model. The infection of new reports ($y_i$) was set as the dependent variable, year was set as the independent variable ($x_i$), and sex and route of infection were set as subgroup variables [13]. Joinpoint regression analysis was performed using JPR software (version 4.9.1.0; Statistical Research and Applications Branch, National Cancer Institute).

The age-period-cohort model, a popular statistical tool for extracting information hidden in morbidities, has been used in long-term trend studies on social change, causes of disease, aging, demographic processes, and dynamic studies [7]. The effects of age, period, and cohort factors on the newly reported HIV infections were analyzed using an R language–based network analysis tool developed by the National Cancer Institute [14].

The model required consistent age, period, and cohort intervals; we divided the study period into four 5-year intervals, divided age into 7 groups, and calculated birth cohort by subtracting the period from age. The age, period, and cohort of the center were selected as controls [14].

Spatial Analysis

ArcGIS software (version 10.8; ESRI Inc) was used to map the spatial distribution of HIV/AIDS cases. The Global Moran I Index was applied to examine the clustering of HIV/AIDS among older adults at the county level in Zhejiang Province to determine whether the clustering elements within the region were statistically significant at $\alpha=.05$ test level [15].

Local spatial autocorrelation was used to analyze the correlation of HIV/AIDS case distribution at the county level. In the Local Indicators of Spatial Autocorrelation (LISA) map, we identified 4 clusters of spatial relationships for the analyzed variables. High-high and low-low clusters are those in which the high or low values of the study variable are surrounded by neighboring areas above or below the mean [16].

The OLS model requires the data to be independently distributed, and the results are global estimates of the parameters that do not reflect the pattern of change in the data with geographical location. The GWR model embeds the spatial location of the data into regression parameters and uses local weighted least squares to estimate the parameters, which is a local statistical model [17]. In the presence of spatial autocorrelation, the traditional OLS model is not applicable to data analysis. In the GWR model, the region-specific regression coefficient is no longer the same value estimated using global information but rather a variable coefficient that varies with geographical location. The $R^2$, adjusted $R^2$, and corrected Akaike information criterion values were used to compare the OLS and GWR models [18]. The GWR model is structured as follows:

$$
\hat{\mu}_{i} = \beta_{0} + \beta_{1}(x_{i}) + \beta_{2}(y_{i}) + \ldots + \beta_{k}(z_{i}) + \epsilon_{i}
$$

where $\mu$ is the coordinate of the geographic center of the $i$th sample space unit and $\beta_k(\mu, \nu)$ is the value of the continuous function $\beta_k(\mu, \nu)$ in the space of the $i$th sample unit.

Result

Demographic Characteristics

Between 2004 and 2021, a total of 12,376 new HIV/AIDS cases among older adults were reported in Zhejiang Province. The number of reported cases increased from 15 in 2004 to 1657 in 2021, and the number of reported infections increased from 0.13 per 100,000 persons in 2004 to 7.00 per 100,000 persons in 2021. In terms of geographical distribution, HIV/AIDS cases were reported in all counties and districts during the study period. In 2004, a total of 9 counties reported HIV/AIDS cases among older adults, while 86 newly reported HIV/AIDS cases were reported among older adults in 2021 (Figure 1). Of the 12,376 patients, 76.9% (9514/12,376) were male and 98.5% (12,196/12,376) of cases involved transmission through sexual contact (10,496/12,376, 84.8% heterosexual transmission, and 1700/12,376, 13.7% homosexual transmission; Table 1).

**Temporal Trend and Joinpoint Regression Analysis**

The newly reported HIV infections in older male individuals, which peaked in 2017 and then fluctuated downward from 2018 to 2021, were significantly higher than those in older female individuals in Zhejiang Province from 2004 to 2021. Heterosexual and homosexual transmission were the predominant routes of HIV/AIDS transmission among older adults, with the number of heterosexual transmission cases growing rapidly over the study period, reaching its highest recorded level in 2019. In contrast, the number of men who have sex with men (MSM) and who are HIV positive grew slower over the study period (Figure 2).

The results of the Joinpoint regression model for the newly reported HIV infections showed that the optimal results of the model were all 2 nodes. There was a significant increase in newly reported HIV infections among older adults in Zhejiang Province from 2004 to 2021 (AAPC = 28.0%, 95% CI -21.6% to 34.8%; Table 2).

From 2004 to 2017, the newly reported infections showed an increasing trend (2004-2010: APC=61.1%, 95% CI –37.9% to 88.2%; 2010-2017: APC=22.0%, 95% CI –17.2% to 27.1%). However, there was no significant difference in the trend in newly reported infections from 2017 to 2021 (2017-2021: APC=1.6%, 95% CI –8.1% to 12.4%). Similar changes were observed in older male and female individuals, with AAPCs of 27.6% (95% CI –19.8% to 36.0%) and 26.6% (95% CI –18.5% to 35.2%) for older male and female individuals, respectively. For the newly reported infections of different routes of transmission, both heterosexual and homosexual transmission showed an increasing trend, with AAPC rates of 28.7% (95% CI –20.8% to 35.2%) and 42.4% (95% CI –23.2% to 64.5%), respectively. However, the annual trend for the other transmission routes was not significant, with an AAPC of 10.2% (95% CI –15.3% to 43.3%).

**Age-Period-Cohort Model Analysis**

**Wald Chi-Square Test Results**

The net drift, all-age deviations, all-period deviations, all-period relative risk (RR), and all-cohort RR of the newly reported infections among older adults in Zhejiang Province from 2004 to 2021 were significant (all P<.001), indicating that changes in the newly reported infections were affected by age, period, and cohort factors (Table 3). As shown in Figure 3A, the net drift of the newly reported HIV infections was 31.501% (95% CI –25.510% to 73.780%). There was no significant change in local drift in the newly reported infections across age groups.

Figure 3. Age-period-cohort effect of reported HIV/AIDS infections among older adults in Zhejiang Province (2004-2021). (A) Net and local drifts, (B) Age effect, (C) Period effect, (D) Cohort effect. RR: relative risk.

**Age Effect**

Figure 3B shows the newly reported HIV infections showed a monotonic increasing trend from 0.01 per 100,000 persons in the age group of 50-54 years to 16.71 per 100,000 persons in the age group of ≥80 years, and the rate of increase was significantly accelerated after the age of 70 years.

**Period Effect**

Using the 2007-2011 period group as a control group (RR=1), an overall upward trend was observed in the period effect of HIV/AIDS risk reported by older adults, with the RR increasing from 0.099 (95% CI –0.052 to 0.185) to 6.23 (95% CI –4.269 to 9.092; Figure 3C).
Cohort Effect
Using the 1940-1944 birth cohort as a control group (RR=1), the cohort effect on the risk of HIV/AIDS among older adults born before 1940 in Zhejiang Province did not change significantly. Since 1944, the birth cohort effect has increased monotonically, with the RR increasing from 4.134 (95% CI –2.999 to 5.700) in the 1945-1949 birth cohort to 1064.394 (95% CI –418.537 to 2706.892) in the 1965-1969 birth cohort (Figure 3D).

Spatial Analysis
Global Spatial Autocorrelation
Global spatial autocorrelation analysis of the newly reported infections for each year of the study period was performed and grouped according to different routes of infection (Multimedia Appendix 2). The results showed no significant differences in the global geographic autocorrelation of newly reported infections for the total population and the heterosexual transmission population. However, the global Moran’s I values for the newly reported rates of older MSM after 2012 were all greater than 0 (P<.05), indicating significant clustering of newly reported infections among older MSM in the Zhejiang Province. Therefore, further spatial clustering analyses are required in this population.

Local Spatial Autocorrelation
LISA cluster distribution maps were used to identify HIV/AIDS hotspots and outlier sites among older MSM in the Zhejiang Province (Figure 4). In 2012, the high-high cluster areas of newly reported HIV infections among older MSM were concentrated in the urban areas of Hangzhou, including Shangcheng, Xiacheng, Gongshu, and Jianggan districts, and there were no low-low cluster areas. In the following years, the high-high cluster areas were also concentrated in the main urban area of Hangzhou, while the low-low cluster areas were small and unstable, scattered in Chun’an and Jiande counties as well as Cangnan and Taishun areas.

Spatial Regression Analysis
In the GWR, the independent variables for the best model in 2020 include urban disposable income, the illiteracy rate of residents aged 15 years or older, and the number of hospital beds per 1000 people. Multimedia Appendix 3 shows that the GWR model is better than the OLS model and has no residual autocorrelation. Figure 5A-C shows the spatial distribution of the independent variables, including the disposable income of urban residents, the illiteracy rate of residents aged 15 years or older, and the number of hospital beds per 1000 people, respectively. Figure 5D-F shows the β coefficients determined using GWR regression, and Figure 5D indicates that the disposable income of urban residents in the Zhejiang Province is positively associated with the newly reported HIV infections among older MSM. The newly reported HIV infections were higher in cities with high urban disposable income in southeastern Zhejiang Province. In Zhejiang Province, the illiteracy rate of residents aged 15 years or older was positively associated with newly reported HIV infections in the population (Figure 5E). Figure 5F shows the newly reported HIV infections associated with the number of hospital beds per 1000 people; respectively.
an increase in reported HIV infections in cities with a high number of hospital beds per 1000 people in northwestern Zhejiang Province was observed.

Figure 5. Spatial distribution of independent variables and regression coefficients.

Discussion

As HIV/AIDS is initially prevalent among individuals aged between 15 and 49 years, there are fewer reports of HIV infections in older adults [4]. The number and proportion of HIV/AIDS cases among older adults have increased significantly in recent years due to aging and the development of the HIV/AIDS epidemic. Yuan et al [8] found that the proportion of older adult cases of all reported HIV/AIDS cases in Sichuan Province, China, increased from 4.1% in 2008 to 59.2% in 2019. In the central and western regions of China, 98.2% of older adults were infected through heterosexual transmission [8], while in Zhejiang Province, 13.7% were infected through...
homosexual transmission. This suggests a slightly different pattern of HIV/AIDS prevalence in the eastern coastal region than in central and western China. However, few studies have used spatial and temporal distributions to analyze the prevalence of HIV/AIDS among older adults in the eastern, developed coastal areas of China. This study summarized the spatial and temporal distribution of the pandemic and its influencing factors, providing a rationale for designing prevention programs and allocating resources more efficiently.

Overall, the Joinpoint regression results showed that the proportion of newly reported HIV/AIDS cases increased significantly from 2004 to 2021. This phenomenon could be illustrated by several factors. First, the Chinese government adopted a policy of expanding testing in recent years, which has significantly improved the detection rate of the virus. This indicates that the expanded testing policy was widely implemented, leading to more HIV/AIDS being detected [19]. Second, at the beginning of the pandemic, HIV/AIDS mainly affected young individuals [20]; therefore, most education catered to that age group, while older individuals were overlooked, which increases their risk of infection in that age group. Third, the main route of HIV/AIDS transmission among older adults was heterosexual transmission (10,496/12,376, 84.8%). Low-cost commercial establishments are a major source of infection in older adults [21]. Simultaneously, older male individuals tend not to use condoms when engaging in heterosexual contact, which also increases their risk of HIV/AIDS transmission [4]. Finally, transportation, communication, and sexual activity have changed over the past decade with advances in technology and economic growth [8]. Access to transportation and communication has enhanced the sex work industry; with economic development, the older population has the financial means to pay for these services. This change also poses significant challenges to traditional HIV/AIDS prevention and control strategies [8]. Male individuals have significantly higher rates of HIV/AIDS than female individuals. Possible reasons for this are the lack of physiological decline in those older than 50 years of age and the high level of physical condition and sexual needs of older male individuals [22]. In summary, the current prevention services are inadequate for addressing the HIV/AIDS epidemic among older adults, and further research and public health interventions are required. Along with expanding testing, sex education for older adults should be strengthened to reduce the incidence of high-risk sexual behavior.

Age, period, and cohort had significant effects on newly reported HIV infections among older adults in Zhejiang Province. Age is an important factor influencing HIV/AIDS. Our findings suggest that, within the same birth cohort, older age correlates with a higher risk of reporting HIV/AIDS, which is consistent with previous results [23]. Lu et al [24] also found that HIV incidence among male individuals in Zhejiang Province peaked between the ages of 20 and 35 years, then declined and peaked again between the ages of 60 and 70 years. In this study, homosexual and heterosexual sexual contact were the main modes of HIV/AIDS transmission among older adults. Contrary to the common belief that sexual activity among older adults decreases with age, older adults still engage in sexual activity [25]. One study found that most older patients found sex with an HIV-positive partner to be acceptable [26]. However, unprotected sexual contact is common among older adults due to lower level of education, which increases their risk of HIV infection [4].

The period effect of newly reported HIV infections among older adults in the Zhejiang Province from 2004 to 2021 was consistent with the change in the Joinpoint regression. The monotonic upward trend in the period effect of newly reported infections was associated with factors such as policies to expand testing and unsafe sex among older adults [8,19,21]. Period effects are an important factor influencing HIV/AIDS transmission among older adults and is linked to medical advances and policy development. As economies and societies advance, multidisciplinary approaches to curb growing HIV/AIDS-related problems must be considered. For example, the Chinese CDC launched a web-based AIDS information system and integrated response information management system in 2006 [27]. This has implemented health promotion strategies within social networks and strengthened sexual health services and partner services.

Cohort effects included the risk of morbidity or mortality in individuals in the same birth cohort with the same exposure to a disease risk factor [24]. In this study, the birth cohort effect on newly reported HIV infections among older adults in Zhejiang Province increased from 2004 to 2021. Cohorts born before 1950 had fewer reported infections, whereas those born after 1950 showed a gradual increase in reported infections with increasing birth year. This may be attributed to the fact that the cohort born after 1950 is in the sexually active age group. A previous study reported higher rates of sexual transmission among people born later in life, which may indicate that they are more sexually active or risky [23].

Spatial analysis revealed a geographic expansion of the newly reported HIV infections among older adults in Zhejiang Province. HIV-positive MSM showed a spatial correlation during the study period. The spatial autocorrelation results showed high clustering of HIV-positive MSM in Hangzhou City. Factors influencing the aggregation of HIV infections include the local HIV burden [28]. The high number of chronically infected individuals in Hangzhou has hindered HIV/AIDS control. Sexual transmission has become a major mode of HIV transmission in Zhejiang Province; however, homosexuality remains highly stigmatized and discriminated against in China [29]. As a result, Chinese MSM tend to hide their identity and engage in sexual behavior in other areas. Most MSM are concentrated in metropolitan areas, where self-identification and sexual partners are available. Hangzhou is the capital city of the Zhejiang Province, with a rapidly growing economy that has attracted migrants, including MSM [30]. Meanwhile, the provincial transmission networks found that Hangzhou plays a central role in the cross-regional transmission of HIV/AIDS among MSM in Zhejiang Province [31]. Studies have found that stigma can also lead to risky behaviors, such as lack of testing and avoidance of treatment. Various forms of stigma, such as substance abuse, depression, and traumatic stress, interact to increase the vulnerability of MSM and increase the risk of HIV infection [32]. The stigma
associated with MSM, coming out, accepting sexual partners, and being perceived as “older” in the gay community can lead to risky behaviors such as avoiding sex education [33]. This study provides clues to the epidemic clustering characteristics of older MSM in Zhejiang Province, which will facilitate the design and implementation of evidence-based interventions. Eliminating stigmatization and discrimination against MSM populations is critical to controlling epidemic aggregation and reducing HIV infection, as stigma and discrimination are barriers to MSM seeking HIV/AIDS services [32].

Overall, the GWR analysis showed that urban disposable income, the illiteracy rate of residents aged 15 years or older, and the number of hospital beds per 1000 people were associated with the reported infections of HIV-positive MSM among older adults in the Zhejiang Province. The economy is an important factor influencing the pattern of HIV-reported infections. People with a higher income and lower awareness of HIV/AIDS were more likely to be HIV-positive [18], and their high disposable income allowed them to have more sexual partnerships. Moreover, illiteracy was positively associated with the reported HIV infections among older MSM in Zhejiang Province. Higher educational attainment is associated with a lower risk of HIV infection; targeted educational programs and attitude changes among people living with HIV/AIDS can help advance voluntary counseling and testing [34]. This study demonstrates the need to provide health education for older adults to further promote sexual health in older adults. Finally, the number of hospital beds per 1000 people was strongly associated with the reported infections among older MSM in Zhejiang Province. Health care is an important determinant of HIV/AIDS prevention. Qin et al [35] found a significant positive association between the number of health care facilities and the number of reported cases of HIV/AIDS. Detection bias is a possible cause, and better health care resources are associated with higher detection rates; therefore, areas with abundant health care resources generally have more diagnosed cases. The provision of good health care is strongly associated with early diagnosis of HIV/AIDS, which can help control the spread of the epidemic.

This study has some limitations. First, since this was an ecological study, it was difficult to determine the causal relationships between the outcomes and variables. Second, the number of newly reported cases differs from the incidence, and the number of reported HIV/AIDS cases among older adults is influenced by the testing intensity, coverage, and efficiency. The number of HIV/AIDS tests decreased by 41% worldwide due to inadequate HIV/AIDS testing in health services as a result of the COVID-19 pandemic [36]. In Zhejiang Province, where the number of reported cases among older adults began to decline for the first time in 2019, future research must assess the impact of the COVID-19 pandemic on HIV/AIDS testing. Third, spatial autocorrelation is influenced by partition effects. In this study, we used county districts as the spatial units of analysis. Different spatial statistical values would have been obtained had the analysis been conducted at the municipal or street levels. Further studies should consider using smaller spatial units for analysis, which may provide more locational information and make the results more comprehensive. Fourth, the GWR model used indicators obtained from the local bureau of statistics, which did not have specific indicators for older people. However, we have attempted to use these indicators to reflect the overall level of development in the area. Despite these limitations, we identified an increasing trend of HIV/AIDS among older adults in the Zhejiang Province, along with spatial clustering in the epidemic distribution.

In summary, the overall number of newly reported HIV infections among older adults in Zhejiang Province has increased in recent years, and older adults have become a key population in the HIV/AIDS epidemic. The majority of HIV/AIDS among older adults is transmitted through heterosexual transmission, but cases among MSM are showing aggregation in some counties. The combination of economic growth and low cognition among older adults are positively correlated with reported HIV infections, so prevention and control strategies should be more inclined to focus on the lower literacy level of older populations in better-off areas. Finally, areas with better health care resources can increase detection; therefore, it is important to comprehensively evaluate testing systems in different regions and improve access to testing services.

Acknowledgments

We would like to thank the physicians and staff at the HIV/AIDS surveillance sites across Zhejiang Province for their dedication to completing the countless data forms that made this work possible.

Abstract

Background: Undernutrition among children younger than 5 years is a subtle indicator of a country’s health and economic status. Despite substantial macroeconomic progress in India, undernutrition remains a significant burden with geographical variations, compounded by poor access to water, sanitation, and hygiene services.

Objective: This study aimed to explore the spatial trends of child growth failure (CGF) indicators and their association with household sanitation practices in India.

Methods: We used data from the Indian Demographic and Health Surveys spanning 1998-2021. District-level CGF indicators (stunting, wasting, and underweight) were cross-referenced with sanitation and sociodemographic characteristics. Global Moran I and Local Indicator of Spatial Association were used to detect spatial clustering of the indicators. Spatial regression models were used to evaluate the significant determinants of CGF indicators.

Results: Our study showed a decreasing trend in stunting (44.9%-38.4%) and underweight (46.7%-35.7%) but an increasing prevalence of wasting (15.7%-21.0%) over 15 years. The positive values of Moran I between 1998 and 2021 indicate the presence
of spatial autocorrelation. Geographic clustering was consistently observed in the states of Madhya Pradesh, Jharkhand, Odisha, Uttar Pradesh, Chhattisgarh, West Bengal, Rajasthan, Bihar, and Gujarat. Improved sanitation facilities, a higher wealth index, and advanced maternal education status showed a significant association in reducing stunting. Relative risk maps identified hotspots of CGF health outcomes, which could be targeted for future interventions.

Conclusions: Despite numerous policies and programs, malnutrition remains a concern. Its multifaceted causes demand coordinated and sustained interventions that go above and beyond the usual. Identifying hotspot locations will aid in developing control methods for achieving objectives in target areas.

Introduction

Child malnutrition continues to pose a significant challenge in low- and middle-income countries. Around 60% of deaths among children younger than 5 years in this countries are attributable to malnutrition [1]. Much of this burden is seen in regions of South Asia, where 2 of every 5 stunted children globally are found [2]. An alarming irony lies in the fact that regions in South Asia such as India, Pakistan, and Bangladesh report child malnutrition rates that are higher than those in sub-Saharan Africa [3]. From the earliest Demographic and Health Surveys (DHS) in the 1990s to the most recent surveys in 2021, all countries have experienced a reduction in the prevalence of stunting. However, India and Pakistan recorded the lowest reductions—2.3 and 0.6 percentage points per year, respectively—compared with Bangladesh and Nepal, which recorded the largest reductions—2.9 and 4.1 percentage points per year, respectively. The Global Hunger Index, a comprehensive instrument used for measuring and monitoring hunger on a global, regional, and national scale, in 2022 ranked India 107th out of the 121 countries; additionally, India has recorded the highest rate of child wasting and has performed comparatively worse than its neighboring countries, with Pakistan scoring 99, Bangladesh scoring 84, Nepal scoring 81, and Sri Lanka scoring 64 [4]. Malnutrition is the leading cause of significant health and developmental issues among children globally, accounting for 3.5 million deaths and 35% of morbidities among children younger than 5 years [5]. For those who survive, malnutrition can cause lasting damage, increase the likelihood of child morbidity, contribute to poor cognitive development in childhood, result in short stature in adulthood, decrease adult productivity, increase the risk of perinatal and neonatal death for women, and heighten the risk for chronic disease if accompanied by overweight in later childhood [6]. Malnutrition bears noteworthy economic ramifications, as India experiences an annual loss of 4% of its gross domestic product due to malnutrition [7].

Childhood malnutrition is a complex issue. Merely increasing household income will not suffice to alleviate the childhood malnutrition if children lack food security, health care, education, water, and sanitation access [8]. According to a recent study, 3 key drivers of malnutrition include poor diet among children in their first years of life, dietary inadequacy among women before and during the pregnancy, and poor sanitation practices at both household and community levels [6,9]. A recent study based on large-scale national representative survey data of India found that the likelihood of stunting increased with decreased regional water availability, unimproved sanitation, and unsanitary toilet disposal methods. Wasting was also exacerbated by a decline in regional water supplies and inadequate sanitation [7]. Household water, sanitation, and hygiene facilities and practices were reported as key mediating factors in the reduction of stunting in the Democratic Republic of Congo [9]. Children with better toilet facilities had a 37% less chance of being wasted [10]. Conversely, poor sanitation facilities could put the child at risk for a variety of infections and health problems [11]. Despite these issues being primarily associated with inadequate feeding patterns [12], addressing them remains challenging, particularly in India, where malnutrition affects both well-nourished and malnourished individuals [13]. According to the India State-Level Disease Burden Initiative, child growth failure (CGF) is responsible for almost one-fifth of all under-5 mortality in India, with a prevalence rate for stunting ranging from 21.3% to 49%, for wasting from 6.3% to 19.3%, and for underweight from 16.5% to 42.2% in 2017, showing a widespread geographical variance [14]. This disparity among Indian states makes achieving the Sustainable Development Goal 2 more challenging [15].

India has several nutrition-specific (food fortification and deworming) and nutrition-sensitive (Public Distribution System, Midday Meal Scheme, and POSHAN Abhiyaan) policies and programs in place to address recognized causes of malnutrition and child development. However, these programs encounter a variety of implementation challenges [16] across states, including poor targeting, leakage [17], inadequate infrastructure [18], corruption, and delayed payments [19]. If these large-scale social safety programs aim to address the fundamental drivers of hunger, it is necessary to bridge these implementation gaps. The provision of safe water and basic sanitation facilities in India has increased, although there remain disparities as indicated by the data reported by Water.org. According to recent statistics, a notable proportion of the Indian populace, specifically 6%, are deprived of access to potable water, whereas a significant majority (54%) lack access to properly managed household sanitation amenities. The score of India in terms of the availability of clean water and sanitation also reduced from 88 (2019) to 83 (2020) [20,21]. To gain a more nuanced understanding of the regional distribution of these indicators in
India, a spatial-regional approach is needed. Additionally, to identify the determining factors holistically and particularly across spatial-regional contexts, this study used a spatial regression model to explain the determinants of the unequal distribution of stunting, wasting, and underweight. Pursuant to this recommendation, our research aims to present the spatiotemporal trends of CGF indicators (wasting, stunting, and underweight) among Indian children younger than 5 years from 1992 to 2020, as well as their correlation with household sanitation practices.

Methods

Overview
This study used data from Indian Demographic and Health Surveys, also known as the National Family Health Surveys (NFHS). The NFHS is a large-scale, multiround survey conducted in a representative sample of households across India. It used a stratified random sampling method at multiple stages, distinguishing between urban and rural areas as natural strata. The survey captures national and state-level data on fertility, infant and child mortality, the practice of family planning, maternal and child health, reproductive health, nutritional status, and use and quality of health and family planning services [22].

A total of 33,026, 51,555, 259,627, and 232,920 children younger than 5 years who participated in NFHS-2 (1998), NFHS-3 (2005), NFHS-4 (2015), and NFHS-5 (2021), respectively, were included in the analysis.

Ethical Considerations
The study is based on a secondary data set from an NFHS survey that contains no personally identifying information about the survey participants. These NFHS data sets can be downloaded from the DHS program website after registration [23]. The NFHS survey had received ethical clearance from the International Institute for Population Science’s ethical review board before the survey. Additionally, the study protocol was reviewed and approved by the institutional research ethics committee of the Post Graduate Institute of Medical Education and Research, Chandigarh, India (vide letter number: NK/7176/MPH/188, July 27, 2021).

Outcome Variables
The nutritional status of children served as the outcome variable in this study. Children with a height-for-age $z$ score of less than $-2$ SD from the reference population median are considered stunted. Those with a height-for-age $z$ score of less than $-3$ SD from the reference population median are classified as severely stunted [24]. Children with a weight-for-height $z$ score of less than $-2$ SD from the reference population median are considered thin (wasted) or acutely undernourished. Those with a weight-for-height $z$ score of less than $-3$ SD from the reference population median are classified as severely wasted [24]. Underweight children have a weight-for-age $z$ score of less than $-2$ SD from the reference population median. Children are considered severely underweight if their weight-for-age $z$ score is less than $-3$ SD from the median [24]. Height and age SD, weight and height SD, and weight and age SD data were provided for these indicators. Anthropometric $z$ scores were calculated based on the World Health Organization (WHO) growth standards of children, as guided by the DHS-7 Guide to DHS Statistics. Children with height-for-age, weight-for-age, or weight-for-height $z$ scores falling outside of the acceptable range were identified as having invalid data.

Exposure Variable
We explored various characteristics that influence the outcome variables, as reported by previous studies [25,26]. The independent variables, along with potential confounding factors, included household sanitation facilities and sources of drinking water. Personal characteristics of children (eg, age and gender), maternal-related factors (eg, mother’s education), and household-related factors (eg, wealth index and ethnicity [caste]) were among these influences. Water supply and sanitation facilities, as defined by the DHS, were divided into 2 categories: improved and unimproved. Households with improved drinking water sources included those with piped water to yard, plot, or dwelling; tube well or borehole; public tap or standpipe; rainwater; protected well; protected spring; boiled water; and reverse osmosis plant. Households with unimproved water sources included those using surface water (dam, river, lake, canal, stream, or pond and irrigation), unprotected springs, unprotected wells, tanker trucks, or carts with a small tank. Improved sanitation facilities comprised flush or pour-flush to piped sewer systems, septic tanks, pit latrines, twin pits, pit latrines with slabs, ventilated improved pit or biogas latrines, and composting toilets. Unimproved sanitation facilities included any type of unimproved toilet facility, shared facilities, and open defecation (no facility, bush, or field).

Data Extraction
Figure 1 illustrates the framework used in the data extraction and analysis for this study. The data set, presented in the Stata(.dta) file format, was extracted from the DHS survey data set files. The extracted data were cleaned for the variables of interest using Stata (StataCorp). Data from NFHS-2, NFHS-3, NFHS-4, and NFHS-5 were used for the trend analysis.
Figure 1. Framework deployed in data extraction and analysis in this study. NFHS, National Family Health Surveys; UT, union territory.

Data Analysis

Spatial Analysis

We used India’s 2011 Census shapefile, which includes 640 districts for spatial analysis using the district-level data from NFHS-2, NFHS-4, and NFHS-5 (Figure 2).

Figure 2. Regions of India.
**Exploratory Spatial Analysis**

The spatial autocorrelation statistic (Global Moran I) was used to assess the clustering or randomness of data, that is, whether the CGF patterns are randomly distributed, scattered, or clustered. If the Moran I value is closest to –1, the prevalence of wasting, stunting, and underweight is distributed; if the Moran I value is closest to +1, these variables are clustered in the study region. A Moran I value of zero, however, indicates a random distribution of CGF indications. Once it was confirmed that the distribution of stunting, wasting, and underweight is nonrandom, local Moran I was used to study the local-level cluster locations of CGF indication in India using the LISA (Local Indicator of Spatial Association) cluster map [27].

Hotspot clusters and cold spot clusters were identified by the local Moran I. Hotspots (High-High) and cold spots (Low-Low) were identified. It also accounted for outliers where high values were mostly surrounded by low values (High-Low) and outliers where the low values were primarily surrounded by high values (Low-High) [28]. The bivariate LISA was used to calculate the relationship between independent variables and CGF indicators.

The LISA significance map was used for hotspot analysis, computing the $P$ value for the estimation of the statistical significance of the clustering area. The $P$ value associated with 99%, 95%, and 90% confidence levels was used in this study to determine the presence of substantial clustering. The software used in this study included GeoDa 1.18 (Spatial Analysis Laboratory of the University of Illinois at Urbana-Champaign) [29] and QGIS 2.18.16 (QGIS Development Team) [30].

**Confirmatory Spatial Analysis**

The regression technique was used to investigate the relationship between the percentage of stunting, wasting, and underweight and background characteristics (improved and unimproved drinking water supply and toilet facilities, maternal education, ethnicity [caste], and wealth index). The choice of the regression technique was determined by the presence or absence of multicollinearity, homoscedasticity (constant variance), and normal distribution in the data. To check if the explanatory variables correspond, the multicollinearity condition number was used. Homoscedasticity was determined using the Breusch-Pagan test. The Jarque-Bera test was used to assess the normality of the error distribution. If the independent variables were found to be uncorrelated, followed a normal distribution, and had a constant variance (homoscedasticity), the ordinary least-squares regression, a nonspatial regression technique, would be used. If this assumption was broken, the use of spatial regression would be justified. Spatial regression is used for predicting the value of the dependent variable based on the collection of values from independent factors while considering spatial dependence. Spatial lag and spatial error are 2 types of spatial dependence. The spatial lag model assumes that the result of the outcome variable is affected by neighboring areas, whereas the spatial error model evaluates the impact of variables that were not included in the regression model but have an impact on the dependent variable [31]. The key difference between the 2 models is the inclusion of error terms of spatial dependence in the spatial error model. The analysis was conducted with the assistance of the RStudio [32] program.

**Results**

**Characteristics**

A total of 24,395, 45,377, 215,511, and 206,112 observations were available from the survey rounds 1998-1999, 2005-2006, 2015-2016, and 2019-2021, respectively. Table 1 describes the sociodemographic characteristics of the samples from NFHS-2, NFHS-3, NFHS-4, and NFHS-5 that were analyzed. Most of the sociodemographic distribution in the sample remained almost the same across NFHS-3, NFHS-4, and NFHS-5. However, in NFHS-2, there was higher representativeness of children from 0 to 24 months, particularly in middle wealth quintile; around 50% of mothers of children were uneducated in both NFHS-2 and NFHS-3, 30% in NFHS-4, and 21% in NFHS-5. There were 22%, 13%, 7.5%, and 4% unimproved sources of water in NFHS-2, NFHS-3, NFHS-4, and NFHS-5, respectively. The percentage of unimproved type of sanitation facility was 71% in NFHS-2, which reduced to 24% in NFHS-5. Table 2 indicates that the prevalence of stunting was 44.5% for NFHS-2, 48% for NFHS-3, 38.4% for NFHS-4, and 35.5% for NFHS-5. Similarly, for wasting, the prevalence was 16%, 20%, 21%, and 19%, respectively, and for underweight, the prevalence was 47%, 43%, 36%, and 32%, respectively. The observed prevalence is adjusted by survey weights according to the DHS guideline [33], and trends are shown at the regional level in Figures 3-5. The results were consistent with the prevalence reported in the DHS reports.

**Figure 3.** Trends of stunting by region; data from Indian Demographic and Health Surveys 1998, 2005, 2015, and 2021. NFHS: National Family Health Survey.
Trends of Stunting, Wasting, and Underweight
From 1998-1999 to 2005-2006, the prevalence of stunting increased in most of the regions, including Central, South, West, and Northeast, and started decreasing from 2005 onward (Figure 3). The prevalence of wasting increased from 1998 to 2015 and decreased in the subsequent 5 years (Figure 4). The prevalence of underweight decreased from NFHS-2 to NFHS-5 in all Indian regions (Figure 5).

Spatial Autocorrelation of Stunting, Wasting, and Underweight Among Children
During the survey rounds NFHS-2 to NFHS-5, the spatial patterns of stunting, wasting, and underweight among children were found to be nonrandom. For stunting, wasting, and underweight, the value of Global Moran I varied from 0.293 to 0.419, 0.253 to 0.033, and 0.404 to 0.584, respectively, indicating significant clustering of these indicators across the country (Table 3) in NFHS-2, NFHS-4, and NFHS-5. In NFHS-4, the Moran I value was the highest, indicating considerable positive spatial autocorrelation, that is, districts with comparable prevalence are clustered together. Similarly, the spatial patterns for the source of drinking water, sanitation, wealth index, maternal education, and caste were found to be nonrandom during the survey rounds NFHS-2 to NFHS-5. The values of Global Moran I varied from 0.344 to 0.352 for the drinking water source, 0.443 to 0.459 for sanitation facility, 0.473 to 0.417 for maternal education, 0.361 to 0.472 for ethnicity, and 0.524 to 0.637 for wealth index (Table 3). The clustering trends were highly significant (>90%) during this study period. Table 4 represents the bivariate Moran I value of the outcome and explanatory variables. The highest bivariate
Moran I (CGF vs explanatory variable) value was for stunting versus maternal education (−0.444), followed by stunting versus improved sanitation facility (−0.439), stunting versus wealth index (−0.426), and underweight versus improved sanitation facility (−0.487) during the NFHS-4 round.

*NFHS, National Family and Health Survey.

**Hotspot Detection**

The data associated with the shapefile, along with the spatial relationship for each district-level observation, are visualized using Moron’s scatter plot. Figure 6 represents the univariate LISA maps for stunting, wasting, and underweight. The hotspot areas (enumeration areas with a high risk of stunting) were identified in districts of Rajasthan, Madhya Pradesh, Jharkhand, Bihar, Uttar Pradesh, Gujarat, West Bengal, and Chhattisgarh. Conversely, Karnataka, Arunachal Pradesh, Assam, Kerala, and Tamil Nadu were identified as the cold spots (areas with a low risk for stunting) in all the 3 surveys (NFHS-2, NFHS-4, and NFHS-5). Meanwhile, Haryana, Punjab, Himachal Pradesh, Manipur, Mizoram, Tripura, Odisha, Andhra Pradesh, Nagaland, Uttarakhand, and Maharashtra were identified as the cold spot regions in the fourth and fifth surveys. The observed blank spots on the Indian map result from a lack of data for the corresponding districts. Similarly, the hotspots for wasting were identified...
found in the districts of Maharashtra, Madhya Pradesh, Bihar, Odisha, Jharkhand, Gujarat, Andhra Pradesh, Rajasthan, Karnataka, West Bengal, and Chhattisgarh. The cold spot exists in Uttar Pradesh, Haryana, Punjab, Assam, Arunachal Pradesh, Uttarakhand, Manipur, Kerala, Nagaland, Mizoram, and Himachal Pradesh. The hotspot areas for underweight were in Uttar Pradesh, Bihar, Maharashtra, Madhya Pradesh, Odisha, Jharkhand, Rajasthan, West Bengal, Andhra Pradesh, Gujarat, Karnataka, and Chhattisgarh. The cold spots were located in Kerala, Manipur, Himachal Pradesh, Punjab, Arunachal Pradesh, Tamil Nadu, Assam, Nagaland, Uttarakhand, Kerala, Mizoram, Haryana, Karnataka, and Punjab.

Figure 6. Univariate LISA (Local Indicator of Spatial Association) maps for the prevalence of (A) stunting, (B) wasting, and (C) underweight. NFHS: National Family Health Survey.

LISA Modeling

Figures 7-9 represent the bivariate LISA maps showing associations of stunting, wasting, and underweight with sanitation, respectively. For stunting and unimproved sanitation facilities, the hotspots are in Uttar Pradesh, Gujarat, Madhya Pradesh, Chhattisgarh, West Bengal, and Meghalaya. Regarding wasting and sanitation, Andhra Pradesh, Maharashtra, Madhya Pradesh, Gujarat, Rajasthan, West Bengal, and Chhattisgarh are the hotspot areas. Similarly, for underweight, Maharashtra, West Bengal, Jharkhand, Uttar Pradesh, Madhya Pradesh, Andhra Pradesh, Gujarat, Chhattisgarh, and Rajasthan are high-risk areas.

Hotspots for stunting and unimproved drinking water sources are in the districts of Rajasthan, Gujarat, Madhya Pradesh, Bihar, West Bengal, Uttar Pradesh, and Maharashtra. For wasting, hotspots are in Gujarat, Maharashtra, Rajasthan, Andhra Pradesh, Karnataka, Madhya Pradesh, Uttar Pradesh, West Bengal, Chhattisgarh, Bihar, and Odisha. The common hotspots for underweight and unimproved drinking water sources are the districts of Uttar Pradesh, Bihar, Chhattisgarh, Andhra Pradesh, Jharkhand, Maharashtra, Gujarat, Karnataka, Madhya Pradesh, Odisha, West Bengal, and Rajasthan. The hotspots for maternal education and CGF indicators are in Jharkhand, Gujarat, Uttar Pradesh, Chhattisgarh, Maharashtra, Madhya Pradesh, West Bengal, and Rajasthan for stunting. For wasting, these areas include Maharashtra, West Bengal, Karnataka, Chhattisgarh, Gujarat, Jharkhand, Odisha, Madhya Pradesh, and Rajasthan. The hotspots for underweight are in Gujarat, Maharashtra, Uttar Pradesh, Odisha, West Bengal, Chhattisgarh, Madhya Pradesh, Rajasthan, and Jharkhand. The hotspots for poor wealth index and CGF indicators are in Bihar, Uttar Pradesh, Gujarat, West Bengal, Madhya Pradesh, and Maharashtra for stunting. The hotspots for wasting are in Andhra Pradesh, Maharashtra, Madhya Pradesh, Rajasthan, Gujarat, and Karnataka. For underweight, Maharashtra, Rajasthan, Madhya Pradesh, and Chhattisgarh are consistently high-risk areas from 1998 to 2006. Uttar Pradesh and Gujarat are the hotspots added during the fourth and fifth rounds only. The hotspot areas for stunting and ethnic groups are Madhya Pradesh, Rajasthan, Jharkhand, West Bengal, Gujarat, Uttar Pradesh, Bihar, and Maharashtra. Similarly, for wasting, the hotspot areas are Uttar Pradesh, Gujarat, Mizoram, Rajasthan, Maharashtra, Kerala, Uttarakhand, Punjab, Andhra Pradesh, Jammu & Kashmir, Odisha, Assam, Tamil Nadu, Manipur, Meghalaya, Karnataka, Bihar, and West Bengal. The underweight hotspots are Uttar Pradesh, Rajasthan,
Bihar, Jharkhand, Gujarat, West Bengal, Andhra Pradesh, Karnataka, Odisha, Maharashtra, and Madhya Pradesh.

The map’s red areas (hotspots) are concerning areas for stunting, wasting, and underweight. Uttar Pradesh, Odisha, Bihar, Rajasthan, Chhattisgarh, Madhya Pradesh, West Bengal, Gujarat, and Jharkhand are some of the hotspot areas for wasting, stunting, and underweight and their background characteristics.

Figure 7. LISA (Local Indicator of Spatial Association) map showing the association between stunting and household sanitation facility between 1998 and 2021.

Figure 8. LISA (Local Indicator of Spatial Association) map showing the association between wasting and household sanitation facility between 1998 and 2021.

Figure 9. LISA (Local Indicator of Spatial Association) map showing the association between underweight and household sanitation facility between 1998 and 2021.
Spatial Regression

The test for multicollinearity suggests that there are unnecessary dependences between the explanatory variables in the data from NFHS-2 and NFHS-4. The Breusch-Pagan test indicates the presence of heteroskedasticity ($P<$0.001), and the Jarque-Bera test reveals a violation of the assumption of normal distribution ($P<0.001$). The rejection of these assumptions suggests that the data are spatially dependent, which necessitates the use of spatial regression. Compared with the lag model, the spatial error model demonstrated a lower Akaike information criterion score for NFHS-2, NFHS-4, and NFHS-5, indicating a better fit for the data from these surveys.

Stunting

Table 5 presents the regression coefficients for the association between stunting and sanitation facility, obtained from both ordinary least-squares (OLS) and the spatial error model. According to the models for NFHS-2, NFHS-4, and NFHS-5, with each unit increment in sanitation facility (%), wealth quintile (%), and mothers’ education (%), the prevalence of stunting is expected to decrease by 0.109-0.145, 0.049-0.111, and 0.058-0.274 units, respectively.

Wasting

Table 6 represents the regression coefficients for the association between wasting and sanitation facility, as obtained from OLS and the spatial error model. In all 3 models, a unit increase in sanitation facility (%) results in an expected decrease in the prevalence of wasting by 0.073 to 0.266 units.

Discussion

Principal Findings

This study used LISA modeling to establish a significant association between improved sanitation facilities and the reduction of growth failure health outcomes in children younger than 5 years in India. The relative risk maps identified the hotspots of CGF health cases, which could be targeted for future interventions. Nutritional status is critical for monitoring a country's development. Moreover, undernutrition is a global concern that poses numerous health, welfare, and well-being challenges [5]. Consequently, it becomes a pressing matter in the context of Sustainable Development Goals. Although global efforts have intensified over the past decade, governments have also strategized to address undernutrition. In addition, research has sought to unravel potential impediments that could lead to health and economic problems in developing countries. Although these issues were primarily associated with inadequate feeding patterns [12], this remains insufficient to address the problem, especially in India where undernutrition affects both the well-nourished and malnourished [13]. Researchers have striven to examine various factors that retard children’s growth, but clear evidence linking it to sanitation, particularly unimproved drinking water sources facilities (open defecation), is yet to emerge.

According to this study’s findings, more than a third of children younger than 5 years are malnourished. A study comparing the nutritional health of Indian children using WHO charts and an Indian synthetic chart also discovered a higher prevalence of undernutrition among this age group [34]. Neighboring countries

https://publichealth.jmir.org/2024/1/e41567 JMIR Public Health Surveill 2024 | vol. 10 | e41567 | p.1729 (page number not for citation purposes)
such as Nepal (36.0%) [35] and Pakistan (37.6%) [36] have nearly identical stunting rates, whereas Bangladesh (18.2%) [37] has comparable wasting and underweight rates. Our study shows a decreasing trend in stunting (44.9% to 38.4%) and underweight (46.7% to 35.7%) but an increasing prevalence of wasting (15.7% to 21.0%) over 15 years. Since 1990, despite a decrease in the prevalence of undernutrition in India, it has been a significant concern. The Global Burden of Disease Study (1990-2017) stated that malnutrition remained the leading risk factor for disease burden in India and that much faster progress is needed to meet India’s 2022 and global 2030 targets [14].

The spatial findings show that the CGF and water, sanitation, and hygiene (WaSH) indices are nonrandom at the national and district levels. Significant clusters for these indicators were found in several states. However, during the NFHS-4 survey, indicators improved for both factors in states such as Haryana, Punjab, Himachal Pradesh, Manipur, Mizoram, Karnataka, Uttarakhand, and Tripura. Many factors, ranging from demographic to socioeconomic, contribute to the increasing prevalence of undernutrition, which can be attributed to regional preferences in food consumption and disparities in the availability of health care facilities [38]. Other factors could be inadequate sanitation and lack of clean water, which elevate the prevalence of soil-transmitted diseases, such as diarrhea, contributing to undernutrition. This finding aligns with a study that found significant geographical variations across child malnutrition across Indian states, with particularly high rates in the central region [39].

The measure of spatial dependence was suggested by Moran I statistics. Stunting, underweight, and toilet facility have higher statistical values, confirming the regional gradient of malnutrition and sanitation in India. The results of the spatial error model show that increased sanitation and the level of mothers’ education are strongly and significantly associated with child malnutrition. As previously noted, poor sanitation can lead to diarrhea and other intestinal infections in children. Furthermore, the positive correlation between child nutrition and a mother’s education status aligns a previous study [40] that found a connection between maternal education and improved nutrition [41]. The findings of this study concerning the spatial relationship and correlation with WaSH factors are comparable to those of an Indian study using NFHS-4 data. Similar to the findings of this study, that study found a clear spatial dependence of the CGF indicator and increased clustering in the districts of Madhya Pradesh, Rajasthan, Bihar, Jharkhand, and Uttar Pradesh. There was also a statistically significant link between malnutrition and maternal education, improved sanitation, and wealth [42]. However, our findings reveal a strong link to WaSH variables, which, according to UNICEF, are important contributors to malnutrition [43]. Several studies have found that a lack of sanitary facilities increases the risk of nutritional deficiencies due to anorexia, fluids loss, and other complications that can lead to undernutrition [44]. Similarly, a study conducted in Ethiopia found that children living in households where open pit or unsanitary pit latrines were used were more likely to have malnutrition [45].

In 2014, the Indian government launched a cleanliness initiative called “Swachh Bharat Abhiyan” to enhance waste management and sanitation quality across the country, aligning with the sanitation aspect of child nutrition [46]. The multifaceted causes of undernutrition necessitate coordinated and consistent interventions that go beyond the norm. Exposure to fecal pathogens poses a significant threat to children’s growth, making improved WaSH conditions essential in all settings [47]. This could be achieved by embracing various aspects of WaSH practices, particularly incorporating sanitation into the nutrition program, strengthening the collaboration between WaSH and nutrition factors, and making WaSH initiatives more nutrition sensitive.

Strength and Limitations

Given the widespread socioeconomic and regional disparities among people in India, this study provides estimates of the prevalence of stunting, wasting, and underweight at the district level. The study’s regional spatial approach will assist policy makers in developing policies that ensure district-specific interventions for improving malnutrition. Moreover, the study’s results can be well generalized by using a nationally representative sample from a well-known large-scale survey in India. However, the study also has some limitations. First, because of the cross-sectional nature of the data, we could not establish a causal relationship among the variables. Second, because of the unavailability of NFHS-3 district-level data, a spatial analysis for NFHS-3 could not be conducted. Third, as the study relied on secondary data, we were unable to investigate community-level factors such as the availability of improved drinking water sources and sanitation facilities that might influence sanitation practice behavior among women. These factors could be investigated more deeply in future qualitative studies.

Conclusions

This study underscores that the malnutrition and undernutrition remain concerns in India. The prevalence of stunting does not seem to be decreasing or increasing consistently. However, wasting and underweight show increasing and decreasing trends, respectively. This study demonstrates that the presence of improved sanitation facilities and the educational status of mothers have a substantial positive correlation with the risk of CGF indicators. Policy makers can incorporate these factors when devising specific interventions to improve malnutrition indicators. The implementation of WaSH interventions should aim to save women’s time; if the time spent fetching water can be reduced, women could devote more time to childcare. Moreover, lack of access to WaSH facilities impacts the academic success of school-aged children, resulting in a decreased likelihood of securing employment, household food insecurity, and perpetuated poverty—all primary factors of child malnutrition. On the other hand, improved sanitation facilities have positive socioeconomic outcomes, such as supporting women’s dignity and safety, increasing girls’ school attendance, and facilitating nutrient recovery.

Abstract

Background: The Joint United Nations Program on HIV/AIDS (UNAIDS) has set the “95-95-95” targets to ensure that 95% of all people living with HIV will know their HIV status, 95% of all people living with HIV will receive sustained antiretroviral therapy (ART), and 95% of all people receiving ART will achieve viral suppression (<1000 copies/mL). However, few countries have currently achieved these targets, posing challenges to the realization of the UNAIDS goal to eliminate the global HIV/AIDS epidemic by 2030. The Chinese government has implemented corresponding policies for HIV/AIDS prevention and control; however, it still faces the challenge of a large number of HIV/AIDS cases. Existing research predominantly focuses on the study of a particular region or population in China, and there is relatively limited research on the macro-level analysis of the spatiotemporal distribution of HIV/AIDS across China and its association with socioeconomic factors.

Objective: This study seeks to identify the impact of these factors on the spatiotemporal distribution of HIV/AIDS incidence in China, aiming to provide scientific recommendations for future policy development.

Methods: This study employed ArcGIS 10.2 (Esri) for spatial analysis, encompassing measures such as the imbalance index, geographical concentration index, spatial autocorrelation analysis (Moran I), and hot spot analysis (Getis-Ord Gi*). These methods were used to unveil the spatiotemporal distribution characteristics of HIV/AIDS incidence in 31 provinces of China from 2009 to 2019. Geographical Detector was used for ecological detection, risk area detection, factor detection, and interaction detection. The analysis focused on 9 selected socioeconomic indicators to further investigate the influence of socioeconomic factors on HIV/AIDS incidence.

Results: The spatiotemporal distribution analysis of HIV/AIDS incidence in China from 2009 to 2019 revealed distinct patterns. The spatial distribution type of HIV/AIDS incidence in China was random in 2009-2010. However, from 2011 to 2019, the distribution pattern evolved toward a clustered arrangement, with the degree of clustering increasing each year. Notably, from 2012 onwards, there was a significant and rapid growth in the aggregation of cold and hot spot clusters of HIV/AIDS incidence in China, stabilizing only by the year 2016. An analysis of the impact of socioeconomic factors on HIV/AIDS incidence in China highlighted the “urbanization rate” and “urban basic medical insurance fund expenditure” as the primary factors influencing the spatial distribution of HIV/AIDS incidence. Additionally, among social factors, indicators related to medical resources exerted a crucial influence on HIV/AIDS incidence.

Conclusions: From 2009 to 2019, HIV/AIDS incidence in China was influenced by various socioeconomic factors. In the future, it is imperative to optimize the combination of different socioeconomic indicators based on regional incidence patterns. This optimization will facilitate the formulation of corresponding policies to address the challenges posed by the HIV/AIDS epidemic.

Introduction

The Joint United Nations Program on HIV/AIDS (UNAIDS) has set the “95-95-95” targets to be achieved by 2025 [1], aiming for 95% of all people living with HIV/AIDS to be aware of their HIV status, 95% of people living with HIV/AIDS to receive sustained antiretroviral therapy (ART), and 95% of those receiving ART to achieve viral suppression (<1000 copies/mL) [2]. The global goal is to eliminate the HIV/AIDS epidemic worldwide by 2030, which is a public health threat [3]. However, a recent report by the UNAIDS titled “The path that ends AIDS: UNAIDS Global AIDS Update 2023” revealed that only 5 countries (Botswana, Eswatini, Rwanda, the United Republic of Tanzania, and Zimbabwe) have achieved the “95-95-95” targets ahead of schedule [4]. China, which is a middle-income country with a relatively high number of people living with HIV/AIDS [3], plays a crucial role in advancing the comprehensive realization of the “95-95-95” targets. Since the report of the first AIDS-related death in China in 1985 [5], the Chinese government has implemented a series of policies for the prevention and control of the HIV/AIDS epidemic, achieving certain successes [6]. However, due to its vast geographical expanse and large population, the HIV/AIDS epidemic in China, despite having an overall low prevalence rate [7], still presents a significant challenge for public health governance due to the substantial number of reported cases [8-10]. An epidemiological analysis of HIV/AIDS in China from 2004 to 2016 also confirmed the escalating severity of the epidemic and the significant regional disparities in HIV/AIDS infection rates [11]. Therefore, for HIV/AIDS prevention and control in China, it is particularly crucial to accurately identify high-risk areas within its vast territory and tailor HIV/AIDS prevention and control policies accordingly. The widespread application of geographic information technology in the field of epidemiological surveillance offers new avenues for addressing this challenge [12,13].

Existing studies have indicated a close correlation between the prevention and control of HIV/AIDS and both geographical spatial factors [14] and socioeconomic elements [15]. For instance, a study using gridded demographic data sets for spatial microsimulation to map HIV/AIDS indicators in low- and middle-income countries emphasized the need for appropriate socioeconomic categorization of data to explain social spatial disparities [16]. Another study conducted geographical clustering analysis of social capital distribution data and HIV/AIDS incidence, revealing that the spatial distribution of social capital would significantly impact HIV/AIDS care and prevention efforts [17]. Additionally, an analysis of the geographical distribution disparities in HIV mortality rates in South Africa identified more pronounced local spatial clustering characteristics in periurban areas and around national highways, and this finding was attributed to these areas being population clusters but lacking sufficient economic support for people living with HIV/AIDS to seek medical assistance [18]. Furthermore, 2 studies on the clustering analysis of HIV mortality rates among children and pregnant women further confirmed this viewpoint [19,20]. From this, it can be seen that studies in other countries have already linked these factors to the prevention and control of HIV/AIDS. However, there is currently a scarcity of research in academia that analyzes the HIV epidemic in China based on these 2 categories of factors, and the limited research conducted often focuses on the spatiotemporal analysis of data from specific regions or populations. For instance, in terms of geographic selection, the majority of current spatiotemporal analyses of HIV/AIDS in China targeted specific regions, with little detailed discussion on the correlation between spatiotemporal factors and socioeconomic factors [21-23]. While some studies have conducted spatiotemporal analyses of HIV/AIDS data across China, they have not linked the findings to socioeconomic factors [24,25]. Additionally, in some spatiotemporal analyses based on the entire HIV/AIDS population in China, characteristics of specific groups, such as youth and men who have sex with men, have been studied. Although these findings have been connected to macroscopic socioeconomic factors, the degree of the influence of corresponding microscopic indicators under these factors on spatiotemporal distribution has not been thoroughly explored [26-28]. This provides research space for our study to further investigate the correlation between the spatiotemporal distribution characteristics of HIV/AIDS incidence across China and the subdivision indicators under socioeconomic factors.

Additionally, it is worth emphasizing that, while the COVID-19 pandemic in China in 2020 posed a threat to HIV/AIDS treatment and health care services [29], the stringent lockdown measures may have influenced the incidence of HIV/AIDS differently [30]. Research in the context of this sudden public health event needs to be carried out separately to ensure scientific rigor. Therefore, this study specifically selected data on the incidence of HIV/AIDS in China before the occurrence of the COVID-19 pandemic. It is important to note that the standard system for assessing the HIV/AIDS epidemic includes infection and mortality data. The reason for choosing the incidence of HIV/AIDS as the core criterion in this study instead of the incidence rate is that the infection rate involves a considerable long incubation period for HIV and issues related to voluntary or mandatory testing [31]. Meanwhile, the mortality rate is, in a sense, an extension of the incidence rate. In terms of selecting socioeconomic indicators, a study on the spatiotemporal distribution and influencing factors of HIV/AIDS incidence in China found that the level of economic development (gross domestic product [GDP]) is the most closely related factor [32]. Another study further demonstrated that, in addition to overall economic conditions, factors, such as the urbanization rate and population density, are closely correlated with HIV/AIDS incidence [33]. Furthermore, several other studies on the access of people living with HIV/AIDS to health care...
services have shown that the accessibility of medical services [34] and individual-level economic conditions [35,36] also impact HIV/AIDS incidence, and this situation can be improved if the government continues to increase public health expenditure [37]. Building upon the aforementioned existing research, we combined statistical data published by the China National Bureau of Statistics (CNBS) with the actual situation of HIV/AIDS prevention and control in China, ultimately selecting 9 representative socioeconomic indicators as variables.

Taking into consideration the aforementioned factors, this study initially employed the imbalance index, geographical concentration index, spatial autocorrelation analysis (Moran I), and hot spot analysis (Getis-Ord Gi*) in ArcGIS 10.2 (Esri). These analyses aim to reveal the spatiotemporal distribution characteristics of HIV/AIDS incidence (both the number of cases and incidence rate per 100,000 people) in 31 provinces of China from 2009 to 2019. Subsequently, Geographical Detector was employed to conduct ecological detection, risk area detection, factor detection, and interaction detection. This analysis explored the impact of 9 indicators related to China’s social and economic factors on the spatiotemporal distribution of HIV/AIDS incidence. The aim was to provide policy recommendations for China to further address the HIV/AIDS epidemic effectively.

Methods

Data Collection

This study integrated HIV/AIDS incidence data from 2009 to 2019 in 31 provinces of China (excluding Hong Kong, Macao, and Taiwan) with socioeconomic indicators to facilitate a comprehensive analysis and causal discussion in both temporal and spatial dimensions. Specifically, social indicators included the number of health care institutions, number of beds in health care institutions, number of health care personnel, urbanization rate, and residential population density. Economic indicators included GDP, expenditure on health care in local finances, per capita disposable income of residents, and urban basic medical insurance fund expenditure. The socioeconomic data were sourced from the CNBS, while the HIV/AIDS incidence data were obtained from the Chinese Public Health Science Data Center (CPHSD). Specifically, the HIV/AIDS incidence data from CPHSD are compiled based on the Chinese Infectious Disease Reporting System. Local hospitals and Centers for Disease Control and Prevention (CDC) regularly report newly diagnosed HIV/AIDS cases through this network system and calculate HIV/AIDS incidence, which is then used by the Chinese Center for Disease Control and Prevention (CCDC) to compile national HIV/AIDS data [38]. Spatial administrative boundary vector data are derived from the China basic geographic information data released by the National Geomatics Center of China (NGCC).

Furthermore, to eliminate differences in dimensional units among various indicators and meet the requirements of the Geographical Detector for operational data, the Natural Breaks method in ArcGIS 10.2 software was employed to categorize the independent variables. Each socioeconomic indicator was divided into 5 levels, represented by X1 to X9 (Table 1).

Ethical Considerations

The study used original data sourced from the CPHSD, an official government institution, which publicly releases data. According to the “Ethical Review Measures for Human Life Science and Medical Research” issued by the National Health Commission of China and the “Scientific Data Management Measures” issued by the General Office of the State Council of the People’s Republic of China, researchers are permitted to conduct secondary analysis of publicly available anonymized data for scientific research purposes without requiring Institutional Review Board (IRB) scrutiny and approval. These regulations exempt research involving pre-existing data that are publicly available or that are recorded in a manner that subjects cannot be identified directly or through identifiers linked to the subjects. Given that the data used in our study were both anonymized and publicly available, IRB review was not necessary for the study. Additionally, the authors have obtained permission to access and use the data, ensuring adherence to data usage policies and ethical standards.
Statistical Methods

Imbalance Index
The imbalance index is a crucial indicator that illustrates the degree of distribution balance of the research subjects in different regions [39]. The imbalance index (S) takes values between 0 and 1, with a larger S value indicating a greater imbalance in the distribution of HIV/AIDS incidence within the study area. Its calculation formula is as follows:

Geographical Concentration Index
The geographical concentration index is a crucial indicator that indicates the degree of geographical concentration of the research object [40]. The geographical concentration index (G) takes values between 0 and 100. A higher G value indicates a more concentrated spatial distribution of HIV/AIDS incidence in China, while a lower value suggests a more dispersed spatial distribution. Its calculation formula is as follows:

Spatial Autocorrelation Analysis (Moran I)
The Moran I index is a significant indicator for analyzing the spatial distribution relationships among units in the study area [41]. It can be used to identify and measure the distribution status and clustering degree of HIV/AIDS incidence in the 31 provinces of China. An I value >0 indicates positive spatial autocorrelation among the units, while a value <0 indicates negative spatial autocorrelation. A larger I value signifies a more significant spatial correlation. The significance of the Moran I index is generally tested using the Z-score formula. When the Z-score exceeds the critical value of 1.96, it indicates the statistical significance of spatial clustering, with the probability of randomly generating this clustering pattern being less than 5%. The calculation formula is as follows:

Hot Spot Analysis (Getis-Ord Gi*)
Hot spot analysis is an important analytical method that explores the similarity and heterogeneity between the attribute values of spatial geographic units and their adjacent units [42]. This method compares the local sum of a particular feature and its adjacent features with the total sum of all features. When the local sum of an area significantly differs from the expected local sum to the extent that it cannot be attributed to random chance, the area is identified as a high- or low-value cluster (hot or cold spot) based on the attribute values. This facilitates the visualization of the spatial distribution of HIV/AIDS incidence. The calculation formula is as follows:

Geographical Detector
The Geographical Detector encompasses 4 detection modes (ecological detection, risk area detection, factor detection, and interaction detection) used to uncover the driving factors behind the spatial distribution of a particular phenomenon [43]. It is applied for detecting and assessing HIV/AIDS incidence. Ecological detection, in this context, aims to determine if there is a significant difference in the mean HIV/AIDS incidence between 2 factors, X_1 and X_2. The calculation formula is as follows:

Among these, risk area detection is used to assess whether there is a significant difference in the mean HIV/AIDS incidence between 2 subregions. The calculation formula is as follows:

Factor detection is a method used to assess the extent to which the 9 socioeconomic indicators can explain the spatial variation of HIV/AIDS incidence. The calculation formula is as follows:

Interaction detection is primarily employed to identify the interactions among the 9 socioeconomic indicators (Xs). It assesses whether the joint effect of any 2 socioeconomic indicators increases or decreases the explanatory power regarding HIV/AIDS incidence. Additionally, it examines whether the impact of these indicators on HIV/AIDS incidence is mutually independent. The results of the interaction can be categorized into the following 5 types: nonlinear attenuation, si-factor nonlinear attenuation, bi-factor authentication, mutually independent, and nonlinear enhancement (Table 2).

Results

Spatiotemporal Distribution Characteristics of HIV/AIDS Incidence in China

This study initially used the imbalance index and geographical concentration index to measure the equilibrium and concentration of the spatiotemporal distribution characteristics of HIV/AIDS incidence in 31 provinces of China from 2009 to 2019. Subsequently, spatial autocorrelation analysis (Moran I) was introduced to account for the spatial proximity of the study objects, further specifying the spatial distribution types of HIV/AIDS incidence from 2009 to 2019. Finally, hot spot analysis was employed to visually depict the evolutionary characteristics of the spatiotemporal distribution of HIV/AIDS incidence in China from 2009 to 2019.

Based on the calculation results of the imbalance index and geographical concentration index (Table 3), there was a slight downward trend in both indices from 2013 to 2018, but the values remained stable within a certain range. Overall, the imbalance index (S) stabilized in the range of 0.4-0.5, and the geographical concentration index (G) stabilized in the range of 24-34, indicating that the spatiotemporal distribution of HIV/AIDS incidence in China from 2009 to 2019 exhibited a certain degree of imbalance and concentration. Moreover, this distribution state demonstrated a certain level of persistence and stability over time.

Using the spatial autocorrelation analysis tool in ArcGIS 10.2, the Moran I value for the spatial distribution of HIV/AIDS incidence in China from 2009 to 2019 was obtained (Table 4). The results indicated that the Moran I value was only 0.05 in 2009-2010, suggesting a random spatial distribution pattern for HIV/AIDS incidence in China during that period. In 2011, the Moran I value increased to 0.07 and passed the significance test at the 5% level, indicating a transition to a clustered distribution pattern. Subsequently, the Moran I value continued to rise, with an increase from 0.07 to 0.25, demonstrating strong positive spatial autocorrelation, and it consistently passed the significance test at the 5% level. This confirms that the distribution pattern of HIV/AIDS incidence in China evolved from a random distribution to a clustered distribution from 2011 to 2019, with the degree of clustering increasing annually, demonstrating strong spatial aggregation and dependence.

^aEvolution from a random distribution to a clustered distribution is indicated.

For the study of spatial distribution characteristics, areas with higher or lower attribute values are often the first to attract attention. However, the high or low values of attributes do not necessarily represent statistically significant hot or cold spots [40]. Therefore, areas that can be considered hot or cold spots should have features with high values (low values) and be surrounded by other features that also have high values (low values). To more precisely illustrate these spatial distribution relationships, this study used the Hot Spot Analysis tool in ArcGIS 10.2 to conduct Getis-Ord Gi* statistical analysis. The analysis identified hot and cold spots in the spatial clustering distribution of HIV incidence in China from 2009 to 2019 (Figure 1). It should be noted that during the data analysis process, we found that the distribution of hot and cold spots did not change from 2016 to 2019. Therefore, the distribution status of hot and cold spots from 2016 to 2019 has been combined and presented as 1 map in Figure 1H.

Figure 1. Spatial distribution map of hot and cold spots of HIV/AIDS incidence in China from 2009 to 2019. (A) 2009, (B) 2010, (C) 2011, (D) 2012, (E) 2013, (F) 2014, (G) 2015, (H) 2016-2019.

The number of cold spot clusters of HIV incidence in China started from 0 in 2009-2010 and experienced significant and rapid growth in 2012. Although there was a slight decline in the number of cold spots in 2014, it did not prevent the overall stability of cold spot clusters at 6-7 from 2012 to 2019. In general, from 2009 to 2019, the spatial extent of low-value cold spot areas expanded significantly, spreading from Shandong Province to the central and northern provinces of China. Ultimately, these cold spot clusters stabilized and concentrated in the central and northern provinces of China (Shandong, Beijing, Tianjin, Hebei, Shanxi, Liaoning, and Inner Mongolia).

In terms of hot spot clusters, the number of hot spot clusters of HIV/AIDS incidence in China showed a trend of first decreasing and then increasing, but the magnitude of the increase and decrease was not significant. It mainly stabilized in 5 southwestern provinces of China (Yunnan, Guangxi, Sichuan,
Guizhou, and Chongqing), with an improvement in both aggregation and significance. Overall, compared to cold spot areas, hot spot areas exhibited a smaller fluctuation range and stronger spatial distribution stability.

**Impact of Socioeconomic Factors on the Spatiotemporal Distribution of HIV/AIDS Incidence in China**

HIV/AIDS, as an infectious disease, is profoundly influenced by socioeconomic factors in its spatiotemporal distribution [44]. This study selected 9 socioeconomic indicators related to HIV/AIDS incidence and employed the Geographical Detector for quantitative exploration, aiming to analyze the extent of the impact of these indicators on the spatial distribution of HIV/AIDS incidence in China.

The results of risk detection and ecological detection indicated, at a significance level of 0.05, that there were no significant differences in the mean values of attributes between subregions of different levels. Among the socioeconomic indicators, only the urbanization rate, per capita disposable income, and population density exhibited significantly different impact capacities. There was no significant difference in the impact of other indicators on the spatial distribution of HIV/AIDS incidence in China. This suggests a certain rationality in the selection and grading of indicators.

The results of factor detection showed the strength of the impact of various factors on the spatial distribution of HIV/AIDS incidence, with the magnitude of q values as follows (Table 5): urbanization rate ($X_8=0.49$) > urban basic medical insurance fund expenditure ($X_4=0.31$) > the number of beds in health care institutions ($X_6=0.28$) > local financial expenditure on health care ($X_7=0.26$) > the number of health care personnel ($X_7=0.26$) > the number of health care institutions ($X_5=0.19$) > provincial GDP ($X_1=0.12$) > nonsignificant impacts for per capita disposable income and population density ($X_3=0.05$ and $X_9=0.06$, respectively).

*aThe indicators are clarified in Table 1.*

Based on the above detection results, it can be concluded that the urbanization rate and the expenditure on urban basic medical insurance were the most influential factors explaining the spatial distribution of HIV/AIDS incidence in China. Provinces with low urbanization rates and minimal spending on urban basic medical insurance were more likely to face a severe situation of HIV/AIDS incidence. The number of beds in health care institutions, local financial expenditure on health care, number of health care personnel, and number of health care institutions were secondary factors influencing the distribution. These 4 indicators belong to health care resource factors within social indicators, indicating that a better health care development situation has a certain inhibitory effect on the distribution of HIV/AIDS incidence in China. GDP had a certain explanatory power for the distribution of the incidence but with a low P value, suggesting lower confidence in its explanatory power and indicating a correlation (not significant) with the spatial distribution of HIV/AIDS incidence in China. Additionally, per capita disposable income and population density had a relatively weak impact on the spatial distribution pattern of HIV/AIDS incidence in China.

The results of interactive detection are shown in Table 6. After the interaction of any 2 of the 9 socioeconomic indicators, all q-values exhibited varying degrees of increase, showing nonlinear enhancement or bivariate enhancement states, with no independent or weakening relationships. This suggests that, compared to single indicators, the coupling effect of any 2 factors can enhance the explanatory power of the spatiotemporal distribution pattern of HIV/AIDS incidence in China, indicating that the spatial distribution differences of HIV/AIDS incidence in China are the result of the interaction of multiple influencing factors. According to the analysis results of ecological detection, the differences in the effects of each indicator were not statistically significant, which indicates the significant importance of the comprehensive synergistic effect of multiple factors in exploring HIV/AIDS incidence.
Furthermore, among all combinations, the enhancement effect of the urbanization rate with other indicators was the most significant. The output results of ecological detection also indicated that only the urbanization rate exhibited a significant difference with other variables. For instance, GDP alone had a weak explanatory effect on the distribution of the disease, but its explanatory effect was strengthened when coupled with the urbanization rate or local financial health expenditure. This indicates that among the 9 indicators, the urbanization rate should be the primary factor of concern. Additionally, after interaction, the factor combinations that achieved an explanatory degree with a q-value above 0.7 included residential population density ($X_9$), per capita disposable income of residents ($X_3$), expenditure on health care in local finances ($X_4$), and urban basic medical insurance fund expenditure ($X_5$). Although residential population density had a low individual impact on disease distribution, its explanatory effect significantly improved when coupled with economic indicators related to health care. This suggests that for HIV/AIDS incidence, residential population density should not be considered in isolation but should be simultaneously considered in conjunction with the synergistic effects of economic factors.

In terms of the type of enhanced interaction, apart from the nonlinear enhancement dominating the interactions of GDP ($X_1$), per capita disposable income of residents ($X_3$), and residential population density ($X_9$), the interactions of the remaining 6 factors were predominantly bivariate enhancement. Furthermore, the detection results of factors $X_1$, $X_3$, and $X_9$ were the weakest. Therefore, it is once again emphasized that GDP, per capita disposable income of residents, and residential population density exhibited relatively weak spatial distribution effects on HIV/AIDS incidence. However, it is important to note that these 3 factors are still relevant factors affecting HIV/AIDS incidence in China, albeit to a lesser extent compared to other factors.

**Discussion**

This study conducted a spatiotemporal distribution analysis of HIV/AIDS incidence in 31 provinces of China from 2009 to 2019. Furthermore, it integrated the analysis with 9 economic and social indicators to explore the extent of the impact of socioeconomic factors on the spatiotemporal distribution of HIV/AIDS incidence in China. The research revealed that the occurrence of HIV/AIDS in China is significantly influenced by a combination of factors, including socioeconomic indicators, beyond the medical origins of the disease.

Before delving into various discussions, it is important to note that from the late 20th century to the early 21st century, China experienced localized outbreaks of HIV/AIDS in certain regions due to specific reasons. For instance, in Henan Province, from the late 1980s to the early 1990s, against the backdrop of official blood donation quotas, market demand from pharmaceutical companies, and the emergence of a blood-selling industry in rural areas, widespread transmission of HIV/AIDS occurred through blood products from rural blood stations due to technical and management flaws in blood collection. In August 2001, the Chinese Ministry of Health first publicized the situation of an “HIV/AIDS village” in Wenlou Village, Shangcai County, Henan Province, where around 43% of the approximately 3710 blood sellers were reported to be HIV positive [45]. In 2004, for the first time, Henan Province conducted a comprehensive HIV/AIDS census across the province. Out of the 280,000 individuals with a history of paid blood donation, 25,000 were found to be people living with HIV/AIDS [46]. Similarly, in Yunnan and Sichuan provinces, which serve as important land routes from southwestern China to Southeast Asia and South Asia, there was a relatively serious drug trafficking problem [47], leading to intravenous drug use becoming the main transmission route for HIV in these areas [48,49]. Existing research data have shown that before 2001, 74.8% of people living with HIV/AIDS identified in Sichuan Province were drug users, while 62.8% of those identified in Yunnan Province from 1989 to 2000 were drug users [50].

After the early 21st century, although the Chinese government increased its attention to the AIDS issue and gradually implemented corresponding prevention and control efforts (such as the “Four Frees and One Care” policy in 2003 and the promulgation of the HIV/AIDS Prevention and Control
Regulation in 2006), the phenomenon of previous HIV/AIDS outbreaks gradually subsided. However, due to the large number of reported HIV/AIDS cases in China prior to these policies taking effect, coupled with a certain lag in policy implementation, HIV/AIDS prevention and control did not immediately curb the nationwide spread of HIV/AIDS. This also explains why the spatial distribution of HIV/AIDS incidence in China was random in 2009-2010 but gradually evolved from random distribution to clustered distribution from 2011 to 2019, as found in this study.

First, as a manageable chronic disease [51], the spatial distribution of HIV/AIDS is influenced by socioeconomic factors. For instance, the government’s investment in public health is one of the influencing factors. Since the end of 2003, China has implemented the “Four Frees and One Care” policy [10]. All people living with HIV/AIDS diagnosed at the CCDC can receive antiretroviral drugs for free. However, it was not until 2012, when important antiretroviral drugs like lamivudine (3TC) and efavirenz (EFV) gradually entered domestic production, that the government could progressively reduce the cost of obtaining drugs [52], thereby enhancing the practical implementation of the “Four Frees and One Care” policy in China. From the analysis of spatial distribution characteristics in this study, it is evident that although the incidence of HIV/AIDS in China from 2009 to 2019 exhibited continuous features of imbalance and concentration in spatial distribution, there was a significant turning point around 2012. This may be related to the continuous expansion of the coverage of the “Four Frees and One Care” policy. Subsequently, the results obtained from our application of the Geographical Detector to analyze the impact of medical factors once again indirectly corroborated this viewpoint. In this regard, it is necessary to acknowledge that some economically underdeveloped regions benefit more because the government can ensure the transfer and distribution of basic antiretroviral drugs (resulting in an increase in cold spots). However, due to differences in economic development and the proportion of public health expenditure among regions, there is a direct impact on the accessibility of new antiretroviral drugs [53]. This has a strong correlation with the spatiotemporal distribution differences in the incidence of HIV/AIDS. In simpler terms, in regions where the incidence of HIV/AIDS was relatively mild but economic development levels and public health expenditure were low, the comprehensive implementation of the “Four Frees and One Care” policy in 2012 ensured the right of people living with HIV/AIDS to receive free antiretroviral drugs. Although subsequent public health challenges in HIV/AIDS prevention and control still exist in these areas, considering the initially low disease burden, the overall incidence is expected to further decrease. In regions where the HIV/AIDS epidemic was already severe, after 2012, they faced more acute local financial difficulties. The lack of momentum in public health expenditure directly results in a large number of people living with HIV/AIDS who are unable to access quality medical resources and new antiretroviral drugs. Consequently, the incidence in these areas has not reached the desired level of control. This finding suggests that, in future reforms of HIV/AIDS prevention and control policies, the Chinese government should pay attention to balancing the relationship between policy and local economic conditions.

Furthermore, parallel to the “Four Frees and One Care” policy, there is an ongoing reform of China’s medical insurance system. In March 2009, China issued the “Opinions on Deepening the Reform of the Medical and Health System” [54], marking a period of improvement in China’s medical security system. This is one of the reasons why this study chose 2009 as the starting point for data observation. In 2012, several government departments in China jointly issued a document requiring the comprehensive implementation of total control over medical insurance payments [55]. This led to a significant increase in the pressure on local public health expenditure at the regional level. This situation is intertwined with the regional disparities in providing free antiretroviral drugs under the “Four Frees and One Care” policy. However, it is crucial to note that there is no absolute proportional relationship between local GDP and the intensity of investment in public health [56]. In other words, a higher GDP in a certain region does not necessarily mean a synchronous increase in investment in public health. This is also clearly reflected in the previous data of this study. However, in 2016, the Chinese Ministry of Human Resources and Social Security, along with the Ministry of Finance, officially initiated the direct settlement of inpatient medical expenses across regions [57], facilitating the access of the public to medical care across different areas. This development is consistent with the earlier findings of our analysis, indicating that from 2016 to 2019, the spatial and temporal distributions of HIV/AIDS incidence in China stabilized and the impact of factors, such as population density and per capita disposable income, on the HIV/AIDS incidence rate decreased. However, despite the potential enhancement of shared health care resources across regions, the actual economic burden borne by individuals still exhibits significant regional economic disparities. For instance, the contribution base for medical insurance, which is closely tied to local fiscal investment in public health, continues to vary markedly across regions [58]. This may explain why, after 2016, the disparity in HIV/AIDS incidence rates among different regions in China did not widen or narrow. This finding suggests a direction for the Chinese government to prioritize and strengthen its focus on certain indicators in the ongoing efforts to combat the HIV/AIDS epidemic.

Looking further, how do these indicators specifically and directly relate to the incidence of HIV/AIDS among individuals, as mentioned previously? First, in terms of economic indicators, the current “Four Frees and One Care” policy provides a combination of free antiretroviral drugs that are categorized into first-line (tenofovir disoproxil fumarate [TDF]/azidothymidine [AZT]/abacavir [ABC]+3TC+nevirapine [NVP]/EFV/rtipivirine [RPV]) and second-line (TDF+3TC+dolutegravir [DTG]/lopinavir combined with ritonavir [LPV/r]; AZT+TDF+3TC+DTG/LPV/r) treatments [52]. Typically, first-line drugs are centrally purchased by the CCDC and systematically distributed to various regions. As for second-line drugs, their availability primarily relies on the level of financial investment by local governments in public health care. This directly results in situations where drugs like LPV/r, previously categorized as a second-line treatment, are not widely accessible in all regions. In comparison with numerous antiretroviral drugs, DTG, which is considered to have fewer side effects and lower susceptibility to resistance, is more accessible in all regions. In this way, the spatial and temporal distributions of HIV/AIDS incidence in China stabilized and the impact of factors, such as population density and per capita disposable income, on the HIV/AIDS incidence rate decreased. However, despite the potential enhancement of shared health care resources across regions, the actual economic burden borne by individuals still exhibits significant regional economic disparities. For instance, the contribution base for medical insurance, which is closely tied to local fiscal investment in public health, continues to vary markedly across regions [58]. This may explain why, after 2016, the disparity in HIV/AIDS incidence rates among different regions in China did not widen or narrow. This finding suggests a direction for the Chinese government to prioritize and strengthen its focus on certain indicators in the ongoing efforts to combat the HIV/AIDS epidemic.
representative [59]. Currently, access to DTG for individuals in different regions can be categorized in 3 ways. First, it is directly obtained for free through the “Four Frees and One Care” policy in certain regions (such as cold spot areas like Beijing). Second, in areas where DTG is included in medical insurance, infected individuals with insurance coverage can purchase DTG and be reimbursed through insurance (such as Zhejiang) [60]. Third, in regions where DTG is not covered by medical insurance, infected individuals have to self-fund the purchase, and in some cases, they have to resort to ordering it through mail from other regions (such as Sichuan and other hot spot areas) [61]. It is evident that economic indicators in different regions influence whether people living with HIV/AIDS can access antiretroviral drugs for free or acquire updated and more effective medications at lower costs, thereby affecting the incidence of HIV/AIDS among individuals.

Certainly, another crucial factor in preventing the onset of the disease is the timely detection of treatment failure (such as drug resistance) in people living with HIV/AIDS. This is closely related to the social indicators mentioned in this study. In our research, we observed that regions with higher levels of health care resources are more effective at suppressing the incidence of HIV/AIDS. In different regions, there are significant variations in whether people living with HIV/AIDS need routine examinations and whether the costs of such checks, which are conducted each time they receive free antiretroviral drugs under the “Four Frees and One Care” policy (as stipulated by the policy, approximately once every 3 months), need to be self-funded by the individuals. In some regions with more developed public health services, there are even provisions to offer 1 to 2 free drug resistance testing services annually for individuals [52]. In other words, in regions with more abundant public health care resources, individuals are more likely to timely detect their drug-resistance situations, enabling targeted changes in antiretroviral drug combinations and thus preventing the onset of the disease. In addition, it is worth noting that China has implemented the “designated hospital” system for HIV/AIDS medical care, as outlined in the 2013 “Notice on Submitting the List of Designated Hospitals for AIDS by the Medical Administration Bureau of the Ministry of Health” [62]. While this system aims to reduce urban-rural disparities in implementing the “Four Frees and One Care” policy, its effectiveness has been a subject of mixed opinions and has, to some extent, led to instances of nondesignated hospitals refusing to provide medical services. A region that is more densely populated, economically developed, and well-endowed with public medical resources usually has more numerous and specialized designated hospitals, with a high degree of professionalism and comprehensive capabilities. For instance, hospitals like You’an Hospital and Ditan Hospital in Beijing (a cold spot region) have become the “most renowned” designated hospitals for people living with HIV/AIDS in the country. In contrast, designated hospitals in regions with relatively scarce public medical resources mainly rely on infectious disease specialist hospitals as they lack comprehensive departmental setups. This directly results in medical challenges for individuals living with HIV/AIDS in those areas. In fact, before the onset of the disease, the medical needs of people living with HIV/AIDS are not limited to the field of infectious diseases, similar to the general population [63]. However, given the vulnerability of the immune system [64], if people living with HIV/AIDS do not receive timely and effective medical services, they are more susceptible to overall health deterioration due to other diseases. This also demonstrates the significant impact of medical accessibility on the onset of the disease. In the future, the Chinese government should continue to optimize medical resource allocation for this specific group of people living with HIV/AIDS to address the public health challenges posed by the HIV/AIDS epidemic.

Finally, this study not only revealed the spatiotemporal distribution of HIV/AIDS incidence in China as a result of the comprehensive impact of multiple influencing factors through the interactive detection of geographic detectors but also discovered that the dual-factor coupling of 9 socioeconomic indicators can have different effects on the spatiotemporal distribution of HIV/AIDS incidence in China. This finding can provide insights for the Chinese government to focus on the combined optimization of socioeconomic indicators when formulating HIV/AIDS prevention and control policies. Specifically, when 2 indicators show a significantly improved coupling effect, the government can enact policies to promote the development of the optimal indicator combination to further reduce the incidence of HIV/AIDS. For example, in the case where the coupling effect of the urbanization rate with other indicators is most noticeable, the government can actively formulate policies to leverage the synergistic effects between this indicator and others while continuing to promote urbanization.

This study has certain limitations. First, due to the lack of authoritative data statistics on the incidence of HIV/AIDS in Hong Kong, Macao, and Taiwan by official institutions, this study used relevant data from 31 other provinces in China. Second, the socioeconomic indicators used in this study are macro and common statistical indicators, but the causes of HIV/AIDS are complex and diverse, and these indicators may not necessarily cover all influencing factors. To overcome these limitations, future efforts should focus on collecting more detailed data and interpreting them in the context of emerging research. However, as one of the few studies addressing this topic, our research covers the majority of China’s regions, and the analyzed content and recommendations have a relatively high degree of universality.

This study conducted a spatiotemporal distribution analysis of HIV/AIDS incidence in China from 2009 to 2019. The findings revealed that, starting from 2012, there was an enhancement in the clustering pattern of HIV/AIDS incidence in China, with cold and hot spots becoming more pronounced. From 2016 to 2019, the clustering of cold and hot spots began to stabilize. Additionally, we investigated the impact of HIV/AIDS incidence from 2009 to 2019 in relation to 9 common socioeconomic indicators. The study findings suggest that optimizing the combination of different socioeconomic indicators can further suppress the incidence of HIV/AIDS. These findings provide insights for the government to adjust relevant policies based on the specific impact of different indicators on HIV/AIDS incidence in the future.

Abstract

Background: Pulmonary tuberculosis (PTB) is a chronic communicable disease of major public health and social concern. Although spatial-temporal analysis has been widely used to describe distribution characteristics and transmission patterns, few studies have revealed the changes in the small-scale clustering of PTB at the street level.

Objective: The aim of this study was to analyze the temporal and spatial distribution characteristics and clusters of PTB at the street level in the Shenzhen municipality of China to provide a reference for PTB prevention and control.

Methods: Data of reported PTB cases in Shenzhen from January 2010 to December 2019 were extracted from the China Information System for Disease Control and Prevention to describe the epidemiological characteristics. Time-series, spatial-autocorrelation, and spatial-temporal scanning analyses were performed to identify the spatial and temporal patterns and high-risk areas at the street level.

Results: A total of 58,122 PTB cases from 2010 to 2019 were notified in Shenzhen. The annual notification rate of PTB decreased significantly from 64.97 per 100,000 population in 2010 to 43.43 per 100,000 population in 2019. PTB cases exhibited seasonal variations with peaks in late spring and summer each year. The PTB notification rate was nonrandomly distributed and spatially clustered with a Moran $I$ value of 0.134 ($P=.02$). One most-likely cluster and 10 secondary clusters were detected, and the most-likely clustering area was centered at Nanshan Street of Nanshan District covering 6 streets, with the clustering time spanning from January 2010 to November 2012.

Conclusions: This study identified seasonal patterns and spatial-temporal clusters of PTB cases at the street level in the Shenzhen municipality of China. Resources should be prioritized to the identified high-risk areas for PTB prevention and control.

(Keywords: tuberculosis; spatial analysis; spatial-temporal cluster; Shenzhen; China)

Introduction

Tuberculosis (TB), caused by the bacillus Mycobacterium tuberculosis, is a chronic communicable disease that is a major public health and social problem and one of the leading causes of death from a single bacterial pathogen worldwide [1]. According to the World Health Organization (WHO) 2023 report, there were 7.5 million new TB cases and 1.3 million deaths caused by TB estimated in 2022 globally [1]. The 30 high-TB-burden countries accounted for 87% of all estimated incident cases worldwide [1]. China had the third highest TB burden in the world in 2022, with an estimated 530,000 new cases of TB, accounting for 7.1% of the global total [1]. To reduce the magnitude and burden of TB, China has implemented several effective interventions such as the adoption and implementation of the End-TB...
Strategy, expansion of directly observed therapy strategies (DOTS), and expansion of multidrug-resistant TB diagnosis and treatment centers. As a result, China has made great progress in reducing the annual TB incidence by 3.4% since 1990 [2]. However, TB remains a major public health problem in China.

Over the past few decades, China’s urbanization process, led by nationwide economic reforms, has been accompanied by the rapid growth of cities, including Shenzhen, due to the migration of the younger population from rural areas owing to more attractive employment opportunities [3], contributing to large-scale domestic migrations. Rural labor migrants might change TB transmission patterns in the cities; moreover, the health problems of migrants, including TB infection and active disease development, might change under the new circumstance of living in the city [4]. As a special economic zone, Shenzhen has experienced remarkable development in terms of both the economic scale and population growth. However, the massive influx of migrants to Shenzhen has brought serious challenges for the prevention and control of TB [3].

Identifying areas where TB is geographically concentrated is particularly essential for the planning, implementation, monitoring, and evaluation of TB control programs and to inform the allocation of resources for targeted and effective interventions [5]. In recent years, spatial-temporal analysis has been widely used to describe the distribution characteristics and transmission patterns of TB, demonstrating that TB exhibits highly dynamic and spatially heterogeneous patterns at provincial, national, and international levels during certain periods of time [6,7]. However, few studies have been performed to reveal the changes in the small-scale clustering of TB cases at the street level. In this study, we performed a spatial-temporal cluster analysis to characterize the distribution and patterns of pulmonary tuberculosis (PTB) cases at the street level in the Shenzhen municipality of China from 2010 to 2019.

**Methods**

**Study Setting**

Shenzhen is a city located in southern China at a longitude of 113°43’-114°38’ East and a latitude of 22°24’-22°52’ North (see Multimedia Appendix 1), with 74 streets among its 10 districts. Shenzhen has greatly benefited from the implementation of reforms and opening-up policies of China in the 1980s and developed quickly from a small fishery village of less than 1 million inhabitants to a modern metropolis with over 10 million inhabitants, making it one of the most developed cities in China [8]. Notably, over 70% of the residents in Shenzhen are migrants and most of these migrants are young, with those 65 years and older accounting for only 3.22% of the population [8]. The gross domestic product (GDP) of Shenzhen has increased by more than 110,000 times in the past 40 years, from less than 200 million yuan in 1979 (~US $28 million) to approximately 2.69 trillion yuan in 2019 (~US $370 billion) [8].

**Data Source**

Data of reported PTB cases in Shenzhen from January 2010 to December 2019 were extracted from the China Information System for Disease Control and Prevention, which is established and operated by the Chinese Center for Disease Control and Prevention (CCDC). Each reported case contains demographic and medical information and is identified by a unique identity card number to avoid duplicate reports.

The annual population data of each administrative street for each year were extracted from Shenzhen Statistical Yearbooks (2010-2019) of the Shenzhen Municipality Bureau of Statistics [8]. Basic map data were obtained from the Shenzhen Geographical Information Public Service Platform. The administrative number of the street was used as a reference at a 1:500,000 scale to correlate and match the data of reported PTB cases on each street to establish the database.

As one of the most serious infectious diseases in China, each diagnosed PTB case must be reported online within 24 hours after diagnosis. The Diagnostic Criteria for PTB (WS288-2017) issued by the Ministry of Health (the former National Health Commission) of the People’s Republic of China in 2017 were used in this study, in which cases of PTB were diagnosed using radiography, pathogen detection, and pathologic diagnosis [9]. All forms of PTB were included in this study, including bacteriologically confirmed and clinically diagnosed PTB, previously treated and new PTB, and childhood and adult PTB.

**Ethical Considerations**

This study was approved by the Ethics Committee of Shenzhen Center for Chronic Disease Control (SZCCC-2023-003-01-PJ). Personal sensitive information such as the name and phone number associated with each case were blocked and excluded in this study to protect the patients’ privacy. A secondary analysis based on reported data was conducted and thus informed consent from individuals was not required. This study was conducted strictly in accordance with Norms for the Management of Information Reporting on Infectious Diseases in China [10].

**Data Analysis**

**Descriptive and Time-Series Analyses**

The epidemiological characteristics of PTB cases were analyzed. PTB cases reported from 2010 to 2019 were aggregated annually by age, sex, occupation, permanent residents and migrant population, and date of onset for PTB notification rate analysis. Comparison between different groups was performed using the $\chi^2$ test or Fisher exact test as appropriate. All statistical analyses were performed in SPSS version 26 and a two-tailed $P$ value less than .05 was considered statistically significant.

In addition, time-series seasonal decomposition analysis was used to identify the seasonality of the PTB notification rate in Shenzhen municipality. The time series of reported PTB cases were decomposed into seasonal variation, long-term trend, and random effect to explore the temporal patterns. The temporal patterns were determined according to the onset date of the monthly registration of all reported PTB cases. The time series included 120 months from January 2010 to December 2019 and were examined using Excel software.
Spatial Autocorrelation Analysis

Moran $I$ was selected as the global index of spatial autocorrelation to detect the spatial distribution pattern of PTB cases in Shenzhen municipality, China. The expression of the global Moran $I$ statistic is as follows:

$$I = \frac{\sum (x_i - \bar{x})(x_j - \bar{x})w_{ij}}{\sum (x_i - \bar{x})^2}$$

where $n$ is the number of units and $x_i$ and $x_j$ are the attribute values of unit $i$ and unit $j$, respectively. The Moran $I$ value varies between $-1$ and $1$; when $|I|$ is larger, the autocorrelation is higher, and $I=0$ indicates no autocorrelation [11]. Both the Z score and $P$ value calculated by GeoDa 1.20 (Arizona State University) were used to test the significance of the Global Moran $I$ value.

Spatial-Temporal Scan Analysis

Kulldorff spatiotemporal scan statistical analysis was performed to explore the spatial, temporal, and spatial-temporal clusters of PTB across different streets geographically and at different time periods [12]. The SaTScan 10.1 software (Kulldorff) was used for spatial-temporal scanning analysis, which is based on a moving-column scanning window that contains geographical information with the height corresponding to time [13]. According to a previous study [6], the maximum radius of the spatial-scanning window and the maximum length of the temporal-scanning window was set to 11% of the population at risk and 30% of the whole study period, respectively. The log likelihood ratio (LLR) of different circle centers and various radii was calculated as follows to compare the notification rate of PTB inside and outside the scanning window [14]:

$$LLR = \log \left( \frac{\sum n_z}{\sum n_g} \right)$$

Where $n_z$ signifies the observed count of events within spatiotemporal window $z$, $n_g$ denotes the total aggregate of events across the entirety of the study area, $u_z$ represents the expected count of events within the particular spatiotemporal window $z$, and $\mu_g$ indicates the overall anticipated count of events within the study area. A larger LLR value indicates a more likely cluster. The Monte Carlo simulation test was used to evaluate whether the likelihood of the cluster was statistically significant, and the relative risk (RR) was calculated as the estimated risk within the cluster divided by that outside the cluster [15,16]. For each possible spatiotemporal cluster, when the $P$ value is less than .05, a larger LLR value indicates that the area covered by the dynamic scanning window is more likely to be a cluster region. The window with the largest LLR value selected from all the scanning windows is considered the strongest cluster and the secondary clusters are the other windows with statistically significant LLR values. ArcMap software (Esri) was used to visualize the scanning results.

Results

Descriptive Analysis of PTB Cases

A total of 58,122 PTB cases were notified in Shenzhen from 2010 to 2019, including 38,358 (66.00%) cases from male patients. Over 60% of cases were from the migrant population; 20,795 cases (35.78%) were detected in workers and 20,629 (35.49%) were from individuals who were unemployed. The mean age of the patients diagnosed with PTB was 34.73 (SD 14.13) years, with a range from 0 to 97 years (Figure 1).
Temporal Patterns of PTB Cases

The annual average notification rate of PTB for the 10-year study period was 51.62 per 100,000 population. As shown in Figure 2, the total notification rate of PTB showed a significantly volatile downward trend over time from the highest rate of 64.97 per 100,000 population in 2010 to the lowest rate of 43.43 per 100,000 population in 2019 ($P < .001$).
The monthly notification rates of PTB showed a trend of volatility and decline over the study period in Shenzhen municipality. PTB cases have shown seasonal variations with the highest number of PTB cases notified in May and July each year, followed by a steady decreasing trend after July and a nadir in January and February (Figure 3).

Spatial Patterns of PTB Cases
As displayed in Table 1, the global spatial autocorrelation analysis showed that the Moran I value of the PTB notification rate in Shenzhen municipality from 2010 to 2019 was positive (0.134) and the P value was consistently less than .05, indicating that the notification rate of PTB in Shenzhen municipality was nonrandomly distributed. Annually, except for the years 2012 and 2014, there was significant global spatial autocorrelation in the PTB notification rates every year with the Moran I value ranging from 0.130 to 0.353. Therefore, further spatial-temporal scan analysis of PTB was needed.

Spatial Clustering of PTB Cases

Spatial clustering analysis of notified PTB cases every year from 2010 to 2019 showed that the most likely clusters have changed dynamically over time. The most likely clusters of PTB in Shenzhen municipality from 2010 to 2014 were concentrated in the southwest regions, covering the streets of Nanshan District and Baoan District. From 2015 to 2019, the most likely clusters were mainly distributed in the central and northern streets of Shenzhen municipality, including Longhua District, Longgang District, and Guangming District (Figure 4).
Temporal Clustering of PTB Cases

As presented in Table 2, the temporal clustering analysis in each year showed that PTB notification rates were concentrated in late spring and summer annually, ranging from March to August. The greatest aggregated time for PTB across the whole study period was observed from March 2010 to September 2010. During this period, there was a total of 4562 notified PTB cases and the risk of PTB-related incidents was 53% (RR 1.53, P<.001) higher than that in other time periods.

Spatial-Temporal Clustering of PTB Cases

The results of spatial-temporal clustering analysis for notified PTB cases in Shenzhen municipality from 2010 to 2019 are shown in Table 3 and Figure 5, indicating that the PTB notification rates were spatiotemporally clustered. A total of 1 most-likely cluster and 10 secondary clusters were detected in this study. The most-likely cluster area was distributed in the southwestern region of Shenzhen municipality and the clustering time was from January 2010 to November 2012 (RR 1.96, P<.001) with a total of 3000 PTB cases notified during this period. In addition, the area centered at Nanshan Street of Nanshan District (22.53 N, 113.94 E) with a radius of 6.39 kilometers covered 6 streets, similar to the most likely cluster identified in the purely spatial clustering analysis. The other 10 secondary clusters were mainly located in the central and northwestern regions of Shenzhen municipality, covering streets in Baoan District, Nanshan District, Longgang District, Guangming District, and Longhua District, along with several relatively small areas (clusters 1, 4, and 8) in Futian District and Luohu District. The main clustering time ranged from January 2010 to March 2013 except for the secondary clusters 2, 5, 6, and 9.

Discussion

Principal Findings

To the best of our knowledge, this is the first study to present a spatial-temporal cluster analysis of PTB at the street level in Shenzhen municipality using routinely collected PTB surveillance data, which identified seasonal patterns and spatial-temporal clusters of PTB in Shenzhen.

The notification rate of PTB in Shenzhen municipality declined steadily during the 10-year study period, decreasing from the peak of 64.97 cases per 100,000 population in 2010 to the lowest of 43.43 cases per 100,000 population in 2019. This downward trend is in line with other municipal, provincial, and national studies [6,17-20]. This achievement is due in large part to the great importance attached by the local government and health administrative department in Shenzhen to PTB control and prevention in recent years. First, financial support received from the government has increased continuously from 28.2 million yuan (~US $3.9 million) in the Twelfth Five-Year Plan (2011-2015) to approximately 197.64 million yuan (~US $27 million) in the Thirteenth Five-Year Plan (2016-2020) for TB control and prevention in Shenzhen. Subsequently, an integrated system under collaboration of the CCDC, tuberculosis-designated hospitals, and community health service centers was established and developed among institutions with a clear division of labor and coordination [21]. In addition, a batch of molecular biological testing equipment for PTB diagnosis and treatment was purchased and distributed to designated PTB medical institutions in various streets and districts of the city [21]. As a result, the diagnosis time of PTB and the possibility of pretreatment transmission have declined, despite an increase in the overall percentage of cases detected and confirmed bacteriologically. At the same time, PTB screening programs were added to the routine physical examination for the older population aged ≥ 65 years and for primary and secondary school students, and rifampicin resistance testing was further strengthened for patients with PTB [22]. In addition to the DOTS recommended by the WHO since 2000, Shenzhen has implemented a series of measures, including providing free drug treatment and a certain degree of reimbursement for examination costs, which enable early diagnosis and timely treatment for patients with PTB to effectively curb the spread of disease. With the implementation of these targeted and effective measures, the PTB epidemic situation has improved substantially, although it remains a great public health challenge in Shenzhen municipality.

According to the time-series analysis, seasonal variations and cyclical trends of PTB cases were observed, with apparent peaks
in late spring and summer, especially in May and July. This is consistent with the findings of neighboring Guangzhou city [23]. Shenzhen has a subtropical monsoon humid climate, a long summer and short winter, abundant sunshine, and abundant rainfall, with an average annual temperature of 20 °C and relative humidity of 80%. This is aligned with the transmission of respiratory infectious diseases and may be related to the spread of PTB. Previous studies indicated that lack of exposure to ultraviolet rays from sunlight and poor ventilation in the indoor environment may increase the risk of PTB infection [24-26]. Consistent with other reports [18,19], we found the lowest number of notified PTB cases in January and February. On the one hand, this may be closely related to the massive public transportation and population flow during the Chinese Spring Festival, which usually occurs in late January or February [23,27], when many migrants leave Shenzhen to return to their hometowns. On the other hand, people are busy celebrating the Lunar New Year at this time, coupled with frequent visits to relatives and friends, and thereby may avoid seeking medical care [18,19]. These multiple factors would result in a significant decline in PTB cases reported but an increased risk of transmission among the infectious source and close contacts during the holiday, concentrating in late spring and summer after an incubation period of several months to half a year, including a 2-month interval from symptom appearance to a medical diagnosis [25]. This may be one of the contributors for the peak months observed in Shenzhen. In addition, the return of migrants and delayed diagnosis should also be considered. Therefore, the detection and tracking of patients with PTB should be strengthened during the Spring Festival, and suspected or confirmed cases should be transferred to designated medical institutions for further diagnosis and treatment as soon as possible to shorten the delay time of treatment and reduce the risk of transmission. Health education should also be emphasized and effective measures such as actively wearing masks and opening windows for ventilation should be promoted, especially in crowded places.

Many studies have confirmed a spatial-clustering distribution of PTB in certain areas [6,18,19,28]. In this study, the global spatial autocorrelation analysis indicated that the notification rate of PTB in Shenzhen municipality displayed an obvious spatial-clustering distribution between 2010 and 2019. The results of advanced local spatial autocorrelation showed that the clusters of PTB at the street level had a dynamic change over time from the southwest to the central and northern part of the city. The hot spots of PTB observed in this study are largely consistent with the PTB notification rates in Shenzhen. PTB has long been known as “the disease of the poor,” and poverty has been considered one of the causes of disease clustering [28-31]. However, a previous study indicated that the incidence of PTB is higher in areas with a better economic situation than in less developed areas because the former areas are more attractive to population inflows [32]. Many migrants are at increased risk of ill health because of the adverse conditions through which they travel and then work and live [33]. Migrant workers are usually not entitled to the social welfare and health resources that are available to local permanent residents, which poses a challenge for this specific population in accessing health care services [34,35]. In this study, most of the notified PTB cases were detected in workers or unemployed individuals, shifting in parallel with the economic development of local areas of the city. The regional economic development in the past 10 years started from Nanshan District and Baoan District in southwest Shenzhen, where the GDP ranked in the top three during the study period. With the change of urban planning, the GDP in central and northern Shenzhen, including Longhua District, Longgang District, and Guangming District, has grown rapidly recently, which has brought about a more obvious population agglomeration effect in these areas [36]. Similar dynamics can also be found in Beijing [37] and Shanghai [38]. Understanding the interaction of TB transmission, population migration, and social development, albeit highly complex and dynamic, is essential for the control and prevention of TB [32].

To consider the role of time when evaluating the geographical distribution of PTB, spatial-temporal scanning analysis was used to supplement the local spatial analysis. The results from the spatial-temporal clustering analysis of the PTB cases from 2010 to 2019 showed that the most likely cluster was concentrated in southwestern Shenzhen, covering 6 streets of 2 districts, and the clustering period was from January 2010 to November 2012. In addition, most of the secondary clustering areas were also found in this period, indicating that this period represents a peak of PTB transmission in Shenzhen. The clusters identified by the spatial-temporal scanning analysis and the simple spatial clustering analysis were similar, which may indicate the robustness of our results. More importantly, these similar findings indicate that more effective and targeted measures should be urgently developed and implemented in the high-risk areas for PTB control and prevention in Shenzhen municipality.

Compared with the Guangdong provincial and China national findings in recent years [39,40], Shenzhen has entered a period with a low epidemic level of PTB. However, there is still a long way to go to reach the WHO’s goal of eliminating PTB. Achieving this ambitious goal requires stronger, more tailored and effective responses. First, the clustering results can serve as a guide to develop more accurate and effective interventions, with a focus on areas where PTB is concentrated, and to strengthen the deployment and implementation of corresponding actions to prevent and discover the outbreak and epidemic status of PTB at the street level. PTB diagnosis, treatment, and care for migrants should be integrated into the general health services, while special efforts may be needed to reach migrants for improving the availability, accessibility, and quality of comprehensive medical services [41]. Screening for PTB contacts and selected high-risk groups should be linked to follow-up, strategies for preventive treatment, or referral to the treatment program [41]. In addition, systematic and extensive health educational campaigns are needed for the provision of more accessible information to raise public awareness of PTB and improve public access to relevant health care services. Third, increasing the speed of referral of newly detected patients with PTB to designated clinics is also crucial to minimize the risk of disease transmission and infections in the community.
Limitations

This is the first study to analyze the spatial-temporal clustering characteristics of PTB at the street level and identify the high-risk areas of PTB in Shenzhen municipality, which provides valuable information for future strategies and measures of PTB prevention and control. However, this study was subject to several limitations. First, our analysis was based on data extracted from the National Surveillance System and we were unable to preclude the possibility of missing cases. This might cause an underestimation of the PTB epidemic in Shenzhen. Second, this study only focused on the spatial and temporal patterns and clusters of PTB cases. Potential risk factors associated with PTB incidence, such as individual habits, socioeconomic status, living conditions, and environmental pollutants, were not evaluated. Further research should take these limitations into consideration.

Conclusions

This study identified spatial and temporal patterns and spatial-temporal clusters of PTB cases at the street level in Shenzhen municipality from 2010 to 2019. A volatile downward trend of PTB incidence over the study period was observed in Shenzhen municipality. The most likely clustering areas changed from the southwest to the central and northern part of the city, and the most likely clustering time was late spring and summer. Resources should be prioritized to high-risk areas for PTB prevention and control.

Acknowledgments

This study was supported by the Chinese Center for Disease Control and Prevention. We appreciate the contributions made by colleagues of the tuberculosis program for their assistance in data collection. This study was supported by the Shenzhen Health Economics Association Research Fund (202369), Shenzhen Medical Key Discipline Construction Fund (SZXK065), National Natural Science Foundation of China (82373641), and Guangdong Scientific and Technological Foundation (2020B111170014). Abstract

Background: The World Health Organization declared mpox an international public health emergency. Since January 1, 2022, China has been ranked among the top 10 countries most affected by the mpox outbreak globally. However, there is a lack of spatial epidemiological studies on mpox, which are crucial for accurately mapping the spatial distribution and clustering of the disease.

Objective: This study aims to provide geographically accurate visual evidence to determine priority areas for mpox prevention and control.

Methods: Locally confirmed mpox cases were collected between June and November 2023 from 31 provinces of mainland China excluding Taiwan, Macao, and Hong Kong. Spatiotemporal epidemiological analyses, including spatial autocorrelation and regression analyses, were conducted to identify the spatiotemporal characteristics and clustering patterns of mpox attack rate and its spatial relationship with sociodemographic and socioeconomic factors.

Results: From June to November 2023, a total of 1610 locally confirmed mpox cases were reported in 30 provinces in mainland China, resulting in an attack rate of 11.40 per 10 million people. Global spatial autocorrelation analysis showed that in July (Moran I = 0.0938; P = .08), August (Moran I = 0.1276; P = .08), and September (Moran I = 0.0934; P = .07), the attack rates of mpox exhibited a clustered pattern and positive spatial autocorrelation. The Getis-Ord Gi* statistics identified hot spots of mpox attack rates in Beijing, Tianjin, Shanghai, Jiangsu, and Hainan. Beijing and Tianjin were consistent hot spots from June to October. No cold spots with low mpox attack rates were detected by the Getis-Ord Gi* statistics. Local Moran I statistics identified a high-high (HH) clustering of mpox attack rates in Guangdong, Beijing, and Tianjin. Guangdong province consistently exhibited HH clustering from June to November, while Beijing and Tianjin were identified as HH clusters from July to September. Low-low clusters were mainly located in Inner Mongolia, Xinjiang, Xizang, Qinghai, and Gansu. Ordinary least squares regression models showed that the cumulative mpox attack rates were significantly and positively associated with the proportion of the urban population (t0.05/2,1 = 2.4041; P = .02), per capita gross domestic product (t0.05/2,1 = 2.6955; P = .01), per capita disposable income (t0.05/2,1 = 2.8303; P = .008), per capita consumption expenditure (PCCE; t0.05/2,1 = 2.7452; P = .01), and PCCE for health care (t0.05/2,1 = 2.5924; P = .01).

The geographically weighted regression models indicated a positive association and spatial heterogeneity between cumulative mpox attack rates and the proportion of the urban population, per capita gross domestic product, per capita disposable income, and PCCE, with high R² values in north and northeast China.

Conclusions: Hot spots and HH clustering of mpox attack rates identified by local spatial autocorrelation analysis should be considered key areas for precision prevention and control of mpox. Specifically, Guangdong, Beijing, and Tianjin provinces should be prioritized for mpox prevention and control. These findings provide geographically precise and visualized evidence to assist in identifying key areas for targeted prevention and control.
Introduction

Mpox is a zoonotic viral disease caused by the mpox virus, primarily circulating in animals but also transmissible to humans [1,2]. The main reservoir of the mpox virus is believed to be rodents and primates such as squirrels, kangaroos, dormice, monkeys, and apes [3,4]. Mpox can be transmitted to humans through direct contact with infected animals, their bodily fluids, or contaminated materials [4]. While human-to-human transmission of mpox is less common, it can occur through respiratory droplets, close physical contact, or contact with skin lesions or bodily fluids of an infected individual [4]. An ongoing outbreak of mpox since January 1, 2022, has primarily affected men who have sex with men in countries outside of West and Central Africa, with cases reported to the World Health Organization (WHO) [5].

Historically, mpox has been mainly observed in Central and West Africa, with mortality rates ranging from 1% to 10% [6,7]. Since 2022, person-to-person transmission of mpox has been significantly increasing, thereby resulting in its widespread occurrence in other countries [8-10]. As of the end of February 2024, 94,707 confirmed cases of mpox, including 181 deaths, have been reported to the WHO from 117 countries and regions worldwide since January 1, 2022 [5]. In September 2022, the first imported case of mpox was reported in Chongqing, China. In June 2023, a local mpox epidemic occurred in China. As of November 30, 2023, 1611 confirmed cases of mpox have been reported from 30 (96.8%) provinces in mainland China, except Xizang, which included 1610 local cases [11].

The WHO declared mpox an international public health emergency on July 23, 2022 [12], which was reaffirmed on February 15, 2023 [13]. A public health emergency of international concern is described in the International Health Regulations (2005) as an extraordinary event that poses a public health risk to other countries through the international spread of a disease, potentially requiring a coordinated global response [14]. On September 15, 2023, mpox was classified as a category B infectious disease for management by the National Health Commission of China, effective September 20, 2023 [15]. In accordance with the Law of Infectious Disease Prevention and Control of the People’s Republic of China, statutory infectious diseases are identified by their transmission, epidemic intensity, and hazard degree. These diseases are classified into 3 categories, totaling 40 types: 2 types in category A, 27 types in category B, and 11 types in category C. Category A infectious diseases are considered compulsory for management, while category B infectious diseases are strictly regulated [16]. According to the WHO, the confirmation of a single case of mpox in a country is considered an outbreak [5]. Therefore, it is crucial to prioritize the mpox pandemic owing to its potentially disastrous consequences for public health, socioeconomic factors, and overall health care systems. Experiences from previous pandemics, such as SARS, Middle East respiratory syndrome coronavirus, and COVID-19, highlight the roles of health administrators and policymakers to promptly develop comprehensive prevention and control strategies in all countries.

Spatial epidemiological studies have accurately visualized the spatial distribution and clustering of diseases via mapping [17-20]. Using geographically precise and visual evidence, priorities for disease prevention and control could be identified, and their effectiveness could be evaluated [21-24]. Various factors can influence the occurrence and prevalence of infectious diseases: natural factors (climate and geography) and social factors (economy and population density). The existing evidence emphasizes the spatial heterogeneity in mpox distribution, indicating complexity and unevenness in the spatial patterns of mpox cases [25-27]. This highlights the significance of conducting spatial analyses in mpox studies. However, there is a scarcity of reports on spatial analyses of mpox.

The attack rate is a crucial indicator for measuring the frequency and intensity of disease occurrence and for evaluating the effectiveness of disease prevention and control within a short period. Therefore, we conducted a spatial epidemiological analysis to comprehensively and accurately describe and analyze the mpox attack rate. Our analysis aimed to identify spatial distribution characteristics and spatial clustering patterns and to determine the presence of cold and hot spots of spatial clustering. Furthermore, we examined the spatial regression relationship between the mpox attack rate and sociodemographic and socioeconomic factors.

Methods

Study Design

A spatial ecological comparison study was designed to conduct a spatiotemporal epidemiological analysis of mpox attack rates in mainland China at a provincial level, focusing on spatiotemporal distribution characteristics and clustering patterns of the mpox attack rate and its spatial relationship with sociodemographic and socioeconomic factors.

Study Area

This study was conducted in 31 provinces of mainland China, excluding Taiwan, Macao, and Hong Kong (Table S1 in Multimedia Appendix 1). According to the Chinese administrative division, the 31 provinces are divided into 6 regions: north China, northeast China, east China, central south China, southwest China, and northwest China. As of the end of 2022, the estimated population of China was 1411.75 million people. The per capita gross domestic product (PCGDP) of China was US $12,720, and the per capita disposable income (PCDI) was US $5472. These data are sourced from the China Statistical Yearbook (2023) of the National Bureau of Statistics [28]. For a visual representation of the study areas and
administrative divisions, please refer to Figure S1 in Multimedi a Appendix 2.

Study Population
This study analyzed all the locally confirmed cases of mpox in mainland China that occurred between June and November 2023. As of November 30, 2023, a total of 1610 locally confirmed cases of mpox have been reported by the National Health Commission of China [11].

Mpx Attack Rate
The provincial-level crude mpox attack rates per 10 million people were calculated by dividing the total number of confirmed mpox cases in each province by its total population. This rate was multiplied by 10 million to obtain the rate per 10 million people.

Sociodemographic and Socioeconomic Variables
Sociodemographic variables included the proportion of the urban population (PUP), natural population growth rate (NPGR), percentage of the illiterate population older than 15 years (PIP), aging rate older than 65 years (AR), and per capita road area (PCRA) [28]. Socioeconomic variables included the PCGDP, PCDI, per capita consumption expenditure (PCCE), and PCCE for health care (PCCEH) [28].

Spatial Analysis
Spatial description and analysis were conducted using ArcGIS (version 9.0; Environmental Systems Research Institute, Inc), with the province as the spatial analysis unit. Thematic maps were created to visually and intuitively display the spatial distribution of the confirmed cases and attack rates of mpox. Global spatial autocorrelation analysis was conducted to probe the presence of spatial clustering in mpox attack rates at a broader level [22]. This analysis used the global Moran I statistic (−1 ≤ values ≤ +1). Spatial autocorrelation was considered to be present if the P value was below .10, with a test level α of .10. The values of Moran I indicate whether the spatial distribution of the mpox attack rates was random (Moran I=0), dispersed (Moran I<0), or clustered (Moran I>0). However, it is important to note that global spatial autocorrelation analysis does not provide information on specific local locations and patterns of spatial clustering.

To accurately identify the geographic locations and patterns of spatial clustering at the provincial level of mpox attack rates within the study area, a local spatial autocorrelation analysis was conducted. The analysis used Getis-Ord-Gi* and local Moran I statistics, which are commonly used spatial techniques for assessing local spatial autocorrelation [22]. The Getis-Ord Gi* statistics identified 2 types of clustering: hot spots and cold spots. Hot spots are identified by positive \( z \) values, indicating that high values of mpox attack rates are clustered among neighboring provinces, while cold spots are identified by negative \( z \) values, indicating that low values of mpox attack rates are clustered among neighboring provinces. The corresponding \( z \) values for the Getis-Ord Gi* statistic at 90%, 95%, and 99% CIs are ±1.65, ±1.96, and ±2.58, respectively. The local Moran I statistic was used to verify and complement the Getis-Ord Gi* analysis, as it allows the detection of areas where spatial outliers exist. The results of the local Moran I highlighted aspects that may have been overlooked in the Getis-Ord Gi* analysis. Local Moran I examines 4 patterns of spatial clustering: high-high (HH) clustering (positive correlation; high values of mpox attack rates clustered among neighboring provinces), high-low (HL) outlier (negative correlation; provinces with high values of mpox attack rates surrounded by those with low values), low-high (LH) outlier (negative correlation; provinces with low values surrounded by those with high values), and low-low clustering (positive correlation; low values clustered among neighboring provinces).

This study used ordinary least squares (OLS) and geographically weighted regression (GWR) models to examine the spatial regression relationship between the mpox attack rates and sociodemographic and socioeconomic factors. The dependent variable was the cumulative mpox attack rate between June 1 and November 30, 2023, and sociodemographic and socioeconomic factors were considered independent variables. The OLS model was used to estimate the global parameters, whereas the GWR model was used to estimate the local parameters, considering the spatial autocorrelation and spatial heterogeneity of the research factors [29,30]. The GWR model was constructed using the weighted least squares method, with the selection criterion and kernel function playing essential roles. The selection criterion determined the adaptive bandwidth size, while the kernel function calculated the weight matrix. This study used the fixed Gaussian and Akaike information criterion as the kernel function and selection criterion, respectively [30].

Ethical Considerations
This study was approved by the ethical committee of Qiqihar Medical University (approval number [2021] 31). This study adhered to the Helsinki Declaration.

Results
Spatiotemporal Distribution of Confirmed Cases and Attack Rates of Mpox
Between June 1 and November 30, 2023, a total of 1610 locally confirmed cases of mpox were reported in mainland China, resulting in an attack rate of 11.40 per 10 million people. The number of confirmed cases and the attack rate of mpox initially increased and then decreased during the study period, as depicted in Figure 1A-C. The peak period was observed between July and August, which accounted for 61.6% (n=992) of the total cases. In August 2023, mpox reached its highest level with 501 confirmed cases and an attack rate of 3.55 per 10 million people. However, by November, the number of confirmed cases and attack rate reached their lowest points and were even lower than the attack rate in June. There were 80 confirmed cases with an attack rate of 0.57 per 10 million people (Figure 1A).
Between June 1 and November 30, 2023, a total of 30 provinces reported confirmed cases of mpox, with Xizang being the only province without any cases (Table S2 in Multimedia Appendix 1 and Figure S2 in Multimedia Appendix 3). Among these provinces, Guangdong, Beijing, Zhejiang, Sichuan, and Jiangsu had the highest cumulative numbers of confirmed mpox cases, with 327, 245, 176, 132, and 114 cases, respectively (Table S2 in Multimedia Appendix 1 and Figure S2A in Multimedia Appendix 3). Furthermore, the highest cumulative attack rates of mpox were observed in Beijing, Shanghai, Tianjin, Zhejiang, and Guangdong provinces, with rates of 112.18, 35.15, 28.61, 26.76, and 25.84 per 10 million people, respectively (Table S2 in Multimedia Appendix 1 and Figure S2B in Multimedia Appendix 3). The number of regions reporting confirmed mpox cases gradually increased between June and September 2023 (Figure 2A,B). Confirmed mpox cases were reported in 6 provinces in June, whereas in September, the number of regions reporting confirmed mpox cases rose to 28. However, from October to November 2023, there was a gradual decline in the number of regions reporting mpox cases (Figure 2A,B). Beijing
consistently exhibited the highest mpox attack rates (Figure 2B). During July and August 2023, the number of confirmed cases and attack rates of mpox in various regions were particularly elevated, especially in Beijing, Guangdong, Shanghai, Sichuan, Tianjin, and Zhejiang provinces, when compared with other regions and months (Figure 2A,B).

**Figure 2.** Spatiotemporal distribution of confirmed cases (A) and attack rates (B) of mpox from June to November 2023. A higher resolution version of this figure is available in Multimedia Appendix 4.

### Global Spatial Autocorrelation Analysis of Mpox Attack Rates

A global spatial autocorrelation analysis was conducted to examine the spatial patterns of mpox attack rates at the provincial level in mainland China (Table S3 in Multimedia Appendix 1). The results showed that in June (Moran $I=-0.0057$, $P=0.50$), October (Moran $I=0.0969$, $P=0.17$), and November (Moran $I=0.0510$, $P=0.39$), the attack rates of mpox were randomly distributed and not statistically significant. However, there was a significant global spatial autocorrelation in July (Moran $I=0.0938$, $P=0.08$), August (Moran $I=0.1276$, $P=0.08$),
and September (Moran I = 0.0934, P = 0.07). This indicates that, during this period, the attack rates of mpox exhibited a clustered pattern and positive spatial autocorrelation (Figure 3).

**Figure 3.** Results of Moran I statistic for global spatial autocorrelation analysis of mpox attack rates.

Local Spatial Autocorrelation Analysis of Mpox Attack Rates

The Getis-Ord Gi* statistics revealed that Beijing and Tianjin consistently exhibited high mpox attack rates from June to October, categorizing them as hot spots. Shanghai was identified as a hot spot in August and October. Jiangsu and Hainan were identified as hot spots in October and November, respectively. No cold spots with low mpox attack rates were detected using the Getis-Ord Gi* statistics (Figure 4A).
According to the results of the local Moran I statistics, Guangdong province consistently exhibited HH clustering in terms of spatial patterns of mpox attack rates from June to November. Beijing and Tianjin were identified as HH clusters from July to September. Beijing was identified as an HL outlier for June, October, and November. Sichuan was determined to be an HL outlier in July, August, and October. Tianjin was identified as an LH outlier in June and November. Jiangsu was identified as an LH outlier in October. Low-low clusters were mainly located in Inner Mongolia, Xinjiang, Xizang, Qinghai, and Gansu (Figure 4B). This implies that areas with low mpox attack rates are clustered in neighboring regions.

**Spatial Regression Analysis Between Mpox Attack Rates and Sociodemographic and Socioeconomic Factors**

The detailed values of the cumulative mpox attack rates and explanatory variables can be found in Tables S4 and S5 in Multimedia Appendix 1 and Figure S3 in Multimedia Appendix 6. The results of the Pearson correlation analysis indicated that
the cumulative mpox attack rates were not significantly correlated with the NPGR, PIP, AR, and PCRA but were significantly and positively associated with the PUP, PCGDP, PCDI, PCCE, and PCCEH. However, there were significant correlations among the PUP, PCGDP, PCDI, PCCE, and PCCEH (Figure S4 in Multimedia Appendix 7). To address multicollinearity, separate OLS and GWR regression models were conducted for the dependent variable and each independent variable. However, multivariate OLS and GWR regression models have not yet been developed.

First, we used OLS regression models to explore the spatial regression relationship between the cumulative mpox attack rates from June 1 to November 30, 2023, as the dependent variable and sociodemographic and socioeconomic factors as independent variables. The cumulative mpox attack rates were not significantly correlated with the NPGR, PIP, AR, or PCRA; while they were significantly and positively associated with the PUP ($t_{0.05/2,1} = 2.4041$, $P = .02$), PCGDP ($t_{0.05/2,1} = 2.6955$, $P = .01$), PCDI ($t_{0.05/2,1} = 2.8303$, $P = .008$), PCCE ($t_{0.05/2,1} = 2.7452$, $P = .01$), and PCCEH ($t_{0.05/2,1} = 2.5924$, $P = .01$). The $R^2$ values of the OLS models for the PUP, PCGDP, PCDI, PCCE, and PCCEH were 0.4190, 0.5743, 0.6469, 0.5583, and 0.5400, respectively; indicating that these 5 variables can explain the 41.90%, 57.43%, 64.69%, 55.83%, and 54% variance of cumulative mpox attack rates at the provincial level (Table S6 in Multimedia Appendix 1).

The GWR regression models were created using only the statistically significant independent variables identified in the OLS regression models, along with the cumulative mpox attack rates. The coefficients and local $R^2$ values of the explanatory variables in the GWR models are presented in Figure 5 and Tables S7-S10 in Multimedia Appendix 1. Generally, the Akaike Information Criterion values of the GWR models were significantly lower than those of the OLS model, indicating that the GWR had a high explanatory power and better fitting ability (Tables S6 and S7 in Multimedia Appendix 1). The GWR model indicated a positive association and spatial heterogeneity between cumulative mpox attack rates and the PUP, PCGDP, PCDI, and PCCE (Figure 5), with high $R^2$ values in north and northeast China.
Figure 5. Spatial distribution of the coefficients (A) and local $R^2$ (B) values of the explanatory variables in the geographically weighted regression model. PCCE: per capita consumption expenditure; PCCEH: PCCE for health care; PCDI: per capita disposable income; PCGDP: per capita gross domestic product; PUP: proportion of the urban population. A higher resolution version of this figure is available in Multimedia Appendix 8.

Discussion

Principal Findings

This study is the first in mainland China to conduct a spatiotemporal epidemiological analysis to comprehensively identify the spatiotemporal characteristics and clustering patterns of confirmed cases and attack rates of mpox at the provincial level. The findings of this study are of great significance for improving the accuracy and effectiveness of mpox prevention and control.

Since June 2023, local cases of mpox have been reported in 30 of 31 provinces in mainland China, excluding Xizang [11]. In June, 6 provinces reported cases, which rose to 28 regions by September. However, from October to November 2023, there
was a gradual decline in the number of regions reporting mpox cases. As of November 30, 2023, a total of 1610 locally confirmed cases of mpox have been reported [11]. The attack rate of mpox is 11.40 per 10 million. The number of confirmed cases and attack rate of mpox exhibited a pattern of increase from June to August, followed by a decrease from September to November. In November, both the number of confirmed cases and the attack rate reached their lowest points, even lower than the level observed in June. These findings highlight the importance of the implementation of preventive and control measures. On June 10, 2022, the National Health Commission of China formulated the “Diagnosis and Treatment Guidelines for Monkeypox (2022 edition)” [3]. Subsequently, on June 27, 2022, the National Health Commission of China released the Technical Guidelines for Monkeypox Prevention and Control (2022 edition) [4]. The guidelines highlight 4 key areas for action: first, enhancing the evaluation of the mpox pandemic situation; second, intensifying quarantine and monitoring measures for mpox; third, enhancing the professional training of health care workers; and finally, ensuring the availability of diagnostic reagents, therapeutic drugs, and vaccines for mpox [31]. On July 26, 2023, the National Disease Control and Prevention Administration developed the Monkeypox Prevention and Control Plan [32]. Subsequently, on August 2, 2023, the AIDS Prevention and Control Center of China created the Core Information of Monkeypox Prevention and Treatment for Key Populations, aiming to enhance awareness and prevention of mpox [33]. On September 15, 2023, mpox was classified as a category B infectious disease for management by the National Health Commission of China, effective September 20, 2023 [14]. These guidelines provide guidance on the diagnosis, treatment, prevention, and control of mpox in various regions, which also emphasizes the need to strengthen prevention and control measures for mpox.

Although the number of regions reporting mpox cases, confirmed cases, and attack rates declined from October to November 2023, the first confirmed case of mpox was reported in Gansu Province in November 2023. Since January 1, 2022, China, including Taiwan, Macau, and Hong Kong, has ranked 10th globally in the number of confirmed cases reported by the WHO [5]. The number of confirmed mpox cases in China (n=2031) was lower than that in the United States (n=31,800), Brazil (n=10,967), Spain (n=7898), France (n=4195), Colombia (n=4090), Mexico (n=4081), the United Kingdom (n=3892), Germany (n=3816), and Peru (n=3812). Therefore, mpox has emerged as a major public health emergency in mainland China, Germany (n=3816), and Peru (n=3812). Therefore, mpox has emerged as a major public health emergency in mainland China, especially Beijing and Tianjin provinces, indicating that areas with high mpox attack rates were clustered among neighboring provinces. Among these provinces, Guangdong consistently exhibited HH clustering in terms of spatial patterns of mpox attack rates from June to November, while Beijing and Tianjin were identified as HH clusters from July to September. In June, October, and November, Beijing was identified as an HL outlier, suggesting that the areas with high mpox attack rates in Beijing were surrounded by other areas with low values. Similarly, Tianjin was recognized as an LH outlier in June and November, indicating that the areas with low mpox attack rates in Tianjin were surrounded by other areas with high values. This finding aligns with the identification of Beijing as an HL outlier in June and November, emphasizing the consistently high mpox attack rates in Beijing. Further research is necessary to comprehend the reasons behind these high attack rates in Beijing, with possible reasons including Beijing’s status as the capital and most densely populated area in China, along with the presence of a large floating population that may contribute to virus transmission. Therefore, the results of the local Moran I highlighted an HH clustering in Guangdong Province that had been overlooked in the Getis-Ord Gi* analysis and verified the result that Beijing and Tianjin were consistent hot spots identified by the Getis-Ord Gi* analysis. Additionally, Sichuan was identified as an HL outlier in July, August, and October, whereas Jiangsu was identified as an LH outlier in October, suggesting that the surrounding Shanghai and Zhejiang provinces had high mpox attack rates. Therefore, all the hot spots and HH clustering of mpox attack rates identified through local spatial autocorrelation analysis should be considered key areas for precision prevention and control of mpox. Specifically, the Guangdong, Beijing, and Tianjin provinces, which consistently exhibited high-value clustering, should be given high priority for mpox prevention and control. These findings provide geographically precise and visual evidence to assist in identifying key areas for the targeted prevention and control of mpox.

The GWR model was used to analyze the spatially varying relationships between independent and dependent variables while considering spatial autocorrelation [34]. It used the weighted least squares method to estimate varying parameters locally, allowing for varied spatial relationships across different geographical regions. This localized approach facilitated the identification of spatial heterogeneity, revealing trends and distribution patterns of the spatial relationship between independent and dependent variables within specific spatial extents [30,34]. In contrast, the OLS model estimated parameters using the OLS method, assuming that spatial relationships in the model were constant across space [30]. However, this global parameter estimation with constant parameters overlooks spatial heterogeneity in the data and fails to capture spatial variation trends [30]. In this study, the GWR model revealed a positive association and spatial heterogeneity between the cumulative mpox attack rates and the PUP, PCGDP, PCDI, and PCCE. This finding aligns with the results obtained from the application of
the Getis-Ord Gi* statistics, which identified hot spots in the Beijing, Tianjin, Shanghai, Jiangsu, and Hainan provinces. Furthermore, the results of the Local Moran I statistics also supported this finding, indicating HH clustering in Guangdong, Beijing, and Tianjin and HL outliers in Sichuan. These areas, which were identified as key regions for the precise prevention and control of mpox through local autocorrelation analysis, are characterized by robust economic development [28].

Limitations
This study had 2 limitations. First, the spatial analysis was conducted at the provincial level, and further studies should consider smaller geographic units for more accurate evidence. Second, this study focused solely on the relationship between cumulative mpox attack rates and sociodemographic and socioeconomic factors; future studies should also consider natural and environmental risk factors.

Conclusions
A total of 1610 locally confirmed mpox cases were reported in 30 provinces in mainland China from June to November 2023, resulting in an attack rate of 11.40 per 10 million people. The hot spots and HH clustering of mpox attack rates should be considered as key areas for precision prevention and control of mpox. Specifically, Guangdong, Beijing, and Tianjin should be given high priority for mpox prevention and control. These findings provide geographically precise and visual evidence for identifying key areas for targeted prevention and control.

Acknowledgments
The authors sincerely thank the workers at the Centers for Disease Prevention and Control for their efforts in collecting and managing data on confirmed cases of Mpox. The authors express their deepest gratitude to Editage (Cactus Communications Private Limited) for their assistance with language editing. This study was supported by the Doctorate Research Foundation of the Qiqihar Medical University (grant QMSI2023B-16). Generative artificial intelligence had no role in the study design and any portion of the manuscript writing.

Data Availability
The data sets used or analyzed during the current study are available from the corresponding author on reasonable request.

Authors' Contributions
YJ and JG did the conceptualization, formal analysis, funding acquisition, and methodology, wrote the original draft, and reviewed and edited the draft. LQ, LD, YQ, LB, and JG did the conceptualization, supervision, and project administration. XC, SM, YH, ZX, and JC did the data curation, software, and formal analysis. Abstract

Background: Cycling is known to be beneficial for human health. Studies have suggested significant associations of physical activity with macroscale built environments and streetscapes. However, whether good streetscapes can amplify the benefits of a favorable built environment on physical activity remains unknown.

Objective: This study examines whether streetscape perceptions can modify the associations between accessibility, land use mix, and bike-sharing use.

Methods: This cross-sectional study used data from 18,019,266 bike-sharing orders during weekends in Shanghai, China. A 500 × 500 m grid was selected as the analysis unit to allocate data. Bike-sharing use was defined as the number of bike-sharing origins. Street view images and a human-machine adversarial scoring framework were combined to evaluate lively, safety, and wealthy perceptions. Negative binomial regression was developed to examine the independent effects of the three perceptual factors in both the univariate model and fully adjusted model, controlling for population density, average building height, distance to nearest transit, number of bus stations, number of points of interest, distance to the nearest park, and distance to the central business district. The moderation effect was then investigated through the interaction term between streetscape perception and accessibility and land use mix, based on the fully adjusted model. We also tested whether the findings of streetscape moderation effects are robust when examinations are performed at different geographic scales, using a small-sample statistics approach and different operationalizations of land use mix and accessibility.

Results: High levels of lively, safety, and wealthy perceptions were correlated with more bike-sharing activities. There were negative effects for the interactions between the land use Herfindahl–Hirschman index with the lively perception ($\beta=-0.63; P=.01$) and safety perception ($\beta=-0.52; P=.001$). The interaction between the lively perception and road intersection density was positively associated with the number of bike-sharing uses ($\beta=0.43; P=.08$). Among these, the lively perception showed the greatest independent effect ($\beta=1.29; P<.001$), followed by the safety perception ($\beta=1.22; P=.001$) and wealthy perception ($\beta=0.72; P=.001$). The findings were robust in the three sensitivity analyses.

Conclusions: A safer and livelier streetscape can enhance the benefits of land use mix in promoting bike-sharing use, with a safer streetscape also intensifying the effect of accessibility. Interventions focused on streetscape perceptions can encourage cycling behavior and enhance the benefits of accessibility and land use mix. This study also contributes to the literature on potential moderators of built environment healthy behavior associations from the perspective of microscale environmental perceptions.

KEYWORDS

built environment; streetscape perceptions; bike-sharing use; cycling; moderation effect; China

Introduction

Several studies have demonstrated that a favorable built environment can promote walking and bike-sharing use, particularly in Chinese cities [1-3]. However, findings on the effects of built environments are usually mixed [4-6]. One potential explanation is that there may be interactions between built environments at different levels, including the moderation effects of streetscape perceptions [7,8]. An in-depth understanding of streetscape perceptions as moderators is not only an important methodological issue for environmental health research [9] but also informative for creating effective interventions in built environments. Despite some efforts
[10,11], however, it remains unclear whether and to what extent good perceptions of streetscapes can enhance the benefits of favorable built environments.

The ecological model of physical activity provides a theoretical foundation for streetscape moderation effects. According to this model, one’s cycling behavior is determined by factors across multiple levels [9]. Such behavior is shaped by interactions among indicators at different levels [9]. Moreover, understanding the benefits of streetscapes in promoting health is important. Microscale streetscapes provide numerous benefits to people’s physical activity [11-13]. Additionally, the built environment at the neighborhood level has essentially been established and fixed over time, and streets have become a focus of high-quality urban development in the era of inventory planning, particularly in Chinese cities.

However, little attention has been given to the moderation effects of streetscapes [8,14,15]. Furthermore, most studies examining environmental perception as a moderator focus on perceived safety [16-18], while little attention has been given to other perceived aspects. Moreover, streetscapes as potential moderators are usually examined from the objective side [8,10] and are less understood from a perceptual perspective. It has been reported that residents’ safety perceptions are more likely to be correlated with physical activity [8,19], especially for those who do not perceive threats from neighborhoods with high crime rates. However, insufficient attention has been given to streetscapes in studies exploring environmental moderation from a perception perspective [8].

To fill the aforementioned gaps, this study aims to address whether streetscape perceptions can modify the effects of accessibility and land use mix on bike-sharing use. To achieve this, we used data from 18,019,266 GPS-based bike-sharing orders and conducted a cross-sectional study in Shanghai, China. This study contributes to the literature on the potential moderation effects of urban environments from the perspective of microscale environmental perception [8,18,20]. The findings are derived from Chinese cities, where urban forms and the leading perception factors as moderators differ significantly from those of Western countries [10,21], which all advance the development of ecological models of health behavior [9]. This cross-sectional study, with its large data volume and spatial coverage, suggests that urban planning initiatives aiming to encourage healthy behaviors among residents should consider microscale streetscapes, which can promote physical activities and enhance the benefits of accessibility and land use mix.

**Methods**

**Research Area**

We examined the moderation effects of streetscape perceptions in central Shanghai, China. The research area was delineated by the Outer Ring Highway of Shanghai (Figure 1), mainly because of the availability of street view images and bike-sharing use data. As one of the four first-tier cities in China, Shanghai is among the largest cities in the world. As of 2017, there were 1.5 million dockless bikes in Shanghai. The terrain is flat, and the climate is relatively favorable, which provides conducive conditions for people’s cycling activities.
Data Source and Research Design

This is a cross-sectional study in nature, with grids as analysis units to allocate data. Bike-sharing use data were provided by the Mobike Technology Co., Ltd, spanning from August 26 to September 8, 2018. Originally, the number of bike-sharing use records was about 19 billion. Each record included information on trip ID, start time and location, and end time and location. As in many studies [2,10], records on rainy days (eg, September 6, 2018) were not included. Additionally, we excluded records with abnormal durations or lengths, retaining records with a trip duration from 2 minutes to 1 hour. After excluding trips with locations out of our research area, the final number of bike-sharing use records in this study was 18,019,266.

Data on street view images were obtained from the Baidu application programming interface [22], with the sampling points at 50-m intervals along the road network. Each sampling point contains street view images with four headings. Data used to measure macroscale built environments included population data derived from EasyGO data and road networks, buildings, and points of interest (POIs) acquired from Baidu Maps [22].

Deriving Bike-Sharing Use

Bike-sharing use is defined as the number of bike-sharing origins on weekends in each grid. Similar to studies examining environmental effects on bike-sharing use [10,23], a 500 × 500 m grid was selected as the analysis unit to allocate each trip, primarily because the size of the grids selected was usually...
considered to be the main activity space in Chinese neighborhoods [21,24]. Table S1 in Multimedia Appendix 1 presents the summary statistics of bike-sharing use, streetscape perceptions, and macroscale built environments. Figure 2A exhibits the spatial distributions of bike-sharing origins on weekends.

Figure 2. Spatial distributions of the number of bike-sharing uses and assessed streetscape perceptions during 2018 in Shanghai, China.

Assessing Streetscape Perceptions
Streetscape perceptions are three positive perceptual indicators (ie, lively, safety, and wealthy) [25]. They were assessed according to a human-machine adversarial scoring framework developed by Yao et al [25]. Briefly, volunteers scored the perceptions based on the displayed street view image, with the scored values ranging from 0 to 100. Subsequently, a random forest model was used to fit the association of volunteer scorings with visual scenic features extracted by the segmentation approach of the fully convolutional neural network–8. Once the first 50 photos were scored by a volunteer, a random forest set was created to fit the perceived scores in the scoring software. When the volunteer rated the subsequent photos, the software provided the recommended scores based on the rules learned from the volunteer’s previous rating. In this process, an iterative feedback module was used to automatically adjust the recommended scores according to the user’s scoring behaviors. When the difference between the recommended and scored values was lower than 5 points, the scoring procedure stopped and a human-machine adversarial scoring module was created.
As reported, errors in the estimated perceptions using the scoring framework were less than 10% [25]. In this situation, the created scoring module was used to assess the three perceptual indicators and then obtain the perceptual scores for each street view image. The perceptual scores for each sampling point were then calculated by averaging the perceptual scores of each of the four images. Finally, perception scores for each grid were calculated by averaging the perceptual scores of sampling points located in the grid. Figures 2 (B-D) and 3 show the spatial distributions of the three perception indicators assessed and their examples.

**Figure 3.** Examples of the assessment for lively, safety, and wealthy perceptions during 2018 in Shanghai, China.

---

**Measuring Macroscale Built Environments**

Macroscale built environments were measured in terms of the 5Ds framework [1]. Population and average building height were used to measure density. The land use Herfindahl-Hirschman index (HHI) was used to assess diversity, with a high value indicating a less mixed degree of different types of land use [26]. Destination accessibility was measured using the number of POIs and distance to the nearest park. Distance to transit was assessed in terms of distance to the nearest metro station and the number of bus stops. The design was measured through the number of road intersections. Distance to the central business district (CBD) was operationalized as the distance between the centroid of a grid and the CBD (km) to control for the effect of location. Figure
4 shows the spatial distributions of macroscale built environment factors.

Figure 4. Spatial distributions of some built environment elements in 2018 at macroscale in Shanghai, China. POI: point of interest.

**Statistical Analysis**

The negative binomial regression model (NBRM) was used to examine the independent effects of streetscape perceptions. This was performed in the univariate model and then the fully adjusted model, controlling for population density, average building height, distance to nearest transit, number of bus stations, number of POIs, distance to the nearest park, and distance to CBD. The NBRM was selected primarily because the outcome variable (ie, the number of bike-sharing origins) was in number format and discrete. Moreover, the variance of the outcome variable is greater than its mean value. Hence, as in many studies [27,28], the NBRM was chosen for the examination.

Subsequently, streetscape moderation effects were examined through the interaction term between macroscale built environment factors and streetscape perceptions using the fully adjusted NBRM. Factors at the macroscale level included land use mix and accessibility, while the three perception indicators were lively, safety, and wealthy. Consequently, 6 total models were produced, with each model examining different combinations of these factors. To mitigate multicollinearity and facilitate comparison between independent variables, independent factors were all standardized into z scores.
Finally, we conducted three sensitivity analyses. Recognizing the potential influence of an uncertain geographic context problem [29], we examined whether the results of streetscape moderation roles are sensitive when investigations are performed at different geographic scales. Consistent with previous studies [3,30], a 1000 × 1000 m grid was selected as the analysis unit. Furthermore, apart from the big data analysis, we further tested whether there were moderation effects of streetscapes using a classic (small sample) statistics approach. Similar to the sampling rate of prior studies [10,31], 20% of the total grids were randomly chosen for further examination. Moreover, we tested streetscape moderation roles when land use mix and accessibility were operationalized differently. Road length and land use HHI calculated based on area of interest data were used as further proxies.

Ethical Considerations

This study was approved by the Human and Artefacts Ethics Sub-Committee at the City University of Hong Kong (reference 27609824). The bike-sharing record data were anonymous and deidentified, including information on trip ID, start time and location, and end time and location, in this study.

Results

Effects of Streetscape Perceptions

In the univariate model, each of the three positive perceptual factors was positively associated with the number of bike-sharing uses on weekends (Table S2 in Multimedia Appendix 1). Among this, the lively perception showed the greatest effect ($\beta$=5.50; $P$<.001), followed by the safety perception ($\beta$=5.38; $P$<.001) and wealthy perception ($\beta$=4.45; $P$<.001). A similar pattern of results was observed in the fully controlled model (Table 1). In particular, the most influential effect was found for the lively perception ($\beta$=1.45; $P$<.001), followed by the safety perception ($\beta$=1.19; $P$<.001) and wealthy perception ($\beta$=0.79; $P$<.001).

Moderation Effects of Streetscape Perceptions

All streetscape perceptions positively moderated the association between the land use HHI and the number of bike-sharing uses on weekends (Table 2). Specifically, streetscape perceptions and the land use HHI were significantly associated with the number of bike-sharing uses on weekends; among the three perceptual indicators, the lively perception showed the greatest effect. Regarding the moderation effect, the effect of the interaction between the land use HHI and each of the streetscape perceptions was smaller than that of each of the two factors; the lively perception presented the strongest moderation role on the effect of the land use HHI, followed by the wealthy perception and safety perception. Specifically, the effect of the interaction between the lively perception and the land use HHI was –0.63 ($P$=.01), greater than those of interactions between the land use HHI with the wealthy and safety perceptions at –0.60 ($P$=.008) and –0.52 ($P$=.001), respectively. This means that livelier, safer, and wealthier street environments can enhance the benefits of land use mix to promote cycling behavior.

There were positive interactions in the number of road intersections with the lively and wealthy perceptions (Table 3). The effects of the number of road intersections, both of the two perceptions, and their interactions were all positive. Different from that of land use mix, the effect of the number of road intersections was close to the impact of the interaction with the
lively and wealthy perceptions. With respect to the moderation role, the lively perception showed the largest moderation effect, although no significant moderation effect was observed for the safety perception. This means that good lively and wealthy perceptions of streetscapes are likely to magnify the role of accessibility in encouraging cycling activities.

Sensitivity Analyses

As indicated in the sensitivity analysis using a 1000 × 1000 m grid as the analysis unit (Figure 5 A-C), there were significant interactions between land use mix (ie, land use HHI) and both lively and safety perceptions of the streetscape, but not the wealthy perception. Similarly, a moderation role on the impact of the number of road intersections was found for the lively perception but not for the wealthy perspective. Figure S1 G-I in Multimedia Appendix 1 illustrates the sensitivity analysis in terms of a randomly selected small sample. Overall, positive moderation roles persisted for all streetscape perceptions on the effect of land use mix and for the lively perception on the impact of the number of road intersections. Furthermore, among the three perception indicators, the lively perception still played the most substantial moderation role in relation to the impact of the land use HHI.

Figure 5 D-F exhibits the sensitivity analysis using the land use HHI calculated using area of interest data and road length as proxies for land use mix and accessibility, respectively. Generally, lively, wealthy, and safety perceptions of streetscapes continued to exhibit positive moderation on the effect of the land use HHI. In particular, the absolute effect of the interaction between land use mix and lively perception was 0.10 ($P$=.001), accounting for 66.14% and 94.22% of the main effects of the two factors, respectively. With regards to accessibility, operationalized by road length in grids, its interactions with lively and wealthy perceptions were still correlated with the number of bike-sharing uses on weekends.
Figure 5. Sensitivity analyses of streetscape moderation effects examined at different geographic scales (A-C) and using different operationalizations (D-F) in 2018 in Shanghai, China.

Discussion

Principal Findings and Comparisons With Prior Work

We found that streetscape perceptions were positively associated with bike-sharing activities. This is consistent with many prior studies [17,32,33]. In particular, a cross-sectional study conducted in Boston, Massachusetts using running data from the Strava Heatmap suggested the positive effects of wealthy and safety perceptions on the amount of running [13]. The mechanisms linking environmental perceptions and physical activity are highly complex and beyond the scope of this work, highlighting the need for further investigation, especially with evidence from a neuroscience perspective.

However, we observed that among three perceptual factors, the lively perception not only plays the strongest effect on bike-sharing use but also emerges as the most influential moderator, which is inconsistent with findings from Western studies [7,13,20]. Typically, among environmental perceptions such as safety and lively, the former usually plays the strongest moderation role on the impact of macroscale built environments in studies outside of mainland China [8,16,20]. In particular, a US study indicated that compared to perceived pleasure, the safety perception plays a greater moderation role in the impact of accessibility on healthy behaviors [8].

The underlying mechanisms behind the lively perception not only playing the largest independent effect but also showing...
the strongest moderation effect are highly complex. There are two potential explanations. On the one hand, among the environmental perceptions (qualities), safety plays a crucial role in physical activity in many Western cities [7,13,20]. However, the lively perception usually takes precedence in residents’ concerns about healthy behavior in the Chinese context [17,34]. This is also consistent with the findings of this study. Regarding accessibility, the main effect of the lively perception on the number of bike-sharing uses on weekends was 1.39 (P<.001), higher than that of the safety and wealthy perceptions at 1.12 (P<.001) and 0.75 (P<.001), respectively. A similar pattern of results was observed for land use mix, with the greatest main effect for the lively perception (β=1.39; P<.001), followed by the safety perception (β=1.22; P<.001) and wealthy perception (β=0.75; P<.001).

On the other hand, livelier places tend to provide various benefits beyond urban liveliness itself. In many Chinese cities, more vibrant and lively urban places are associated with large population inflow and increased greenery [35,36]. A large number of people on the street and more green space can strengthen the sense of safety [37-39], thus promoting healthy behaviors more effectively [8,10]. The findings extend the results of prior studies by highlighting that, in the Chinese context, a lively perception, rather than a safety perception, usually plays the strongest moderation effect on the built environment–healthy behavior relationship.

This study provides significant implications for public health. Usually, urban planning initiatives aiming to promote residents’ physical activities target interventions in built environments at the macroscale level, which are time-consuming and less actionable. Our findings suggest that favorable microscale environments can promote cycling behavior and enhance the benefits of accessibility and land use mix as well. This underscores the need for interventions on microscale streetscapes, which are less time-consuming and more readily modifiable than those on macroscale built environments.

Limitations
Several limitations should be clarified. First, similar to many studies [6,8,19], the use of 500 × 500 m grids as the analysis unit to examine moderation effects of streetscape perceptions may be susceptible to the uncertain geographic context problem [29]. In our study, the selected analysis unit was usually considered as the main activity space in most Chinese neighborhoods [21,24]. Moreover, a 1000 × 1000 m grid was used as the analysis unit to test the robustness of streetscape moderation effects. However, careful research design is essential to address the uncertain geographic context problem in future work.

Second, this is an aggregated study in nature with grids to allocate bike-sharing data. Hence, as in many bike-sharing studies [2,19], the impacts of individual characteristics on cycling were not controlled. Furthermore, streetscape perceptions were assessed by the public in terms of street view images, which may collectively influence the findings. Despite the negligible differences between respondents’ socioeconomic characteristics reported in some prior studies [40,41], future research should associate environmental perceptions with riders to draw more scientifically grounded conclusions. Finally, further study can delve into the mechanisms of moderation roles by microscale urban environments, either on the objective or perceived side, which remain unclear and could be better understood with individual-level data.

Conclusions
Livelier and safer perceptions of streetscapes can magnify the benefits of land use mix for cycling activity; the lively perception has a similar effect on accessibility. The findings emphasize that sufficient microscale streetscape interventions can encourage cycling behavior and amplify the positive effects of accessibility and land use mix.

Abstract

Background: Nitrogen dioxide (NO₂) has been frequently linked to a range of diseases and associated with high rates of mortality and morbidity worldwide. However, there is limited evidence regarding the risk of NO₂ on a spectrum of causes of mortality. Moreover, adjustment for potential confounders in NO₂ analysis has been insufficient, and the spatial resolution of exposure assessment has been limited.

Objective: This study aimed to quantitatively assess the relationship between short-term NO₂ exposure and death from a range of causes by adjusting for potential confounders in Guangzhou, China, and determine the modifying effect of gender and age.

Methods: A time series study was conducted on 413,703 deaths that occurred in Guangzhou during the period of 2010 to 2018. The causes of death were classified into 10 categories and 26 subcategories. We utilized a generalized additive model with quasi-Poisson regression analysis using a natural cubic splines function with lag structure of 0 to 4 days to estimate the potential lag effect of NO₂ on cause-specific mortality. We estimated the percentage change in cause-specific mortality rates per 10 μg/m³ increase in NO₂ levels. We stratified meteorological factors such as temperature, humidity, wind speed, and air pressure into high and low levels with the median as the critical value and analyzed the effects of NO₂ on various death-causing diseases at those high and low levels. To further identify potentially vulnerable subpopulations, we analyzed groups stratified by gender and age.

Results: A significant association existed between NO₂ exposure and deaths from multiple causes. Each 10 μg/m³ increment in NO₂ density at a lag of 0 to 4 days increased the risks of all-cause mortality by 1.73% (95% CI 1.36%-2.09%) and mortality due to nonaccidental causes, cardiovascular disease, respiratory disease, endocrine disease, and neoplasms by 1.75% (95% CI 1.38%-2.12%), 2.06% (95% CI 1.54%-2.59%), 2.32% (95% CI 1.51%-3.13%), 2.40% (95% CI 0.84%-3.98%), and 1.18% (95% CI 0.59%-1.78%), respectively. Among the 26 subcategories, mortality risk was associated with 16, including intentional self-harm, hypertensive disease, and ischemic stroke disease. Relatively higher effect estimates of NO₂ on mortality existed for low levels of temperature, relative humidity, wind speed, and air pressure than with high levels, except a relatively higher effect estimate was present for endocrine disease at a high air pressure level. Most of the differences between subgroups were not statistically
significant. The effect estimates for NO$_2$ were similar by gender. There were significant differences between the age groups for mortality due to all causes, nonaccidental causes, and cardiovascular disease.

**Conclusions:** Short-term NO$_2$ exposure may increase the risk of mortality due to a spectrum of causes, especially in potentially vulnerable populations. These findings may be important for predicting and modifying guidelines for NO$_2$ exposure in China.

**Introduction**

Ambient air pollution is one of the greatest environmental risks to human health, with 8 million deaths reported worldwide every year [1]. Rapid industrialization in China over the last decades has significantly increased the emission of pollutants. Both short and long-term exposure to ambient air pollution increases the risk of death, years of life lost, and years of disability, thereby increasing the burden of disease [2-6]. Exposure to air pollution, including particulate matter (PM), nitrogen oxides (NO$_x$), ozone, and sulfur dioxide, may increase the risk of respiratory disease through oxidative damage, which occurs via inflammatory injury and the production of reactive oxygen species [7].

Nitrogen dioxide (NO$_2$) is a toxic gas that is present in traffic emissions, and chronic exposure to NO$_2$ is associated with respiratory inflammation, allergies, infections, and other symptoms. The current acceptable limits of NO$_2$ exposure in China are 105 ppb (200 μg/m$^3$) over 1 hour and an average of 21 ppb (40 μg/m$^3$) annually [8]. In recent decades, however, the concentration of NO$_2$ in China has exceeded the global average level [9]. Guangzhou is the capital and largest city of Guangdong province in China, with a population of 13,964,637 [10]. According to data released by the World Health Organization [11] in 2018, the annual average concentration of NO$_2$ reached 50 μg/m$^3$, which exceeds air quality standards (25 μg/m$^3$).

Evidence clearly demonstrates that short-term exposure to NO$_2$ is related to an increased risk of mortality from different diseases, showing independent and linear trends [12-16]. For instance, a multicity analysis showed NO$_2$ exposure increased the all-cause mortality rates, as well as mortality due to cardiovascular and respiratory diseases [12]. However, other studies have reported a lower mortality risk due to chronic diseases in the event of NO$_2$ exposure [17]. Research on the mechanisms by which NO$_2$ affects mortality has come to limited conclusions. For example, it is not yet known whether NO$_2$ exposure can cause endocrine disease and neoplasms.

Regarding the effect of NO$_2$ on diseases, there is less evidence for the different effects caused by stratification of meteorological factors. The significance of other meteorological risk factors, such as temperature, humidity, air pressure, and wind speed, has been less frequently explored. In addition, most of the studied disease outcomes affected by NO$_2$ have included only cardiovascular and respiratory diseases. Moreover, the influence of age and gender on the association between NO$_2$ and mortality is still unclear. Therefore, it is essential to fully explore predisposing diseases associated with NO$_2$ exposure.

To this end, we aimed to examine the relationship between short-term NO$_2$ exposure and a spectrum of causes of mortality in Guangzhou to identify the influencing factors. Our research may offer unique insights into the health effects of NO$_2$ and the underlying factors and help formulate public policies to protect potentially vulnerable subgroups [18].

**Methods**

**Sample and Data**

The daily death count in Guangzhou during the period between 2010 and 2018 was obtained from the city registry, which included all permanent residents and is published by the Guangzhou Center for Disease Control and Prevention [19]. Using the 10th Revision of the International Classification of Diseases (ICD-10), the causes of the deaths were classified as all causes (A00-Z99), nonaccidental causes (A00-R99), cardiovascular diseases (I00-I99), neoplasms (C00-D48), endocrine diseases (D50-D89, E00-E90), nervous system diseases (G00-G99), respiratory diseases (J00-J99), digestive diseases (K00-K93), genitourinary diseases (N00-N99), and external causes (V01-Y89). These 10 groups were divided further into 26 subgroups, with each group containing at least an average number of deaths per day, ensuring that the model was convergent.

**Measures of Variables**

Data on the average daily level of NO$_2$ from 2010 to 2018 were obtained from the Guangzhou Bureau of Environmental Protection. The data were collected from 11 fixed-point air pollution monitoring stations across the city (Figure 1). At the same time, the daily concentration of atmospheric dynamic diameter particulate matter (PM$_{10}$ or PM$_{2.5}$), ozone (O$_3$), sulfur dioxide (SO$_2$), carbon monoxide (CO), and other gaseous pollutants were obtained at the same sites and were used to adjust for potential hybrid co-pollutants during model building. Exposure levels were determined by calculating the average daily concentration level at each monitoring station. General data on the mean temperature (°C), mean relative humidity (%), mean air pressure (hPa), sunshine duration (h), wind speed (km/h), and daily air quality index were obtained from the China Meteorological Data Sharing Service System [20].
Models and Data Analysis Procedure

A generalized additive model with Poisson regression analysis was used to determine the relationship between NO$_2$ exposure and each cause of mortality after adjusting for potential covariates. A natural cubic spline function (NS) of 7 degrees of freedom ($df$) per year was used to control for long-term and seasonal trends in mortality. In the $df$ adjustment of other weather factors, the NS functions of 6, 3, and 3 $dfs$ were used to adjust the $dfs$ of temperature, relative humidity, wind speed, and atmospheric pressure, respectively. The day of the week and public holidays were added to the model as indicator variables. The method and selection of model parameters have been described in a previous research analysis [21,22]. After establishing the basic model, we used an NS of 2 to 6 $dfs$ to investigate the relationship between NO$_2$ concentration and mortality as a result of each cause of death. Based on the most likely days of lag, a moving average method was used to correlate the cumulative effects of pollutants over the defined lag period. This is consistent with a previous study [15,23] that selected an empirical maximum of 4 $dfs$ for NO$_2$ and used a lag model structure of 0 to 4 days to obtain an estimate of the cumulative risk of NO$_2$ exposure during the first 4 days.

To identify potentially vulnerable subpopulations at a particular risk of mortality due to NO$_2$ exposure on a spectrum of mortality causes, stratified analyses were conducted based on age groups (0-64 and ≥65 years) and gender (men and women) based on the causes of death that showed a significant association with NO$_2$. In addition, in order to analyze the interactive health effects between meteorological factors and NO$_2$, the stratification analyses were conducted based on the levels of temperature, humidity, wind speed, and air pressure, with their median values as the cutoff. The difference between the 2 groups was analyzed using a $z$ test, as follows [24]:

$$E_1 - E_2 \pm \sigma_{E_1 - E_2}$$

where $E_1$ and $E_2$ are the logarithms of risk ratios for 2 categories, such as men and women or 0-64 years and ≥65 years, and $SE_{E_1}$ and $SE_{E_2}$ were used to indicate the relevant standard error [25,26].

Multiple sensitivity analyses were conducted to evaluate the robustness of the model and parameter validation estimates. The $dfs$ for the time variable were set as 3 years to 7 years, and the $dfs$ for the weather variable were set as 3 to 6. To adjust for the mixing effect of temperature during longer lag days, 2-dimensional, cross-basis NSs and 4 $dfs$ were used for temperature and lag dimensions, respectively, and a maximum lag of 21 days was used for the distributed lag nonlinear model (DLNM) [27]. Dual pollutant models were constructed to verify the robustness of the main model after adjusting for confounders by adding another air pollutant (O$_3$, PM$_{2.5}$, PM$_{10}$, CO, SO$_2$) to the main model.

All statistical analyses were performed using the mgcv and dlnm packages of R software (version 3.4.1) by major models [28]. The change in mortality was calculated for every 10 $\mu$g/m$^3$ increase in NO$_2$ grade. All statistical results are presented as 2-sided values, while a $P$ value <.05 was considered to indicate statistical significance.

Ethics Approval

Ethics approval was not required for secondary analysis of the anonymous data in this study.
Results

The average annual temperature, humidity, daily NO$_2$ concentrations, and number of cause-specific deaths are summarized in Table 1. The Spearman correlation between air pollution and weather conditions is shown in Figure S1 in Multimedia Appendix 1. The correlation coefficients between NO$_2$ and other constituents ranged from 0.1 to 0.94. Temperature and wind speed were negatively correlated with NO$_2$, while NO$_2$ was negatively correlated with other meteorological factors and air pollutants.

The average annual NO$_2$ level was 47 $\mu$g/m$^3$. During the study period of 2010 to 2018, 413,703 all-cause deaths were recorded in Guangzhou, with 126 deaths occurring daily, on average. The majority (391,543/413,703, 94.6%) of the deaths were due to nonaccidental causes. Other causes included cardiovascular diseases (160,226/413,703, 38.7%), respiratory diseases (63,290/413,703, 15.3%), digestive diseases (12,787/413,703, 3.1%), nervous system diseases (3659/413,703, 0.9%), genitourinary diseases (5314/413,703, 1.3%), external causes (22,147/413,703, 5.4%), endocrine diseases (14,972/413,703, 3.6%), and neoplasms (115,703/413,703, 28%; Table S1 in Multimedia Appendix 1).

The association between NO$_2$ exposure and mortality due to specific causes over 6 days (lags 0 to 6) and stratified by gender and age are shown in Table 2 and Figure S2 in Multimedia Appendix 1. For all-cause mortality, the highest risk of death due to NO$_2$ exposure was observed at the lag of 2 or 3 days and was usually limited to 4 days. Effect estimates of NO$_2$ were stronger for women and older subgroups for different diseases before the lag of 4 days, and the effects stabilized thereafter. The mortality risk increased linearly with NO$_2$ concentrations at a lag of 0 to 4 days (Figure 2). Finally, we examined the stability of the model by using lag 0 days for NO$_2$ and observed a similar linear relationship between NO$_2$ and mortality (Figure S4 in Multimedia Appendix 1). The results of the generalized Poisson regression are shown in Table S2 in Multimedia Appendix 1. The goodness of fit index $R^2$ of the model was 0.69, which meant that the model was well constructed.
Table 2. The relative risk of death resulting from the different causes associated with an increase of 10 μg/m³ in NO₂ levels with a 1-day delay (lag days of 0, 1, 2, 3, 4, 5, and 6) for each gender and age group.

Figure 2. The dose-effect of the curves of NO$_2$ and mortality as a result of (A) all causes, (B) nonaccidental causes, (C) cardiovascular diseases, (D) respiratory diseases, (E) digestive diseases, (F) nervous system diseases, (G) genitourinary diseases, (H) external causes, (I) endocrine diseases, and (J) neoplasms at 7 degrees of freedom with a lag of 0 to 4 days, stratified by gender and age (years).

Among 10 categories, for every 10 $\mu$g/m$^3$ increment in NO$_2$ at a lag of 0 to 4 days, the risks of mortality increased due to all causes by 1.73% (95% CI 1.36%-2.09%) and due to nonaccidental causes, cardiovascular diseases, respiratory diseases, endocrine diseases, and neoplasms by 1.75% (95% CI 1.38%-2.12%), 2.06% (95% CI 1.54%-2.59%), 2.32% (95% CI 1.51%-3.13%), 2.40% (95% CI 0.84%-3.98%), and 1.18% (95% CI 0.59%-1.78%), respectively. On the other hand, NO$_2$ did not significantly impact deaths due to digestive diseases, genitourinary diseases, nervous diseases, and external causes (Table 3 and Figure S3 in Multimedia Appendix 1).

JMIR Public Health Surveill 2024 | vol. 10 | e44648 | p.1797
(page number not for citation purposes)


Among the 26 disease subcategories, after NO\textsubscript{2} exposure, there were significant increases in the top 10 causes with the highest risk of mortality: intentional self-harm (3.99%, 95% CI 0.22%-7.90%), hypertensive diseases (3.39%, 95% CI 1.80%-4.99%), ischemic stroke (2.84%, 95% CI 1.35%-4.35%), cerebrovascular diseases (2.48%, 95% CI 1.70%-3.27%), stroke (2.48%, 95% CI 1.55%-3.42%), influenza and pneumonia (2.47%, 95% CI 1.35%-3.60%), chronic obstructive pulmonary disease (2.33%, 95% CI 1.12%-3.56%), chronic lower respiratory disease (2.33%, 95% CI 1.16%-3.52%), chronic rheumatic heart disease (2.32%, 95% CI 1.56%-3.08%), and diabetes (2.04%, 95% CI 0.12%-3.99%; Table 3 and Figure S3 in Multimedia Appendix 1).

The results of the stratified analysis are summarized in Table 3. For all-cause mortality, the impact of NO\textsubscript{2} was relatively higher among women than men, but the difference was not statistically significant (P=.32). Older adults were at a higher risk than the younger age groups (P=.02), and their death rates due to NO\textsubscript{2} exposure increased by 2.15% (95% CI 1.68%-2.62%) and 1.15% (95% CI 0.66%-1.63%), respectively. Age was a particularly significant factor for deaths due to nonaccidental causes and cardiovascular diseases.

Stratification analyses by meteorological factor levels were further conducted (Table 4). We observed relatively higher effect estimates of NO\textsubscript{2} on mortality for low levels of temperature, relative humidity, and wind speed than high levels, although most of the differences between the subgroups were not statistically significant. For air pressure, relatively higher effect estimates were found for all causes, nonaccidental causes, cardiovascular diseases, respiratory diseases, and neoplasms at low levels of air pressure than at high levels of air pressure. However, the opposite was true for endocrine diseases.

The sensitivity analysis showed that each of the different modeling strategies provided roughly similar results. First, the calendar date and weather variables were varied using 3 to 7 \textit{dfs} and 3 to 6 \textit{dfs}, respectively, year-on-year. Second, we used DLNM to adjust for temperature and found that the estimated effect of NO\textsubscript{2} was slightly attenuated but still statistically significant. Third, the main findings were stable with additional adjustment for SO\textsubscript{2}, PM\textsubscript{2.5}, O\textsubscript{3}, PM\textsubscript{10}, and CO in the 2-pollutant model. As shown in Figure S5 in Multimedia Appendix 1, the model demonstrated stability and reliability after using alternative \textit{dfs} to control for the meteorological confounders.

### Table 4. Stratified analysis of the percent increase in mortality as a result of different diseases per 10 \(\mu\text{g/m}^3\) increase in NO\textsubscript{2} at a lag of 0 to 4 days during 2010 to 2018 in Guangzhou, China.

The principal findings of this study indicate a significant correlation between NO\textsubscript{2} exposure and multiple causes of mortality, with notable increases in cardiovascular, respiratory, and endocrine diseases. The results highlight the importance of considering both acute and long-term effects of NO\textsubscript{2} on public health, necessitating further research into the mechanisms underlying this association and potential interventions to mitigate health impacts.
increased the risk of all-cause mortality by 1.73% and had a similar impact on deaths due to nonaccidental causes (1.75% increase), cardiovascular diseases (2.06% increase), respiratory diseases (2.32% increase), endocrine diseases (2.40% increase), and neoplasms (1.18% increase). Following NO\textsubscript{2} exposure, older adults were at a higher risk of death due to all causes, nonaccidental causes, and cardiovascular diseases. Furthermore, the impact of NO\textsubscript{2} was higher in warm temperatures than in cold temperatures.

Multiple studies have found that low wind speeds lead to high atmospheric stability and high levels of air pollution, which in turn have led to higher numbers of COVID-19–related infections and deaths [29,30]. Atmospheric stability based on low wind speeds reduces the diffusion of gases and air pollution particles [29]. The results of our analyses were similar. However, several studies found that wind speed and COVID-19 are positively correlated. An inverted U-shaped dose-response curve was found for wind speed and COVID-19 [30]. A Japanese study involving 74 participants reported that low humidity and high air pressure contribute to brain hemorrhage [31]. In contrast, a hospital-based study in Mexico showed no significant relationship between barometric pressure and stroke [32]. However, the influence of humidity and air pressure may be not as strong as other weather conditions such as temperature. Therefore, we included humidity, wind speed, and air pressure as confounding factors in the model to avoid potential bias.

Previous studies on the association between NO\textsubscript{2} and mortality mainly focused on overall causes, cardiovascular diseases, and respiratory diseases [13,15,16]. Our study also showed a statistically significant association between NO\textsubscript{2} and endocrine system diseases. We found that the impact of NO\textsubscript{2} exposure on mortality rates associated with endocrine, respiratory, and cardiovascular diseases was higher than that reported in a previous meta-analysis [33]. Studies previously conducted in China also reported that, for every 10 μg/m\textsuperscript{3} increase in NO\textsubscript{2} concentration, mortality rates related to all causes, endocrine diseases, cardiovascular diseases, and respiratory diseases increased by 0.96%, 1.13%, 1.01%, and 1.22%, respectively [34,35]. In western countries, available data indicate that NO\textsubscript{2} exposure leads to an increase in total mortality as well as mortality associated with endocrine diseases, cardiovascular diseases, and respiratory diseases, by 0.33%, 0.38%, 0.40%, and 0.38%, respectively [13,36]. These differences could be attributed to racial factors and the varying analytical techniques among the different studies.

NO\textsubscript{2} can affect disease-related mortality through various mechanisms. For instance, altered immune responses and inflammatory reactions following NO\textsubscript{2} exposure may lead to endocrinological disorders. Inhaled NO\textsubscript{2} triggers production of proinflammatory cytokines by alveolar macrophages, resulting in local oxidative stress. Furthermore, the cytokines enter systemic circulation and affect distant tissues, contributing to autoimmune responses and metabolic dysfunction [37,38]. NO\textsubscript{2} is also a respiratory irritant that generates highly reactive, free radicals [39], which can cause severe lung injury, and death can occur depending on the dose and duration of exposure [40]. In addition, for individuals exposed to NO\textsubscript{2}, levels of inflammatory markers such as IL-12 and C-reactive protein in the blood are elevated, which may destabilize atherosclerotic plaques and result in their rupture, leading to increased blood pressure and enhanced thrombosis formation [41].

Gender and age affect the level of sensitivity to air pollution [42,43]. The impact of the aforementioned factors on the effects generated by NO\textsubscript{2} were largely inconclusive in previous studies. We found that gender was not a determinant of mortality risk due to NO\textsubscript{2} exposure, which is consistent with previous studies [15,44-46]. However, one study showed that men are more susceptible to the detrimental effects of NO\textsubscript{2} [14], which can be attributed to occupational and physiological differences. Furthermore, several studies have shown that older adults are predisposed to NO\textsubscript{2}-related mortality risk [13,15,23,47]. Consistent with this, the older adults in our cohort showed a higher risk of death due to all causes, nonaccidental causes, and cardiovascular diseases following NO\textsubscript{2} exposure. A possible explanation is that older people have higher rates of chronic diseases and weaker immune systems, which may exacerbate the pathological effects of environmental NO\textsubscript{2} pollution [48]. However, one study showed a link between NO\textsubscript{2} exposure and the first episode of atrial fibrillation in young adults but not older adults [49]. NO\textsubscript{2} is a significant risk factor for sudden death and melancholia among younger individuals, which may explain these results. Considering the rapidly aging population and changes in disease patterns, public policymaking, risk assessment, and air pollution standards should be modified to reduce the impact of NO\textsubscript{2} on public health in China.

The highest risk of death due to NO\textsubscript{2} exposure was observed at a lag of 1 or 2 days and persisted for 4 days. However, some studies have observed the strongest link between NO\textsubscript{2} levels and the number of hospital admissions on day 0 [46]. Similar trends in the effects of a lag of NO\textsubscript{2} exposure have been reported for the mortality due to all causes, cardiovascular diseases, and respiratory diseases [13]. Moreover, the shape of the lag effects can be described by 2 different patterns. The first is that the NO\textsubscript{2} levels recorded on the previous 2 days have a greater effect on mortality due to all causes, nonaccidental causes, circulatory diseases, respiratory diseases, endocrine diseases, and tumors. The second is that mortality resulting from digestive, nervous, and urogenital diseases as well as external systems tends to be more evenly distributed during the first 6 days. These inconsistencies may be a result of differences in the biological mechanisms that underlie the biological effects of NO\textsubscript{2}.

We also found that the impact of NO\textsubscript{2} exposure was higher on cold days, which is consistent with the findings of previous studies. For instance, studies conducted in Shanghai and Wuhan have shown that the effects of NO\textsubscript{2} are highest in the winter [50,51]. Moreover, other research groups in China reported no substantial variation in the effects of NO\textsubscript{2} on mortality due to nonaccidental causes and cardiovascular diseases across different seasons [23,52,53]. However, a large time series analysis conducted in the northeast United States reported a peak mortality risk from NO\textsubscript{2} exposure in the summer [54].
Likewise, an Italian study conducted between April and September also found a stronger association between NO$_2$ and mortality due to natural causes, cardiac diseases, and respiratory diseases [14]. A meta-analysis further demonstrated that NO$_2$ had a greater impact on hospital admissions and mortality in hot weather (May 1 to September 30) [55]. One possible explanation is that people are exposed to higher levels of NO$_2$ during the warmer periods of the year due to greater involvement in outdoor activities [14]. Furthermore, the production of NO$_2$ also increases at higher temperatures [56]. Another reason is that heat may promote thrombosis by increasing blood viscosity and secondary cholesterol levels [57]. Finally, individual susceptibility to air pollutants may increase in the summer [58]. These inconsistent results may be due to the influence of concentrations of NO$_2$ components, regional gaseous pollutants, climatic conditions, resident exposure patterns, socioeconomic characteristics, and different data analysis methods.

This study has several salient points. First, the study showed that NO$_2$ was related not only to all-cause mortality but also to cause-specific mortality. Second, the relationship between NO$_2$ and mortality due to different causes and the potential modifying effects of gender, age, and season were analyzed. These findings may have important implications for developing targeted strategies to protect vulnerable populations from the harmful effect of NO$_2$. The detrimental effects of NO$_2$ can be minimized by reducing time spent outdoors and physical exertion, wearing a mask when going out, avoiding heavily trafficked roads, and increasing immunity [59].

Nevertheless, there are several limitations that need to be considered. First, our study was limited to the Guangzhou area, and the results cannot be generalized to other regions due to differences in the population structure and environmental characteristics. Second, environmental monitoring data may only indicate population averages rather than individual levels, which may have introduced inevitable measurement bias [60]. Third, the classification of the cause of death was based only on ICD-10 codes and does not detail the actual cause of death of the patient, which may also lead to bias. Finally, causal relationships and the underlying pathophysiology of our findings could not be ascertained and warrant further research.

**Conclusions**

In summary, our study comprehensively examined the association between NO$_2$ exposure and a spectrum of causes for the risk of mortality. Through subgroup analysis, we found that gender did not significantly modify the NO$_2$-related mortality risks, while older adults were more susceptible to death due to all causes, nonaccidental causes, and cardiovascular diseases when exposed to NO$_2$. Furthermore, the association between NO$_2$ and cause-specific mortality is stronger in the warm season. We found a relatively higher effect of NO$_2$ on health on days with higher temperatures, relative humidity, and wind speed but lower pressure levels, though the between-group differences were not statistically significant. Considering heterogeneity in socioeconomic characteristics and population structure among different regions, as well as the limitations of the inaccuracy of monitoring data and measurement error of ICD classifications, our findings still need to be confirmed in other regions. Our study provides new evidence to develop prevention-oriented health policies, highlighting that it is necessary to strengthen air quality standards to protect public health from NO$_2$ pollution.

Abstract

Background: Childhood obesity has emerged as a major health issue due to the rapid growth in the prevalence of obesity among young children worldwide. Establishing healthy eating habits and lifestyles in early childhood may help children gain appropriate weight and further improve their health outcomes later in life.

Objective: This study aims to classify clusters of young children according to their eating habits and identify the features of each cluster as they relate to childhood obesity.

Methods: A total of 1280 children were selected from the Panel Study on Korean Children. Data on their eating habits (eating speed, mealtime regularity, consistency of food amount, and balanced eating), sleep hours per day, outdoor activity hours per day, and BMI were obtained. We performed a cluster analysis on the children’s eating habits using k-means methods. We conducted ANOVA and chi-square analyses to identify differences in the children’s BMI, sleep hours, physical activity, and the characteristics of their parents and family by cluster.

Results: At both ages (ages 5 and 6 years), we identified 4 clusters based on the children’s eating habits. Cluster 1 was characterized by a fast eating speed (fast eaters); cluster 2 by a slow eating speed (slow eaters); cluster 3 by irregular eating habits (poor eaters); and cluster 4 by a balanced diet, regular mealtimes, and consistent food amounts (healthy eaters). Slow eaters tended to have the lowest BMI (P<.001), and a low proportion had overweight and obesity at the age of 5 years (P=.03) and 1 year later (P=.005). There was a significant difference in sleep time (P=.01) and mother’s education level (P=.03) at the age of 5 years. Moreover, there was a significant difference in sleep time (P=.03) and the father’s education level (P=.02) at the age of 6 years.

Conclusions: Efforts to establish healthy eating habits in early childhood may contribute to the prevention of obesity in children. Specifically, providing dietary guidance on a child’s eating speed can help prevent childhood obesity. This research suggests that lifestyle modification could be a viable target to decrease the risk of childhood obesity and promote the development of healthy children. Additionally, we propose that future studies examine long-term changes in obesity resulting from lifestyle modifications in children from families with low educational levels.

**Introduction**

Childhood obesity has emerged as a major health issue due to the rapid growth in the prevalence of obesity among young children and the higher risk of developing cardiovascular and metabolic diseases in adulthood [1,2]. To address these health problems, childhood obesity has been studied for decades, and great efforts have been made to identify and characterize potential predictors of childhood obesity [3]. However, more studies are needed to understand the factors involved and their complex relationship with the development of childhood obesity [4].

Obesity can be caused by a combination of biological factors such as an individual’s genes, insulin resistance, disease, and metabolic processes, as well as socioeconomic factors such as the surrounding family and environment leading to obesity-related behaviors [5-7]. Although, fundamentally, excessive energy due to an imbalance between energy intake and consumed energy is known to cause fat formation and obesity, Davison and Birch [8] explain the various causes of childhood obesity as a micro- and macrosystem surrounding the child and provide evidence of the need for great efforts to change behavior to improve children’s health.

Eating habits affect dietary intake and obesity through various behaviors such as meal frequency, amount, speed, and snacking habits [9]. A prospective cohort study in which eating habits were measured repeatedly confirmed that there were individual differences in the development of food enjoyment and satiety responsiveness, which affect eating habits after the age of 4 years. These results suggest that eating habits are dynamic behaviors in the first years of life and may change beyond preschool age [10]. The GUSTO study measured the eating habits of children aged 5 and 6 years and found that obesity and overweight in children were related to rapid eating speed [11]. Therefore, understanding the early-life factors that influence these behaviors may help identify areas for intervention to curb the progression of being overweight or obese in children [12].

In terms of obesity prevention, the period of childhood before the age of 5 years is very important as an opportunity to establish new behaviors rather than change existing ones that have become entrenched in adulthood, which presents a difficult challenge [13]. Children’s eating habits begin with solid foods at the age of 3-6 months. From that time until the age of 5 years, preschool children learn autonomous eating habits from their parents and form eating habits based on their own preferences and previous experiences [14]. Additionally, preschool children aged 5 years or younger who are obese are more likely than children with a normal weight to become overweight during adolescence and are 5 times more likely to become obese as adults. Thus, prevention through healthy lifestyle habits early in childhood is important [15]. The importance of these early childhood lifestyle habits is highlighted by the World Health Organization’s guidelines for children’s health, which also discuss the importance of forming lifestyle habits in children before the age of 5 years [16].

Establishing a healthy lifestyle early in life is important to improve health outcomes later [17]. A recent literature review on childhood obesity revealed that, to prevent childhood obesity, changes need to be made in children’s overall lifestyle, including their daily living habits, rather than limiting management to food intake [18,19]. However, a number of studies generally recommend limiting the intake of high-calorie foods, sugary drinks, and fast foods and eating more fruit and vegetables to prevent childhood obesity [20-22]. As an eating practice guideline, dietary habits, such as eating breakfast, balanced eating, and eating slowly, are recommended during mealtimes, but studies on the relationship between these eating habits and early childhood obesity are limited [23,24]. Additionally, previous obesity research using machine learning explored the relationship between demographic factors, some behaviors, and childhood obesity but had limitations due to single cross-sectional methods and small sample sizes [25,26]. Therefore, this study is designed to identify characteristic patterns of preschool children’s eating habits using unsupervised machine learning techniques and to determine the impact of these eating habits on children’s BMI. Our results provide evidence that can guide healthy eating habits to prevent childhood obesity.

**Methods**

**Study Design and Data**

This study used data from the Panel Study on Korean Children (PSKC), which was designed to follow a sample of children from 2008 to 2027 to confirm the impact of families and communities on children’s growth and development. The PSKC is a nationally representative sample using stratified sampling that considers all the regions in South Korea. For this panel survey, parents with children born between April and July 2008 were recruited from 30 hospitals. In the first survey, a total of 2150 parents participated in face-to-face interviews and completed a self-administered questionnaire [27]. However, only 1280 children were included in this study because they had both the sixth and seventh surveys of the PSKC. For this study, the sixth data set (at the age of 5 years) and seventh data set (at the age of 6 years) were obtained for the data analysis after excluding missing and incomplete data (Multimedia Appendix 1). The data used for this study is considered a representative sample of national data in terms of the national demographics (male 649/1280, 50.7% and female 631/1280, 49.3%) and prevalence of childhood obesity (overweight 122/1280, 9.5% and obese 54/1280, 4.2%) [28].

**Measurements**

**Eating Habits**

Eating habits were assessed based on four questions that mothers (or fathers) were asked to answer: “Is your child’s eating speed
fast?” “Does your child have meals at regular times?” “Is the amount of food your child eats consistent?” and “Does your child eat all kinds of food?” Responses to each question were assessed using a 5-point Likert scale ranging from “not at all” to “agree very strongly.” A higher score indicated a greater tendency in the diet habit.

**BMI**

Obesity status, the primary outcome of this study, was defined according to BMI, which was calculated using the children’s weight and height [29]. The categories, such as normal, overweight, and obese, were defined based on the Korean child growth chart: children in the 85 to 95 percentile were categorized as overweight, and those over the 95 percentile were categorized as obese [30,31].

**Physical Activity**

For the children’s activity levels, we used hours spent in outdoor activity as perceived by their mothers. They calculated the average number of hours their child spent daily on outdoor activities.

**Sleep Duration**

For the children’s sleep hours, we used the average amount of sleep time as perceived by their mothers. The child’s average sleep time at night was calculated as the difference between the mother’s reported bedtime and wake-up time.

**Characteristics of Parents and Family**

Parental age, education level, and employment status were obtained as parent characteristics; the number of family members and family income (Korean won per month) were obtained as family characteristics.

**Ethical Considerations**

This study was approved by the Hospital Ethics Committee, Seoul, South Korea (No. 4-2023-0418). The PSKC database was created with the voluntary consent of participants to investigate the growth and development of Korean children. If a participant decides to withdraw, they are excluded from the database. Digitally anonymized data sets were obtained after obtaining consent from PSKC in relation to the data. This study rigorously followed the guidelines recommended by the PSKC [32].

**Statistical Analyses**

All the continuous variables were tested for normality using the Shapiro-Wilk and Kolmogorov tests. The Shapiro-Wilk statistic was significant ($P<.001$), and the plots (regression of standardized residuals) showed no clear signs of violating the normality assumption [33].

Cluster analyses were performed in R (version 4.1.3; The R Project for Statistical Computing) using the packages “tidyverse,” “cluster,” “factoextra,” and “NbClust.” Clustering is an unsupervised machine learning technique to find natural groupings of participants based on a data set’s inherent structure. To identify the clusters, we used 4 eating habits (eating speed, mealtime regularity, food amount consistency, and balanced eating) as the input variables. For the ordinal variables measured on a 5-point Likert scale, we scaled by considering the means and SDs of the variables [26]. Principal component analysis was used to check the data distribution and independence of the 4 eating habits. Before the data set was considered significantly clusterable, the Hopkins statistic was applied iteratively using a threshold of 0.5, and the data set was confirmed to be above the threshold. The clustering analysis was performed by applying 2 hierarchical clustering methods (agglomeration and division) and Ward’s approach based on Euclidean distance and $k$-means [34]. We used the R NbClust package to explore the optimal number of clusters in our data set by varying all combinations of cluster number, distance measure, and clustering method and considered the Elbow method ($k=4$) and Scott index ($k=4$) for optimal cluster selection (Multimedia Appendix 2) [35]. Finally, the number of clusters ($k=4$) was selected by visually inspecting the data (clusters 1, 2, 3, and 4). After selecting the number of clusters, clusters were formed by repeating the $k$-means algorithm, which is most commonly used in unsupervised machine learning techniques, until the center value of the cluster did not change. Once the clusters were identified [35], a radar chart was created to explore the functionality of the final clusters (Figure 1).
A 1-way ANOVA with a Bonferroni posthoc comparison and a chi-square test were used to assess the group differences [36]. The power of this study was calculated using G^*power (version 3.1) with a 95% degree of confidence, and the number of participants and study design were considered through a comparison of the differences between clusters. Statistical significance was defined as a 2-sided $P<.05$.

**Results**

**Children’s Characteristics**

Of the children analyzed, 50.7% (649/1280) were boys, and the mean birth weight was 3.26 (SD 0.41) kg. The average baseline BMI was 15.99 (1.60) kg/m$^2$ at the age of 5 years and 16.20 (2.01) kg/m$^2$ at the age of 6 years. At the age of 5 years, the children’s average time spent on outdoor activities was 1.14 (0.81) hours per day, and the average sleep duration per day was 9.87 (0.73) hours. The children’s average time spent on outdoor activities was 1.08 (0.71) hours per day, and the average sleep duration per day was 9.76 (0.68) hours at the age of 6 years.

A bachelor’s degree was the most prevalent education level for both mothers (485/1280, 37.89%) and fathers (552/1280, 43.13%). Most of the fathers (1226/1280, 96.09%) were employed, and the average family income was ₩4,275,100 (US $3186.64) per month (Multimedia Appendix 3).

**Cluster Developed by Eating Habits**

The analysis identified 4 clusters, and their characteristics are similar on a radar chart (Figure 1). Cluster 1 (fast eaters) is characterized by a high eating speed and represents 512 children (aged 5 years) and 440 children (aged 6 years); cluster 2 (slow eaters) represents 293 five- and 415 six-year-old children with a slow eating speed. Cluster 3 (poor eaters) represents 283 children (aged 5 years) and 243 children (aged 6 years) with irregular mealtimes, inconsistent food amounts, and imbalanced eating habits, and cluster 4 (healthy eaters) represents 192 children (aged 5 years) and 182 children (aged 6 years) with regular mealtimes, consistent food amounts, and balanced eating (Table 1).

**Cluster Changes From 5 to 6 Years of Age**

Changes in clusters according to children’s eating habits are shown in Table 2. Of the total 1028 children, 553 (53.8%) remained in the same eating habits cluster as classified as being aged 5 years. A total of 44.7% (229/512) of children were in the fast eater group, 52.6% (154/293) in the slow eater group, 38.2% (108/283) in the poor eater group, and 32.3% (62/192) in the healthy eater group remained in the same cluster a year later.
Table 2. The cluster changes from 5 to 6 years of age. The bar graph represents the number of participants in the clusters at 5 years old who moved to another cluster at 6 years old.

**Characteristic Differences by Clusters at the Age of 5 Years**

Among children’s characteristics, there was a significant difference in BMI at the age of 5 years between groups \((P<.001)\). Fast eaters also had the highest BMI at the age of 5 years (mean 16.17 kg/m\(^2\)); slow eaters had the lowest BMI (mean 15.59 kg/m\(^2\)). The proportion of children with obesity differed significantly between groups \((P=.03)\). A higher proportion of children with obesity, based on BMI at the age of 5 years, was reported among poor eaters (16/283, 5.7%) and fast eaters (28/512, 5.5%). There was a significant difference in sleep duration; fast eaters were associated with longer sleep duration (9.93 hours per day) than slow eaters \((P=.005)\). Among parental and family characteristics, healthy eaters had a higher proportion of mothers with master’s degrees or higher, and poor eaters had a higher proportion of mothers who were high school graduates or lower \((P=.03)\). There were no significant differences in the time children spent outdoors, family income, or parents’ employment status (Table 3).

**Characteristic Differences by Clusters at the Age of 6 Years**

Among children’s characteristics, there was a significant difference between groups in BMI at the age of 6 (<i>P</i>&lt;.001). Fast eaters also had the highest BMI at the age of 6 years (mean 16.55 kg/m<sup>2</sup>); slow eaters had the lowest BMI (mean 15.85 kg/m<sup>2</sup>). The proportion of children with obesity differed significantly between groups (<i>P</i>&lt;0.01). A higher proportion of children with obesity, based on BMI at the age of 6 years, was reported among fast eaters (40/440, 9.1%) and healthy eaters (16/182, 8.8%). There was a significant difference in sleep duration; healthy eaters were associated with longer sleep
duration (9.89 hours per day) than fast eaters ($P=.03$). Among parental and family characteristics, healthy eaters had a higher proportion of fathers with master’s degrees or higher, and poor eaters had a higher proportion of fathers who were high school graduates or lower ($P=.03$). There were no significant differences in the time children spent outdoors, family income, or parents’ employment status (Table 4).

**Discussion**

**Overview**

Using a nationally representative sample, we identified 4 distinct clusters based on the eating habits of children aged 5 and 6 years. These children’s eating habits showed a pattern of 4 clusters a year later. However, in approximately half of the children, individual children changed their eating habit cluster after 1 year in this study, providing valuable insight into the timing of early obesity management [37]. Additionally, the higher proportion of children who had overweight and obesity and the higher BMI of children who ate quickly indicate that fast eating is associated with obesity. Children aged 5 years who are fast eaters need age-appropriate training to reduce their eating speed. Importantly, strategies to prevent progression from having overweight to having obesity in young children should be developed to improve children’s overall health status.

While a few studies have attempted to identify the relationship between eating habits and obesity in young children [4,23,38,39], none of them investigated eating habits concurrently, such as eating speed, balanced eating, mealtime regularity, and food amount consistency. In this study, we found that a large number of young children fell into the category of fast eaters and had a higher BMI. This relationship between fast eating habits and obesity can be explained by the mechanism that fast eating lowers satiety and consequently increases food intake by delaying the effects of brain signals and hormones [40]. The results of this study also suggest childhood obesity could be prevented by increasing eating time [39]. Regarding another eating habit related to childhood obesity, a recent systematic review identified mealtimes as a mechanism that explains obesity by affecting changes in metabolic efficiency, hormones, and gut microbiota throughout the day [14]. Paoli et al [41] emphasized the importance of regular eating times for obesity prevention through the regularity of fasting periods between meals.

Regarding the relationship between sleep duration and childhood obesity, insufficient sleep could contribute to the development of obesity through appetite, diet, and daytime activity levels [42,43]. These studies did not support previous reports of late bedtimes and short sleep duration in children with obesity [44]. However, in this study, sleep duration per cluster was more than 9 hours, so all the children had enough sleep, which limits exploration of the relationship between sleep duration and obesity in this study. Additional research on sleep and childhood obesity is recommended.

Among the risk factors for childhood obesity, a more important explanatory factor is sedentary time, such as TV watching time, rather than outdoor activity [45]. Similarly, this study found no difference in outdoor activity levels between the groups classified based on eating habits. The relationship between childhood obesity and physical activity levels should be explored by considering various activities, such as sedentary time and indoor activities, in addition to outdoor activities.

Besides children’s sleep duration and activity levels, the parents’ education level differed among the clusters. The proportion of parents with a high school diploma or lower was higher in the group of poor eaters than in the other eating groups. These results are similar to those of previous studies showing that mothers of children with overweight or obesity had a lower education level [4]. This suggests that parents’ level of education is a factor related to the development of childhood obesity. However, the single influence of the mother or father by age, rather than both parents, is thought to account for differences in parental influence as the child ages and requires further research [46]. The prevalence of childhood obesity is known to be high in low-income households and communities with low socioeconomic status, and the relationship between childhood obesity and families’ economic status has been well documented in large samples in several countries [42,47,48]. However, family income in this study did not differ between the clusters, which suggests that primary caregiver education is the key factor in forming eating habits to consider for the prevention of obesity in children [43].

**Limitations**

This study has several strengths and limitations that should be noted. Although the individual clusters had different BMI tendencies, the inclusion of only eating habit variables in the cluster analysis could limit our understanding of the development of childhood obesity since it omits interrelated variables such as physical activity and sleep. In addition, the results should be interpreted with caution because each eating habit was measured using a single item based on a Likert scale. However, we found evidence for the impact of dietary guidelines to prevent obesity in young children, including specific eating habits. Another limitation of this study was the reliance on parental reports. Nevertheless, the study is meaningful in that it used panel data that are representative longitudinal data of a country’s child population, and the derived results used machine learning techniques to solve complex phenomena targeting a relatively large sample of children.

**Conclusions**

Our results show that eating habits, such as eating speed, regularity of meals, meal amount consistency, and balanced eating habits, can be considered risk factors for developing childhood obesity. In addition, changed clusters by eating habits within 2 years in children highlights the need for early childhood obesity management. Besides eating habits, children’s sleep duration and maternal education levels differed significantly across the clusters. These findings suggest that a modification in lifestyle could be a good target to decrease the risk of childhood obesity and develop healthy children. In addition, we also propose that future studies examine long-term changes in obesity with lifestyle modification in children from families with low educational levels.

Abstract

Background: Childhood obesity is a significant public health problem representing the most severe challenge in the world. Antibiotic exposure in early life has been identified as a potential factor that can disrupt the development of the gut microbiome, which may have implications for obesity.

Objective: This study aims to evaluate the risk of developing obesity among children exposed to antibiotics early in life.

Methods: An Italian retrospective pediatric population-based cohort study of children born between 2004 and 2018 was adopted using the Pedianet database. Children were required to be born at term, with normal weight, and without genetic diseases or congenital anomalies. We assessed the timing of the first antibiotic prescription from birth to 6, 12, and 24 months of life and the dose-response relationship via the number of antibiotic prescriptions recorded in the first year of life (none, 1, 2, and ≥3 prescriptions). Obesity was defined as a BMI z score >3 for children aged ≤5 years and >2 for children aged >5 years, using the World Health Organization growth references. The obese incidence rate (IR) × 100 person-years and the relative 95% CI were computed using infant sex, area of residence, preschool and school age, and area deprivation index, which are the covariates of interest. A mixed-effect Cox proportional hazards model was used to estimate the hazard ratio and 95% CI for the association between antibiotic exposure in early life and child obesity between 24 months and 14 years of age, considering the family pediatricians as a random factor. Several subgroup and sensitivity analyses were performed to assess the robustness of our results.

Results: Among 121,540 children identified, 54,698 were prescribed at least an antibiotic within the first year of life and 26,990 were classified as obese during follow-up with an incidence rate of 4.05 cases (95% CI 4.01-4.10) × 100 person-year. The risk of obesity remained consistent across different timings of antibiotic prescriptions at 6 months, 1 year, and 2 years (fully adjusted hazard ratio [aHR] 1.07, 95% CI 1.04-1.10; aHR 1.06, 95% CI 1.03-1.09; and aHR 1.07, 95% CI 1.04-1.10, respectively). Increasing the number of antibiotic exposures increases the risk of obesity significantly (P trend<.001). The individual-specific age analysis showed that starting antibiotic therapy very early (between 0 and 5 months) had the greatest impact (aHR 1.12, 95% CI 1.08-1.17) on childhood obesity with respect to what was observed among those who were first prescribed antibiotics after the fifth month of life. These results were consistent across subgroup and sensitivity analyses.

Conclusions: The results from this large population-based study support the association between early exposure to antibiotics and an increased risk of childhood obesity. This association becomes progressively stronger with both increasing numbers of antibiotic prescriptions and younger age at the time of the first prescription.

Introduction

Childhood obesity is a significant public health problem representing the most severe challenge in the world that can have long-term consequences [1]. In the United States, 1 in 3 children and adolescents are overweight or obese [2]. In Europe, the prevalence has been increasing over the past few decades. According to the World Health Organization (WHO) and the European Childhood Obesity Surveillance Initiative, 38% of Italian children were found to be overweight (including obesity), with boys more affected than girls (41% and 35%, respectively). Moreover, the overall prevalence of obesity in Italy was 16% and more common in boys (20%) than girls (13%) [3].

Obesity is a chronic and complex disease characterized by excessive adiposity that can impair health, leading to various health complications, including an increased risk of developing chronic conditions such as type 2 diabetes, cardiovascular diseases, and mental health issues. It can also have social and emotional consequences, such as low self-esteem and stigmatization [4]. Considering these dramatic consequences, it is crucial to implement interventions to prevent the occurrence of this condition in children, which is also the goal of Health4EUkids, the European Joint Action for the implementation of Best Practices for the promotion of health and the prevention of obesity [5].

Early childhood obesity has been associated with several factors, such as maternal prepregnancy BMI, nutritional intake, physical activity, sleep duration, and screen time [6]. In particular, sleep deprivation can disrupt hormones that regulate appetite and metabolism, and excessive screen time can contribute to early childhood obesity by reducing physical activity and promoting unhealthy eating habits. In addition, emerging evidence suggests that the composition and function of the gut microbiome can influence various aspects of human health, including energy metabolism and body weight regulation. Previous studies demonstrated that the intestinal microbiome plays an important role in host energy metabolism, including gene expression that impacts energy availability from short-chain fatty acids and the processing of otherwise indigestible polysaccharides [2]. The microbial ecosystem begins taxonomic diversification at birth and completes its development during the early years of life [7]. The establishment and maturation of the gut microbiome are influenced by a complex interplay of internal and external factors, including environmental factors, the type of delivery (natural birth or cesarean delivery), and diet. While the gut microbiome is relatively stable, it can experience periods of acute or chronic perturbation in certain disease states or due to new exposures such as antibiotic therapies [8]. Antibiotic exposure in early life has been identified as a potential factor that can disrupt the development and composition of the gut microbiome, which may have implications for obesity later in life [7]. Previous epidemiological studies have provided valuable insights into the relationship between the gut microbiome, antibiotic exposure in early life, and obesity [2]. Early-life antibiotic exposures can modify the bacterial diversity of the intestinal microbiome in infants and delay microbiota maturation. These effects were most pronounced with antibiotic exposure during the first year of life, while no significant effect was observed with later exposures [9]. However, it is important to note that other confounding factors, such as genetic predisposition, diet, lifestyle, and socioeconomic factors, could contribute to both antibiotic use and obesity risk. Furthermore, the specific antibiotics used, the timing and duration of exposure, and the individual's age at the time of exposure may influence the observed associations.

The objective of this study is to examine the risk of developing obesity among children exposed to antibiotics early in life in a large population-based Italian birth cohort with a detailed assessment of antibiotic use and long-term follow-up to assess the development of obesity identified through standardized anthropometric measurements.

Methods

Study Population

We used data from Pedianet [10], an independent network of more than 400 family pediatricians (FPs) established in 1998, to collect information from outpatient routine clinical care in Italy; detailed information was explained elsewhere [11]. In particular, in this study, we used information regarding demographic data, prescriptions (pharmaceutical prescriptions identified by the Anatomical Therapeutical Chemical code), and growth parameters. In Italy, FPs have been considered by the Ministry of Health as physicians responsible for performing regular “mandatory” well-child visits for preventive medicine purposes at specific time points during which the child’s anthropometric measurements are recorded [12].

We identified all children born between 2004 and 2018, followed from birth to at least 4 years (maximum follow-up of 14 years). Children were required to have at least 2 visits during the first 2 years of life at least 6 months apart [13], born at term (≥27 gestational weeks) and with birth weight greater than 2500 g, and without genetic diseases (ie, achondroplasia, Cornelia de Lange, Down, Prader-Willi, Turner, and Williams syndromes [14-21]) or congenital anomalies. The final cohort consisted of 121,540 children (Figure S1 in Multimedia Appendix 1).

Ethical Considerations

This is an observational, retrospective, noninterventional study. According to a bylaw on the classification and implementation of observational drug-related research, as issued by the Italian National Drug Agency (an entity belonging to the Italian Ministry of Health), this study does not require approval by an ethics committee in Italy (Italian Drug Agency note on August 3, 2007). This study was conducted in accordance with the tenets of the Declaration of Helsinki and was compliant with the European Network of Centres for Pharmacoepidemiology and Pharmacovigilance’s Guide on Methodological Standards in
Pharmacoepidemiology. Data generated during routine patient care were collected and handled anonymously, in compliance with Italian regulations, and stored under a unique numerical identifier. Ethical approval of the study and access to the database was approved by the Internal Scientific Committee of So.Se.Te. Srl, the legal owner of Pedianet.

Infant Antibiotic Exposure Assessment

Antibiotic exposure (Anatomical Therapeutical Chemical code: J01.*) was assessed using the outpatient prescription data recorded during the primary care visits. We assessed (1) the timing of the first antibiotic prescription from birth to 6, 12 (ie, the primary exposure of interest), and 24 months of life (Table S1 in Multimedia Appendix 1) and (2) the dose-response relationship via the number of antibiotic prescriptions recorded in the first year of life (none, 1, 2, and ≥3 prescriptions). Moreover, specific classes of antibiotics were categorized based on the spectrum of action (ie, narrow and broad-spectrum antibiotics) and independent assessment (ie, penicillins, cephalosporins, macrolides, and others; Table S2 in Multimedia Appendix 1) [22].

Child Obesity Assessment

Data for weight and height were retrieved from the growth parameters recorded during the primary care visits and ascertained longitudinally from 2 years until the last parameter recorded at the end of the study or the completion of the 14th year of life. BMI was calculated as weight (kg)/length (m²) and transformed into age- and sex-specific z score using the WHO Growth References [23-25]. Obesity was defined as a z score >3 SDs above the mean for children aged ≤5 years and a z score >2 SDs for children aged >5 years [26]. Children without growth parameters recorded from the second birthday or with implausible BMI z score values (ie, z score <4 and z score >8) were excluded from the analysis [27]. We also performed a sensitivity analysis where obesity was redefined based on the Centers for Disease Control and Prevention (CDC) Growth Charts, identifying children as obese for values of the BMI z score >2 [28].

Covariates

Additional factors such as the birth year, infant sex, area of residence (ie, north, center, south, and islands of Italy), the area deprivation index (ADI — least deprived: ADI 2, 3, 4, 5—most deprived; and ADI missing [29]), and the FP were considered of interest. The ADI is based on 5 items that recurrently describe social and material deprivation and is categorized in quintiles based on the regional ADI level to ensure within-region appropriately represented categories.

Statistical Analysis

Demographic characteristics were summarized through frequency and percentages and compared obese with nonobese children. The chi-square test was used to assess differences. Moreover, the obese incidence rate (IR) per 100 person-year (PY) and the relative 95% CI were computed using infant sex, area of residence, preschool (ie, obese within ≤5 years of age), school-aged children (ie, obese over >5 years of age), and ADI.

A mixed-effect Cox proportional hazards model was used to estimate the hazard ratio and 95% CI for the association between antibiotic exposure within the first year of life (exposure at 1 year) and child obesity between 24 months and 14 years of age, considering the FPs as a random factor. The proportional hazard assumption for the time-fixed covariates was tested using Schoenfeld residuals [30]. The follow-up began after 2 years of age and ended with the last anthropometric measure available at the end of the study (ie, December 31, 2022), the completion of the 14th year of life, or the end of pediatric assistance. We performed 2 levels of adjustment, including (1) infant sex, area of residence, and year of birth, and (2) infant sex, area of residence, year of birth, and ADI as categorical variables (considering missing as the sixth category).

In addition, we evaluated the association between (1) the timing of the first antibiotic prescription from birth to 6 (exposure at 6 months) and 24 (exposure at 2 years) months, (2) the dose-response relationship by assessing the number of antibiotic prescriptions recorded at 1 year, and (3) the individual-specific age of the antibiotic therapy initiation by assessing the age at the first prescription within 1 year (0–<5, 5–<8, and 8–12 months) and the development of childhood obesity. The SAS software (version 9.4; SAS Institute) and R (R Foundation for Statistical Computing) were used for the analyses. For all hypotheses tested, 2-tailed P < .05 were considered to be significant.

Subgroup and Sensitivity Analyses

We also performed several subgroup analyses. We assessed the association between child obesity with (1) the type of antibiotics prescribed in the first year based on the spectrum of action (ie, narrow and broad-spectrum antibiotics vs none) and the antibiotic class (ie, penicillins, cephalosporins, macrolides, and others vs none), (2) the preschool and school age children, and (3) the infant sex.

We performed several sensitivity analyses to examine the robustness of our findings. We repeated the main analysis (1) including only children with a birth weight within the normal range (ie, not exceeding 4000 g; n = 41,443, 34.4% excluded), (2) excluding from the cohort those children with missing values for the ADI (n = 16,582, 13.6% excluded), (3) restricting the cohort to only those children resident in the Veneto region since it is the most representative region of Italy in Pedianet (n = 49,772, 41% included), and (4) redefining the outcome variable calculating the BMI z score using the CDC Growth Charts.

Results

Description of the Cohort

Among 121,540 children identified in the Pedianet network within birth, 45% (54,698/121,540) were prescribed at least 1 antibiotic within the first year of life. The median follow-up period was approximately 6 (IQR 5–10) years.

Of the overall cohort, 22% (26,990/121,540) were classified as obese during follow-up, with an IR of 4.05 cases (95% CI 4.01–4.10) × 100 PY (Table 1). The IR of obesity was quite similar among male and female participants (IR 3.96 vs 4.16 × 100 PY, respectively), more than double in school-aged than school-aged children (ie, obese over >5 years of age), and ADI.
preschool-aged children (IR 3.68 vs 1.48 × 100 PY, respectively), and higher in children from the south and islands (IR 3.56, 4.01, and 5.16 × 100 PY, respectively for children from north, center, and south of Italy). Moreover, the incidence of obesity increased with increasing deprivation index (IR 3.69 vs 4.23×100 PY for least and most deprived children, respectively; Table 1).

Among children without antibiotic prescription during their first year of life, 21% (13,956/66,842) were observed to be obese, while 24% (13,034/54,698) of those with antibiotic exposure were obese, with an IR of 3.82 × 100 PY (95% CI 3.76-3.89) and 4.34 × 100 PY (95% CI 4.26-4.41), respectively. The incidence of obesity was higher among antibiotic-exposed children than unexposed children across all baseline characteristics considered (Table 2; Table S3 in Multimedia Appendix 1).

### Association Between Early Antibiotic Exposure and Incidence of Obesity

The findings presented in Table 3 are directly relevant to the central goal of this research investigation. The risk of obesity remained consistent across different timing of antibiotic prescriptions at 6 months, 1 year, and 2 years (fully adjusted HR [aHR] 1.07, 95% CI 1.04-1.10; aHR 1.06, 95% CI 1.03-1.09; aHR 1.07, 95% CI 1.04-1.10, respectively). No significant differences were observed between partially and fully adjusted analyses, even when restricting the cohort to complete cases for the ADI. Increasing the number of antibiotic exposures increases the risk of obesity significantly (\(P\) for trend<.001). Compared to children with no antibiotic prescriptions, those with 1, 2, or \(\geq\)3 prescriptions had an increased risk of 4% (95% CI 1-7), 6% (95% CI 2-10), and 14% (95% CI 9-18), respectively. The individual-specific age analysis showed that starting antibiotic therapy very early (between 0 and 5 months) had the greatest impact (aHR 1.12, 95% CI 1.08-1.17) on childhood obesity with respect to what was observed among those who were first prescribed antibiotics between 5 and 8 months of life (aHR 1.08, 95% CI 1.04-1.12) and the 8-12 months of life (aHR 1.03, 95% CI 0.99-1.06).

Subgroup analyses showed a higher risk of obesity among preschool-aged children (aHR 1.11, 95% CI 1.05-1.18) than school-aged children (aHR 1.05, 95% CI 1.02-1.09). When examining the subgroup of male and female participants separately, antibiotic exposure in the first year of life was associated with an increased risk of obesity of 4% (95% CI 1%-8%) and 10% (95% CI 7%-15%), respectively. However, the difference between female and male participants in the risk of obesity was not significant (\(P=.11\)). The increased risk of obesity among exposed children was consistent when analyzing only children with a birth weight within the normal range (aHR 1.08, 95% CI 1.04-1.12) and from the Veneto Region (aHR 1.07, 95% CI 1.02-1.11). In addition, using the CDC definition of obesity showed results consistent with the WHO definition (aHR 1.08, 95% CI 1.04-1.13).

Table 4 presents analyses based on the spectrum of action and class of antibiotic in the first year of life. Exposure to narrow-spectrum antibiotics appears associated with a higher risk of obesity (aHR 1.09, 95% CI 1.06-1.12) compared to broad-spectrum antibiotics (aHR 1.06, 95% CI 1.02-1.09). However, the difference between narrow- and broad-spectrum antibiotics in the risk of obesity was not significant (\(P=.52\)). In addition, the class of macrolides showed a stronger association with the risk of obesity (aHR 1.13, 95% CI 1.08-1.17) compared to other categories (aHR 1.10, 95% CI 1.00-1.20), while penicillins (aHR 1.07, 95% CI 1.04-1.10) and cephalosporins (aHR 1.07, 95% CI 1.03-1.12) had a similar extent of association.

Discussion

Principal Findings

In this pediatric population–based cohort study of 121,540 children, we found a 6% (aHR 1.06, 95% CI 1.03-1.09) increased risk of developing childhood obesity among children exposed to antibiotics within the first year of life compared to unexposed children. This relationship is stronger as the number of prescriptions increases and as the individual’s age at the first prescription of antibiotics decreases. The results were consistent across all sensitivity and subgroup analyses conducted.

Obesity is a significant public health concern worldwide, especially among children and young people. Italy is one of the countries in Europe with the highest rate of childhood obesity: according to the latest report by “OKkio alla Salute” from the Ministry of Health in 2019, 38% are overweight and 16.5% are obese among school-aged children; they also used the WHO Growth References [31]. There continued to be a large difference between countries. Overweight prevalence in children varied remarkably from 6% in Tajikistan to 43% in Cyprus. Similarly, obesity rates spanned a wide spectrum, from a minimal 1% in Tajikistan to a concerning 19% in Cyprus. In our cohort, 22% of children were classified as obese at least in 1 measurement during the follow-up when the age- and sex-specific z score was calculated using the WHO Growth References, with respect to 10% when the CDC Growth Charts were used. The reason for this discrepancy relies on the fact that while the CDC 2000 Growth Charts represent the reference growth charts for the US pediatric population, the WHO 2006 ones are intended to serve as growth chart standards, describing how children should grow globally and not how they did grow in a specific nation. Indeed, while the CDC Growth Charts were developed from 5 nationally representative survey data sets from the United States (the National Health Examination Surveys), the WHO ones were based on data from a Multicenter Growth Reference Study that collected a highly selective sample of children from 6 sites around the world (Brazil, Ghana, India, Norway, Oman, and the United States), consisting of children who were not subjected to socioeconomic constraints on growth, who were fed according to the study feeding recommendations, who were healthy term singleton births, and whose mothers did not smoke; the growth of these children was considered to represent optimal growth. Several studies have subsequently observed a significant difference in the rate of overweight or underweight children depending on the growth charts used in national prevalence studies [32-34].

Previous studies have investigated the association between early antibiotic exposure and childhood obesity and reported inconsistent results [2,29-33]. Our results confirm previous findings demonstrating a positive association through several exhaustive analyses, even with attenuated estimations [35-39]. Moreover, our results confirmed previous evidence that the risk of childhood obesity was more significant in those children who received more than 3 antibiotics in the early years of life [37] and with earlier start-exposure timing [39]. However, our results did not support previous evidence showing stronger associations between obesity risk and the male sex of the children. In fact, we found an increased risk of obesity among female participants (aHR 1.10, 95% CI 1.07-1.15) compared with male participants (aHR 1.04, 95% CI 1.01-1.08) [39].

Furthermore, we explored the impact of different spectrums of action and types of antibiotics on childhood obesity. Conversely to Bailey et al [2] who found a stronger association for broad-spectrum antibiotics but not for narrow-spectrum therapy, our findings revealed a positive association with both narrow- and broad-spectrum antibiotics.

The causes of childhood obesity are complex and multifactorial, although the hypothesis that gut microbiota plays a crucial role in the pathogenesis of obesity is well established [40-43]. Recent studies have indicated that antibiotic use leads to alterations in the gut microbiota, potentially affecting nutrient absorption and resulting in metabolic imbalances that contribute to obesity [7]. Our results corroborate what has already been shown in various laboratory models, supporting the notion that weight gain induced by antibiotics is mediated through the drug’s impact on the gut microbiome and the consequently altered circulating levels of substances (eg, short-chain fatty acids, secondary biliary acids, and branched and aromatic amino acids) that influence human metabolism [7]. Changes in microbiota caused by antibiotic use are defined as dysbiosis, a microbial imbalance correlated with impaired health, including increased susceptibility to infections, impaired immune function,
gastrointestinal symptoms, and even long-term effects on metabolic health and obesity [44]. Obesity is a chronic and complex disease with significant long-term effects; hence, it is crucial to implement interventions to prevent this condition in children. Preventing and addressing childhood obesity require a comprehensive, multisectoral approach involving individuals, families, communities, educational institutions, health care systems, and policy makers. Strategies may include promoting healthy eating habits, increasing physical activity opportunities, improving food environments, and implementing policies that restrict the marketing of unhealthy foods to children as also supported by the Health4EUkids project; the European Joint Action for the Implementation of Best Practices for the promotion of health and the prevention of obesity [5].

There are several potential limitations to consider in this research. First, exposure to antibiotics was defined by prescription, assuming that a prescription led to actual medication use. However, this assumption may not always hold true, leading to possible misclassification of the exposure. Anyhow, this misclassification is likely to bias the results toward the null hypothesis. Moreover, antibiotics prescribed in a private setting or hospitals are not recorded. Second, important confounding factors related to both pregnancy and early life were not captured in Pedianet. This includes factors like maternal BMI before and during pregnancy, breastfeeding, method of complementary feeding, dietary patterns, sugar-sweetened beverages consumption, eating behavior (eg, skipping breakfast and family dinners), meal frequency and composition (fast foods and snacking), portion size, physical activity, screen media exposure, and sedentary behavior [45,46]. These factors could potentially influence the results and lead to residual confounding. We adjusted the models for various sociodemographic characteristics to address some of these limitations. Notably, we included the area-level socioeconomic deprivation index, which is commonly used in public health research. It serves to quantify the extent of geographically determined social inequalities in health or assess the independent effect that area characteristics have on health beyond individual socioeconomic position. In addition, this index can help substitute missing individual-level data in epidemiological studies and account for confounding socioeconomic factors.

This study also has several strong points. First, using a pediatric population–based registry allowed for a large unbiased cohort with extended follow-up, thereby minimizing selection and recall bias. Second, to ensure accuracy and avoid potential exposure or outcome misclassification, we included only children who were consistently monitored by their FP during the first 2 years of life and had at least 1 reliable BMI measurement after completing the second year of life. Furthermore, setting the end of follow-up as the date of the last BMI measurement for each child helped minimize outcome misclassification. Finally, we used all the anthropometric measures (N=564,066) recorded during the pediatric visits performed by children included in the cohort. To our knowledge, no previous study has been conducted with this level of comprehensiveness and detail in terms of anthropometric data collection.

Conclusions

In conclusion, the results from this large population-based study support the association between early exposure to antibiotics and an increased risk of childhood obesity. This relationship becomes more pronounced as the number of prescriptions increases and as the age specific for the first prescription of antibiotics decreases.

Abstract

Background: Globally, over 39% of individuals are obese. Metabolic syndrome, usually accompanied by obesity, is regarded as a major contributor to noncommunicable diseases. Given this relationship, the concepts of metabolically healthy and unhealthy obesity, considering metabolic status, have been evolving. Attention is being directed to metabolically healthy people with obesity who have relatively low transition rates to noncommunicable diseases. As obesity rates continue to rise and unhealthy behaviors prevail among young adults, there is a growing need for obesity management that considers these metabolic statuses. A nomogram can be used as an effective tool to predict the risk of transitioning to metabolically unhealthy obesity from a metabolically healthy status.

Objective: The study aimed to identify demographic factors, health behaviors, and 5 metabolic statuses related to the transition from metabolically healthy obesity to unhealthy obesity among people aged between 20 and 44 years and to develop a screening tool to predict this transition.

Methods: This secondary analysis study used national health data from the National Health Insurance System in South Korea. We analyzed the customized data using SAS (SAS Institute Inc) and conducted logistic regression to identify factors related to the transition from metabolically healthy to unhealthy obesity. A nomogram was developed to predict the transition using the identified factors.

Results: Among 3,351,989 people, there was a significant association between the transition from metabolically healthy to unhealthy obesity and general characteristics, health behaviors, and metabolic components. Male participants showed a 1.30 higher odds ratio for transitioning to metabolically unhealthy obesity than female participants, and people in the lowest economic status were also at risk for the transition (odds ratio 1.08, 95% CI 1.05-1.1). Smoking status, consuming >30 g of alcohol, and insufficient regular exercise were negatively associated with the transition. Each relevant variable was assigned a point value. When the nomogram total points reached 295, the shift from metabolically healthy to unhealthy obesity had a prediction rate of >50%.

Conclusions: This study identified key factors for young adults transitioning from healthy to unhealthy obesity, creating a predictive nomogram. This nomogram, including triglycerides, waist circumference, high-density lipoprotein-cholesterol, blood pressure, and fasting glucose, allows easy assessment of obesity risk even for the general population. This tool simplifies predictions amid rising obesity rates and interventions.

Introduction
In the last 40 years, the number of people with obesity has more than tripled worldwide; as of 2016, 39% of the global population was estimated to have a BMI ≥25 kg/m² [1]. Obesity, usually accompanied by metabolic syndrome (MetS), is a major risk factor for noncommunicable diseases (NCDs), such as cancer, musculoskeletal problems, and cardiovascular diseases [2]. Epidemiological studies showed that 20%-45% of people have MetS. Furthermore, MetS prevalence is anticipated to increase to >50% by 2035 [3].

Recent studies have increasingly emphasized metabolically healthy obesity (MHO) and metabolically unhealthy obesity (MUO), with rising interest in the connection between obesity and MetS [4-6]. Studies revealed that individuals with MHO have a significantly reduced incidence of common obesity-related disorders, such as stroke, cancer, cardiovascular disease, and type 2 diabetes [7]. However, recent research indicates that individuals with MHO might eventually transition to MUO [6], with up to 50% of the population with obesity possibly falling into the MHO category [8]. This underlines the need for research and treatment to prevent or interrupt the transition from MHO to MUO.

On the other hand, young adults face higher mortality from obesity than older people. As social relationships that foster independence evolve, the prevalence of unhealthy lifestyle behaviors, such as smoking, alcohol consumption, and physical inactivity, has been rapidly increasing, contributing to chronic diseases in the population with obesity [9,10]. Additionally, the COVID-19 pandemic caused increased psychological stress, decreased physical activity, and altered eating patterns in young adults, contributing to obesity [11]. Young adults are more aware of obesity than older populations but engage less in weight loss programs and achieve less intentional weight loss [12], underscoring the need for proactive interventions and tailored programs for this age group.

This study identified risk factors and developed a screening tool with a nomogram to prevent the transition from MHO to MUO. A nomogram, a graphical tool that can perform a complicated approximation calculation, provided a clear interpretation of which predictors could be more critical factors [13]. The use of this scale also allows the general population to intuitively and easily assess the likelihood of transitioning to MUO. Therefore, this study aimed to predict the transition from MHO to MUO among young individuals with obesity using the nomogram.

Methods

Study Setting
The Korean government provides health checkups for 97% of the South Korean population through public health insurance, while the remaining 3% receive these checkups through medical aid programs. Residents are encouraged to undergo biennial health checkups, covering measurements such as height, weight, BMI, blood tests, and urinary tests. The National Health Insurance System (NHIS) is tasked with collecting medical records, insurance statuses, and other pertinent data through these enrollment methods, and providing corresponding services [14].

Measures
MHO and MUO are defined based on the metabolic status of the population with obesity. Obesity is characterized by an abnormal or excessive accumulation of adipose tissue, and BMI is primarily used to define it [1]. According to evidence regarding the high risk of type 2 diabetes or cardiovascular diseases with lower BMI standards, the World Health Organization (WHO) proposed each country make decisions about obesity definitions [15,16]. The Korean Society for the Study of Obesity defined obesity as a BMI (weight in kg divided by the square of height in meters) ≥25 kg/m² [17]. Indicators for assessing metabolic status include waist circumference, fasting blood glucose levels, blood pressure, high-density lipoprotein (HDL) cholesterol levels, and fasting triglyceride levels. This study used the cutoff points ≥90 cm in male participants and ≥85 cm in female participants for waist circumference (a Korean-specific cutoff point) [17]; ≥130/85 mmHg or using antihypertensive medications for blood pressure; ≥100 mg/dL or using antidiabetic medications for fasting blood glucose; ≥150 mg/dL for fasting triglycerides; and <40 mg/dL in male participants and <50 mg/dL in female participants for HDL cholesterol [18]. An individual is defined as metabolically unhealthy if ≥3 of these 5 indicators yield abnormal results. Therefore, MUO is a state of obesity with 3 or more abnormal indicators of metabolic status. Those who do not meet these criteria are defined as MHO [5].

In this study, healthy behaviors (smoking, alcohol consumption, and regular exercise), which are representative factors influencing MetS and obesity, were examined. Participants were classified according to their smoking status. Alcohol consumption was assessed by categorizing participants into individuals who consume alcohol heavily (heavy; ≥50 g/day), moderate alcohol (moderate; 30-49 g/day), and do not drink alcohol (none) [19]. Regular exercise was defined as engaging in high-intensity exercise for at least 20 minutes, ≥3 times per week, or moderate-intensity exercise for at least 30 minutes, ≥5 times per week [20].

Study Population
We identified participants (aged ≥20 years) who had health checkups in 2009-2010 and 2013-2014. A total of 3,351,989 individuals were obese (BMI ≥25 kg/m²) during both examinations. From this group, we excluded those who had MUO during the first examination and selected those aged between 20 and 44 years during the second examination. We also excluded individuals diagnosed with cancer or cardiovascular diseases (myocardial infarction and stroke) before
the second examination. After excluding missing values, the final sample size included in the analysis was determined to be 562,765 individuals.

Data Analysis

Young adults’ general characteristics, health behaviors, and metabolic statuses were summarized using the chi-square test and 2-tailed t tests. We used logistic regression analysis to examine the association between the transition to MUO and general characteristics, health behaviors, and metabolic states. Based on the results of the logistic regression, factors associated with the transition to MUO were identified, and scores were assigned ranging from 0 to 100. The prediction model for calculating the risk of the transition to MUO was depicted using a nomogram. P values <.05 were considered statistically significant. Statistical analysis was conducted using SAS (version 9.4; SAS Institute Inc).

Ethical Considerations

The project was submitted for evaluation to the institutional review board of Chung-Ang University (1041078-202203-HR-080). Since the study was a secondary analysis using the NHIS data, the institutional review board exempted the study from formal ethical approval. All participants who underwent health checkups through NHIS consented to provide the results and answers for research purposes. The data were deidentified by the NHIS and provided with permission.

Results

General Characteristics and Metabolic Status of Participants According to Metabolic Status After 4 Years

The general characteristics of participants who transitioned from MHO to MUO over a 4-year period, compared to those who did not, are outlined in Table 1. A higher proportion of male participants was observed in the group that transitioned to MUO, with a statistically significant difference (P<.001). Age, income level, and health behaviors (smoking status, alcohol consumption, and regular exercise) showed statistically significant differences as well (P<.001). Both groups showed significant differences regarding metabolic status based on the screening time point, even at the initial screening. Mainly, the group that transitioned to MUO exhibited remarkable changes in metabolic status, with variations in triglyceride, fasting glucose, waist circumference, blood pressure, and HDL.
Table 1. General characteristics of participants according to metabolic status after 4 years.

Logistic Regression Analyses of the Transition From MHO to MUO

We identified factors contributing to the transition from MHO to MUO through logistic regression analysis (Table 2). Adjusting for all significant characteristics identified in Table 1, we constructed model 2. The model demonstrated that transitioning from MHO to MUO was independently associated with an increase in age.

aModel 1 was not adjusted, and model 2 was adjusted for age, sex, income, smoking, drinking, regular exercise, waist circumstance, fasting glucose, blood pressure, HDL-cholesterol, and triglycerides; all variables had a statistically significant association with the transition to metabolically unhealthy obesity (P<.001).

bNot applicable.

cQ1-Q4, first through fourth quartiles.

dHDL: high-density lipoprotein.
For each additional year of age, the odds ratio (OR) of transitioning to MUO was 1.04 times higher (95% CI 1.002-1.005). Male participants showed a 1.30 times higher OR of transitioning to MUO than female participants (95% CI 1.27-1.32). People belonging to the lowest economic group showed a 1.08 higher OR of transitioning to MUO than other economic status groups (95% CI 1.05-1.1). Regarding healthy behaviors, having a history of smoking and being an individual who currently smoke showed 1.1 (95% CI 1.09-1.12) and 1.27 (95% CI 1.25-1.29) higher OR of transitioning to MUO than people without a smoking history. Individuals consuming alcohol heavily had a 1.26 higher OR (95% CI 1.23-1.28) of transitioning to MUO compared to people not drinking alcohol. People participating in regular exercise had a 0.72 lower OR (95% CI 0.7-0.73) of transitioning to MUO than people not regularly exercising. Abnormal waist circumference at the initial screening (OR 2.11, 95% CI 2.08-2.14), impaired fasting glucose or related medication use (OR 1.69), hypertension or related medication use (OR 1.76, 95% CI 1.76-1.78), low HDL cholesterol or related medication use (OR 1.89, 95% CI 1.86-1.92), and elevated triglyceride or related medication use (OR 2.25, 95% CI 2.22-2.28) were all statistically significantly associated with the transition to MUO.

Prediction of the Transition From MHO to MUO

A nomogram (Figure 1) was constructed to assist clinical predictions, providing a quantitative estimation of the probability of transitioning to MUO. This is a screening tool for predicting the transition from MHO to MUO with 66% discriminative ability (Figure 2). According to individual characteristics, each value is located based on each variable in the nomogram. At each variable point, a vertical line is drawn up to the scale of “points,” followed by identifying the point of the variable. After marking all values based on variables, all points of each variable are summarized, and the point on the scale of “total points” is marked. At the total point, after drawing a vertical line to the scale of “predicted value,” the matched point will be the individual’s predicted value of transitioning from MHO to MUO. Using multivariate logistic regression, we identified 11 independent predictors, assigning the highest score in the nomogram to each variable (eg, 44 years: 9 points; male participant: 32 points; first income level quartile: 9 points; individual who smokes: 29 points; individual who drinks: 29 points; no regular physical activity: 41 points; abnormal waist circumference: 92 points; abnormal fasting glucose or taking diabetes medications: 65 points; abnormal blood pressure or taking hypertension medication: 70 points; abnormal HDL level or taking dyslipidemia medications: 78 points; abnormal serum triglyceride level or taking dyslipidemia medication: 100 points; and total points: 344 points). When the total points reached 295, the prediction rate for transitioning from MHO to MUO was determined to be higher than 50%. As depicted in Figure 3, the nomogram showed close agreement between predicted and observed outcomes in the study population, with a slight tendency for overestimation in the 0.1-0.2 and 0.5-0.6 intervals. Figure 2 shows the receiver operating characteristic curve used to validate the nomogram, yielding an area under the curve of 0.66 (95% CI 0.658-0.661).

The dotted line represents the ideal concordance between the predicted and actual probabilities. The solid line represents the performance of the nomogram.
Discussion

Principal Findings

The prevalence of obesity is escalating globally, accompanied by MetS, increasing the risk of NCDs. This upward trend among young adults can be attributed to lifestyle alterations during adulthood [10] and, more recently, decreased physical activity or changed dietary habits due to the COVID-19 pandemic [11]. Moreover, individuals with MUO face substantially elevated risks of NCDs compared to those with MHO [4]. Considering that MHO might merely represent a “honeymoon phase” preceding the shift to MUO [6], the urgency of managing MHO among young adults is underscored.

This study investigated the influence of sociodemographic factors, metabolic status, and health behaviors on MetS development. By comparing young adults who transitioned from MHO to MUO with those who maintained their health status, we identified associations between the transition and factors with sex, low socioeconomic status, 5 metabolic variables, and health-related behaviors (drinking, smoking, and irregular physical activity). The nomogram was constructed to predict the transition from MHO to MUO using the data from the results.

Transitioning to MUO was higher in male participants than in female participants. In a previous study, MetS prevalence based on sex showed various results according to age. A cross-sectional study using data from the Third National Health and Nutrition Examination Survey in America showed a similar result to this study: a higher prevalence of MetS in male individuals [21]. However, they identified that women showed a higher MetS prevalence than men in older age. Using a similar perspective, a cohort study from Switzerland reported that the sex-based prevalence of MetS could be different according to the age range [22]. In Korea, the MetS fact sheet for 2010 using data from the Korean National Health and Nutrition Examination Surveys from 2007 to 2018 reported a higher prevalence in the male population but increasing trends in the female population aged >70 years [23]. Thus, our participants were constrained to young adults. Additionally, the results of this study were similar to those of previous studies. Regarding economic status, individuals with lower income levels showed a higher risk of transitioning to MUO, aligning with previous studies on risk factors for MetS development [24,25]. Our findings align with the reality that obesity is more prevalent than underweight, especially in low-income countries [1]. Furthermore, dietary issues in these regions correlate with diet-related NCDs [1]. Consequently, the findings emphasize the need to consider sex and the importance of health care provision for those in low socioeconomic positions within the community in the management of individuals with MHO to prevent transitioning to MUO.

The associations between obesity and health behaviors, that is, smoking status [26], alcohol consumption [27], and physical activity [28], have been widely investigated and linked to MetS [29]. This study further validated the significance of health-related behavior patterns in the transition from MHO to MUO in young adults with obesity. We found that moderate alcohol consumption (<30 g of alcohol daily) was associated with a decreased transition to MUO. Similar to the result, previous research [30] indicated a positive correlation between moderate alcohol consumption and a reduced risk of MetS. However, a study targeting Asian populations indicated that even moderate alcohol intake might affect metabolic status [31]. Recognizing that alcohol consumption itself could affect dietary habits in the population with obesity, as well as the possibility that the frequency of alcohol consumption might influence the occurrence of MetS more than the quantity consumed, is crucial [32]. Therefore, a particular caution, including restricting the frequency of consumption, is required regarding alcohol consumption to prevent the onset of MetS in patients with obesity.

We found that abnormal metabolic factors played a crucial role in the transition to MUO over a 4-year span. Specifically, abnormal waist circumference and triglyceride levels showed nearly ≥2 higher ORs for the transition to MUO. Waist circumference was recognized as a more pertinent obesity measure than BMI [33] and is frequently used to forecast cardiometabolic disorders [34]. Waist circumference is strongly linked to abnormal fasting glucose [35] and lipid profiles [36], both affecting metabolic states. Our findings underscore the importance of waist circumference control by demonstrating its association with the development of MUO, with an OR >1.6 for other abnormal metabolic variables. Unlike other metabolic conditions that might demand pharmacological management, waist circumference is a physical attribute that can be reduced through lifestyle changes, such as exercise, dietary adjustments, and curbed alcohol consumption [37]. Managing waist circumference is not only a strategy for combating obesity but also for improving other abnormal metabolic disorders [37]. Therefore, tailored interventions aimed at trimming waist circumference are essential. Additionally, our findings revealed a pronounced association between triglyceride levels and the transition to MUO, connecting high triglyceride levels with prevalent issues such as type 2 diabetes and abnormal HDL in people with obesity [38]. Approximately 15 years ago, a cross-sectional study in America revealed that abnormal triglyceride and HDL levels were one of the most prevalent MetS combination factors in young male participants and female participants [39]. Still, the research even proposed triglyceride levels and waist circumference as specific indicators for predicting MetS in African American people [40]. For individuals with MHO with abnormal metabolic factors, proactive management, possibly including medication control and lifestyle modifications, is vital. More intensive interventions might be warranted in abnormal waist circumference and serum triglyceride cases.

The nomogram was developed with identified factors, predicting the transition from MHO to MUO. As a simplified tool [13], the nomogram allows young adults with MHO to directly calculate their risk of transitioning to MUO with their health examination results. Created using data from the NHIS, it can serve as a valuable resource for adults undergoing regular health checkups, enabling them to assess their risk and formulate personalized health plans. Individuals can easily evaluate their risks without relying on health care professionals or medical
experts. People with MHO can efficiently use this tool to tailor their interventions by entering their sex, health behaviors, and metabolic status scores into the nomogram.

**Limitations**

The study had some limitations as a secondary analysis of Korean health examination data. Although dietary habits or nutrition consumption are critical factors for obesity or MetS, we could not include them as variables since we used publicized NHS data. Second, while clinical measurements were accurately performed in a hospital setting, health behavior results—obtained through self-response surveys—might be subjective. Third, further validation for other racial groups is needed. Differences in obesity [41] and MetS [42] prevalence among various races or ethnicities necessitate cautious adaptation and validation for broader applicability.

The other limitation of the nomogram is that prediction variables are multifaceted, comprising several modifiable factors that interact. Since changes in one variable can influence other variables, predicting outcomes based on single-variable changes can be intricate. However, enhancing these factors and embracing healthy behaviors can lead to improved metabolic status and potentially aid in obesity mitigation.

Despite the limitations, a comprehensive analysis was conducted using the data of all participants with obesity in South Korea over 4 years. The study and the developed nomogram can be applied generally to Koreans to predict the transition to MUO. For the next step, the research can be extended to people without obesity, finding associations between MHO and MUO and comparing risk factors among them. Since the nomogram can show intuitive results of predictions and be interpreted easily by any reader [13], it can be broadly used as a screening tool, leveraging national-level examination results. Coupled with advancements in digital health, telehealth, and wearable devices [43], the screening tool targeting metabolic status will play an essential role in directing appropriate interventions to those in need.

**Conclusions**

The study explored the dynamics of young adults with obesity in South Korea, pinpointing factors that correlate with the transition from MHO to MUO and creating the predictive nomogram. In this study, the scoring arrangement for transitioning to MUO revealed that the major variables were triglycerides, waist circumference, HDL cholesterol, blood pressure, and fasting glucose. Although these risk factors were highlighted in previous studies [33-36], the significance of this study lies in the development of a nomogram that enables even the general population to easily and intuitively assess their likelihood of transitioning to MUO.

With the rising prevalence of obesity and increasing intervention strategies, our screening tool simplifies the prediction using easily identifiable factors for the general population. However, this study serves as a starting point, and further research should broaden models to include racial characteristics, thereby improving the relevance of the nomogram across diverse populations.

Abstract

Background: The prevalence of type 2 diabetes mellitus (DM) and pre–diabetes mellitus (pre-DM) has been increasing among youth in recent decades in the United States, prompting an urgent need for understanding and identifying their associated risk factors. Such efforts, however, have been hindered by the lack of easily accessible youth pre-DM/DM data.

Objective: We aimed to first build a high-quality, comprehensive epidemiological data set focused on youth pre-DM/DM. Subsequently, we aimed to make these data accessible by creating a user-friendly web portal to share them and the corresponding codes. Through this, we hope to address this significant gap and facilitate youth pre-DM/DM research.

Methods: Building on data from the National Health and Nutrition Examination Survey (NHANES) from 1999 to 2018, we cleaned and harmonized hundreds of variables relevant to pre-DM/DM (fasting plasma glucose level ≥100 mg/dL or glycated hemoglobin ≥5.7%) for youth aged 12-19 years (N=15,149). We identified individual factors associated with pre-DM/DM risk using bivariate statistical analyses and predicted pre-DM/DM status using our Ensemble Integration (EI) framework for multidomain machine learning. We then developed a user-friendly web portal named Prediabetes/diabetes in youth Online Dashboard (POND) to share the data and codes.

Results: We extracted 95 variables potentially relevant to pre-DM/DM risk organized into 4 domains (sociodemographic, health status, diet, and other lifestyle behaviors). The bivariate analyses identified 27 significant correlates of pre-DM/DM (P<.001, Bonferroni adjusted), including race or ethnicity, health insurance, BMI, added sugar intake, and screen time. Among these factors, 16 factors were also identified based on the EI methodology (Fisher P of overlap=7.06×10^6). In addition to those, the EI approach identified 11 additional predictive variables, including some known (eg, meat and fruit intake and family income) and less recognized factors (eg, number of rooms in homes). The factors identified in both analyses spanned across all 4 of the domains mentioned. These data and results, as well as other exploratory tools, can be accessed on POND.

Conclusions: Using NHANES data, we built one of the largest public epidemiological data sets for studying youth pre-DM/DM and identified potential risk factors using complementary analytical approaches. Our results align with the multifactorial nature of pre-DM/DM with correlates across several domains. Also, our data-sharing platform, POND, facilitates a wide range of applications to inform future youth pre-DM/DM studies.

**Introduction**

Type 2 diabetes mellitus (DM) is a complex disease influenced by several biological and epidemiological factors [1, 2], such as obesity [3], family history [4], diet [1, 5], physical activity level [1, 6-8], and socioeconomic status [9-11]. Prediabetes, characterized by elevated blood glucose levels below the diabetes threshold, is a precursor condition to DM [12]. There has been an alarming increasing trend in the prevalence of youth with pre–diabetes mellitus (pre-DM) and DM both in the United States [13-19] and worldwide [20, 21], and the numbers of newly diagnosed youth living with pre-DM/DM are also expected to increase [14, 20, 22]. The latest estimate based on nationally representative data showed that the prevalence of pre-DM among youth increased from 11.6% in 1999-2002 to 28.2% in 2015-2018 in the United States [13]. This growth is particularly concerning because pre-DM/DM disproportionately affects racial and ethnic minority groups and those with low socioeconomic status [9-11, 22-24], leading to significant health disparities. Having pre-DM/DM at a younger age also confers a higher health and economic burden resulting from living with the condition for more years and a higher risk of developing other cardiometabolic diseases [25-30]. This serious challenge calls for increased translational research into factors associated with pre-DM/DM among youth and how they can collectively affect disease risk and inform prevention strategies.

In particular, the most critically needed research in this direction is exploring the collective impact of various risk factors across multiple health-related domains. While clinical factors, such as obesity, have been mechanistically linked to insulin resistance [31], it is important to consider the broader perspective. There is an increasing recognition that social determinants of health (SDoH) play a significant role in amplifying the risk of pre-DM/DM and their related disparities. For example, factors such as limited access to health care, food and housing insecurity, and the neighborhood-built environment have been identified as influential contributors [9-11, 32]. However, to gain a comprehensive understanding, it is essential to delve into other less studied variables, such as screen time, acculturation, or frequency of eating out, and examine how they interact to increase the risk of pre-DM/DM among youth [2].

One of the major challenges that has limited translational research into youth pre-DM/DM risk factors is that there are not publicly available, easily accessible data comprehensively profiling interrelated epidemiological factors for young individuals [2]. Specifically, most available public diabetes data portals focus on providing aggregated descriptive trends, such as pre-DM/DM prevalence for the entire population or subgroups stratified by race and ethnicity [33-36], which does not allow in-depth examination of the relationships between multiple risk factors and pre-DM/DM risk using individual-level data. While there do exist a few individual-level public diabetes data sets [37-41], they include mainly clinical measurements, while other important risk factors such as those related to diet, physical activity, and SDoH are limited. In addition, these data sets are not available for youth populations, as they focus exclusively on adult populations and not on youth specifically [37, 39-41]. Furthermore, these data sets are not accompanied by any user-friendly web-based portals that can help explore or analyze these data to reveal interesting knowledge about youth pre-DM/DM. This shows that there is a lack of a comprehensive data set that includes multiple epidemiological variables to study youth pre-DM/DM and easily usable functionalities to explore and analyze data.

To directly address this data gap, we turned to the National Health and Nutrition Examination Survey (NHANES), which offers a promising path for examining pre-DM/DM among the US youth population by providing a rich source of individual- and household-level epidemiological factors. As a result, NHANES has been a prominent data source for studying youth pre-DM/DM trends and associated factors [18, 42-45]. However, the use of NHANES data requires extensive data processing that is laborious and time-intensive [46]. This represents a major challenge for the widespread use of these high-quality and extensive data for studying youth pre-DM/DM.

In this work, we directly addressed the above challenges by processing NHANES data from 1999 to 2018 into a large-scale, youth diabetes–focused data set that covers a variety of relevant variable domains, namely, sociodemographic factors, health status indicators, diet, and other lifestyle behaviors. We also provided public access to this high-quality comprehensive youth pre-DM/DM data set, as well as functionalities to explore and analyze it, through the user-friendly Prediabetes/diabetes in youth Online Dashboard (POND) [47]. We demonstrated the data set’s use and potential through 2 case studies that used statistical analyses and machine learning (ML) approaches, respectively, to identify important epidemiological factors that are associated with youth pre-DM/DM.

Through this work, we aim to advance youth diabetes research by providing the most comprehensive epidemiological data set available through a public web portal and illustrating the value of these resources through our example case studies based on statistical analyses and ML. Our overarching goal is to enable researchers to investigate the multifactorial variables associated with youth pre-DM/DM, which may drive translational advances in prevention and management strategies.

**Methods**

**Overview**

Figure 1 [48] shows the overall study design and workflow. In the following subsections, we detail the components of the workflow.
Figure 1. Study design and workflow. We processed data from 10 survey cycles (1999-2018) from the National Health and Nutrition Examination Survey (NHANES), which yielded 15,149 youths with known pre-DM/DM status. We extracted 95 variables that were relevant to pre-DM/DM and organized them into 4 domains: sociodemographic, health status, diet, and other lifestyle behaviors. We made the data set easily accessible to the public through the user-friendly POND (Prediabetes/diabetes in youth Online Dashboard) web portal, enabling users to navigate, visualize, and download the data. In addition, we conducted 2 case studies with complementary statistical and machine learning methods that are designed to illustrate the translation potential of our data set and point. Both analyses identified predictive variables associated with youth diabetes, and the results can be explored in POND (some images in this figure were obtained from an open-source collection). DM: diabetes mellitus.

Data Source and Study Population

We built the youth pre-DM/DM data set based on publicly available NHANES data [49] spanning the years from 1999 to 2018. Developed by the Centers for Disease Control and Prevention, NHANES is a serial cross-sectional survey that gathers comprehensive health-related information from nationally representative samples of the noninstitutionalized population in the United States. The survey uses a multistage probability sampling method and collects data through questionnaires, physical examinations, and biomarker analysis. Each year, approximately 5000 individuals are included in the survey, and the data are publicly released in 2-year cycles. Figure 2 details the process used to define our study population. Briefly, of the total 101,316 participants in 1999-2018 NHANES, we excluded individuals who (1) were not within the 12-19 years age range, (2) did not have either of the biomarkers used to define pre-DM/DM status, and (3) answered “Yes” to “Have you ever been told by a doctor or health professional that you have diabetes?” The youth pre-DM/DM outcome of this work was derived as follows: youth were considered at risk of pre-DM/DM if their fasting plasma glucose (FPG) was at or greater than 100 mg/dL, or their glycated hemoglobin (HbA1c) was at or greater than 5.7%, according to the current American Diabetes Association (ADA) pediatric clinical guidelines [2].
**Validation of the Study Population**

We estimated pre-DM/DM prevalence across the 10 survey cycles (1999-2018) by incorporating the NHANES design elements in the analysis and compared the general trend with those reported in the literature [18,19]. We also specifically applied the analytical methods reported in a recent study [13] based on NHANES data to our study population to replicate the trends in pre-DM among youth in the United States from 1999 to 2018 reported in that analysis. Specifically, that study selected a youth population from 12-19 years of age with positive sampling weight from the fasting subsample (i.e., nonzero and nonmissing Fasting Subsample 2 Year Mobile Examination Centers Weight ['WTSAF2YR']; personal communication) without a self-reported physician-diagnosed DM. In addition, that study focused only on pre-DM, which was defined as an HbA1c level between 5.7% and 6.4% or an FPG level between 100 mg/dL and 125 mg/dL [13].
Development of Youth Pre-DM/DM Data Set

Based on the most recent ADA standard of care recommendations including factors related to pre-DM/DM risk and management [2], we selected 27 potentially relevant NHANES questionnaires and grouped them into 4 domains: sociodemographic, health status, diet, and other lifestyle behaviors. For example, under the health status domain, BMI was included as a potential risk factor for youth pre-DM/DM [2]. Similarly, lifestyle and behavioral variables included factors, such as diet and physical activity, that have been shown to be critical for pre-DM/DM prevention in both observational studies and randomized clinical trials [50-52]. Our sociodemographic domain included demographic, socioeconomic, and SDoH variables (eg, age, gender, poverty status, and food security). Except for commonly available clinical measurements, such as blood pressure and total cholesterol, we did not include laboratory data (eg, triglycerides, transferrin, C-reactive protein, interleukin-6, and white blood cells), since these measurements were not collected for all NHANES participants and were not commonly accessible for the general population.

From the selected questionnaires, we identified a list of 95 variables based on the aforementioned methodology. The complete list of variables is provided in Table S1 in Section S1 of Multimedia Appendix 1 [13,49,53-62] and on our POND web portal [47]. All the code developed, processed data, and detailed description of variables are also available on the web portal [47]. The process of extracting these variables involved extensive examination of the questions that were asked, consultation of the literature, and discussions to reach consensus within the study team. The details of this process are provided in Figure S1 and Section S2 of Multimedia Appendix 1. We used SAS (version 9.4; SAS Institute) and R (version 4.2.2; R Core Team, 2022) in R Studio (version 4.2.2; R Core Team, 2022) for data processing and data set development.

Building the POND

To facilitate other researchers’ use of our youth pre-DM/DM data set and make our methodology transparent and reproducible, we developed POND to share our processed data set and enable users to understand and explore the data on their own. The web portal was developed using R markdown and the flexdashboard package [63] and was published as a Shiny application [64]. Table S2 and Section S3 in Multimedia Appendix 1 provide details of all the R packages used to develop POND, and the related code is available on the portal’s download page.

Case Studies in Using the Data Set to Better Understand Youth Pre-DM/DM

Overview

To examine the validity and use of our data set for advancing translational research on youth pre-DM/DM, we conducted 2 complementary data analyses. We first conducted bivariate analyses to identify variables associated with pre-DM/DM status. We used both the aforementioned capabilities of EI to build and interpret a predictive model of youth pre-DM/DM status using NHANES data [67-69], and we have previously used these algorithms to predict pre-DM/DM status specifically among youth in a subsample of our current study population [42]. We expanded these existing analyses by taking into account the multidomain nature of our data set with the goal of building an effective and interpretable predictive model of youth pre-DM/DM. To that end, we leveraged our recently developed ML framework, Ensemble Integration (EI) [53,54], with all 4 domains and their variables in our data set. EI incorporates both consensus and complementarity in our data set by first inferring local predictive models from the individual domains, that is, sociodemographic, health status, diet, and other lifestyle behaviors, that are expected to capture information and interactions specific to the domains. These local models and information are then integrated into a global pre-DM/DM, comprehensive pre-DM/DM prediction model using heterogeneous ensemble algorithms [70] (Figure S2, Table S3, and Table S4 under Section S5 in Multimedia Appendix 1). These algorithms, such as stacking, allow the integration of an unrestricted number and variety of local models into the global predictive model, thus offering improved performance and robustness. EI also enables the identification of the most predictive variables in the final model, thus offering deeper insights into the outcome being predicted.

We used both the aforementioned capabilities of EI to build and interpret a predictive model of youth pre-DM/DM status based on our data set. We also compared the predictive performance of the model with three alternative approaches: (1) a modified form of the ADA screening guideline [55], which is based on BMI, total cholesterol level, hypertension, and race or ethnicity, to assess the use of data-driven screening for youth pre-DM/DM
(Table S5 in Multimedia Appendix 1); (2) EI applied to individual variable domains, namely, sociodemographic, health status, diet and other lifestyle behaviors, to assess the value of multidomain data for youth pre-DM/DM prediction; and (3) extreme gradient boosting (XGBoost) [71] applied to our combined multidomain data set as a representative alternate ML algorithm. This alternative was chosen as XGBoost is considered the most effective classification algorithm for tabular data [72], since it can potentially capture feature interactions across different domains [73,74]. The prediction performance of EI and all the alternative approaches were assessed in terms of the commonly used area under the receiver operating characteristic curve (AUROC) [75] and balanced accuracy (BA; average of specificity and sensitivity) [76] measures. The performance of the ML-based prediction approaches, namely, multi- and single-domain EI and XGBoost, was evaluated in a 5-fold cross-validation setting repeated 10 times [77]. These performance scores were statistically compared using the Wilcoxon rank sum test, and the resultant P values were corrected for multiple hypothesis testing using the Benjamini-Hochberg procedure to yield false discovery rates (FDRs) [78]. More details of ML model building; the alternative approaches; and the evaluation methodology, including cross-validation, model selection, and comparison, are available in section S5 in Multimedia Appendix 1. Finally, we used EI’s interpretation capabilities [53,54] to identify the variables in our data set that were the most predictive of youth pre-DM/DM status and compare them with the variables identified from the bivariate analyses described in the above subsection.

Ethical Considerations

This study used existing deidentified and anonymized data in the public domain directly downloadable from the NHANES website and thus, according to the Common Rule, was exempt from institutional review board review and the informed consent requirement. NHANES was conducted by the Centers for Disease Control and Prevention National Center for Health Statistics. NHANES survey procedures and protocol were approved by the National Center for Health Statistics ethics review board for each survey cycle [79].

Results

Study Population Derived From NHANES

Our study population consisted of 15,149 youths aged 12-19 years who participated in the 1999-2018 NHANES cycles and met our selection criteria (Figure 2). Approximately 13.3% (2010/15,149) of US youth were at risk of pre-DM/DM according to the clinically standard criteria for defining pre-DM/DM per ADA guidelines (FPG $\geq 100$ mg/dL and HbA$_1c$ $\geq 5.7$%); Table 1).

\(a\) Unweighted statistics of some key variables describing the study population in the youth pre-DM/DM data set overall and by pre-DM/DM status. More detailed statistics for all the variables in our data set can be found in the Data Exploration section of POND.

\(b\) Pre-DM/DM: pre–diabetes mellitus and diabetes mellitus.

\(c\) CHIP: child health insurance program.

\(d\) Hypertensive was defined by blood pressure ≥90th percentile or ≥120/80 mm Hg for children 13 years of age and older [2].

\(e\) eq: equivalent.
Validation of the Study Population

We estimated that the survey-weighted prevalence of pre-DM/DM in our study population rose substantially from 4.1% (95% CI 2.8-5.4) in 1999 to 22% (95% CI 18.5-25.6) in 2018 (Figure S3 and section S6 in Multimedia Appendix 1). This increasing trend of pre-DM/DM prevalence was consistent with that reported in other NHANES-based studies, which had pre-DM/DM prevalence ranging from 17.7% to 18% [18,19]. We also applied the study population and pre-DM definition criteria reported in a recent study [13] to NHANES data and derived a similarly sized study population (n=6656 vs n=6598 in the current vs previous analysis [13]) and youth pre-DM prevalence, which ranged from 11.1% (95% CI 8.9-13.3) to 37.3% (95% CI 31.0-43.6) in our analysis compared with from 11.6% (95% CI 9.5-14.1) to 28.2% (95% CI 23.3-33.6) in the study by Liu et al [13] (Table S6 in Multimedia Appendix 1).

Youth Pre-DM/DM-Focused Data Set

We extracted 95 epidemiological variables from NHANES and organized them into 4 pre-DM/DM-related domains, namely, sociodemographic, health status, diet, and other lifestyle behaviors (Table S1 in Multimedia Appendix 1). Table 1 shows the unweighted statistics of some key study population characteristics. Among youth with pre-DM/DM (n=2010), the proportion of youth who were non-Hispanic Black, non-Hispanic White, Hispanic, and other race or ethnicity (including non-Hispanic persons who reported races other than Black or White and non-Hispanic Asian) were 33.6% (n=676), 21.4% (n=431), 35.4% (n=711), and 9.6% (n=192), respectively.

Approximately, half (7719/15,149, 51%) of the population were male, and they represented 65.6% (1319/2010) of those with pre-DM/DM. Approximately 32.4% (4528/15,149) of the youth had a family income below poverty level, and 69.4% (7833/15,149) were from households receiving food stamps. The proportion of youth covered by private insurance was higher among those with than with no pre-DM/DM (5648/13,139, 43.8% vs 744/2010, 37.7%). Overall, 21.5% (3214/15,149) of the youth were obese as defined by having a BMI at or above the 95th percentile based on age and gender, and the proportion was 33.3% (663/2010) among youth with pre-DM/DM. Youth with pre-DM/DM tended to have less fruit and vegetable intake and ate lower amounts of protein and total grains than those with no pre-DM/DM. Youth with and with no pre-DM/DM showed similar amounts of physical activity with 209 and 210 minutes per week, respectively (Table 1).

Pre-DM/DM in Youth Online Dashboard

To facilitate other researchers’ use of our youth pre-DM/DM data set and make our methodology transparent and reproducible, we developed POND, which is available on [47]. Users can navigate POND through its built-in functionalities. For example, users are able to explore the details of the 95 individual variables (Figure 3A) and their distributions by pre-DM/DM status (Figure 3B), examine the risk factors of youth pre-DM/DM identified from the case studies described below (Figure 3C), as well as download the data for customized analysis and the analytical code to replicate our findings (Figure 3D). In addition, we make available all the code used to develop the data set, our case studies, and POND itself.

Figure 3. Screenshots of different functionalities available in POND (Prediabetes/diabetes in youth Online Dashboard). (A) Detailed dictionary of the 95 variables included in our youth pre-DM/DM database organized by 4 domains. (B) Data exploration section showing the distribution of user-selectable variables by pre-DM/DM status. (C) Case study section detailing the results of bivariate association analyses and the prediction of youth pre-DM/DM status from machine learning approaches. Case Studies Using Our Data Set to Better Understand Youth Pre-DM/DM

Overview

We examined the validity and use of our processed multidomain data set for translational studies on youth pre-DM/DM by the following 2 complementary types of data analyses.

Identifying Individual Variables Associated With Pre-DM/DM Status

In our bivariate analyses, we found 27 variables to be significantly ($P < .001$, Bonferroni adjusted) associated with pre-DM/DM status (Figure 4 and Table S7 in Multimedia Appendix 1). These variables spanned all 4 domains and included gender, race or ethnicity, use of food stamps, health insurance status, BMI, total protein intake, and screen time. Similar results were found when repeating these bivariate association tests after accounting for NHANES survey design elements (Table S7 in Multimedia Appendix 1).

Predicting Youth Pre-DM/DM Status With ML

We used an ML framework, EI [53,54], to leverage the multidomain nature of our data set and predict youth pre-DM/DM status. We also compared EI’s performance with alternative prediction approaches, most prominently the widely used XGBoost algorithm [71].

The best-performing multidomain EI methodology, stacking [75] using logistic regression, predicted youth pre-DM/DM status (AUROC=0.67; BA=0.62) more accurately than all the alternative approaches (Figure 5), namely, XGBoost (AUROC=0.64; BA=0.60; Wilcoxon rank sum FDR=1.7×10^4 and 1.8×10^4, respectively), the ADA pediatric screening guidelines (AUROC=0.57, BA=0.57; Wilcoxon rank sum FDR=1.7×10^4 and 1.8×10^4, respectively), and 4 single-domain EI (AUROC=0.63-0.54; BA=0.60-0.53; FDR <1.7×10^4 and 1.8×10^4, respectively).

The multidomain EI also identified 27 variables (the same as the number of significant variables from bivariate analyses) that contributed the most to predicting youth pre-DM/DM status. Among these variables, 16 overlapped with those identified from the bivariate statistical analyses (Figure 6; Fisher $P$ of overlap=7.06×10^-6). These variables identified by both approaches included some established pre-DM/DM risk factors such as BMI and high total cholesterol, as well as some less-recognized ones such as screen time and taking prescription drugs [2].
Figure 5. Comparison of the performance of multiple approaches for predicting youth pre-DM/DM status based on machine learning approaches. We compared the performance of the multidomain Ensemble Integration (EI) approach with 3 alternative prediction approaches. The alternative approaches were (1) a modified form of the American Diabetes Association (ADA) screening guideline (vertical red line), (2) single-domain EI-based prediction based on each of the 4 individual domains, and (3) the commonly used extreme gradient boosting (XGBoost) algorithm applied to our whole data set. Performance was measured in terms of the area under the receiver operating characteristic curve and balanced accuracy (average of sensitivity and specificity) measures. For each machine learning approach, the horizontal bar shows the average of the corresponding scores and the error bar indicates the corresponding standard error measured over 10 rounds of 5-fold cross-validation. AUROC: area under the receiver operating characteristic curve; EI: Ensemble Integration.

Figure 6. Variables associated with youth pre-DM/DM selected by bivariate analyses and the multidomain Ensemble Integration (EI) approaches. Venn diagram summarizing the overlap between the 27 significant variables identified in the bivariate analyses and the 27 most predictive variables identified from the multidomain EI model. We found that 16 variables overlapped between the 2 methods (Fisher $P=7.60\times10^{-6}$) and were drawn from all 4 domains (shown in different colors), indicating the multifactorial nature of youth pre-DM/DM. DM: diabetes mellitus; HH: household; ML: machine learning.
Discussion

Principal Findings

Leveraging the rich information in NHANES spanning nearly 20 years, we built the most comprehensive epidemiological data set for studying youth pre-DM/DM. We accomplished this by selecting and harmonizing variables relevant to youth pre-DM/DM from sociodemographic, health status, diet, and other lifestyle behaviors domains. This youth pre-DM/DM data set, as well as several functionalities to explore and analyze it, is publicly available in our user-friendly web portal, POND. We also conducted case studies using the data set with both traditional statistical methods and ML approaches to demonstrate the potential of using this data set to identify factors relevant to youth pre-DM/DM. The combination of the comprehensive public data set and POND provides avenues for more informed investigations of youth pre-DM/DM.

The future translational impact of pre-DM/DM research, facilitated by comprehensive data sets such as the one developed in this study, holds significant promise for advancing our understanding of the disease and its risk factors among youth. By enabling researchers to investigate multifactorial variables associated with pre-DM/DM, this data set contributes to several areas of research and has a broader impact on the scientific community. First, the data set’s comprehensive nature allows researchers to explore the collective impact of various risk factors across multiple health domains. By incorporating sociodemographic factors, health status indicators, diet, and lifestyle behaviors, researchers can gain a holistic understanding of the interplay between these factors and pre-DM/DM risk among youth. This knowledge can be used to generate hypotheses for further studies and inform the development of targeted interventions and prevention strategies that address the specific needs of at-risk populations. Furthermore, the data set provides an opportunity to delve into less-studied variables and their interactions in relation to pre-DM/DM risk. Variables such as screen time, acculturation, or frequency of eating out, which are often overlooked in traditional research, can be examined to uncover their potential influence on pre-DM/DM risk among youth. This expands the scope of translational research and enhances our understanding of the multifaceted nature of the disease.

One of the major contributions of our work was POND, our publicly available web portal, which provided access to all materials related to our data set and analyses, thus enabling transparency and reproducibility. Although several such portals are available in other biomedical areas, such as genomics [76-78], there is a general lack of such tools in epidemiology and public health. We hope that, in addition to facilitating studies into pre-DM/DM, POND illustrates the use of such portals for population and epidemiological studies as well.

The results of the case studies and validation exercises we conducted were also consistent with existing literature. The case studies identified known pre-DM/DM risk factors, such as gender [15,17,19], race and ethnicity [2,9,10,24], health measures (BMI, hypertension, and cholesterol) [2,55], income [9,11], insurance status [9,10], and health care availability [9,10], thus affirming the validity of the data set. In addition, our analyses revealed some less studied variables, such as screen time, home ownership status, self-reported health status, soy and nut consumption, and frequency of school meal intake, which may influence youth pre-DM/DM risk. Further study of these variables may reveal new knowledge about pre-DM/DM among youth. More generally, such novel findings further demonstrate the use of our data set and data-driven methods for further translational discoveries about this complex disorder.

Limitations

Although our work has several strengths and high potential use for youth pre-DM/DM studies, it is not without limitations. First, as our data set was derived from NHANES, we adopt limitations to the survey in our data set. Since NHANES is a cross-sectional survey, the pre-DM/DM status and its related variables provide only consecutive snapshots of youth in the United States over time across the available survey cycles. Thus, the associations identified are better suited for hypothesis generation purposes and require in-depth investigation using prospective longitudinal and randomized trial designs. In addition, we modified the ADA guideline for determining pre-DM/DM status according to variable availability. Due to the high missingness of 45% in family history (DIQ70) and the complete missingness of maternal history (DIQ175S) from 1999 to 2010 in the raw NHANES data, we were unable to include family history of diabetes in the data set. Similarly, NHANES does not provide data regarding every condition associated with insulin resistance. Therefore, we used hypertension and high cholesterol as proxies for insulin resistance. On the other hand, as our main purpose is to use POND as a conduit between this comprehensive youth pre-DM/DM database and interested researchers, our method can be adopted to longitudinal data sets should they become available in the future. Second, for the prediction of pre-DM/DM status, EI’s performance was found to be significantly better than the alternative approaches, including a modified form of the suggested guideline [45]. However, this performance assessment was based only on cross-validation, which is no substitute for validation on external data sets that is necessary for rigorous assessment. Finally, while our preliminary case study analyses identified a wide range of variables associated with youth prediabetes and diabetes, other known risk factors, such as current asthma status [80-82], added sugar consumption [83-85], sugary fruit and juice intake [83-86], and physical activity per week [6-8,50], were not identified. This limitation can be addressed by using other data analysis methods beyond our bivariate testing and ML approaches, highlighting more potential use cases of our data set.

Conclusions

Overall, the future impact of translational pre-DM/DM research facilitated by comprehensive data sets and web servers like ours extends beyond individual studies. It creates opportunities for interdisciplinary collaboration and reproducibility, strengthens evidence-based decision-making, and supports the development of targeted interventions for the prevention and management of pre-DM/DM among youth. By providing rich resources, our work can enable researchers to build upon existing knowledge.
and push the boundaries of translational pre-DM/DM research, ultimately leading to improved health outcomes for at-risk populations.

Acknowledgments
This study was enabled in part by computational resources provided by Scientific Computing and Data at the Icahn School of Medicine at Mount Sinai. The Ensemble Integration used in this work was implemented by Jamie JR Bennett. This work was funded by National Institutes of Health grants R21DK131555 and R01HG011407.

Data Availability
The data set and code used in this study are available at Zenodo [87] and our web portal POND [47].

Authors' Contributions
BL and GP contributed equally as cosenior and cosupervisory authors. NV, BL, and GP conceptualized the project. CM, YCL, NV, BL, and GP designed the methodology. CM and BL implemented the data curation and bivariate analyses. YCL implemented the ML case study and POND. CM and YCL conducted formal analysis and visualization. CM, YCL, NV, BL, and GP wrote the manuscript. NV, BL, and GP supervised the project.

Abstract

Background: The worldwide incidence of Crohn disease (CD) in childhood and adolescence has an increasing trend, with significant differences between different geographic regions and individual countries. This includes an increase in the incidence of CD in countries and geographic regions where CD was not previously prevalent. In response to the increasing incidence, the pediatric care landscape is facing growing challenges.

Objective: This systematic review and meta-analysis were undertaken to comprehensively delineate the incidence rates of CD in pediatric populations across different countries and to explore potential influencing factors.

Methods: We performed a systematic review of PubMed and Embase (via Ovid) for studies from January 1, 1970, to December 31, 2019. In addition, a manual search was performed in relevant and previously published reviews. The results were evaluated quantitatively. For this purpose, random effects meta-analyses and meta-regressions were performed to investigate the overall incidence rate and possible factors influencing the incidence.

Results: A qualitative synthesis of 74 studies was performed, with 72 studies included in the meta-analyses and 52 in the meta-regressions. The results of our meta-analysis showed significant heterogeneity between the individual studies, which cannot be explained by a sample effect alone. Our findings showed geographical differences in incidence rates, which increased with increasing distance from the equator, although no global temporal trend was apparent. The meta-regression analysis also identified geographic location, UV index, and Human Development Index as significant moderators associated with CD incidence.

Conclusions: Our results suggest that pediatric CD incidence has increased in many countries since 1970 but varies widely with geographic location, which may pose challenges to the respective health care systems. We identified geographic, environmental, and socioeconomic factors that contribute to the observed heterogeneity in incidence rates. These results can serve as a basis for future research. To this end, implementations of internationally standardized and interoperable registries combined with the dissemination of health data through federated networks based on a common data model, such as the Observational Medical
Outcomes Partnership, would be beneficial. This would deepen the understanding of CD and promote evidence-based approaches to preventive and interventional strategies as well as inform public health policies aimed at addressing the increasing burden of CD in children and adolescents.

## Introduction

Crohn disease (CD), ulcerative colitis (UC), and indeterminate colitis are chronic inflammations of the gastrointestinal tract and are summarized under inflammatory bowel disease (IBD). Since the beginning of the 21st century, a progression in incidence, mainly due to CD, has been observed in both industrialized and emerging countries [1,2]. IBD is an immune-mediated disease that can affect people of all ages. However, about 20% of IBD cases are diagnosed before one is 20 years old, with an adverse shift in the age of diagnosis to early childhood years. Approximately 25% of children and adolescents are younger than 10 years at diagnosis and 4% are younger than 5 years [2-5]. International epidemiologic data on CD vary considerably concerning the country and calendar year, and temporal trends are also controversial [1,6]. With an annual incidence of IBD of 5 to 11 per 100,000 children and adolescents, pediatrics face growing problems [3,5,7]. The incidence of CD is significantly higher compared to UC [1,8]; therefore, the following will focus on CD.

The etiology of CD is still not definitively understood. However, the etiology seems to be multifactorial and consists of an interaction of genetic, environmental, and lifestyle factors [9-11]. For IBD, the Western lifestyle has been discussed as the cause of CD for some time [12,13]. A similar international progression of incidence has also been observed for other immune-mediated chronic diseases, and differences have been made about the influence of the Western lifestyle as measured by socioeconomic factors. For example, in their meta-analysis of diabetic ketoacidosis in type 1 diabetes, Große et al [14] identified an association between incidence and geographic as well as socioeconomic factors. Several studies also reported variations between incidence and geographic latitude for IBD [10,15]. The increase in CD incidence with latitude supports the hypothesis that higher residential sun exposure is associated with a lower risk of IBD. The results of these studies have been interpreted to suggest that low vitamin D status may be a risk factor for IBD [16]. The prevalence of vitamin D deficiency is global. Available data suggest that it occurs regardless of the development of the respective countries or the geographic latitude. Accordingly, consistent evidence indicates that the prevalence of vitamin D deficiency is highest in Asia, the Middle East, Africa, and countries with higher latitudes [17,18]. The medical and health-economic relevance of treating children and adolescents with IBD continues and is based on observations in several international studies, with the result that the number of pediatric IBD has increased and the onset of the disease seems to be shifting to early childhood. The impact of this shift in new cases is associated with a high individual as well as the societal burden of disease and will place a heavy burden on the respective health care systems [5,13,19,20]. This study aims to describe global trends in the incidence of CD since 1970 and to identify possible factors influencing the increasing incidence.

## Methods

### Study Design

A systematic review was conducted for IBD disorders. Studies were initially included from 1970 to 2019. To improve transparency in methodology, the study protocol for this review was published as “Study Protocol Epidemiology of Inflammatory Bowel Disease in Childhood and Adolescence: a Systematic Review” [21].

This systematic literature search was performed in the PubMed and Embase databases via Ovid. In addition, a manual search was performed in bibliographies of previously published and relevant systematic reviews. For detailed methodology and screening of this systematic review, we refer to the published study protocol [21].

For this study, we updated the previous systematic review from 2019 and 2020 to 2022. In this update, which was carried out until August 2022, we used the same search term as before but also included studies published up to December 31, 2021, which covered the observation period from 1970 to 2019. The complete search strategy can be viewed in Multimedia Appendix 1. The inclusion and exclusion criteria shown in Table 1 were defined for this study.
In addition, we used the mean latitude to calculate the absolute distance to the equator irrespective of the northern or southern location [15]. We extracted the UVI from the United Nations Sustainable Development Goals data from the World Health Organization database [93].

The second dimension of possible moderators included socioeconomic factors. For this purpose, we used the percentage of gross domestic product (GDP) spent on health, which we extracted from the Organisation for Economic Co-operation and Development database “Health expenditure and financing” [94]. The Human Development Index (HDI) was included in the analysis as another possible moderator. The HDI assesses a country’s developmental state and combines life expectancy at birth, expected years of schooling, and gross national income per capita [95]. The values relevant to this study were extracted from the United Nations Development Programme’s Human Development Reports [95] from 1990 onward and averaged for statistical analysis. In addition, data on the GDP of the respective included countries from the GENESIS database of the Federal Statistical Office were used for further moderator analysis [96]. Furthermore, the universal health coverage (UHC) service coverage index Sustainable Development Goals 3.8.1 was extracted from the World Health Organization database [93]. UHC quantifies coverage of essential health services and is defined as the average coverage based on tracer interventions that include reproductive, maternal, newborn, child health, infectious diseases, noncommunicable diseases, service capacity, and access among the population [97].

**Statistical Analysis**

We performed random-effects meta-analyses and meta-regressions to assess the variability of incidence rates. Analysis was performed with R (version 4.2.1.; R Foundation for Statistical Computing) software using the `metafor` package version 3.8-1 [98]. Meta-analysis was performed on a log scale (log incidence rates) using the general inverse variance method. Random effects and the extent of heterogeneity were estimated using the restricted maximum likelihood estimator. For the meta-regression, a multivariate model was constructed to control for multiple factors and to account for potential confounders.

The title and abstract screening and the full-text screening were carried out independently by 2 project participants. The extraction of the data and the corresponding consistency checks were also carried out by 2 project participants. In case of disagreement, a third project participant was consulted for mediation. All included studies were evaluated for study quality. The critical appraisal tools Critical Assessment of Structure Prediction and Scottish Intercollegiate Guidelines Network were used for this purpose. In addition, a risk of bias analysis, following the procedure described in the Cochrane Handbook [22], was performed (see Multimedia Appendix 2 [5-7,23-92]). Studies of poor quality were not excluded from the quantitative synthesis to avoid loss of information.

**Ethical Considerations**

An ethics vote was not required for this systematic review because patients were not directly involved in this study.

**Data Extraction**

All included studies were independently screened for incidence rates and study characteristics using a standardized table summary of findings. In case of missing data, contact with the authors was made. The data were exported to a database and processed for statistical analysis. For studies by 1 author that reported multiple incidence rates for children and adolescents, the mean values of incidence rates and study sizes were calculated for the respective observation period.

For the planned meta-regression, we classified possible moderators of heterogeneity into 2 dimensions: geographic and environmental factors on the one hand, and socioeconomic factors on the other. Longitude and latitude as well as exposure to UV sunlight (UV radiation index [UVI]) were assigned to the first dimension of geographical and environmental factors. The geographic data were extracted from Geoplaner (version 3.1; Martin Nathensen). When studies are nationwide or involve multiple centers within a country, the mean latitude value applied to the corresponding country or area was considered. In addition, we used the mean latitude to calculate the absolute

https://publichealth.jmir.org/2024/1/e48682
identify further moderators of heterogeneity in incidence rates. The pooled incidence rates for each observation period formed the dependent variable. The observation period for each study was averaged and assigned as the starting time of the given study. The absolute distance of the included countries from the equator, UVI, HDI, health expenditure as a percentage of GDP, GDP, and UHC were included as additional independent variables in the regression model. In addition to the estimate of $\tau^2$, the Q-test for heterogeneity and the $I^2$ statistic are reported. The $I^2$ value was interpreted according to Higgins and Thompson [99] as follows: 0% to 40%, possibly insignificant; 30% to 60%, moderate heterogeneity; 50% to 90%, substantial heterogeneity; and 75% to 100%, considerable heterogeneity [99]. The influence of the moderators was evaluated using the $R^2$ statistic as a measure of the explained heterogeneity. An a priori significance level of 0.05 (5%) was set for all statistical methods. To control the risk of publication bias, statistical methods such as the Egger regression test and the rank correlation test were applied to quantitatively assess the risk of publication bias. In addition, we applied the trim-and-fill analysis and the fail-safe N-analysis (Rosenberg method) to consider and control the potential risk of publication bias.

Results

Data Basis and General Assessment of Studies

A total of 3153 studies were found from the previous systematic search conducted in 2019. The update of the systematic literature search yielded another 83 records. After removing duplicates, 77 studies were screened in the systematic literature search update. Another 5 studies from the update were included in the qualitative and quantitative synthesis. In total, the systematic literature research resulted in 81 findings from 29 countries with the search terms CD, UC, and indeterminate colitis. CD was the subject of a total of 74 studies, which were included in the qualitative synthesis of this work. Further, 2 studies had to be excluded retrospectively due to the lack of population reference. The meta-analysis included 72 studies from 26 countries and the meta-regression included 52 studies (Figure 1 [100]). The references of the included studies and a table summary of included studies can be viewed in Multimedia Appendices 3 [6,7,23-75,77-92] and 4 [7,23-75,77-92,101].

In the 72 studies eligible for meta-analysis, the incidence rates on the linear scale varied from 0.14/10^5 to 11.40/10^5. Performing a random-effects meta-analysis revealed that the overall mean incidence rate was 2.64/10^5 (95% CI 2.09 to 3.34; on log-scale –10.54, 95% CI –10.78 to –10.31), whereas the $I^2$ value of 97.88% suggests that the substantial heterogeneity of this study’s results cannot be explained by a sampling effect alone (Multimedia Appendix 5 [5-7,23-92]). In the following, we set out to identify factors that can account for the substantial dispersion in study results. Interestingly, the individual weights for each study were largely dominated by the contribution of the between-study variance while the study-specific variance (ie, the sampling effect) had a smaller effect. Consequently, the
studies in the random-effects meta-analysis have rather similar relative weights.

**Time as a Moderator of CD Incidence**

We included studies from a 50-year observation period, from 1970 to 2019. To assess whether the time point of this study influenced the CD incidence, we performed a meta-regression in which time is considered the continuous variable, whereas incidence rates are the dependent variable. Figure 2 confirms that the moderator time has no significant effect on incidence rates for CD. Moreover, time as a moderator cannot explain the heterogeneity, so the remaining heterogeneity remains substantial (test of moderators $P=0.39; I^2=97.85\%; R^2=0.00$; see also Multimedia Appendix 6-11 [5-7,23-92] subgroup analysis incidence CD in 10-year steps). These results suggest that there must be other moderators to explain the observed heterogeneity. Figure 2 also displays a slight negative trend with a simultaneous increase in heterogeneity. Some of the studies with low incidence values (depicted in the lower right corner) are from Taiwan, Finland, Saudi Arabia, Mexico, and Argentina, reinforcing the impression of greater geographical division. In the next step, we specifically examine the influence of the geographic component on CD incidence rates.

**Figure 2.** Meta-regression: incidence over time: dependent variable incidence CD, independent variable time, bubbles symbolize the studies that have been included, with each bubble’s size corresponding to the weighting assigned to the respective study (k=72, estimator: REML): test of moderators $F_{\text{test}}=0.71; P=0.39; I^2=97.85\%$; variance explanation via $R^2 \%$. CD: Crohn disease; REML: restricted maximum likelihood.

**Geographical and Environmental Factors as Moderators of CD Incidence Rates**

It is interesting to see that the highest mean incidence rates per 100,000 children and adolescents during the observation period from 1970 to 2019 were observed in Australia (11.12 new cases/10⁵), Finland (6.31/10⁵), Canada (7.12/10⁵), Germany (6.15/10⁵), and New Zealand (6.07/10⁵). The lowest incidence rates were reported in studies from countries in Asia and South America. Strikingly, an incidence of CD almost twice as high was reported in Australia compared to the other included countries (Figure 3 and forest plot geographic variation in incidence rates of CD in Multimedia Appendix 12). These data suggest geographic heterogeneity, which we first consider at the continental level.
Indeed, a meta-regression with the variable *continents* indicated that 41.34% of the heterogeneity can be explained. The test for moderators is significant ($P<.001$). Comparing this regression model with a more complex model in which we added the factor *time* to the moderator *continents*, an ANOVA showed no significant model improvement, confirming the notion that time does not act as a major moderator. In a further step, we examined the development of the incidence of CD over time for each continent individually. The results of this analysis suggest that the incidence of CD has developed differently in relation to the continents. Increasing trends were noted for North America, Europe, and Asia. For South America and Australia or the Pacific region, we found no confirmation of increasing incidence because of too few data points (see Multimedia Appendices 13 and 14).

The results also suggest that distance from the equator may affect the incidence of CD. A corresponding meta-regression, which included *absolute distance from the equator* as a moderator, showed that CD incidence increased significantly with increasing distance from the equator (Figure 4). Extrapolated to 1000 km, the incidence rate increased by 0.36%. The test for moderators yielded a significant result ($P<.001$). However, given the considerable heterogeneity in study results, distance from the equator formally contributed only moderately to better explain this variance ($R^2=29.14\%$; Table 1 and Figure 4). We found similar results when we recalculated the analysis for the *country-specific UVI* instead of the *absolute distance from the equator*. The results show that incidence rates decrease with increasing UV exposure. The results with this factor were significant in the test of moderators ($P<.001$) and 18.57% heterogeneity was resolved (Table 1 and Figure 4). Given the correlation between the moderators of absolute distance from the equator and UVI ($r=-0.87$, $P<.001$), we refrained from a joint regression model to avoid problems of collinearity and unreliable coefficient estimates.
Figure 4. Meta-regression, (A) increasing incidence with increasing distance from the equator; variable incidence CD, independent variable absolute distance from the equator (k=52, estimator: REML): test of moderators F test=18.78; P<.001; I²=96.29%; variance explanation via R² 29.14%. (B) Decreasing incidence with increasing UVI; variable incidence CD, independent variable UVI (k=52, estimator: REML): test of moderators F test=11.35; P<.001; I²=96.94%; variance explanation via R² 18.57%; bubbles symbolize the studies that have been included, with each bubble’s size corresponding to the weighting assigned to the respective study. CD: Crohn disease; REML: restricted maximum likelihood; UV: ultraviolet; UVI: ultraviolet radiation index.

Socioeconomic Factors as Moderators of CD Incidence Rates

In the next step, we investigated the extent to which socioeconomic factors could be considered moderators of heterogeneity. The results of the corresponding meta-regression showed that the HDI, health expenditure as a percent of GDP, and the UHC index acted as moderators. Accordingly, the frequency of CD increases with increasing values of each moderator (Table 2 and Figure 5). To avoid issues with collinearity and unreliable coefficient estimates resulting from the correlations between the socioeconomic factors, we decided not to use a joint regression model.

Table 2. Meta-regression results. Dependent variable: incidences CD⁵; independent variables: absolute distance to the equator and UVI⁶. ME⁷ model (k=52, estimator: REML⁸).

**Multifactorial Regression Model to Explain CD Incidence Rates**

In our analysis, we identified different widely independent factors - study timing, absolute distance from the equator, and HDI or UHC - as univariate moderators of CD incidence rates. To explain the high degree of heterogeneity between studies that we observed during the analyzed study period, we used a multifactorial meta-regression model that accounted for these complementary moderators as the final step of our investigation. As a result, the corresponding model showed a joint R² of 62.5%, indicating that almost two-thirds of the heterogeneity can be explained by these 3 moderators. The test for moderators was significant at P<.001 (see Tables 3 and 4).

Discussion

Our systematic review with meta-analysis and meta-regression examined global trends in the incidence of CD. Although several individual studies reported an increase in incidence rates for CD in a certain (national) cohort, few high-quality studies were able to substantiate and quantify such an increase (risk of bias analysis in Multimedia Appendix 2). Furthermore, some of the studies reporting temporal trends in CD incidence rates were controversially discussed [1,6]. Different study designs also made it difficult to compare incidence rates over time, which may further contribute to the substantial heterogeneity in incidence rates.

In this systematic review, we evaluated a total of 72 studies from 26 countries on the incidence of CD over a 50-year observation period. We found substantial heterogeneity in incidence rates, which was confirmed by meta-analysis using a random effects model (Cochrane Q=3349.38; P<.001; R\(^2\)=97.88%). Despite the large heterogeneity of the data, we obtained several interesting results. First, we found no clear evidence of a general global trend toward increasing CD incidence rates over time. While incidence rates might increase within individual countries, it rather appears that the inclusion of studies from a broader range of countries also increases the overall between-study heterogeneity to the extent that a global temporal trend is not identifiable. While incidence rates might increase within individual countries, it rather appears that the inclusion of studies from a broader range of countries also increases the overall between-study heterogeneity to the extent that a global temporal trend is not identifiable. This might be a result of differences in methodology and how individual studies reported incidence rates over time and needs further investigation in future research. The fact that little data were available in certain regions may also have contributed to the fact that a global trend over time was not discernible from our analyses. Kuenzig et al [102] reported similar issues in this regard. Due to the different reporting of incidence rates of IBD in childhood and adolescence, they also had difficulties in describing a clear temporal trend. Second, we observed a dependency of the incidence rates on the geographic location, with increasing incidence for countries that are further away from the equator. Third, we observed a similar effect for several socioeconomic factors, in which higher scores correlated significantly with higher CD incidence rates.

Regarding the geographic differences in incidence rates of CD, several studies reported a north-south gradient. For example, Nerich et al [15] reported the effects of latitude on the geographic distribution of CD. However, quantification of the gradient by latitude was not performed. Armitage et al [23] similarly reported a significant north-south gradient for CD in Scotland. Since recent epidemiologic studies have reported an increasing incidence of IBD worldwide, including in southern countries, particularly also in the southern hemisphere [2,103], we decided to use absolute distance from the equator as a factor to represent and quantify a relationship between incidence and geographic location. The result of our meta-regression showed that incidence rates increased with increasing distance from the equator. This result corresponds with the results of our further analysis of possible moderators of incidence rates. We found that countries with a high UVI, other than Australia, have a lower incidence of CD. Our results correlate with findings from other studies showing that higher exposure to UV radiation, or sunlight, is associated with a lower risk of CD and IBD [16,104]. In our results, Australia stood out with a high incidence. Although Australia is considered sun-rich, 17% of Australian adolescents have vitamin D deficiency [104]. Vitamin D is formed in the skin when exposed to UV radiation. We therefore suspect a correlation between vitamin D status and the incidence of CD. Further studies should therefore examine in particular whether a low vitamin D status is a risk factor for CD or IBD or a consequence. However, studies show that patients with IBD and especially CD also show a low vitamin D status and indicate a correlation with disease activity. Unfortunately, disentangling causality and correlation is an unresolved challenge in the ongoing debate about the interplay between vitamin D and IBD [105-107].

Although latitude or absolute distance from the equator and UV exposure are correlated, they cannot be fully replaced in our statistical analysis.

Our results concerning the socioeconomic factors contribute to the hypothesis that CD might correlate with industrialized, urbanized societies, largely due to a Western lifestyle and other associated environmental factors [13] which themselves go along with higher socioeconomic scores. It is also known that...
the incidence and prevalence of CD vary between countries with different HDIs [108-110]. Although there are few epidemiologic studies of CD in low- and middle-income countries, the incidence of CD is increasing significantly worldwide, affecting even countries previously considered to be at low risk [103,111]. It has been observed that the incidence and prevalence in middle-income countries are also increasing in children and adolescents, which has been attributed to the rapid modernization and Westernization of the population [13]. Our findings seem to follow a global pattern, namely that the process of industrialization has an impact on the incidence of CD. In this regard, we also follow the view of Takahashi et al [109] and Ananthakrishnan et al [103] that the level of development of countries and Western lifestyles are related to the level of incidence. However, causality cannot be inferred from our study. Further research is needed for this purpose. In recent times, there has been a growing significance attributed to observational research conducted on real-world data, leading to the establishment of global research networks, exemplified by the Observational Health Data Sciences and Informatics community. These networks aim to facilitate large-scale studies grounded in the Observational Medical Outcomes Partnership (OMOP) common data model (CDM). Consequently, the use of observational studies that use real-world data is a valuable way to study CD and IBD in the future [112].

Limitations
This study is limited by the use of 2 databases for systematic literature search. Another limitation of this study is the exclusion of studies that were not published in English, Spanish, French, or German. Given that the included studies were mainly from countries with good access to the health care system (UHC >70), the underreporting of countries with poorer access to the health care system should be discussed. We controlled the risk of publication bias using the Eggers regression test, rank correlation test, trim and fill analysis, and fail-safe N analysis (Rosenberg method). Although these methods did not statistically indicate a bias due to publication bias, a small bias cannot be completely ruled out.

Conclusions
Based on available study data from 1970 to 2019, we could not identify a global, temporal trend toward increasing CD incidence rates, although these effects are reported for individual countries or regions. Instead, we could demonstrate that a substantial part of the observed heterogeneity between the published study results can be explained by geographic location and socioeconomic factors. Our study can be used to provide quantitative estimates of these trends for CD in childhood and adolescence. However, to establish causal relationships regarding potential risk factors, further studies are necessary, including those conducted in countries with lower levels of development. Nevertheless, our analysis provides valuable information to drive future research and health policies aiming to reduce the incidence of CD among children and adolescents. This needs continuous global monitoring of the incidence of IBD in childhood and adolescence to fully understand the trends in IBD incidence [102]. To this end, the implementation of internationally standardized and interoperable registries, coupled with the dissemination of health data via federated networks grounded on a CDM, such as the OMOP CDM, is deemed advantageous. The OMOP CDM aligns most closely with the requisites conducive to expediting data exchange within longitudinal studies [112,113]. The usage of such registries and data networks holds the potential to streamline the exhaustive and standardized accumulation as well as dissemination of data. This, in turn, would enhance our comprehension of CD and foster evidence-based approaches for preventive and interventional strategies.

Abstract

Background: A challenge in achieving the malaria-elimination target in the Greater Mekong Subregion, including Thailand, is the predominance of Plasmodium vivax malaria, which has shown extreme resilience to control measures.

Objective: This proof-of-concept study aimed to provide evidence for implementing primaquine mass drug administration (pMDA) as a strategy for P. vivax elimination in low-endemicity settings.

Methods: The study employed a mixed-methods trial to thoroughly evaluate the effectiveness, safety, acceptability, and community engagement of pMDA. The quantitative part was designed as a 2-period cluster-crossover randomized controlled trial. The intervention was pMDA augmented to the national prevention and control standards with directly observed treatment (DOT) by village health volunteers. The qualitative part employed in-depth interviews and brainstorming discussions. The study involved 7 clusters in 2 districts of 2 southern provinces in Thailand with persistently low P. vivax transmission. In the quantitative part, 5 cross-sectional blood surveys were conducted in both the pMDA and control groups before and 3 months after pMDA. The effectiveness of pMDA was determined by comparing the proportions of P. vivax infections per 1000 population between the 2 groups, with a multilevel zero-inflated negative binomial model adjusted for cluster and time as covariates and the interaction. The safety data comprised adverse events after drug administration. Thematic content analysis was used to assess the acceptability and engagement of stakeholders.

Results: In the pre-pMDA period, the proportions of P. vivax infections in the pMDA (n=1536) and control (n=1577) groups were 13.0 (95% CI 8.2-20.4) and 12.0 (95% CI 7.5-19.1), respectively. At month 3 post-pMDA, these proportions in the pMDA (n=1430) and control (n=1420) groups were 8.4 (95% CI 4.6-15.1) and 5.6 (95% CI 2.6-11.5), respectively. No statistically significant differences were found between the groups. The number of malaria cases reduced in all clusters in both groups, and
Conclusions: pMDA was associated with high adherence, safety, and tolerability, but it may not significantly impact \( P. vivax \) transmission. As this was a proof-of-concept study, we decided not to scale up the intervention with larger clusters and samples. An alternative approach involving a targeted primaquine treatment strategy with primaquine and DOT is currently being implemented. We experienced success regarding effective health care workforces at point-of-care centers, effective collaborations in the community, and commitment from authorities at local and national levels. Our efforts boosted the acceptability of the malaria-elimination initiative. Community engagement is recommended to achieve elimination targets.

Introduction

Background

As part of the World Health Organization (WHO) campaign for “zero malaria,” the Greater Mekong Subregion (GMS) of Southeast Asia has developed a strategic plan for regional malaria elimination by 2030, while Thailand aims to achieve this goal by 2024 [1,2]. One major challenge facing the GMS is the predominance of \( P. vivax \) malaria [3,4], which has shown extreme resilience to control measures [5,6]. Initiatives to eliminate malaria have an excellent impact on \( P. falciparum \) but not on \( P. vivax \) worldwide due to the various unique aspects of \( P. vivax \) biology. One challenge is asymptomatic infections with \( P. vivax \), which are undetected and untreated, potentially contributing to transmission over several weeks or months [7]. Asymptomatic infections are especially common in low-endemicity areas where control tools have reduced the malaria burden [8-10]. A study along the Thailand-Myanmar border noted that while the proportion of severe \( P. vivax \) malaria varied across different geographic regions and transmission settings, a significant proportion of the community had asymptomatic parasitemia, even in low-transmission areas [9].

The identification and appropriate treatment of asymptomatic infected individuals, who are typically missed by clinical case-based surveillance, have become critical for interrupting malaria transmission in the final elimination phase [11,12]. Several approaches have been proposed to accelerate \( P. vivax \) elimination, for example, novel serological test-and-treat interventions, radical cure strategies, case-centered surveillance and response systems, and mass drug administration (MDA) [13-15]. To deal with low blood parasitemia and the formation of hypnozoites associated with \( P. vivax \) infection that evade conventional diagnosis, presumptive preventive treatment of an endemic population by MDA using a hypnozoiticidal drug, such as primaquine, is often the chosen strategy to eliminate residual \( P. vivax \) transmission [15-17]. Large-scale MDA with pyrimethamine and PQ was associated with decreased \( P. vivax \) transmission in central and southern China [14].

The WHO mentioned the lessons learned from MDA implementation (so-called “mass primaquine preventive treatment [MPPT]”) in several temperate countries, for example, MPPT combined with vector control and other preventive measures resulted in the rapid containment of \( P. vivax \) epidemics and may have contributed to the interruption of transmission in low-transmission settings [18]. Prior to 2019, there were no data on the implementation of MPPT in tropical and subtropical areas. In 2019, when this project started in Thailand, the WHO reported 2 MDA studies in the GMS with differing results, with one study demonstrating only a short-term reduction in \( P. vivax \) transmission and the other study finding no effect [18]. It appears that MDA with PQ has been successful in eliminating \( P. vivax \) in the temperate zone [11,15,19,20], but its applicability and effectiveness for eliminating \( P. vivax \) in tropical countries remain to be evaluated.

Therefore, as part of the International Center of Excellence for Malaria Research (ICEMR) project, supported by the US National Institutes of Health (U19 AI089672), this study was conducted to evaluate the effectiveness, safety, and acceptability of MDA with PQ in low-endemicity areas in a tropical country. Particularly, this study was considered a proof-of-concept evaluation of MDA with PQ (termed primaquine mass drug administration [pMDA]) using a cluster-crossover randomized trial design to provide the evidence base for designing and implementing a pMDA strategy in low-malaria-endemic settings in Thailand. With the planning of the pMDA strategy by the National Malaria Control Program in Thailand, we also sought to critically assess the acceptability and engagement of stakeholders at various levels. According to the main ICEMR project, if pMDA (phase I) was proven to be effective, safe, and acceptable, the pMDA intervention would be scaled up to cover over 100,000 villagers in 200 clusters in 8 provinces (phase II) using a stepped-wedge design to provide a statistically robust evaluation of pMDA.

Objectives

The goal of this proof-of-concept study was to thoroughly assess the effectiveness, safety, acceptability, and community engagement of pMDA as a strategy for malaria elimination in Thailand. The specific aims were as follows: (1) to compare the...
proportions of P. vivax infections between communities under the national standard of prevention and control (SPC) program and communities under the SPC program augmented with pMDA, (2) to assess the safety of PQ implemented in the communities, and (3) to assess the acceptability and stakeholder engagement of the pMDA intervention for possible scale-up to phase II.

Methods

Trial Design
The study employed a mixed-method design comprising quantitative and qualitative approaches. The quantitative part, which was used for assessing the effectiveness and safety of the pMDA intervention, adopted a cluster-crossover randomized controlled design, a modified cluster randomized design, which is particularly feasible in pragmatic clinical trials in health care systems [21,22]. This design was selected as it is suitable for determining the effectiveness of a routinely used intervention in health care practice, in which the intervention is randomized (turned on and off) at the community level instead of the individual level [23]. In this study, clusters were randomized to a sequence of treatment conditions. A group of clusters received pMDA in the first period (year 1) and the SPC program in the second period (year 2), while the other group of clusters received these preventive activities in reverse order.

The qualitative part, which was used for assessing the acceptability and stakeholder engagement of the pMDA intervention, used in-depth interviews (IDIs) and brainstorming sessions among stakeholders. Stakeholders were primarily sensitized before the study started and informed regularly during the study period.

Settings and Locations
The study was conducted in 2 districts of 2 southern provinces in Thailand (Yala and Narathiwat), which had persistently low P. vivax malaria transmission. The study sites comprised 7 purposively selected villages, the smallest administrative unit in Thailand, with each typically having about 200-400 residents. The 7 villages were selected according to their reported malaria incidences in 2018 from routine passive case detection in the malaria surveillance system of Thailand (unpublished data). Five villages (#1, 2, 4, 5, and 6) were in Yala Province, with P. vivax incidence rates of 4%-7%, and 2 had unexpectedly high rates (over 30%) in 2018. Two villages (#3 and 7) were in Narathiwat Province, with P. vivax incidence rates of 1%-2%. For the study design, one group of villages served as the pMDA treatment group, while the other served as the control group. In the following year, the intervention was swapped between the 2 groups of villages. A map showing locations and distances among the 2 sets of 7 clusters (clusters 1-3 vs clusters 4-7) in the 2 provinces is presented in Figure 1. The nearest distances between 2 sets of clusters were 3.7-4.5 km. It should be noted that primary health care management in each village was independent. On average, a village health volunteer (VHV) is responsible for providing health care services to 10 households in the village. Each VHV assists the local health workers in promoting health, preventing diseases, and providing basic health services to local communities. In this study, VHVs were assigned to implement pMDA and collect data from the study participants in the nonoverlapping households for which they were responsible.
Study Participants

For the quantitative study, all villagers living in the selected clusters were invited to join the study if they were aged 1 year or older. For PQ administration, the exclusion criteria were as follows: (1) pregnancy and lactation, (2) age <7 years, (3) glucose-6-phosphate dehydrogenase (G6PD) deficiency, (4) hemoglobin level <8 g/dL, (5) body weight <15 kg, (6) history of allergy to PQ, and (7) history of drug reactions, such as hemolysis or dark urine, after PQ intake.

For the qualitative study, key informants included stakeholders representing the following 4 levels of engagement and participation: national level (malaria experts or consultants, Thailand Ministry of Public Health [MOPH]), regional and provincial level (health officers or authorities), district level (personnel at operational units of district hospitals), and local level (community leaders, religion gatekeepers, and VHVs). Villagers in the community were also invited, regardless of whether they participated in pMDA activities.

Intervention

The control group was exposed to the SPC program, a routine malaria prevention and control program, implemented by the MOPH. The SPC program includes routine case reports, case investigations, and disease- or vector-control activities at the village level. Besides routine activities, eligible subjects within the pMDA group received a dose of 0.25 mg/kg of PQ daily for 14 days. The 0.25 mg/kg dose was selected according to the WHO recommendation and evidence supported by previous studies, as it is well tolerated in G6PD-normal individuals [11,24]. Those who were G6PD deficient were excluded from PQ administration. Directly observed treatment (DOT) was performed to ensure compliance.

Outcomes and Study Procedures

For the quantitative study, the primary outcome was the proportion of P. vivax infections among the study participants within each cluster before and after 2 rounds of pMDA. The secondary outcome was the safety of the study participants who took PQ, which was closely monitored during the 14-day treatment. The study procedure is shown in Figure 2. Baseline demographic information was collected using a structured questionnaire at the start of the study. One-time testing for G6PD was performed for all villagers, using the qualitative CareStart G6PD rapid diagnostic test, before pMDA to assess the eligibility of study participants to receive PQ. For each round of pMDA, an initial cross-sectional blood survey (CSS) was conducted in both the pMDA and control groups before pMDA implementation, and a follow-up CSS was performed 3 months after pMDA. As an additional postintervention follow-up, a CSS was performed for both groups 6 months after the second round of pMDA. At each survey, finger-prick blood was collected from each participant to prepare dried filter-paper blood spots, which were later used for Plasmodium detection by quantitative polymerase chain reaction (qPCR) to identify asymptomatic infection cases in the CSS population. At the
time of each survey period, those in the CSS population who had clinical symptoms and were detected by the microscopic method in the routine MOPH malaria surveillance system were also subsequently verified by qPCR and counted as confirmed \(P. \text{vivax}\)–infected cases. The prevalence, defined as the proportion of confirmed \(P. \text{vivax}\) infections at the community level in different periods, was calculated from the number of PCR-confirmed \(P. \text{vivax}\) cases (both asymptomatic and symptomatic cases) divided by the total number of cases in each round of the CSS.

**Figure 2.** Study procedures to assess the effect of primaquine mass drug administration (pMDA) for reducing \(P. \text{vivax}\) infection in the community in a 2-period cluster-crossover randomized controlled trial during the period 2019-2022. CSS: cross-sectional blood survey; DOT: directly observed treatment; FU: follow-up; G6PD: glucose-6-phosphate dehydrogenase.

For the qualitative study, the primary outcome was information about the acceptability and stakeholder engagement of the pMDA intervention implemented in the localities. Information was collected using IDIs at the study participants’ homes and community meeting places. A brainstorming meeting at the regional health office was also arranged for collective opinions among representative authorities at the national, regional, and provincial levels. Data collection was performed after round 2 at the conclusion of the study.

**Sample Size**

For the quantitative study, the sample size was calculated with the notation that it was a proof-of-concept study to assess the potential impact of pMDA implementation. A go or no-go decision to scale up the study with a larger sample size would be made based on the potential effectiveness and feasibility of the intervention according to the interclass cluster correlation effect obtained from this study. We planned for a sample size of 1500 study participants per group. With this sample size, the power to detect differences between the 2 groups varied according to the baseline proportions of \(P. \text{vivax}\) in the study areas, with a 2-tailed type I error of 5%. With a sample size of 1500 per group, when the baseline proportion of \(P. \text{vivax}\) in the cluster is low at 3% (30 in 1000) and the effect sizes (difference between the pMDA and control groups) are 50% and 75%, powers of 79.1% and 99.5%, respectively, would be achieved. In areas with a very low baseline at 1% (10 in 1000) and effect sizes of 50% and 75%, the study would have detection powers of 35.5% and 74.1%, respectively.

For the qualitative study, IDIs were planned to include study participants from 24 families and at least six key informants from 2 villages of each province, including those who completed PQ administration, those who did not complete pMDA, and those who did not participate in pMDA. IDIs were planned for stakeholders in pMDA areas, including 12 VHV’s (at least six per province), 4 health care authorities (district and provincial levels), and 4 local leaders or gatekeepers (village heads and religious masters). A brainstorming meeting at the conclusion of the study was planned with 15 representatives, including MOPH consultative experts, authorities from regional and district vector-borne units, authorities from regional and district health offices, staff from hospitals at the subdistrict level, and staff who worked in the selected areas.

**Randomization**

To plan and evaluate the intervention, we subdivided the selected study areas into villages, which are the smallest administrative units in Thailand. A village is considered a cluster and treated as the unit of randomization. The sizes of the purposively selected clusters by authorities in the study areas were about 150-250, with a larger size of around 600 residents. Considering the cluster sizes and the distances between clusters, we purposively allocated 2 out of 5 villages in Yala and 1 out of 2 villages in Narathiwat to receive the pMDA intervention in round 1 (year 1) and switch to the control group in round 2 (year 2).

**Statistical Methods**

The potential effectiveness of pMDA was explored in terms of reductions in the prevalences and proportions of confirmed \(P. \text{vivax}\) infections on qPCR in the CSS population, with a comparison between the intervention and control groups. This was a 2-period cluster-crossover study involving 2 cluster periods and multiple CSSs before and after pMDA in each period. As suggested in the literature, the data should be analyzed with hierarchical models with random effects in order
to allow for different outcome probabilities in each period, cluster, and cluster period [25,26]. With a cluster-level randomization design, it is statistically more efficient to employ a model adjusted for the cluster effect [22]. As a proof-of-concept for a pragmatic trial in the community setting, the potential effectiveness of pMDA was thus determined by comparing the proportions of P. vivax infections between the 2 groups at each period of CSS, with the 2 periods combined representing the overall impact of the intervention. An additional comparison of the proportions of P. vivax infections between the 2 groups at 6 months after round 2 was also performed to explore the longer-term effect. As the study was conducted in low-endemic areas, it is more likely that most study participants would not be infected. Therefore, the analysis used the R package NBZIMM, which provides functions for setting up a multilevel zero-inflated negative binomial model adjusted for random intercepts of the clusters [27,28]. The model for the overall impact of the intervention in the 2-period crossover was adjusted for the cluster effect plus time period and the interaction between the time period and intervention. The prevalence ratio and its 95% CI from the model have been reported, and statistical significance was set at \( P < .05 \).

The safety of the pMDA strategy was monitored in terms of adverse events that occurred after drug administration throughout the follow-up period. All events have been presented descriptively. The prevalence of G6PD deficiency has been described with its 95% CI.

The acceptability and stakeholder engagement of the pMDA strategy were examined using qualitative analysis. IDIs and brainstorming sessions were led by trained facilitators, including an experienced lead facilitator, 4 co-facilitators and note-takers, and 2 local health care staff. All team members had been trained on ethical considerations for human research subjects and had read the study protocol and data collection methodologies. They discussed the important points to be explored. Audio recordings of the IDIs and meetings were transcribed, and the transcripts were reviewed and classified into key themes according to the study objectives and themes that emerged during the reviews. Thematic analyses were conducted on the notes of participant responses and the determined themes. The content was analyzed to identify themes by manually exploring, interpreting, and categorizing the data via consensus among facilitators. The priority themes set according to the study objectives included the following: perceptions, expectations, engagement, factors influencing the decision to participate or not to participate, factors influencing noncompletion of the 14-day regimen, perceived achievements, blockage and solutions in pMDA, and challenges in pMDA implementation.

### Ethical Considerations

This study was approved by the Ethics Committee of the Faculty of Tropical Medicine, Mahidol University, Bangkok, Thailand (approval number: MUTM 2019-031-01). All participants consented to participate in this study before enrollment. Participants younger than 18 years were consented or assented along with consent from their parents. Community leaders and authorities in national and local health facilities were informed. Moreover, they provided consent and were involved as part of the community sensitization prior to the study initiation. All staff responsible for research activities were trained in human subject research protection. The identifiable information of study participants was treated as confidential information, and the participants' identification numbers were coded. To treat pMDA as an additional part of the routine malaria prevention activities by health care personnel and VHVs in natural settings, no compensation was provided to the consented study participants. Generative AI was not used in any portion of manuscript preparation.

### Results

#### Study Participant Characteristics and Intervention Implementation and Coverage

A total of 2550 individuals resided in 7 clusters. In round 1, 1624 participants consented to the CSS, with 925 in clusters 1-3 and 699 in clusters 4-7 being allocated to the pMDA and control groups, respectively. In the 3 villages allocated to pMDA, 70.8% (655/925) of individuals were eligible according to the inclusion and exclusion criteria, and 87.8% (575/655) received pMDA. The follow-up CSS at 3 months after PQ administration was performed among 1423 study participants, with 92.0% (851/925) in the pMDA clusters versus 81.8% (572/699) in the control clusters.

In round 2, the clusters were crossed over, and 1489 participants consented to the CSS, with 878 in clusters 1-3 and 611 in clusters 4-7 being switched to the control and pMDA groups, respectively. In the 4 villages that switched to pMDA, 66.8% (408/611) of individuals were eligible according to the inclusion and exclusion criteria and 91.9% (375/408) received pMDA. The follow-up CSS at 3 months after pMDA in round 2 was conducted among 1427 study participants, with 94.8% (579/611) in the pMDA clusters and 96.6% (848/878) in the control clusters. The additional postintervention CSS at 6 months after the second PQ administration was performed among 1401 study participants, with 92.9% (568/611) in the pMDA group and 94.9% (833/878) in the control group. Figure 3 presents the CONSORT (Consolidated Standards of Reporting Trials) diagram showing the flow of participants throughout the trial [29,30]. The CONSORT checklist is presented in Multimedia Appendix 1.

The demographic attributes and G6PD deficiency statuses of the study participants in the 7 clusters are shown in Tables 1 and 2. Based on the census data, there were slightly fewer male participants than female participants, with an age range of 1 to 96 years in both rounds of pMDA. Testing for G6PD deficiency revealed an overall prevalence of 5.4% (95% CI 4.3%-6.6%) in the 7 clusters. G6PD-deficient individuals were excluded from PQ administration.

**Potential Effectiveness of pMDA**

To explore the potential effectiveness of pMDA, we compared the prevalences of *P. vivax* infections between the 2 study groups in each CSS period and the combined 2-period crossover. With the very low number of cases found for each CSS period, the prevalences were reported as the proportions of confirmed *P. vivax* infections per 1000 population. Among the CSS population in the pre-pMDA period of round 1 (July 2019), the proportions of *P. vivax* infections in the 2 groups were similar at around 14-15 per 1000 population. Among the CSS population in the 3-month post-pMDA period (November 2019), the proportions in the pMDA and control clusters reduced to 12.9 and 8.7 per 1000 population, respectively. Comparisons of the *P. vivax* proportions per 1000 population between the 2 groups (pMDA vs control) at each time period of round 1 showed no statistically significant differences (Table 3).

Among the CSS population in the pre-pMDA period of round 2 (July 2020), the proportions of *P. vivax* infections in the cross-over pMDA (clusters 4-7) and control (clusters 1-3) clusters were slightly different at 11.5 and 9.1 per 1000 population, respectively. Among the CSS population in the 3-month post-pMDA period (November 2020), the proportions in the pMDA and control clusters reduced to approximately 1.7 and 3.5 per 1000 population, respectively. Similarly, no statistically significant differences were found between the 2 groups in the round 2 study (Table 4). During the postintervention follow-up period, at 6 months after round 2 (March 2021), the proportions of *P. vivax* infections in the pMDA group (clusters 1-3) and control group (clusters 4-7) were 2.4 and 1.8 per 1000 population. Comparisons between the 2 groups also showed no significant differences (Table 4).

The inclusive effectiveness of pMDA for the 2-period crossover is shown in Table 5. In the pre-pMDA period, the inclusive numbers of participants across the 7 clusters (clusters 1-7), who
received the pMDA intervention and control intervention, were 1536 (round 1 + round 2: 925+611) and 1577 (878+699), respectively. The proportions of *P. vivax* infections per 1000 population in the pMDA and control groups before pMDA were slightly different at 13.0 and 12.0 per 1000 population, respectively, with no statistically significant difference. In the 3-month post-pMDA period, the inclusive numbers of participants across the 7 clusters, who underwent the pMDA intervention and the control intervention, were 1430 (round 1 + round 2: 851+579) and 1420 (848+572), respectively. The proportions of *P. vivax* infections per 1000 population in the pMDA and control groups at 3 months after pMDA were 8.4 and 5.6, respectively, with no statistically significant difference.

Safety and Adverse Drug Reactions of PQ During pMDA

Adverse events potentially due to PQ intake were recorded in approximately 5% of participants in each round (30/575, 5.2% in round 1 and 20/375, 5.3% in round 2) (Table 6). Although study participants with G6PD deficiency were excluded, about 1% of the participants who received PQ showed symptoms suggesting acute hemolysis. Six participants had hemoglobin levels of <8 g/dL, and another 4 participants had dark urine. Major chief complaints after taking PQ varied and included headache, weakness, muscle ache and pain, and dry throat. All
study participants with safety concerns were stopped from further PQ intake.

Acceptability of the pMDA Program

Information was collected from community representatives, including 12 from 2 villages in Yala Province and 12 from 2 villages in Narathiwat Province. Key informants also included 11 VHWs in the selected villages (7 from Yala and 4 from Narathiwat) and 18 representatives of health care personnel who worked in the study areas and MOPH consultative experts. Among the 53 key informants, 34 were male and 19 were female, and their age ranged from 18 to 86 years. Some of the study participants were community and religious leaders. Most VHWs and their family members participated in the pMDA activities. In assessing the acceptance of the pMDA program and stakeholder engagement, 5 themes were explored, namely, perceptions, expectations, and engagement; factors influencing the decision to participate or not participate; factors influencing noncompletion of the 14-day regimen; perceived achievements, blockages, and solutions in pMDA; and challenges in pMDA implementation.

Perceptions, Expectations, and Engagement

Study participants informed us that they were willing to participate in pMDA because they recognized that malaria was a major problem around their residential areas. Many of them, particularly the older generation, had experienced malaria. All villagers who agreed to the CSS, but could not participate in pMDA due to the exclusion criteria, perceived the program’s benefits. On the other hand, all those who rejected pMDA stated that they or their families had never been infected with malaria, that they would seek treatment should they be infected, and that prevention was not necessary based on these factors. VHWs, who were key players in pMDA implementation, perceived the program’s benefits. Almost all of them indicated that it would not be a burden as they have to perform home visits and other activities in the villages as part of their routine job anyway. All local health care officers at the district and subdistrict levels noted that they expected the program to help reduce malaria cases in their areas. They said that they had no worries about program implementation, as they could easily collaborate with community leaders and VHWs.

There were many malaria cases in our province – in the top ranking in Thailand. After the pMDA project, the malaria cases were reduced to none in our village… Some VHWs from other villages asked us why the project only came to our village. [VHV]

Factors Influencing the Decision to Participate or Not Participate

Many participants said that they took a decision after going to one of several community engagement meetings arranged by the research team, community and regional leaders, and VHWs. Being well-informed about drug safety and the G6PD deficiency survey, most participants felt safe participating in the CSS and pMDA program.

Both of us took the drug for 14 days without any side effects. We decided to participate after attending the community meeting. We had no worries about taking the drug and the blood draw because we both used to get malaria. If we have to take the drug once a year, we still want to do so. We will ask our children to do so next time. [pMDA-compliant husband and wife]

In contrast, all VHWs and local health care staff indicated that most teenagers and small children did not participate in the program. With the drug problem (including illegal herbs, amphetamine, cocaine, and other drugs), particularly among...
teenagers, they feared that the CSS would reveal their drug status. Some mentioned that taking medication for 14 days was too long and that they might participate in a shorter regimen. Cultural beliefs also affected the idea of taking medication. One community leader stated that some local people believed that eating durian (a local fruit) with malaria drugs might affect people’s health.

Two of us in the family did not participate even though we used to get malaria – this is because we had to go work in the forest and had no time for DOT. ... My son aged 18 years old did not participate in the project because he had to go and study out of town... [pMDA nonparticipant]

Factors Influencing Noncompletion of the 14-Day Regimen
All pMDA participants who did not complete the 14-day regimen indicated that they had to stop taking PQ because they had adverse drug reactions. A few had to withdraw via the VHVs owing to safety issues (eg, dark urine and hemoglobin <8 g/dL).

There are 5 of us in the family – only 3 participated in drug administration, the other 2 did not because of their pregnancies. I took the drug for only 4 days and stopped because I had a headache – if not, I would take it for the whole 14-days. [pMDA noncompliant person]

Perceived Achievements, Blockages, and Solutions in pMDA
The brainstorming meeting reached a consensus that pMDA had an important impact on identifying asymptomatic infections because routine qPCR was not performed at local sites. The screening test for G6PD deficiency also contributed to significant implications, as there was little knowledge about G6PD deficiency prevalence in this region. Knowing the G6PD deficiency status instilled confidence in the local staff for PQ delivery during pMDA.

When asked about pMDA activities that required improvement, government officers recognized that community engagement still did not reach all target groups, and this was confirmed by villagers and VHVs. All stakeholders suggested that there should be greater coverage and more frequent community sensitization and engagement, which should be specific to the target groups (nonparticipant populations). Though willing to perform home visits, some VHVs noted that there should be some ways to handle intensive 14-day DOT. The brainstorming session also indicated a lack of resources (both workforce and financial support) that could obstruct the success of prevention and control measures.

At the beginning, we felt worried about our skills and the heavy workload of performing 14-day follow-ups. We also worried about getting villagers to understand the project, about taking the drug and the blood draw... The situation was better when we worked together with community leaders. [Local health care officer]

Challenges in pMDA Implementation
As noted during the brainstorming session, human resources would be a major challenge when moving forward and upsizing pMDA. A few health authorities mentioned that in order to have a successful program, it must be a top-down approach, which means the policy must be initiated by authoritative bodies at higher levels and delegated to local operational entities. On the other hand, another MOPH authority noted that the local level should initiate the idea and propose it to the upper level. There were concerns about not only the human workforce but also budget allocation.

Taking a 14-day regimen requires a G6PDd screening test. This test is rather expensive – but if you do not do it, the villagers may not want to take the drug. This is important and we need to communicate well with villagers to have them take the drug. Importantly, we also need the full endorsement of higher-level authorities, i.e., MOPH. If the MOPH had such a policy, the local offices would do it. [MOPH authority at the local level]

Discussion
Overview
The main goals of this study were to evaluate the effectiveness, safety, acceptability, and stakeholder engagement of pMDA to accelerate P. vivax elimination in Thailand and to provide the information needed by the Thai MOPH for evidence-based decision making. The study employed a mixed-methods approach. The quantitative part of the study employed a 2-period cluster-crossover randomized trial design assessing pMDA in addition to standard prevention and control measures. The qualitative part was performed by IDIs and brainstorming discussions.

Effectiveness and Safety of the pMDA Intervention
As a proof-of-concept study, the potential effectiveness of the pMDA intervention was assessed by comparing the proportions of P. vivax infections between clusters under pMDA and clusters under SPC in each period and after the 2-period crossover. The study results indicated no statistically significant differences between the 2 groups both before and after pMDA implementation. However, there were reducing trends in P. vivax prevalence after pMDA implementation in both the treatment and control groups. In a systematic review in the Cochrane database, it was found that studies on MDA in Cambodia, Laos, Myanmar, and Vietnam in very low- to low-endemicity settings showed varying degrees of reductions in P. vivax prevalence immediately following the intervention, but the effects were not sustained [31]. Similarly, WHO guidelines for malaria in 2023 noted that MDA for P. vivax conducted in 8 countries showed rapid reductions in transmission with immediate- to short-term benefits 1-3 months after the last round of MDA, but long-term benefits at 12-24 months were not apparent [32]. In this study, the comparable reduction trends in the pMDA and control groups may reflect that pMDA was not as effective as anticipated. This might be due to the Hawthorne effect (the alteration of behavior by the
study subjects due to their awareness of being observed), since both study participants and health care workers in the study areas were aware of the additional pMDA activities in their vicinity. It is also important to note that since the start of the study in 2019, drastically decreasing incidences have been observed across the country and not only in the study clusters. Moreover, people’s mobility was limited and malaria risk behaviors were less frequent during the COVID-19 pandemic, which coincidently started in 2019. Thus, it is difficult to reach definitive conclusions about the effectiveness of the pMDA intervention.

Consistent with the findings in other studies [15,20,33], pMDA was safe and well-tolerated. Testing for G6PD deficiency at the point of care before PQ administration is a precondition for safe administration [19]. Several previous studies noted that the tolerability of PQ has been good, with a low frequency of adverse events reported even with heterogeneous levels of G6PD deficiency [15,18]. This study, however, excluded individuals with inborn G6PD deficiency. As a safety monitoring measure, VHV’s performed the intensive 14-day DOT of PQ receivers residing in households for which they were responsible. Other studies also reported that pMDA under supervision with good monitoring mechanisms for adverse events in the population would result in less severe adverse events related to PQ [15,18,19]. This study and other pMDA studies involving dihydroartemisinin-piperquine and PQ showed similar common adverse events, including gastrointestinal disturbances (diarrhea, vomiting, abdominal pain, and nausea), dizziness, headache, and general body weakness [18,20,34]. Severe adverse events suggesting acute hemolysis occurred in 1.1% of PQ receivers, resulting in treatment cessation.

Acceptability and Stakeholder Engagement in pMDA Activities

In the WHO manual for antimalarial MDA implementation, high coverage and adherence of the target population (ie, >80%) must be ensured, preferably implementing centralized distribution at a fixed site and performing DOT. In this study, only about 60% of participants consented to the initial CSS, but over 90% of them were retained in the 3-year study. Among those, only 70% were eligible for MDA, with 90% taking PQ and 90% completing the 14-day regimen under DOT. The qualitative part of this study suggested that acceptance of pMDA among study participants was predominantly due to their trust in health care representatives (VHVs) who actively performed home visits to provide health care support. This study confirmed that DOT, although labor-intensive, could maintain full adherence and reassure study participants about the purposes and safety of the MDA activities, pMDA and DOT heightened the morale and relationships between villagers and health care personnel in the study areas. Similarly, another study on reactive drug administration for *P. vivax* elimination in Thailand suggested that good acceptance of the program was related to education and sensitization campaigns on the purpose and rationale of the intervention [35]. Moreover, the WHO guidelines 2023 noted that a systematic review of 18 studies reported that the most common barrier to the acceptability of MDA for *P. vivax* was fear of adverse events, and some studies mentioned that sensitization on the benefits of MDA helped reduce concerns about adverse effects [32]. Community engagement is critical to the success of MDA for *P. vivax* infection as it affects participation rates and full treatment compliance, while lack of engagement with local health care providers limits treatment adherence [32]. A systematic review of published, unpublished, and gray literature documenting past MDA experiences identified the importance of operational implementation and community engagement, with drug distribution and DOT being mainly performed by community volunteers and local health workers [36]. A review of previous studies noted in the WHO guidelines 2023 also reflects that the impact of MDA on *P. vivax* infection, whether positive or negative, is likely related to the level of acceptance of the intervention among the malaria program staff, and there have been no surveys of these key stakeholders regarding this issue [32]. As suggested in the literature, all aspects of community engagement in MDA must be tailored to local (social, cultural, and political) circumstances [37,38]. This study involved community members as part of the intervention team and considered their customs and opinions. Study participants and public health care providers at local and national levels willingly accepted and believed that the preventive and control activities in this study (regardless of being in the pMDA or control groups) had boosted awareness in the community and led to personal changes in malaria-preventive behaviors. The qualitative part of this study confirmed the key determinants of pMDA, and it was shown that the feasibility of maintaining or upscaling the MDA intervention was related to the existence of active and continuous activities for community engagement, community sensitization, and maintaining collaborations with those from the point-of-care level up to authorities at local and national levels.

Limitations of the Study

This study had several limitations. The number and size of clusters were small, and the study may not have observed heterogeneities among different groups. Limited mobility due to the COVID-19 pandemic coinciding with pMDA activities during the study follow-up period might have caused the malaria prevalence in all study clusters to decline drastically. Such circumstances complicate and hinder the interpretation of the results. Moreover, there were significant heterogeneities among the different clusters, making comparisons between the pMDA and control groups difficult. Regarding the study design, this study employed a cluster-crossover randomized trial design, which is particularly feasible for pragmatic clinical trial in health care systems [21,22]. The design is highly efficient and should be considered as it breaks up the total trial duration into a series of repeated measures. Thus, the required number of clusters could be substantially reduced while potentially providing generalizable, robust, and internally valid evidence for the evaluation of effects across settings or clusters [21,39,40]. Although the cluster-crossover design is robust when the number of clusters is small [26], this study involved only 7 clusters and the crossover sample size was around 1500 per group. Given the predictably large variation in malaria prevalence within each cluster, a larger sample size would have been needed. Thus, the results of this study may not have external validity and may not
be generalizable to other settings with different natures of target populations and degrees of transmission.

Conclusions

pMDA under DOT showed high adherence, safety, and tolerability, but it may not significantly impact *P. vivax* transmission, particularly in low-transmission areas. Although the impact of pMDA was inconclusive, the results were consistent. Malaria cases reduced in all clusters, regardless of whether they were in the pMDA group. The Hawthorne effect may reflect the trigger or accelerator of elimination by involving significant political, logistical, and financial commitments of coordinating bodies and collaborative efforts among various levels of stakeholders. We experienced success regarding effective health care workforces at point-of-care centers, effective collaborations in the community, and commitment from authorities at local and national levels. Such community engagement efforts boosted the acceptability of the malaria-elimination initiative.

Despite the safety and exemplary acceptance of the intervention, we cannot proclaim the effectiveness of pMDA. As we planned this study as a proof-of-concept study, the results were considered as a basis for decision making. A conditional recommendation in the WHO guidelines 2023 suggested the use of MDA for *P. vivax* infection when there is evidence of the acceptability, feasibility, impact (incidence or prevalence of malaria infection at the community level), and potential harm of MDA (including testing for G6PD deficiency) [32]. Since we did not observe the impact of pMDA on *P. vivax* transmission during the study period and the malaria incidence in Thailand increased in 2023 after the study period, we decided not to scale up the study with larger clusters and samples. Instead of implementing pMDA in the population within the intervention clusters, we are working on an on-going project with an alternative approach involving a targeted PQ treatment strategy that provides PQ via DOT only to the targeted population in households around each index case living in the intervention cluster. The effectiveness of such an alternative approach remains to be determined.

Acknowledgments

We sincerely appreciate the study participants, village health volunteers, and local health care personnel in the communities for their kind contributions to testing the study concept. We gratefully acknowledge all staff from the Thai Ministry of Public Health for their active roles in primaquine mass drug administration implementation and all staff who worked under the International Centers of Excellence for Malaria Research (ICEMR) project for performing their assigned activities and assisting in data collection. We would like to thank Paul Adams for English editing and proofreading. This work was supported by the National Institute for Allergy and Infectious Diseases, National Institutes of Health (NIH) (U19 AI089672).

Data Availability

All data and codes used in this analysis are presented in the manuscript.

Authors' Contributions

JK, SL, JS, WR, and WN designed the study. WR, WN, ST, PS, and PP implemented the intervention in the communities. WR, WN, AK, RP, PJ, PS, and MK collected the data, accessed and verified the data, and performed initial data analysis. JK, CN, and SL designed the statistical analysis. JK and MK led the qualitative data analysis. JK and WR wrote the first draft of the manuscript. JS, DMP, and LC provided important comments on the draft manuscript. All authors read and approved the manuscript. The corresponding author had full access to all the data in the study and had final responsibility for the decision to submit for publication.

Conflicts of Interest

None declared.

Abstract

Background: Cholera-like diarrheal disease (CLDD) outbreaks are complex and influenced by environmental factors, socioeconomic conditions, and population dynamics, leading to limitations in traditional surveillance methods. In Malawi, cholera is considered an endemic disease. Its epidemiological profile is characterized by seasonal patterns, often coinciding with the rainy season when contamination of water sources is more likely. However, the outbreak that began in March 2022 has extended to the dry season, with deaths reported in all 29 districts. It is considered the worst outbreak in the past 10 years.

Objective: This study aims to evaluate the feasibility and outcomes of participatory surveillance (PS) using interactive voice response (IVR) technology for the early detection of CLDD outbreaks in Malawi.

Methods: This longitudinal cohort study followed 740 households in rural settings in Malawi for 24 weeks. The survey tool was designed to have 10 symptom questions collected every week. The proxies’ rationale was related to exanthematic, ictero-hemorrhagica for endemic diseases or events, diarrhea and respiratory/targeting acute diseases or events, and diarrhea and respiratory/targeting seasonal diseases or events. This work will focus only on the CLDD as a proxy for gastroenteritis and cholera. In this study, CLDD was defined as cases where reports indicated diarrhea combined with either fever or vomiting/nausea.

Results: During the study period, our data comprised 16,280 observations, with an average weekly participation rate of 35%. Maganga TA had the highest average of completed calls, at 144.83 (SD 10.587), while Ndindi TA had an average of 123.66 (SD 13.176) completed calls. Our findings demonstrate that this method might be effective in identifying CLDD with a notable and consistent signal captured over time ($R^2=0.681404$). Participation rates were slightly higher at the beginning of the study and decreased over time, thanks to the sensitization activities rolled out at the CBCCs level. In terms of the attack rates for CLDD, we observed similar rates between Maganga TA and Ndindi TA, at 16% and 15%, respectively.

Conclusions: PS has proven to be valuable for the early detection of epidemics. IVR technology is a promising approach for disease surveillance in rural villages in Africa, where access to health care and traditional disease surveillance methods may be limited. This study highlights the feasibility and potential of IVR technology for the timely and comprehensive reporting of disease incidence, symptoms, and behaviors in resource-limited settings.

Introduction
Cholera-like diarrheal diseases (CLDDs) are a group of diarrheal illnesses that share similar pathogenesis and symptoms with cholera but are caused by agents other than the *Vibrio cholerae*, such as *Escherichia coli* and some strains of *Campylobacter*, *Yersinia*, *Aeromonas*, and other pathogens [1]. Typically, CLDDs are responsible for milder and shorter episodes of diarrhea than cholera, but a comprehensive clinical assessment, including laboratory testing, is essential for accurate diagnosis, especially when occurring in cholera-endemic areas like Malawi [1-3]. The epidemiological profile of CLDD is characterized by seasonal patterns, often coinciding with the rainy season when contamination of water sources is more likely [4-6]. Therefore, the global burden of diarrheal disease lies heavily in regions that face disruptive environmental and socioeconomic conditions that affect the water supply and sanitation infrastructure. Most of these regions are in Sub-Saharan Africa, where cross-border cholera outbreaks, lack of testing capacity, and surveillance system limitations add an extra layer of complexity to the situation [7-14]. On December 5, 2022, cholera was declared a public health emergency, and it has been considered the country’s worst outbreak of the past 10 years [15]. The rise in cases expected during the wet season has extended to the dry season, with deaths reported in all 29 districts since March 2022 [15,16].

The situation grew even more alarming after the flooding caused by Tropical Storm Ana and Cyclone Gombe in January and March 2022, respectively [17]. These phenomena led to population displacement and water, sanitation, and hygiene (WASH) infrastructure disruption, exacerbated by longstanding issues such as the inadequate preparedness for disease control, the absence of a reliable and geographically distributed early detection system, and shortages in the oral cholera vaccine and other treatments due to multiple outbreaks within the African region [2,5,15,17-19]. As of April 4, 2023, the World Health Organization (WHO) has reported 160,756 cases of suspected cholera in the African region with a case fatality ratio (CFR) of 2.1%. Malawi has been significantly affected, accounting for 35% (n=56,763) of the total cases and 52% (n=1722) of the total fatalities, demonstrating a consistently high CFR above 3% [16]. Unfortunately, the true burden of cholera is likely higher than the reported figures due to underreporting and lack of access to health care in many areas [7,8].

In line with the urgent need for comprehensive action, it is crucial to focus on viable strategies that can complement traditional epidemiological surveillance and foster community engagement [20]. In this field, participatory surveillance (PS) has proven to be valuable for the early detection of epidemics. This system engages the community in a bidirectional manner, capturing strategic data from the community, processing the acquired knowledge, and providing nearly real-time information back [21-23]. This approach involves the active participation of community members, health workers, and other stakeholders in the surveillance process, including reporting and monitoring of disease incidence, symptoms, and behaviors. PS has demonstrated applicability in different scenarios and diseases, such as influenza, cholera, COVID-19, Zika virus, and others [21,24-31]. One of the main advantages of PS is that it overcomes several challenges associated with traditional disease surveillance methods. PS empowers communities to take ownership of their health and well-being, allowing for more comprehensive and timelier case reporting [32,33].

PS using interactive voice response (IVR) technology is a promising approach for disease surveillance in rural villages in Africa for collecting timely and comprehensive data on disease incidence, symptoms, and behaviors in resource-limited settings [34,35]. Additionally, IVR technology is cost-effective and has the potential to improve disease surveillance and control efforts in low-income settings [35-37]. Furthermore, it is an easy-to-use technology that requires minimal training and can reach a wide range of people, including those in remote and rural areas, where access to health care and traditional disease surveillance methods may be limited.

This study aims to evaluate the feasibility and outcomes of low-cost, high-frequency, and high-quality data collection through PS for the early detection of CLDD outbreaks in Malawi, implementing a system to identify its early signals.

Methods
Overview
This longitudinal prospective cohort study followed 740 rural households in Malawi for up to 24 weeks. It was rolled out in 2 Traditional Authorities (TAs) located in Salima District, the central region of Malawi (Figure 1). The choice of the TAs took into consideration the broader context of a larger study—the Child Development Study, an initiative to leverage high-frequency data collection and novel technologies for understanding child development in low-income settings. Therefore, logistical considerations and resource availability guided the choice of these TAs as suitable candidates for inclusion.

A total of 4051 households were enrolled in the Child Development Study. From this total, a sample randomization was performed, selecting 740 households from both TA areas, representing 3743 household members, including 2393 children. For the purpose of this study, it is imperative to highlight the definition of a household in Malawi as “one or more persons, related or unrelated, who make common provisions for food and who regularly take their food from the same pot and/or share the same grain house (nkhowwe) or pool their incomes together for the purpose of purchasing food” [38].

The recruitment strategy was implemented by the Kamuzu University of Health Sciences (KUHEN) local team, together with trained enumerators responsible for collecting the households’ phone numbers, conducting a baseline survey, and
gathering metadata. All these interactions, including the sensitization campaigns promoted throughout the study, took place at the community-based childcare centers (CBCCs), as the inclusion criteria for the main study required at least 1 child attending a CBCC.

Figure 1. Study area highlighting the locations of the Salima district, Maganga Traditional Authority (TA), Ndindi TA, and the community-based childcare centers (CBCCs).

Ethical Considerations
The College of Medicine Research and Ethics from Malawi (COMREC; reference no P_11_20_3202) and the Human Subjects Committee of the Faculty of Economics, Business Administration, and Information Technology at the University of Zurich (2018-046) approved this study. All participants signed the informed consent prior to enrollment and were compensated for their time spent reading and responding to messages in accordance with COMREC guidelines. Additionally, all phone costs were covered by the project.

Data Collection via IVR Technology
The survey instrument was designed with 10 questions about symptoms to be answered weekly by the same household member over a period of 24 weeks (Table 1). Additionally, the design allowed all types of phones to be included, with participants required to simply type, press, or dial the numbers indicated by the voice message to respond with “yes” or “no.” The IVR was live from July 18, 2022, until January 8, 2023. Calls were conducted in Chichewa, the primary language spoken in Malawi. The survey content was pretested with in-country KUHES representatives to reduce events of loss in translation and misinterpretation. The survey asked whether anyone in the household had experienced specific symptoms in the past 7 days, including fever, headache, joint pain, vomiting/nausea, jaundice, chills, body ache, bleeding, and diarrhea. Additionally, participants were asked if anyone in the household had undergone a malaria test during the same period, with response options including “took a test with a negative result,” “did not take a test,” and “took a test with a positive result.”

The proxies, and consequently, the questions used in the survey were selected based on the literature [39,40]. Special attention was given to designing questions capable of gathering comprehensive information while minimizing participant fatigue and enhancing adherence, as the same questions were repeated weekly. For this reason, the survey used proxies for malaria, rash, respiratory diseases, and CLDD. The rationale for these proxies was based on different disease characteristics: (1) exanthematic and ictero-hemorrhagic for endemic diseases or events and (2) diarrhea and respiratory for targeting both acute and seasonal conditions. This study specifically focused on reports related to CLDD, defined by the occurrence of diarrhea AND fever OR vomiting/nausea. Other proxies and their associated syndromes will be explored in future studies.

The household heads received calls from Monday to Friday, between 8 AM and 10 AM (a retry pattern of 2 calls with 2-hour intervals) and follow-up calls in the evening between 5:30 PM and 7:30 PM, running with this pattern throughout the week. An extract, transform, and load (ETL) process was performed weekly to feed data into a dashboard, allowing for near-real-time data visualization of the compiled results.
Sensitization Campaigns and Participant Engagement

Sensitization campaigns were conducted to raise awareness among participants before the calls officially started. Additionally, during the development of the study, we organized meetings at each CBCC used as a reference point for the study (Figure 1). Based on the eligibility criteria, all households involved in the study had at least 1 child who regularly attended the CBCCs. To ensure widespread coverage and engagement, we conducted sensitization campaigns at the CBCC locations. This approach made it easier for participants to access the information and encouraged their active involvement. The campaigns were held at various times and on different days to maximize participation and reach as many people as possible. They were facilitated by an Assistant Environmental Health Officer, a social welfare representative, and the Association of Early Childhood Development Personnel in Malawi. These campaigns aimed to raise awareness and inform participants about the process of calls and interactions. They addressed any concerns or questions about technical issues related to using mobile phones in this specific context, reinforced that the repetitive calls were intentional and not spam or mistakes, and discussed the importance of preventive health measures. Table 2 describes the framework of the sensitization campaigns.

Table 2. Sensitization campaigns framework for engaging participants during the prospective cohort.

</tbody>
</table>
Statistical Analysis

We computed the household attack rate as an indication of how many households were at risk over the studied period. We assumed household reports as a proxy for the risk of presenting any of those symptoms related to CLDD. The attack rate is expressed as follows:

\[
\text{Attack Rate} = \frac{N_{hp}}{T_{hh}}
\]

where \(N_{hp}\) is the household positive reports (number of true reports on the given proxy), and \(T_{hh}\) is the total number of households in the study.

We used a polynomial generalized additive model (GAM) to analyze a time-series data set, given that the independent variable was time. The covariates were CLDD reports, diarrhea-like reports, fever-like reports, and vomiting/nausea-like reports, and they were chosen as nonparametric due to the uncertain relationship with the outcome.

The GAM is a flexible regression technique that allows for nonlinear relationships between the predictor variables and the response variable. To evaluate the performance of the polynomial GAM, we calculated \(R^2\), deviance explained, generalized cross-validation (GCV), and scale estimate. The \(R^2\) values ranged from 0 to 1, with higher values indicating a better fit of the model to the data. The following formula was used to estimate the coefficient of determination:

\[
R^2 = 1 - \frac{\sum_{i=1}^{n} \text{res}_i^2}{\sum_{i=1}^{n} (y_i - \hat{y}_i)^2}
\]

where \(SS_{res}\) is the sum of squared residuals, and \(SS_{tot}\) is the total sum of squares.

Deviance explained measures the reduction in deviance, which is a measure of the difference between the observed data and the fitted values, achieved by the model. Deviance-explained values range from 0 to 1, with higher values indicating a better fit of the model to the data. The formula is described as follows:

\[
\text{Deviance Explained} = 1 - \frac{\text{Deviance}_{null}}{\text{Deviance}_{model}}
\]

where \(\text{Deviance}_{null}\) is the deviance of a null model with no predictors, and \(\text{Deviance}_{model}\) is the deviance of the model being evaluated.

The GCV score is the average of the squared differences between the predicted values and the actual values. To estimate the GCV score, we used the following formula:

\[
\text{GCV} = \frac{\sum_{i=1}^{n} \text{res}_i^2}{n - p - 1}
\]

where \(n\) is the sample size, \(p\) is the number of predictors in the model, and \(\text{res}\) are the residual differences between the observed response variable and the predicted response variable.

A kernel estimator was used to evaluate the spatial density of the events. This technique is a nonparametric method that can estimate the probability density function (PDF) of a random variable based on observed data. In the case of CLDD reports, the PDF represents the distribution of cases across a population, which is an important factor in understanding the spread of the disease and identifying high-risk areas. The formula is defined as:

\[
\hat{f}(x) = \frac{1}{n} \sum_{i=1}^{n} K\left(\frac{x - x_i}{h}\right)
\]

where \(x\) is the point at which the estimate is being made, \(x_i\) represents the \(i\)th observation in the data set, \(n\) is the number of observations in the data set, \(h\) is the bandwidth parameter, and \(K\) is the kernel function.

In this study, to safeguard participant privacy and avoid disclosing sensitive information, we used the coordinates of CBCCs. Notably, CBCCs cater to multiple villages that are usually close to the facility. The households included in this study had at least 1 child attending the CBCC. Consequently, given the dynamic social landscape within these villages, the CBCC locations served as a suitable proxy for the frequently visited vicinities by households. These measures ensured participant confidentiality while allowing for accurate spatial analysis within the study’s scope.

Results

During the study period, our data comprised 16,280 observations, achieving a weekly participation rate of 35%. Maganga TA showed the highest average of completed calls, at 144.83 (SD 10.587), while Ndindi TA showed an average of 123.66 (SD 13.176) completed calls. The participation rates were slightly higher at the beginning of the study and declined over time, with no significant drop, possibly influenced by the sensitization efforts implemented at the CBCC level. Figure 2 displays the participation rates for each week throughout the study period, while Figure 3 presents these data disaggregated by TA area.

Regarding the attack rates for CLDD, we found similar rates between Maganga TA and Ndindi TA, at 16% and 15%, respectively (Table 3). While fever-like reports could be taken as more sensitive than diarrhea-like reports and vomiting/nausea-like reports, using the proxy for CLDD might have helped to envelop the sensitivity of the signal, decreasing the potential number of false positives Figure 4.

Considering the aggregated view, CLDD showed a consistent signal over time (\(R^2=0.681404\)) and was even stronger when isolating diarrhea-like symptoms and fever-like symptoms, as
shown in Table 3. When breaking down by TA area, Maganga (Table 4) demonstrates a better performance than Ndindi (Table 5). At the beginning of the cohort, the highest activity in the time-series distribution could be explained by the initial efforts and participants’ fresh recall of the project. After 5 weeks of reports, the signal began increasing again, which might be related to the occurrence of the cholera outbreaks that hit that region during those months. The first report of cholera case in the Salima District was found on September 14, 2022, 2 days after all signals showed a spike (Figure 5). Although official reports were scarce, a hyperlocal media website confirmed the first cholera case in the Salima District [41].

\(a\)GAM: generalized additive model.

\(b\)TA: Traditional Authority.

\(c\)GCV: generalized cross-validation.

\(d\)CLDD: cholera-like diarrheal disease.

Figure 5. Time-series visualization of the signals, including the trend line polynomial generalized additive model, (GAM) of cholera-like diarrheal disease (CLDD), diarrhea-like reports, fever-like reports, and vomiting/nausea-like reports aggregated by Salima District. It also includes the date of the first cholera case reported in the district. The y-axis shows the percentage of reports that answered positively for the symptoms or syndrome.

In the subsequent weeks, the peak of cholera cases in the Maganga TA area was detected, where an ascending pattern in the diarrhea-like reports could be observed (Figure 6; [42]). Three weeks before this peak, CLDD reports were at their highest level when this area was considered in isolation.

Regarding the spatial distribution of the CLDD reports, even assuming a homogeneous distribution of these events over the regions, there is a notable concentration near the lake vicinity (Figure 7). The Salima District Council locally issued a “Cautionary Statement on Cholera” on October 13, 2022, aiming to provide the populace with guidance. In this statement, they reported: “Salima District has registered a total of 54 cases as of 13 October 2022 with TA Maganga along the lake shore being the most affected, with 45 cases” [43]. This observation corroborates the proxies’ ability to identify trends indicative of a possible cholera outbreak in high-risk areas.
Discussion

Principal Findings

In this study, we implemented a PS system using IVR in 2 districts of Malawi and assessed its feasibility, acceptability, and effectiveness in detecting early signals of CLDD outbreaks. During the 24-week follow-up period, the system captured 16,280 observations, and the average weekly participation rate was 35%, indicating the strategy’s feasibility and acceptability according to the literature [24,44-46].

In summary, our findings demonstrate that this method might be effective in identifying CLDD with a notable and consistent
signal being captured over time ($R^2 = 0.681404$). The signal showed a significant increase coinciding with cholera outbreaks in the region. This pattern was notably observed with the first cholera case in the Salima District, detected shortly after a spike in our CLDD data (Figure 5). Despite limited official reporting, this outbreak was confirmed through hyperlocal media sources. Furthermore, a subsequent analysis highlighted a peak in cholera cases in the Maganga TA area, preceded by a rise in CLDD reports of diarrhea-like symptoms underscoring the potential of CLDD in early outbreak detection and response facilitation. The local media released a breaking news report on October 15, 2022, highlighting the “Cautionary Statement on Cholera” that the Salima District Council issued on October 13, 2022. Signed by the Director of Health and Social Services, the statement aimed to provide guidance to the population. It mentioned a total of 54 cholera cases in Salima, emphasizing that TA Maganga accounted for 45 cases. The statement also underscored that the regions most affected were those in close proximity to the lake [43].

Traditional surveillance systems can have limitations in detecting early signals of outbreaks, particularly in resource-limited settings [7,10,14]. Therefore, PS has been proposed as an additional approach that leverages the local knowledge and resources of communities to identify early outbreak signals.

The successful implementation of PS must consider the site's geolocation, epidemiological profile, seasonality, and available telecommunication infrastructure [47]. In this study, Maganga and Ndindi encompass a vast territorial area bordered by Malawi Lake, the ninth-largest freshwater lake on Earth [48,49]. The lake plays a vital role in the region's economy, demographic density, and definition of 2 different seasons—the dry and wet seasons [48]. Thus, during the wet season between December and April, the population expects floods followed by disruptions in the WASH infrastructure, and consequently, an increase in overall diarrhea cases [16,48].

Moreover, in 2019, there were more than 5 million mobile subscriptions, with a gradual increase in mobile penetration over the years, predominantly through prepaid subscriptions [50]. The growth in mobile penetration is evident, with reports indicating approximately 12.27 million mobile subscribers at the beginning of 2022 [51]. Regarding internet coverage, the International Telecommunication Union showed that only 10% of the Malawi population was using the internet until 2019 [49]. Although internet penetration is growing, reports from 2022 showed that almost 80% of the country’s population remained offline, with internet access being particularly low in areas away from cities [52]. Bearing that in mind, models of PS conducted through mobile apps, such as Flu Near You, AlyaData, or the Guardians of Health platform, would likely not achieve significant engagement in the most remote areas of Malawi. Therefore, the choice of a self-report survey via IVR may be the most appropriate strategy for this setting [33,40,44,53,54].

PS strategies have been applied worldwide with positive results in different settings and events, successfully tracing pandemics such as Zika, H1N1, and COVID-19. PS has the potential to anticipate outbreaks and provide a quicker overview, guiding authorities to the hotspots of specific diseases [25,53-55]. Despite limitations in the field of technology and communication, PS strategies can rely on affordable systems that have been successfully implemented in underresourced areas, such as Malawi [26]. By leveraging the IVR design, it is possible to establish a less expensive, flexible, scalable, and reliable system that captures data voluntarily and provides information that is not possible to capture using traditional surveillance methods. This approach can empower communities to take an active role in anticipating disease outbreaks, even in settings where internet coverage is limited [34,56,57].

**Study Limitations**

Our study has several limitations. In terms of study design, population displacement and changes in the household configuration affected the consistency of the individuals being reported using the same household phone number. Constant phone number changes resulted in us losing contact with an entire household. Pitfalls in the adherence rate over the weeks could occur due to recipients perceiving the repeated calls with identical questions as spam, potentially leading them to avoid answering that specific phone number.

Selection bias is another significant limitation. Not all individuals may have access to a mobile phone, and those who have may differ in socioeconomic status, education level, or other factors that may affect their willingness to participate in the study. This could result in an unrepresentative sample and affect the generalizability of the results.

Another limitation is that the quality and accuracy of the data collected through IVR may be affected by factors such as poor network coverage, low battery, or other technical issues that may prevent individuals from completing the survey or lead to missing data. Additionally, individuals may not always report their symptoms accurately or truthfully, which could affect the validity of the data collected through IVR. Validating PS data with traditional sources in low-income settings is also challenging due to the scarcity of disease surveillance data. In many low-income settings, disease surveillance systems may be underresourced or underdeveloped, resulting in delays in the collection, analysis, and reporting of disease data. Consequently, it can be challenging to validate the accuracy of the data collected through PS with traditional sources. This sum of constraints can lead to a lack of confidence in the accuracy of the PS data and limit its usefulness for public health decision-making. Moreover, traditional sources of disease data, such as hospital records or laboratory test results, may not always be available or accessible in low-income settings, further complicating the validation process. Therefore, while PS has the potential to provide valuable data on disease trends and outbreaks in low-income settings, its usefulness and advantages may be limited by the lack of timely and reliable validation data from traditional sources.

**Conclusion**

IVR systems have the potential to facilitate PS in low-income and low-resource countries by enabling efficient and cost-effective data collection. In this study, weekly automated phone calls were made to a representative sample of the
population over a 6-month period, during which participants answered a consistent set of 10 questions related to cholera and malaria and associated risk factors. In low-income countries and settings with limited technological resources, PS using this method can be particularly useful in preventing CLDD outbreaks for several reasons. First, IVR allows for the timely detection of cases by rapidly identifying suspected CLDD cases within communities, providing public health officials with real-time data to respond promptly and contain potential outbreaks. Second, by using a standardized set of questions, the IVR system ensures that data collected across different participants and time points are consistent and comparable, thus improving the surveillance system’s reliability. Additionally, the use of phone-based surveys enables data collection from geographically dispersed and hard-to-reach populations, overcoming logistical barriers typically encountered in low-resource settings. Finally, by longitudinally monitoring the same set of participants over 6 months, the IVR-based PS system can capture temporal trends and identify emerging risk factors, enabling targeted and context-specific interventions to prevent and control disease outbreaks.

Abstract

Background: HIV surveillance among key populations is a priority in all epidemic settings. Female sex workers (FSWs) globally as well as in Rwanda are disproportionately affected by the HIV epidemic; hence, the Rwanda HIV and AIDS National Strategic Plan (2018-2024) has adopted regular surveillance of population size estimation (PSE) of FSWs every 2-3 years.

Objective: We aimed at estimating, for the fourth time, the population size of street- and venue-based FSWs and sexually exploited minors aged ≥15 years in Rwanda.

Methods: In August 2022, the 3-source capture-recapture method was used to estimate the population size of FSWs and sexually exploited minors in Rwanda. The field work took 3 weeks to complete, with each capture occasion lasting for a week. The sample size for each capture was calculated using shinyrecap with inputs drawn from previously conducted estimation exercises. In each capture round, a stratified multistage sampling process was used, with administrative provinces as strata and FSW hotspots as the primary sampling unit. Different unique objects were distributed to FSWs in each capture round; acceptance of the unique object was marked as successful capture. Sampled FSWs for the subsequent capture occasions were asked if they had received the previously distributed unique object in order to determine recaptures. Statistical analysis was performed in R (version 4.0.5), and Bayesian Model Averaging was performed to produce the final PSE with a 95% credibility set (CS).

Results: We sampled 1766, 1848, and 1865 FSWs and sexually exploited minors in each capture round. There were 169 recaptures strictly between captures 1 and 2, 210 recaptures exclusively between captures 2 and 3, and 65 recaptures between captures 1 and 3 only. In all 3 captures, 61 FSWs were captured. The median PSE of street- and venue-based FSWs and sexually exploited minors in Rwanda was 37,647 (95% CI 31,873-43,354), corresponding to 1.1% (95% CI 0.9%-1.3%) of the total adult females in the general population. Relative to the adult females in the general population, the western and northern provinces ranked first and second with a higher concentration of FSWs, respectively. The cities of Kigali and eastern province ranked third and fourth, respectively. The southern province was identified as having a low concentration of FSWs.
Conclusions: We provide, for the first time, both the national and provincial level population size estimate of street- and venue-based FSWs in Rwanda. Compared with the previous 2 rounds of FSW PSEs at the national level, we observed differences in the street- and venue-based FSW population size in Rwanda. Our study might not have considered FSWs who do not want anyone to know they are FSWs due to several reasons, leading to a possible underestimation of the true PSE.

Introduction
Increased risk for HIV transmission is highly associated with social marginalization, and those individuals who are socially marginalized may not identify themselves as such when accessing services. This makes it difficult to track them in HIV program registers and impedes efforts to plan and have informed resource allocations for high impact. Those individuals are considered to be key populations for HIV and include female sex workers (FSWs), men who have sex with men, transgender women, and people who inject drugs—all of whom are at increased risk for HIV infection compared with the population at large [1,2]. In 2021, key populations and their sexual partners accounted for 70% of HIV infections globally, with 51% in sub-Saharan Africa, and the risk of HIV acquisition among FSWs is 30 times higher than that in adult females globally [2-4].

Rwanda, an East African country, is surrounded by 4 neighboring countries: Tanzania, Uganda, Democratic Republic of the Congo, and Burundi. Rwanda is divided into 5 administrative regions—4 provinces and the City of Kigali—and 30 districts as another subnational unit level. Rwanda experiences a mixed HIV epidemic, generalized in the adult population, with an adult (age 15-49 years) HIV prevalence stabilized at around 2.6% and with aspects of a concentrated epidemic among specific key populations at higher risk of HIV infection, with 45% among FSWs [5]. In Rwanda, FSWs are considered among the key populations for HIV prevention and care in the HIV and AIDS National Strategic Plan (2018-2024) [6].

Since 2010, the Rwanda Biomedical Center (RBC) has conducted 3 rounds of street- and venue-based FSW population size estimations (PSEs) nationally. The first was implemented in 2010 [7], where 3 methods were used, namely, 2-source capture-recapture (CRC), enumeration, and the multiplier method [8]. Using CRC and enumeration methods yielded the FSW PSE slightly more than 3000 [7]. Two years later, in 2012, through a household survey, RBC estimated the size of FSWs to range from 25,000 to 45,000 in Rwanda [9]. Lastly, in 2018, RBC conducted a national exercise of FSW size estimation by using the 3-source CRC (3S-CRC) method, where findings showed FSW PSE to range from 8328 to 22,806 with a median of 13,716 [10].

The recent 5th Rwanda Population and Housing Census in 2022 reported an average annual growth rate of 2.3%, where the current resident population increased beyond 13 million from 10.5 million in 2012 [11]. This rapid increase in the general population reflects the need for regular update of key population size estimates to inform HIV programming and planning in Rwanda. As affirmed by the Joint United Nations Program on HIV/AIDS or World Health Organization in the publication guidelines for second generation HIV surveillance [12], HIV surveillance among key populations is a priority in all epidemic settings. Identifying the key population groups, their locations, and their sizes helps in understanding and prioritizing the current needs for HIV prevention, diagnosis, treatment, and care services. It also helps in projecting the future needs for those services. Rwanda’s HIV and AIDS National Strategic Plan (2018-2024) has adopted routine surveillance of key populations, including regularly conducting PSEs of FSWs every 2-3 years [13]. This study aims at providing for the fourth time the population size estimate of street- and venue-based FSWs and sexually exploited minors aged 15 years and older operating in Rwanda, where the 3S-CRC method was used for the second time.

Methods
Study Population
The study population consists of biologically born females (girls or women), aged 15 years and older, who self-reported having any type of sex with men in exchange for goods, money, or services in the last 3 months and practicing sex work at street- and venue-based hotspots. Those fulfilling the above criteria and who were younger than 18 years are herein referred to as sexually exploited minors.

Study Design and Setting
This was a cross-sectional national FSW and sexually exploited minor PSE by using the 3S-CRC method [14]. The method involved visiting hotspots, where FSWs are known to congregate, on 3 separate occasions and sampling FSWs who were found at the hotspots on each occasion, calculating the degree to which FSW samples overlapped across 3 consecutive occasions. In this framework, an encountered FSW at the visited hotspot was referred to as captured, and each encounter occasion was referred to as a capture round in the CRC method context. A resampled FSW at a subsequent capture round was referred to as recaptured, and the intuition was that the degree to which FSW samples overlap across the 3 consecutive capture rounds was inversely proportional to the population size.

The objects used to tag FSWs who were presented at the hotspots were small, inexpensive, and branded with specific messages so that they would have a memorable design, and
these would only be available from the study staff who distributed them. During the first capture, a small bag branded with the “imigongo” traditional art form was offered; for the second capture, a purse branded with a flower and the key message “Rinda ubuzima” (protect your life) was offered; and during the third capture, a hair comb branded with a tree picture as a key message was offered.

**Sampling and Sample Size**

**Sampling Design**

A stratified multistage sampling design was used, with administrative provinces considered as strata and FSW hotspots as primary sampling units. Information from FSW’s hotspot mapping exercise was used as the sampling frame for this FSW PSE in 2022. Prior to this survey, the RBC conducted an FSW hotspot mapping exercise across the country from March to May 2022 to collect some key information that would inform future studies involving FSWs. Hotspot mapping consisted of teams going to the field to identify active venues and streets where FSWs congregate to find sexual clients. The FSW hotspot mapping exercise was facilitated by key informants identified by implementing partners who provide health services to FSWs to guide mapping teams. The mapping exercise identified 668 hotspots (street- and venue-based) countrywide and collected some beneficial data, including hotspot name, hotspot size, pick days, pick hours, and corresponding geocoordinates, to guide the sampling process.

The principal sampling processes were as follows: from the national list of FSW hotspots resulting from the hotspot mapping exercise, FSW hotspots were stratified by administrative provinces and the City of Kigali, and then a specific number of hotspots was selected using probability proportional to the size of the FSW populations. Hotspot sampling was performed using probability proportional to size for generating samples. In probability proportional to size sampling, the probability that a hotspot was sampled was proportional to the estimated size of FSWs observed at that hotspot during the hotspot mapping exercise. In practice, this means that hotspots with many FSWs are more likely to be sampled than hotspots with fewer FSWs. To enhance the geographical representativeness of the sample, hotspots were listed by the corresponding administrative provinces, and provinces were considered strata. To execute hotspot sampling, we listed all the hotspots in the order of the number of FSWs observed during the mapping exercise within a strata (to reflect the relative sizes of the FSW populations).

Then, we calculated the cumulative number of FSWs for each hotspot listed, determined the sampling interval, picked a random starting point, and finally selected a hotspot based off the random starting point, sampling interval, and cumulative FSW population size. This process was repeated in each capture round to minimize list dependency between capture occasions, and this resulted in the selection of 62 hotspots countrywide in each capture round.

**Sample Size Calculation**

The expected sample size for each capture round and statistical power were calculated using MS-CRC Power Analysis of the shinyrecap application [15]. Using the previously estimated size of FSWs in Rwanda of 23,495 [10], we set the application to simulate 500 CRC studies and report the amount of variability in the estimates based on the posited population and the sample size in each capture event to 2000 at an α level of .05. We found that there is a 95% chance that the CRC study’s population size estimate will be within 7.6% of the true value, corresponding to 1780 absolute accuracy. Considering the 11% nonresponse rate from the previous study, 2000 was found to be an appropriate sample size for each capture round (Multimedia Appendix 1). The number of objects distributed to each hotspot was proportional to the total number of FSWs estimated at the hotspot according to the 2022 mapping data.

To select the number of FSWs to be offered unique objects within a selected FSW hotspot, we used a systematic sampling approach for the distribution of unique objects. The unique object distribution process started with the FSW key informant conducting visual head counts of FSWs present at the hotspot and then estimating the distribution interval by dividing the head counts by the assigned hotspot unique objects. If the result of the division was 1, every FSW present at the hotspot should have received the unique object; otherwise, a random start would be randomly selected within the distribution interval following the physical standing position of FSWs in the hotspot. Table 1 shows the provincial distribution of the sampled 62 hotspots and the 2000 unique objects assigned in each capture round.

**Table 1.** Provincial level sample size replicated at each of the 3 capture rounds in Rwanda in 2022.

Data Collection

Data collection was conducted in sampled hotspots and lasted for a 3-week period from August 1 to August 21, 2022. All data collectors were trained about questionnaire administration using tablets as well as good clinical practice [16]. The 3 captures followed each other consecutively, each lasting for 1 week. Two data collectors from the 32 trained data collectors were randomly assigned to 28 districts (2 districts did not meet the minimum requirement to be included in the survey) of Rwanda in a team of 2 and shuffled on every capture round. Once they arrived in the selected hotspots, the data collection team was assigned a local FSW guide (key informant) who helped in object distribution among FSWs who were congregated in the selected hotspots. The hotspot visiting time depended on the selected pick days and hours for each venue or street, and the objects were distributed systematically by determining the interval according to the number of FSWs present at the hotspots and the number of assigned unique objects. The unique objects were distributed by FSW key informants under the supervision of data collectors, and the latter only recorded responses of whether the approached FSW accepted or refused the unique object. Those who accepted the unique object were marked as successful capture. For the successful captures, FSWs were asked if they had received a previously distributed unique object, and this information was also recorded on the tablet. If a successfully captured FSW claims to have received the previously distributed unique object, then she was asked to present it to the key informant in case she had it with her. Otherwise, a laminated card with different unique objects, including the correct distributed unique objects, was shown to her to point out the object she claimed to have received, and the data collector recorded if she successfully pointed out the correct unique object. As different unique objects were distributed in each capture round, depending on the type of object presented physically or pointed out on the laminated card, the data collector would mark the corresponding capture round from which that object was distributed on the tablet. Furthermore, a visual estimation of the age group for the approached FSWs was recorded. Data were collected at individual level encounters, that is, for each approached FSW, a record would be opened, filled, and saved in the tablet before moving forward to the next FSW. In summary, 4 major assumptions must be met for the CRC to give reliable population estimates; these were considered during data collection. These assumptions include that individual captures should be independent, the population should be closed during the data collection period, each target population member’s capture history should be correct, and the chance of getting captured should be homogeneous [17]. To minimize dependencies between captures, we repeated the sampling process of FSW hotspots in each capture round. To reduce recall bias and to ensure that the closed population assumption was met for all 3 captures, we maintained a 1-week period between consecutive capture rounds. Within sampled FSW hotspots, FSWs were sampled systematically to receive the distributed unique objects to ensure that the probability of being sampled was homogeneous. For details, please refer to the sampling and sample size section above. Finally, data collection was monitored in real time to ensure data quality and to ensure that each individual capture history was correct.

Data Management

Data were collected electronically using a tablet questionnaire programmed in Open Data Kit and transferred to the central server, with the process monitored by a qualified data manager. Electronic data files, computers, and other storage devices that contained data were password-protected, and electronic survey data files had encryption protection. Data files were transferred to the central encrypted server immediately after individual encounters. If the internet connection was not strong enough to upload data to the server, the records would be backed up on the tablet and sent later once the team reached the area with strong internet connectivity.

Data collectors were trained on the process of data collection and the use of tablets to ensure data quality. All data were anonymized, and no personal identifying information was collected. Participant-level data were line-listed and uniquely identified by a tablet-generated unique study ID. Data extracted from the central server were transferred into Microsoft Excel, maintained on a password-protected computer, and backed up on an external hard drive to ensure the security of the data, and kept in a locked, secure location. On a daily basis, the data manager who had access to the secure data would download the received data in Excel and conduct a quality check to ensure that high-quality data standards were met, including data logical flow and skip patterns. Whenever an error was identified, the data manager would immediately reach out to the concerned data collector for clarifications and rectify the error.

Statistical Analysis

Data cleaning was conducted using STATA 17 and RStudio (shinyrecap) for 3S-CRC for data analysis [18]. In preparation for the analysis, participant-level data were exported into RStudio (R package: shinyrecap) for Windows, and cleaning was performed based on preset exclusion criteria (self-reporting to be an FSW and accepting the offered unique object) and data logical flow following skip patterns. The data set was subset by province to have provincial-level FSW population size estimates. Aggregated data sets detailing counts of each CRC combination were produced for each subset. Table 2 shows how data were aggregated by overall and provincial $2^k - 1$ contingency tables for analysis preparation, where k stands for the number of capture occasions and $n_i$ represents aggregated counts, where i stands for a specific capture occasion.
Frequentist log-linear models [19], Bayesian nonparametric latent class [20], and Bayesian Model Averaging [21], which are flexible and able to accommodate various forms of heterogeneity in capture probabilities, were used to produce the final PSE with credibility sets from aggregated data sets. The median population size with 95% credibility sets and confidence intervals for 3S-CRC data were produced overall and by province. The selection of the best model to report among the 3 mentioned ones was based on whether the data presented list dependency (capture events independently drawn from the population) of captures or capture heterogeneity (individuals in the population have the same probability of being captured).

**Ethics Approval**

The survey received ethics approval from the Rwanda National Ethics Committee (IRB00001497). It was also reviewed in accordance with the US Centers for Disease Control and Prevention human research protection procedures and was determined to be not research. A waiver for consent was obtained, and no compensation was offered, as data collectors did not interact with the participants. The survey protected the anonymity of participants to avoid any stigmatization, and no personally identifiable information was collected. A referral form was available for sexually exploited minors, which included referrals to health and legal services.

**Results**

Of the 1778 FSWs approached during capture 1, 1768 (99.4%) were newly captured (ie, they were not captured elsewhere within the same week). Among those newly captured, unique object acceptance was high at 99.9% (1766/1778). For 1870 FSWs approached during capture 2, 1851 (98.9%) were newly captured within the second week of capture. Among those newly captured in capture 2, unique object acceptance was high at 99.8% (1848/1851). During capture 3, 1910 FSWs were approached, and 1867 (97.7%) were newly captured. The main reasons for unique object refusal documented were not being willing to receive the object and being willing to receive money instead of a unique object. Table 3 presents the results by capture round.

The majority of the FSWs sampled were presumed to be 25 years old, while only few sexually exploited minors aged 15-17 years were captured across all 3 capture rounds. Table 4 describes the sampled FSWs in each capture round by age and province.

A total of 1766 unique objects were distributed countrywide during capture 1, 1848 objects during capture 2, and 1865 objects during capture 3. In a 3-week survey implementation exercise, 62 hotspots were visited countrywide in each capture round; however, bigger hotspots were resampled in the subsequent capture rounds. Two hotspots were resampled between capture 1 and capture 2; 8 hotspots were resampled between capture 2 and capture 3; 6 hotspots were resampled between capture 1 and capture 3; and 2 hotspots were resampled in all 3 capture rounds. Figure 1 shows the maps of the individual captures, highlighting the venue and street hotspots visited. The aggregated and cleaned final 3S-CRC data set was imported into shinyrecap for analysis.

For all 3 capture rounds, 1766 FSWs, 1848 FSWs, and 1865 FSWs were sampled, of which 1408 FSWs, 1471 FSWs, and 1529 FSWs were observed strictly during capture 1, capture 2, and capture 3, respectively. There were 169 exclusive overlaps between capture 1 and capture 2, 210 exclusive overlaps between capture 2 and capture 3, and 65 recaptures between capture 1 and capture 3. Finally, 61 FSWs were recaptured in all 3 capture rounds. Figure 2 presents the Venn diagram illustrating the aggregated data of the capture history results for single, double, and triple captures to construct a structured 3S-CRC data set.
Out of the 231 FSWs recaptured between capture 1 and capture 2, 96 physically presented the unique objects received during capture 1, while out of 135 who did not have the unique objects with them, 134 were able to correctly describe and identify the received unique object on a laminated card, bringing the total number of recaptures to 230. Of the 127 FSWs recaptured between capture 1 and capture 3, 53 brought the unique objects with them, while of the 74 who did not have the unique objects with them, 73 were able to correctly describe and identify the received unique object on a laminated card. Of the 272 FSWs recaptured between capture 2 and capture 3, 111 had the received unique objects with them, while 160 who did not have the unique objects with them were able to correctly describe and identify the received unique object on a laminated card. Table 5 highlights the 2 methods used to record the recapture histories.

aN/A: not applicable.

Out of the 135 FSWs who claimed to have been offered capture 1 unique object during capture 2, only 1 was unable to describe and correctly identify the object received on the laminated card. Out of the 74 FSWs in capture 3 who claimed to have been offered a unique object but who did not have the objects with them, 73 were able to describe and correctly identify the object received on the laminated card. Only 1 FSW out of 272 FSWs who claimed to have been offered capture 2 unique object during capture 3 was unable to describe and correctly identify the object received on the laminated card. The FSW population size presented in Table 6 is based on 3 models: log-linear, Bayesian Model Averaging (using noninformative prior), and Bayesian nonparametric latent class models.

aDenominators are the national total number of adult females aged 15 years and older in the 5th Rwanda Population and Housing Census in 2022.
bPoisson model, which assumes that captures may have different probabilities and that individuals may be heterogeneous.

Based on the outputs and model diagnostics (Multimedia Appendices 1-4), the data were found to contain list dependence; therefore, Bayesian Model Averaging with noninformative prior was chosen, which best dealt with list dependence, as it automatically detected potential dependencies in the data. After fitting the model, the population size of street- and venue-based FSWs in Rwanda was estimated to be within a credible set ranging from 31,873 to 43,354 with a median of 37,647, corresponding to 1.1% (95% CI 0.9%-1.3%) of the general population of adult females aged 15-49 years in Rwanda (Table 7). Relative to adult females in the general population, the western and northern provinces ranked first and second with a higher concentration of FSWs, respectively. The City of Kigali and eastern province ranked third and fourth, respectively. The southern province was identified as having a lower concentration of FSWs.
In 2012, the population size of FSWs was estimated to range from 23,000 to 39,000. Later, after 6 years, in 2018, the national population size of FSWs was estimated to range from 8328 to 22,806, with a median of 13,716. These differences in the population size of FSWs might be attributed to different reasons, including but not limited to methodological or geographical coverage differences. Compared with the previous 3 rounds of FSW PSE exercises, we observed a difference in the FSW population size in our study, which also might be attributed to the reasons stated above.

There are several methods to estimate the population size of population groups without sampling frames [23,24]. Each method presents its own unique strengths and weaknesses. Our study uses the 3S-CRC method to produce FSWs and sexually exploited minors’ PSEs nationally and at the subnational level for 5 administrative provinces. Two captures are used in the classic CRC method; however, additional captures can be added to increase the number of data points from which estimates are generated, resulting in increased ability to account for the potential interaction; so, the assumption of independence between captures may be relaxed [20]. Due to its mathematically grounded and logical results, 3S-CRC is increasingly utilized in epidemiology to estimate the size of the key populations targeted by health intervention programs for certain health disorders [25-27]. The 3S-CRC approach has been utilized in numerous studies to estimate the size of specific population groups—including FSWs, men who have sex with men, and people who inject drugs—without sampling frames [28-32].

As affirmed by the Joint United Nations Program on HIV/AIDS or World Health Organization in the publication guidelines for the second generation Know Your HIV epidemic [12], HIV surveillance among key populations is a priority in all epidemic settings. Identifying the key population groups, their locations, and their sizes helps in understanding and prioritizing the current needs for HIV prevention, diagnosis, treatment, and care services. It also helps in projecting the future needs for those services.

Despite the limitations mentioned above, policy makers and planners should be able to monitor HIV pandemic control nationwide, specifically among FSWs, by using the findings from the 2022 PSE of FSWs. They should also be able to plan for other health services such as sexually transmitted infection prevention and treatment. Even though these estimates can be applied at the national and provincial levels, more work on small area estimation is needed to match PSE results with the targeted geographical coverage.

### Discussion

This study provides both national and provincial-level estimates of the population size of street- and venue-based FSWs and sexually exploited minors aged 15 years and older in Rwanda. In our study, the population size of street- and venue-based FSWs and sexually exploited minors was estimated to be within a credible set ranging from 31,873 to 43,354, with a median of 37,647, corresponding to 1.1% (95% CI 0.9%-1.3%) of the adult females aged 15 years and older in the general population. Our results indicate a significant difference in the FSW population size as compared to the 2018 population size of FSWs aged 15 years and older, which was estimated to range from 8328 to 22,806 credible sets with a median of 13,716 [10]. This difference may be attributed to several factors, including but not limited to differences in the estimation models used and the geographical coverage.

Furthermore, our study provides a provincial-level population size estimate of street- and venue-based FSWs and sexually exploited minors aged 15 years and older for the very first time. The largest population size estimate was obtained in the western province, followed by the northern and eastern provinces. The City of Kigali and southern province were found to have relatively lower estimates of the FSW population as compared to other provinces. Differences in the estimates distribution across the country may reflect long-term internal movement patterns among FSWs, from rural to more urbanizing areas as well as from smaller to larger urbanized contexts, as indicated by the Rwanda Population and Household Census 2022 [22].

The findings from the 2022 FSW PSE might not have considered high-profile FSWs and those FSWs using web-based and social media platforms to reach their clients, leading to a slight possible underestimation of the true population size. Furthermore, we acknowledge possible methodological limitations that might influence the final FSW PSE in this study. Compared to the program coverage data of the Rwanda Health Management Information System, the key strength of our study is that it is powered to provide national and provincial-level PSE for FSWs in Rwanda for the very first time.

So far, 3 rounds of FSW PSE have been conducted in Rwanda since 2010 [7,9,10]. The 2010 FSW size estimation using CRC and multiplier methods estimated the national population size of FSWs to range from 2998 to 3412 with a median of 3205. In 2012, the population size of FSWs was estimated to range from 23,000 to 39,000. Later, after 6 years, in 2018, the national population size of FSWs was estimated to range from 8328 to 22,806, with a median of 13,716. These differences in the population size of FSWs might be attributed to different reasons, including but not limited to methodological or geographical coverage differences. Compared with the previous 3 rounds of FSW PSE exercises, we observed a difference in the FSW population size in our study, which also might be attributed to the reasons stated above.

There are several methods to estimate the population size of population groups without sampling frames [23,24]. Each method presents its own unique strengths and weaknesses. Our study uses the 3S-CRC method to produce FSWs and sexually exploited minors’ PSEs nationally and at the subnational level for 5 administrative provinces. Two captures are used in the classic CRC method; however, additional captures can be added to increase the number of data points from which estimates are generated, resulting in increased ability to account for the potential interaction; so, the assumption of independence between captures may be relaxed [20]. Due to its mathematically grounded and logical results, 3S-CRC is increasingly utilized in epidemiology to estimate the size of the key populations targeted by health intervention programs for certain health disorders [25-27]. The 3S-CRC approach has been utilized in numerous studies to estimate the size of specific population groups—including FSWs, men who have sex with men, and people who inject drugs—without sampling frames [28-32].

As affirmed by the Joint United Nations Program on HIV/AIDS or World Health Organization in the publication guidelines for the second generation Know Your HIV epidemic [12], HIV surveillance among key populations is a priority in all epidemic settings. Identifying the key population groups, their locations, and their sizes helps in understanding and prioritizing the current needs for HIV prevention, diagnosis, treatment, and care services. It also helps in projecting the future needs for those services.

Despite the limitations mentioned above, policy makers and planners should be able to monitor HIV pandemic control nationwide, specifically among FSWs, by using the findings from the 2022 PSE of FSWs. They should also be able to plan for other health services such as sexually transmitted infection prevention and treatment. Even though these estimates can be applied at the national and provincial levels, more work on small area estimation is needed to match PSE results with the targeted geographical coverage.

Abstract

Background: Population size, prevalence, and incidence are essential metrics that influence public health programming and policy. However, stakeholders are frequently tasked with setting performance targets, reporting global indicators, and designing policies based on multiple (often incongruous) estimates of these variables, and they often do so in the absence of a formal, transparent framework for reaching a consensus estimate.

Objective: This study aims to describe a model to synthesize multiple study estimates while incorporating stakeholder knowledge, introduce an R Shiny app to implement the model, and demonstrate the model and app using real data.

Methods: In this study, we developed a Bayesian hierarchical model to synthesize multiple study estimates that allow the user to incorporate the quality of each estimate as a confidence score. The model was implemented as a user-friendly R Shiny app aimed at practitioners of population size estimation. The underlying Bayesian model was programmed in Stan for efficient sampling and computation.

Results: The app was demonstrated using biobehavioral survey-based population size estimates (and accompanying confidence scores) of female sex workers and men who have sex with men from 3 survey locations in a country in sub-Saharan Africa. The consensus results incorporating confidence scores are compared with the case where they are absent, and the results with confidence scores are shown to perform better according to an app-supplied metric for unaccounted-for variation.

Conclusions: The utility of the triangulator model, including the incorporation of confidence scores, as a user-friendly app is demonstrated using a use case example. Our results offer empirical evidence of the model’s effectiveness in producing an accurate consensus estimate and emphasize the significant impact that the accessible model and app offer for public health. It offers a solution to the long-standing problem of synthesizing multiple estimates, potentially leading to more informed and evidence-based decision-making processes. The Triangulator has broad utility and flexibility to be adapted and used in various other contexts and regions to address similar challenges.

Introduction

One of the more daunting tasks for policy makers in the public health arena is the synthesis of data and information into actionable insights. Population size, prevalence, and incidence are crucial metrics that play a significant role in shaping public health programs and policies. However, stakeholders are often faced with multiple estimates of these quantities, originating from different sources and of differing quality. Often, estimates
of the same quantity will be incompatible, with confidence bounds completely disjoint from one another.

Stakeholders face the task of weighing their knowledge about the population along with the various estimates to triangulate to a single number that represents the most likely value. Typically, this has been done without a formal framework, where decisions about how the final number was arrived are shrouded by a nontransparent process. How much stock was each estimate given by the stakeholders? Did any of the stakeholders express strong prior beliefs about what the true number was that could affect the result? Did political considerations color the findings, and if so, how? Without transparency, these questions are difficult to answer.

The goal of this study is to present a statistical tool that can be used to guide the triangulation process. Prior beliefs, study quality, and estimate uncertainty are all components of the process of generating a consensus estimate. However, because these components are put together in a rigorous statistical framework, all of them are made completely transparent and inspectable by third parties.

A particular focus is paid to population size estimation (PSE). PSE is one of the fundamental estimates required for policy decisions in HIV treatment and prevention. Understanding the population size is essential for determining the appropriate scale of the public health response. Without this knowledge, it becomes challenging to tailor interventions effectively. This is especially true for key populations (KP), which are less visible groups disproportionately at risk for HIV, such as female sex workers (FSW), men who have sex with men (MSM), and people who inject drugs [1]. Globally, KP and their sexual partners account for more than half of the new HIV infections as of 2019 [2]. Reliable estimates of KP sizes are needed to inform the planning and implementation of prevention and treatment programs as well as to assess the outcomes of these control measures. In particular, evaluating progress toward the Joint United Nations Programme on HIV/AIDS 95-95-95 goals (95% of people living with HIV know their status, 95% of those who know their status are receiving antiretroviral therapy [ART], and 95% of those receiving ART are virally suppressed) [3] requires accurate population size estimates.

Although these estimates have significant implications, there is currently no gold standard method for PSE [4]. In the absence of such a standard, various techniques have been developed, each with varying degrees of rigor [5]. On the one hand, estimates can be based on nonempirical data such as the opinion or experience of subject matter experts, such as the wisdom of crowds [6,7] or the Delphi method [8,9]. On the other hand, empirical data–driven biobehavioral survey (BBS)–based techniques including service or unique object multipliers [10] and recruitment information captured in surveys using respondent-driven sampling [11] can provide more reliable population size estimates [12] but can still produce incongruous results [13]. Moreover, CIs only capture part of the uncertainty we have in an estimate. Mistakes in implementation, violation of method assumptions, and incorrect statistical model application can all add additional bias and uncertainty that are not captured by the CI. A major question is how to synthesize multiple estimates of varying quality and certainty, given the practical need of policy makers and scientists for a single best estimate of population size. Although a range of estimates with uncertainty bounds derived from multiple statistical methods may be a more comprehensive snapshot, multiple estimates are often challenging to interpret if they are disparate and difficult to apply to problem-solving or performance evaluation.

To address this issue, a consensus best estimate is often arrived at somewhat arbitrarily by round table discussions of subject area experts; however, the absence of empirical evidence in such processes makes them susceptible to bias or statistical errors.

Recently, more rigorous statistical methods have emerged for finding a consensus-based estimate based on approaches in the field of meta-analysis. Meta-analysis is a branch of statistics concerned with synthesizing the results of multiple studies that aim to estimate the same quantity, often an effect size, in medical or epidemiological studies [14]. Traditional meta-analysis approaches have been based in frequentist statistics, although Bayesian techniques are becoming more common. Table 1 shows a component of the spectrum of frequentist models in meta-analysis for combining the effects of studies. In the fixed effects model, it is assumed that each study estimates the same effect, and only within-study variation is incorporated. In the random effects model, each study is assumed to estimate a different effect drawn from a population distribution and thus incorporates between-study variation. However, both models take the results of each study at face value. With the goal of incorporating bias adjustment into more traditional models, the quality effects model [15] has recently been introduced, and it has been shown to have fewer limitations than competing models [16]. In the quality effects model, each study considered is appraised on its methodological quality and given a quality score, which is then used to adjust the study variance within the model. Although other meta-analysis methods have Bayesian PSE analogs, such as the Anchored Multiplier, which draws on both fixed and random effects models [17,18], the quality effects model has yet to be adapted for use triangulating public health quantities.

In this study, we present a Bayesian hierarchical model to synthesize multiple study estimates that allow the user to incorporate the quality of each estimate as a study confidence score. We developed a mathematical framework for the model as well as a metric to assess the variation between estimates that have been captured by the model. We also introduced an implementation of the model as a user-friendly R Shiny app aimed at practitioners of PSE. To demonstrate both the model and the app, we provide several examples of their use in combining KP size estimates in several cities in a country in sub-Saharan Africa, showing the potential of our model to provide a valid best estimate in a practical context.
Methods
Overview
We began the construction of our model by considering a Bayesian hierarchical model that is fundamental in meta-analysis [19]. The primary goal of such a meta-analysis is to estimate the mean of the distribution of effect sizes, synthesizing the estimates of individual studies. Our goal was similar: to estimate a population quantity of interest \( \theta \) which can be a population size, population proportion, incidence, among others. We aimed to synthesize several estimates \( y_j \) of this quantity from different studies, where the variance \( \sigma_j^2 \) of each estimate is known.

Despite the assumption that the variance \( \sigma_j^2 \) is known (ie, has been computed during the processing of the \( j \)th study), it may not truly reflect the uncertainty in the estimate of \( y_j \). The variance \( \sigma_j^2 \) only accounts for the sampling uncertainty and not any additional uncertainty that there may be about potential bias in the study design. For example, in PSE, certain size estimation techniques result in incongruous estimates and nonoverlapping CIs [13], indicating that there is additional nonsampling error not accounted for by the CIs and \( \sigma_j^2 \). Nonsampling bias can be introduced for a number of reasons, including study design assumption violation, a mismatch between the study population and the population of interest, or an out-of-date sample. Our model provides a simple way for the user to account for their assessment of the degree of this additional uncertainty in the study. We allow the model user to adjust this uncertainty based on their confidence level \( c_j \in (0,1) \) in the study, where \( c_j = 1 \) represents full confidence in the study’s estimate and uncertainty. The SD is scaled by the transformation \( \sigma_j \to \sigma_j / c_j \) to adjust for this additional uncertainty at the discretion of the user. This allows practitioners and experts, whose expertise may carry information about each estimate not accounted for in the given CIs, to manually incorporate the potential for study bias.

The synthesis itself is based on a Bayesian hierarchical model that is often used in meta-analysis. At the first level of the hierarchy, we assume that each \( y_j \) is a point estimate of the quantity \( y_j \) estimated by the \( j \)th study:

\[
y_j 
\]

A normal model is chosen because many point estimates tend to be asymptotically normal according to the central limit theorem. That the \( y_j \) are estimates of \( v_j \), and not \( \theta \) directly, is an important distinction; individual studies may have bias, and that bias may not be accounted for by the user-specified study confidences. At the second level of the hierarchy, we assume that each study’s quantity of interest \( v_j \) itself is centered around the true population quantity of interest \( \theta \) with uncertainty characterized by the between-study variance \( \tau^2 \). At this level, we assume that the \( v_j \) are distributed normally as

\[
\]

Although the \( v_j \) provide a bridge between the data \( y_j \) and the target quantity \( \theta \), the between-study variance \( \tau^2 \) provides an important source of uncertainty beyond the adjusted study-level variances (\( \sigma_j^2 / c_j^2 \)). When \( \tau^2 \) is small, the \( v_j \) are similar, and most of the uncertainty in the model comes from the data level; when \( \tau^2 \) is large, most of the uncertainty comes from differing \( v_j \). However, from a practical perspective, the \( v_j \) represent a nuisance parameter that can significantly slow down the computational model. Eliminating this parameter by marginalizing it out yields the reduced model (refer to Multimedia Appendix 1 [18] for details):

\[
\]

In collapsing the hierarchical model to a single level, we can quickly and efficiently infer the mean of the distribution of the quantity of interest, given our data \( y_j \).

Prior Distribution for \( \theta \) and \( \tau^2 \)
As this is a Bayesian model, we must consider the distribution of the hyperparameters \( \theta \) and \( \tau^2 \). In general, we assume a normal prior for \( \theta \) with mean \( \mu_0 \) and variance \( \sigma_0^2 \):

\[
\]

The specification of this prior distribution for \( \theta \) is an important part of the inference process, as experts and stakeholders will often have informed beliefs about reasonable values for the population quantity.

Setting a prior distribution for \( \tau^2 \) is more complex, as there are multiple candidate distributions, each with advantages and
disadvantages; refer to the study by Williams et al [20] for discussion of the choice of prior on $\tau$ and why it may be desirable to place the prior on $\tau$ instead of $\tau^2$. We choose a half-Cauchy distribution for our prior on $\tau$, which is a Cauchy distribution truncated so that only positive values have a nonzero probability density. The distribution is heavy tailed, which is important because the model must allow for the possibility of large between-study variance. That said, we wish to trust that our stakeholders have accounted for the additional study variability in the confidence score step and thus wish to construct an informative prior that puts most of its mass at a very small $\tau^2$ but which allows for it to be large if the data are incompatible with a small $\tau^2$. This has the effect of flexibly controlling the model complexity, with the $v_j$ values only being appreciably different from $\theta$ if the data require it.

We control this distribution with a single-scale parameter $\gamma$, and thus, we choose that parameter to accumulate most of the probability mass for $\tau^2$ at 0. We use an empirical Bayes–flavored choice, which is scaled to be a fraction of the sample SD of the estimates $y_j$:

$$s^2 = \text{Var}(y_j).$$

As a heuristic justification for the choice of 0.1 as the value of the multiplier on the sample SD, we note that the quantile function for a half-Cauchy distribution with scale parameter $\gamma$ is $\gamma$, and thus, the 95th percentile is given by $Q(0.95) = 12.7\gamma$. As such, with $\gamma = 0.1$, a little more than 95% of the probability mass of $\tau^2$ is below the sample SD $s$ which we have found is often sufficient to create a high burden for values of $\tau^2$ away from 0.

### Transforming the Data and Parameter Space

The hierarchical model assumed a normal distribution for the estimates. This is generally justifiable, as most estimates follow the central limit theorem and are therefore approximately normal if the sample size of the study is large enough. However, depending on the quantity, the central limit theorem may be applied to smaller sample sizes when transformed. Regardless, the Delta method provides some assurance that transformed point estimates are asymptotically normal if the untransformed estimate is also asymptotically normal.

For instance, a log transform is typically used in PSE, where log-linear models are a prime example. Models of proportions often involve a logistic transformation, as seen in techniques such as logistic regression. With our model, the user may apply a transformation to the data, run the model, and then apply an inverse transformation to obtain inferences regarding the quantity of interest.

Working in a transformed space also transforms the prior, which can be desirable in and of itself. The log transform of PSE causes the prior to be log-normal. This may be a more reasonable prior distribution for this quantity because it is always >0. Similarly, for the logistic transform, the prior becomes a logistic normal distribution whose values are bounded from 0 to 1.

Transformations may induce infinities in some edge cases (eg, a point estimate of zero or one with a logistic transformation). In these cases, either the estimate may be dropped, or the analyst can choose not to use a transformation.

### Relationship With Frequentist Meta-Analysis Models

The frequentist methods in Table 1 describe increasingly complex models for estimating the combination. The fixed effect model simply calculates a weighted average of the estimates, weighted by the inverse variance of each estimate. Our model is the Bayesian analog of this fixed effect model when all study confidences are set to 100% and $\tau \rightarrow 0$. For $\tau >0$ and the study confidences set to 100%, our model is the Bayesian analog of the frequentist random effects model, where the $\tau$ in the random effects model is approximately analogous to our $\tau$. By positing a heavy-tailed prior for $\tau$ highly concentrated at 0, our model leans toward a fixed effect model when the data are compatible with it and a random effects model when the data are not compatible with it.

The quality effects model introduces a researcher-defined quality metric to the random effects model in much the same way that our study confidence does. Thus, when study confidence was included, the features of the quality effects model were incorporated.

### Explained Variance and Unaccounted-For Variation

Although we use the reduced model for computational reasons, the full multilevel model contains information about the sources of uncertainty that may have a significant impact on the confidence a user has in the resulting estimate of $\theta$. To quantify the sources of uncertainty, we computed a metric called explained variance, or $R^2$, which describes each level of the full model [21]. In the full multilevel model, $R^2$ calculated at the study (data) level is defined as

$$R^2 = \frac{\text{var}(\text{Estimate}) - \text{var}(\text{Estimate} - \text{Null})}{\text{var}(\text{Estimate})}.$$  

where $\text{var}(\cdot)$ is the posterior mean and $\text{var}(\cdot)$ is the sample variance operator. From this definition, an observation can be made: when the $v_j$ more closely approximate the $y_j$, $R^2$ is closer to 1, and when the $v_j$ more closely approximate $\theta$, $R^2$ is closer to 0. In the case where there is considerable variation in the estimates $y_j$, $R^2$ reflects the proportion of estimate variability attributable to unaccounted-for study bias. When the variation in the estimates is largely owing to unaccounted-for study bias, the $v_j$ will approximate the $y_j$, leading to high $R^2$. When study bias is accounted for by increasing the uncertainty of the estimates, the $v_j$ will more closely approximate $\theta$, leading to low $R^2$. To reflect this relationship, we use the term unaccounted-for variation to refer to $R^2$.

A complication with the abovementioned formula is that it relies on the parameters $v_j$ that have been eliminated in the reduced model. However, we can compute $R^2$ at the study level using the data and posterior draws of $\theta$ and $\tau^2$ that are specific to the model at hand. We find that
A full derivation of the preceding formulas can be found in Multimedia Appendix 1 [18].

Example Using BBS-Based PSE Methods

Overview

The population size estimates used to demonstrate the Bayesian hierarchical model using the Shiny app were all part of a 2019 BBS conducted among FSW in 3 cities (location A, location B, and location C) and MSM in 2 cities (location B and location C) of a country in sub-Saharan Africa. Priors and corresponding plausibility bounds were based on nonempirical stakeholder consensus during the 2014 BBS. In each survey city and for each key population (FSW and MSM), 2 methods of PSE were implemented: multipliers and successive sampling.

Multipliers

As part of a BBS, unique object, event, and service multipliers provide data sources to facilitate PSE. Multipliers have 2 overlapping components, both of which include members of a target population such as FSW or MSM. For each of the 3 multipliers, the first component takes place shortly before the BBS implementation. For unique object multipliers, small, inexpensive, and memorable unique objects (gifts) are distributed to target populations by teams of key population peers within the survey catchment area. For event multipliers, a party or concert is hosted for target population members. For service multipliers, client lists from HIV service providers are cleaned and deduplicated. The counts are tallied of individuals who received a gift, attended an event such as a survey kick-off party or concert, or accessed HIV services from a particular provider during defined dates. The second component is the weighted proportion of BBS respondents who reported receiving a gift, attending an event, or accessing HIV services. A population size estimate results when the counts are divided by the weighted proportion. These are reported with the corresponding 95% CIs.

For FSW in all 3 locations and MSM in location C, the survey multipliers included a unique object distributed in the survey catchment areas, a special event for the target population, 2 providers of testing services, and 1 outreach provider. The MSM survey at location B included an additional fourth outreach service multiplier.

Successive Sampling

As part of a BBS using respondent-driven sampling for recruitment, participants were asked a series of questions to determine their personal network size that informs the survey weighting. One assumption is that individuals with larger social networks are more likely to be sampled and more socially visible and, thus, recruited into surveys earlier than those with smaller networks [22]. The successive sampling PSE (SS-PSE) method has been described elsewhere [23] and applies this assumption to self-reported personal network size and the order of recruitment to estimate the population size. The SS-PSE used in this study uses imputed visibility to adjust for errors in network size reporting [24]. The SS-PSE was generated for FSW and MSM in all survey locations.

Confidence Scores

The purpose of the confidence score is to quantify, on a scale of 0 to 100, the quality or reliability of each individual PSE generated by various methods. It aims to provide a measure of how much trust or confidence one should place in each PSE. Confidence scoring requires knowledge of the methods and quality of PSE. Elements to consider for each PSE include whether the definitions of the populations are aligned; when (ie, Were the various studies conducted concurrently as part of the same BBS? Within 1 to 2 years of each other? Several years apart?) and how each of the PSE methods were implemented and analyzed; and how to apply that information to each PSE independent of, not relative to, other PSE. We have more confidence in empirical methods implemented concurrently in the same catchment area among populations with the same or similar characteristics, such as age range, sex, residence, and behaviors, with high-quality, complete data and minimal errors. Therefore, we assigned a high score that reflects the confidence we have in the PSE derived from an activity meeting these criteria. In contrast, if we have data from similar but not the same populations, conducted several years apart and sampling different catchment areas, with some missing data, we have less confidence in those PSE and assign a low score. Adjusting confidence scores or dropping low-quality PSE to produce a specific, desired outcome is strongly discouraged.

All PSE methods are subject to errors during implementation. Unique object, service, and event multipliers are commonly included with BBS. The first of the multipliers (or, if sampled twice before a survey, 3-source capture-recapture) involves offering unique objects to key population members in hot spots, typically carried out by teams of their peers (eg, FSW teams distributing unique objects to fellow FSW in venues where they congregate, often referred to as hot spots). The selection of which hot spots to visit (geographic coverage), who is responsible for distributing the unique objects (ideally, peers within the key population to increase acceptability), and the distribution method used (eg, hasty, clustered distribution vs a more systematic approach to peers in the hot spot) can vary significantly, potentially introducing bias into the data collection process. Broad geographic coverage implemented by peers using a systematic or random approach to distribute enough (eg, twice the survey sample size) unique objects would earn a high score. Next, health service client lists may be outdated (ie, include former or expired clients), contain duplicates, or exclusively cover a portion of the population (eg, an ART client registry representing only individuals who are HIV positive and actively receiving treatment). These challenges would result in a low score. Events may draw only a specific subgroup of the target population or fail to attract enough participants, which may compromise the reliability of the PSE. This was particularly apparent when the PSE produced by the event multiplier was smaller than the survey sample size. This scenario would result in a nonplausible PSE and a very low score.

In respondent-driven sampling surveys, participants were tasked with providing information regarding their personal network
size. This can present a significant challenge for respondents to estimate, as it is a function of the clarity of survey questions and a respondent’s ability to quantify the size of their network quickly and accurately. The response may not reflect the actual size. Even after adjusting the self-reported network size for social visibility, the resulting data could potentially impact the subsequent PSE during the successive sampling process. Confidence scores were independently applied to each PSE method and reflected the quality of implementation based on the elements described in this section as well as the plausibility of the estimates.

Ethical Considerations

The BBS survey was reviewed and approved by the ministry of health in the sub-Saharan African country; the implementing partner; and the Centers for Disease Control and Prevention Global Health Center in Atlanta, United States. The data collection staff completed training on human subjects research and signed a confidentiality agreement before commencing their survey duties. All participants provided written informed consent.

Results

Confidence Scores

We reviewed all PSE methods for FSW and MSM at each survey location and assigned a confidence score (Table 2). The confidence score was based on our knowledge of the rigor of the methods used for PSE and the quality of implementation of those methods. The scores were assigned to each method independent of other methods implemented in the survey; thus, a confidence score for one method was neither relative nor comparative to another method. Confidence scores were selected from the interval (0,100), with 100 representing full confidence. These scores were then divided by 100 to yield the confidence score $c_j \in (0,1)$, as described in the Methods section.

$^a$FSW: female sex workers.
$^b$MSM: men who have sex with men.
$^c$Not applicable (this refers to the fact that confidence scores are only applicable to the estimates).
$^d$N/A: not applicable (this refers to the fact that an estimate of type Service 4 was not collected).
$^e$95% CI refers to the credible interval.
$^f$SS-PSE: successive sampling population size estimation.
$^g$The implementation of PSE methods was similar across all survey locations for FSW and MSM, so our confidence scores were applied consistently by method. This was appropriate because our FSW and MSM populations had the same population definitions across survey sites and the methods were concurrently and consistently implemented. Had any survey site or population struggled with implementation, that site and the PSE method would have been assigned a lower score. At all survey sites, enough unique objects were broadly distributed across the survey catchment area, and the PSE from unique object distribution in FSW and MSM hot spots was plausible; thus, we assigned a high confidence score of 80. Providers of HIV testing and outreach services reviewed and used similar methods to clean their client lists; however, the services did not represent the entire FSW or MSM population in any of the cities, only those who pursued testing or engaged in outreach services. The service providers were unable to guarantee that the lists contained only current clients (ie, no former or expired clients) and were fully deduplicated; thus, they were assigned confidence scores of 60. The service providers varied by key population and city but were provided with the same instructions on how to clean and deduplicate the client lists, so the confidence scores...
were applied consistently for FSW and MSM services across all cities. Finally, all event multipliers indicated low overall participation, with only a small proportion of survey respondents reporting attendance. The events were similar in content and attendance for FSW and MSM across the survey cities. The resulting PSE for FSW and MSM in each survey city was smaller than the survey sample sizes. Despite being a low-quality, nonsensical PSE, the results were not dropped from the model; they were assigned a low confidence score of 5. The distributions of self-reported personal network sizes for FSW and MSM in each survey city were plausible with a few outliers; therefore, we adjusted for social visibility to reduce the impact of those outliers on the PSE. The SS-PSE using imputed visibility for FSW and MSM was consistent with previous study results and program data, so SS-PSE was assigned a high confidence score of 70.

**Using the Shiny App**

The confidence-scaled consensus estimation model is deployed in an easy-to-use Shiny app that requires only a few inputs from the user. There are 3 pages on the app: Enter Estimates, Define Prior Beliefs, and Synthesis.

As an example, we consider estimating the size of the population of FSW in location A of our example country in sub-Saharan Africa. The 6 PSEs and the prior are all specified in Table 2. The results of the model after running the app are also included in Table 2.

The prior estimate for the population is 800 FSW, with plausible bounds of (300, 2000). This prior was arrived at by consensus among stakeholders and experts based on the 2014 BBS-based population size estimates using nonempirical methods such as the wisdom of crowds and literature reviews. The relatively wide bounds cover most of the new PSEs, which are all similar except for the Event and Service 2. The low Event estimate is mitigated by its low confidence, and as such, it will have less of an effect during synthesis. However, the high Service 2 estimate has relatively high confidence, so we would expect this estimate to pull the posterior mean higher.

The estimates are entered in the Enter Estimates tab of the app (Figure 1A) along with the upper and lower bounds of the CI and the confidence in the study (ranked out of 100). The other choice that the user must make on this tab is whether to apply a transformation to the data, with the options being no transformation, log transformation, and logit transformation. The log transformation is recommended when working with population size estimates, whereas the logit transformation is recommended for percentage or proportion data.

**Figure 1.** The (A) Enter Estimate tab and the (B) Define Prior Beliefs tab of the Shiny app. The Enter Estimates tab requires the user to input any number of estimates, upper and lower bounds of the 95% CIs of those estimates, and confidence scores (out of 100) as well as input the estimate type to determine the most appropriate transformation of the input data. The Define Prior Beliefs tab requires users to input the median and 75th percentile for the prior distribution of the quantity being estimated and optionally maximum and minimum values that the quantity estimated can take on.

The prior beliefs are then entered in the Define Prior Beliefs tab (Figure 1B). The median of the prior should match the prior estimate of the population size. The 75th percentile, which is used to determine the spread of the prior, is also required. This is meant to be a practical and flexible way to characterize the uncertainty in the prior. If the user has reliable information about the prior uncertainty, such as the 95% CI, the 75th percentile can be computed and entered. If the user does not have reliable information about the uncertainty, they may try several options for the 75th percentile, and the app will resample to create the prior distribution shown in Figure 1B until the user believes the distribution shown reasonably reflects their knowledge of the population size.

The lower and upper bounds on the prior are not required for the model to run but can speed up the computation and provide a more reliable synthesis of the estimates by ruling out impossible prior values. In this example, the lower bound is set to 1 because there must be at least 1 FSW to make the population size worth estimating. The upper bound is set to 3000, which is somewhat arbitrary but makes improbably large population sizes unlikely.

Once prior information has been entered, the model can be run on the Synthesis tab. One additional input is the \( \tau \) multiplier, which helps to set the scale parameter for the prior on \( \tau \). We have found that this default works well in most cases, although it is possible that it may be appropriate to change it in some circumstances. For instance, one might wish to decrease the
multiplier (eg, to 0.01 or 0.001) if there is good reason to believe that all PSEs are of precisely the same population, such as if the studies were done at the exact same time with the exact same catchment area. In this case, barring errors in the implementation of the studies, the between-study variance would be expected to be close to 0, and thus, the prior on \( \tau \) can be adjusted to make high values of \( \tau \) unlikely. In contrast, if less is known about the implementation of the studies and there is reason to believe that there might be some true between-study variance, the multiplier could be increased (eg, to 1) to allow \( \tau \) to take on larger values or to make the prior less informative.

The results show both the prior and the posterior distributions of the population size \( \theta \) as well as descriptive statistics for the posterior distribution of \( \theta \) (Figure 2). Notably, the posterior median was higher and the uncertainty was lower when compared with the prior. The observation that the posterior variance is smaller than the prior variance is generally true: even if the PSEs are given very low confidence (and thus very high uncertainty), the posterior will look very similar to the prior. Refer to the Discussion section for further observations on this point. This tab also reports the unaccounted-for variation at the study level (\( R^2 \)) as the “percent of estimate variability attributable to unaccounted-for study bias.” In this example, \( R^2 = 11\% \), indicating that the confidence scaling in the model accounts for most of the nonsampling error that explains the differences among the study estimates. This is compared with the unscaled case (Table 2), where \( R^2 = 92\% \), indicating the incongruity of the estimates. A forest plot of the prior, estimates, and consensus results (for both confidence scaled and unscaled) is also shown in Figure 2, with both the reported CIs for the estimates (solid) as well as the scaled CIs (dotted).

Figure 2. The Synthesis tab of the Shiny app, which includes the consensus estimate and a forest plot of the prior, the estimates, and the consensus estimate as well as the unaccounted-for variation. For the estimates in the forest plot (black), the solid lines represent the unscaled 95% CI, whereas the dotted lines represent the confidence-scaled 95% CI.

### Other Cases

To further demonstrate the range of the model, we considered 4 other populations to estimate in our example country in sub-Saharan Africa: FSW and MSM in location B and FSW and MSM in location C (Figures 3 and 4). For each population, we consider an unscaled consensus estimate (each estimate’s confidence level is set to \( c_j = 1 \)) as well as a confidence-scaled estimate, where the confidence levels for each estimate are selected by expert opinion. The priors, estimates, and consensus estimates for these 4 populations are shown in Table 2. These 4 estimates show that the effects of confidence scaling are not limited to always increasing or decreasing the consensus estimate. Using confidence scaling over the unscaled version of the model, the point estimate for the population size decreased by 3% for FSW in location B, decreased by 14% for MSM in location B, increased by 13% for FSW in location C, and increased by 1% for MSM in location B. Furthermore, the magnitude of difference in the estimates for FSW in location C and MSM in location B shows that confidence scaling can have a major effect on the estimates.

The unaccounted-for variation for both the confidence-scaled and unscaled estimates for each population also shows the positive effects of having expert-selected confidence levels for the estimates. For the unscaled estimates, the proportion of estimate variation owing to unaccounted-for study bias is 0.89 for FSW in location B, 0.84 for MSM in location B, 0.90 for FSW in location C, and 0.91 for MSM in location C. For the confidence-scaled estimates, the proportion of estimate variability attributable to unaccounted-for study bias is 0.011 for FSW in location B, 0.02 for MSM in location B, 0.16 for FSW in location C, and 0.23 for MSM in location C. These results indicate that for the confidence-scaled models, there is
less unexplained variation in the $y_j$ owing to between-estimate variation when compared with the unscaled models.

Figure 3. Forest plots of prior distribution of the true population size $\theta$, population size estimates, and consensus estimates for (A) female sex workers (FSW) in location B, (B) men who have sex with men (MSM) in location B, (C) FSW in location C, and (D) MSM in location C. Consensus estimates include unscaled confidence (ie, all study confidence levels set at 100) and confidence scaling (with confidence scores given in Table 2).

Figure 4. Prior and posterior distributions of the true population size $\theta$ for (A) female sex workers (FSW) in location B, (B) men who have sex with men (MSM) in location B, (C) FSW in location C, and (D) MSM in location C. The prior is shown in red, the posterior with unscaled confidence (ie, all study confidence levels set at 100) is shown in green, and the posterior with confidence scaling is shown in blue.
Discussion

Principal Findings

In this study, we presented a Bayesian hierarchical model for triangulating estimates of public health interest, with our examples focusing on PSE. It is a major challenge for stakeholders to come up with a single population size estimate for a given population informed by multiple, potentially contradictory, estimates. Approaches used in the past could be overly simplistic, such as the use of a simple median, or opaque, with stakeholders picking a number after a discussion with no record of their full reasoning.

The model we have proposed assists and formalizes the triangulation process. It makes the decision for a consensus estimate from stakeholders transparent and explicit, while allowing them to retain control over how credible they find each individual estimate. Furthermore, the tool we developed to implement this model has a built-in assessment of the consensus process in the form of unaccounted-for variation; thus, the Shiny app can provide instant feedback on how successfully the individual estimates were combined in consensus. For users working with population size estimates, we recommend rounding results when presenting them to stakeholders to avoid any confusion stemming from noninteger counts of people. For all estimates, we strongly encourage transparency by presenting confidence scores with a rationale for each.

We presented a use case that represents a common challenge: the need to synthesize multiple estimates, often derived from methods of varying quality. In our example, we had the benefit of all empirical PSE and knowing the limitations and errors made during survey implementation. This provided a valuable context for confidence scoring, which affects the consensus estimate. When this information on implementation is not available, the next best option may be to base confidence scores on the strength of the method used to produce each estimate. For example, we presented the PSE derived from events, and all were smaller than the survey sample size. We did not need to know about the implementation errors to know these were nonsensical results that merited very low confidence scores. The PSE were all produced from the same survey; therefore, there were no differences in the age of our PSE to impact confidence scores (eg, we would have low confidence in older PSE and high confidence in the current PSE). As described earlier, our priors were several years old and based on stakeholder consensus. We were not present for the discussions years before our survey and do not know whether this consensus effort was influenced by a few with strong voices or more representative of the entire group of experts. Analysis of our data presented in Figures 3 and 4 suggests that the more disparate our individual estimates were, the more influential the prior was in the consensus estimate. Therefore, we encourage users to gather as much information as possible on the quality of the prior and how it was derived to provide context for the consensus estimate.

Strengths and Limitations

Other Bayesian approaches such as the Anchored Multiplier model [17,18] have been proposed for PSE. Our model differs from the Anchored Multiplier (and its Variance-Adjusted counterpart) in 4 ways. First, our model can directly handle any estimated quantity, including both population proportions and absolute sizes from any PSE technique, whereas the Anchored Multiplier is designed for estimates of population proportions and requires the selection of denominators to handle absolute sizes. Second, the Anchored Multiplier uses a binomial distribution as the sampling distribution and a beta distribution as the prior distribution, whereas our model uses normal distributions for both the sampling and prior distributions, with transformations tailoring the model to the estimate type. The effect of this difference in model structure is explored in detail in Multimedia Appendix 1 [18]; the differing structures give the models strengths in different cases, and as such, they represent complementary rather than competing approaches. Third, in the variance-adjusted case, the Anchored Multiplier uses a frequentist estimator of $\tau^2$ to extend the CIs of the estimates, whereas in our model, $\tau$ is a parameter that is fit during the sampling process. This distinction is important, as the DerSimonian-Laird estimator [25] used by the Anchored Multiplier has the potential to underestimate the true value of tau squared [26] and produces confidence (or credible) intervals that are overly narrow, particularly when the number of estimates is small or the true between-study variance is large [27], both of which are frequently encountered when dealing with PSE. A wholly Bayesian approach, such as the one offered by the Triangulator, may better account for between-study variance [27]. Fourth, and most critically, our model provides users with a clear and transparent platform to input their confidence for each estimate, which is displayed alongside the estimates data and consensus results on the final tab of the Shiny app. This is in contrast with the Anchored Multiplier and other techniques, where any adjustments to the uncertainty surrounding the estimates must be made before entering the data, which may lead to confusion among observers regarding the source of the data.

Results from the Triangulator are subject to several user limitations. First, if a user lacks knowledge of the quality of the estimates to be synthesized by the Triangulator, the confidence scores may not reflect the actual quality. High scores given to poor-quality data in the presence of other confidence-scaled estimates may result in a biased consensus estimate, as can low scores given to high-quality data. Next, users may try to adjust the confidence scores and model parameters after running the models to fit a specific, desired consensus estimate. Whether this affects the Triangulator more than similar models is debatable; the Triangulator, the data, confidence scores, and prior information are all transparently presented in the app, whereas with other methods, the inputs may be obfuscated. We provided tutorials for the proper use of the Triangulator to avoid spurious results by making such adjustments.

Conclusions

As a user-friendly app, the Triangulator has broad utility for statisticians, epidemiologists, and other public health officials—anyone seeking to combine multiple estimates of population size, incidence, prevalence, or other quantities into a single consensus estimate. It offers a solution to the
long-standing problem of synthesizing multiple estimates, potentially leading to more informed and evidence-based decision-making processes. Single-point estimates are widely used in decision-making, resource allocation, and policy development. Ministries of health rely on them to meet global health reporting requirements. Humanitarian organizations and multilateral government donors use single-point estimates to establish targets and assess their performance against those targets. The Triangulator leverages the user’s knowledge of the quality of the original estimates as well as prior knowledge of the quantity being estimated. Although technical parameters can be adjusted to meet the needs of certain users, for most use cases, no additional information is required outside of the estimates to be combined (and their uncertainty), confidence scores for each estimate, and parameters to set the prior on the quantity of interest. The functionality increases accessibility to public health teams that may not have statistical support but need to synthesize multiple estimates into a single estimate with uncertainty bounds. The Triangulator has the flexibility to be adapted and used in various other contexts and regions to address similar challenges.

Software, including the Shiny web app source code, is freely available and can be accessed on the internet [28]. The Shiny app is hosted at Epi apps for convenient use [29].

Acknowledgments
The authors would like to thank Dr. Ray Shiraishi (Division of Global Health & TB, Centers for Disease Control) for his comments and contributions to the model design and analysis in this study. This project has been supported by the President’s Emergency Plan for AIDS Relief through the Centers for Disease Control and Prevention. The findings and conclusions in this manuscript are those of the authors and do not necessarily represent the official position of the funding agencies.

Data Availability
All data generated or analyzed during this study are included in this published article.

Authors’ Contributions
IEF conceived of the model, CC and IEF designed the model and performed technical analysis, AFM, as a survey coinvestigator, conducted the original population size estimation analysis and assigned confidence scores included in the model and CC wrote and revised the manuscript with input from IEF and AFM. All authors have read and approved the final manuscript.

Conflicts of Interest
None declared.

Multimedia Appendix 1
Derivations of the model equations, a sensitivity analysis of the posterior estimate of tau, and a comparison of the model presented in this manuscript to an existing model in the literature.

Abstract

Background: Estimating the size of key populations, including female sex workers (FSW) and men who have sex with men (MSM), can inform planning and resource allocation for HIV programs at local and national levels. In geographic areas where direct population size estimates (PSEs) for key populations have not been collected, small area estimation (SAE) can help fill in gaps using supplemental data sources known as auxiliary data. However, routinely collected program data have not historically been used as auxiliary data to generate subnational estimates for key populations, including in Namibia.

Objective: To systematically generate regional size estimates for FSW and MSM in Namibia, we used a consensus-informed estimation approach with local stakeholders that included the integration of routinely collected HIV program data provided by key populations’ HIV service providers.

Methods: We used quarterly program data reported by key population implementing partners, including counts of the number of individuals accessing HIV services over time, to weight existing PSEs collected through bio-behavioral surveys using a Bayesian triangulation approach. SAEs were generated through simple imputation, stratified imputation, and multivariable Poisson regression models. We selected final estimates using an iterative qualitative ranking process with local key population implementing partners.

Results: Extrapolated national estimates for FSW ranged from 4777 to 13,148 across Namibia, comprising 1.5% to 3.6% of female individuals aged between 15 and 49 years. For MSM, estimates ranged from 4611 to 10,171, comprising 0.7% to 1.5% of male individuals aged between 15 and 49 years. After the inclusion of program data as priors, the estimated proportion of FSW derived from simple imputation increased from 1.9% to 2.8%, and the proportion of MSM decreased from 1.5% to 0.75%. When stratified imputation was implemented using HIV prevalence to inform strata, the inclusion of program data increased the proportion of FSW from 2.6% to 4.0% in regions with high prevalence and decreased the proportion from 1.4% to 1.2% in regions with low prevalence. When population density was used to inform strata, the inclusion of program data also increased the proportion of FSW in high-density regions (from 1.1% to 3.4%) and decreased the proportion of MSM in all regions.

Conclusions: Using SAE approaches, we combined epidemiologic and program data to generate subnational size estimates for key populations in Namibia. Overall, estimates were highly sensitive to the inclusion of program data. Program data represent a supplemental source of information that can be used to align PSEs with real-world HIV programs, particularly in regions where population-based data collection methods are challenging to implement. Future work is needed to determine how best to include...
and validate program data in target settings and in key population size estimation studies, ultimately bridging research with practice to support a more comprehensive HIV response.

**Introduction**

There have been significant declines in HIV incidence in countries across southern Africa over the last 10 years, including in Namibia [1]. This progress largely reflects the expanded availability of comprehensive HIV prevention and treatment, including the rollout of pre-exposure prophylaxis and increased access to antiretrovirals for people living with HIV. In Namibia, approximately 95% of those living with HIV are aware of their status, 95% of those aware of their status are on treatment, and 92% of those on treatment are virally suppressed [2]. Despite these investments and progress toward the Joint United Nations Programme on HIV/AIDS (UNAIDS) 95-95-95 targets, key populations in Namibia, such as female sex workers (FSW) and gay, bisexual, and other men who have sex with men (MSM), continue to experience a disproportionate burden of HIV compared to other adults of reproductive age [3], with an estimated prevalence of 20.9% and 8.4%, respectively. Viral suppression among individuals living with HIV ranges between 31.2% and 75.5% among FSW and between 55.8% and 76.1% among MSM, with significant variation across geographic regions [2].

Key populations in Namibia face individual, network, and structural barriers to HIV prevention and treatment that increase population-level risks for HIV acquisition and transmission. Sex work is criminalized in Namibia [4], limiting the extent to which FSW are able to safely access sexual and reproductive services without the fear of stigma or penalization by law enforcement. Power imbalances within sexual relationships, high rates of sexual and physical violence, and a lack of social protections for sex workers can compromise sexual autonomy and increase the risk of HIV [5,6]. For MSM, laws that criminalize same-sex relationships between men and other intersectional stigmas have been found to increase depression and impact stress-response behaviors in Namibia, such as substance use, increasing the risk of acquiring HIV [7]. Further, enacted stigmas in clinical settings have been found to limit access to comprehensive health services for MSM, including prevention and treatment for HIV and other sexually transmitted infections [2,8-10].

Differrentiated HIV services that are responsive to the needs of key populations can improve the overall quality of care and increase the uptake of HIV testing and treatment, but data are needed to guide the rollout and scale-up of these programs in Namibia [11]. Studies to determine population size for FSW and MSM in Namibia have historically been conducted in mostly urban settings, where community-led HIV programs are well-established. However, due to the high cost of incorporating less densely populated areas into empiric data collection efforts, population size estimates (PSEs) for key populations are lacking for the majority of the country.

Determining the number or size of key populations in Namibia may help identify existing gaps in programming and guide the prioritization of interventions aimed at addressing the transmission, prevention, and treatment of HIV [12]. Methodological approaches that use existing PSEs along with auxiliary data sources to determine the size of key populations are well-established [13-15]. However, these small area estimation (SAE) approaches typically exclude the use of program data as key inputs. Additionally, key population PSEs are often generated using multiple methods, and thus numerous and competing estimates may be produced for the same district or region [16,17]. While HIV programs frequently provide services in the same regions where size estimates are available and thus collect substantial data on the number and type of key populations accessing services, program data have not been used to systematically inform the triangulation of these size estimates [18]. By comparison, sentinel surveillance data and national HIV service delivery program data are regularly combined to inform estimates for the “general population,” but this approach is not currently used for key population-related estimation.

In this study, we used a consensus-informed approach with local stakeholders alongside routinely collected HIV program data provided by key population implementing partners to systematically generate subnational size estimates and demonstrate the use of the inclusion of program data for FSW and MSM in Namibia.

**Methods**

**Direct Estimates and Sources of Auxiliary Data**

Direct size estimates were generated using empiric data collection methods between 2012 and 2014 through Integrated Bio-Behavioral Surveillance Studies (IBBSS) in Zambesi, Ohangwena, Erongo, and Khomas for FSW [19] and in Karas, Oshana, Erongo, and Khomas for MSM (Table S1 in Multimedia Appendix 1) [20]. In the IBBSS, direct estimates were derived using multiple methods of size estimation, including mapping, key informant interviews, unique object identifiers, wisdom of the crowds, literature review, and stakeholder consensus [16,19]. These methods have been described previously [16,19]. Respondent-driven sampling was used to recruit all participants. Briefly, a set of 6-9 seeds from 4 study sites were selected, and each seed used coupons to refer others into the study. Recruitment continued until the desired sample size was reached [19,20]. Eligible FSW were aged 18 years or older and had received monetary payment for sex in the previous 6 months. Eligible MSM were aged 18 years or older and reported...
engaging in sex with other men in the previous 6 months. Both FSW and MSM were required to have resided in the study region for the last 6 months.

Auxiliary data to inform extrapolated estimates were identified in consultation with implementing partners and key stakeholders of key population programs in Namibia and were accessed through the Data.FI Consortium, a 5-year collaboration funded by the President’s Emergency Fund for AIDS Relief (PEPFAR) through the United States Agency for International Development (USAID) [21]. Specific data types included census data and geographically disaggregated population-level data such as regional literacy rates and HIV prevalence estimates. Auxiliary data sources comprised the Namibia 2011 Census [22], Namibia Population Projections calculated by the Namibia Statistics Agency [23], and the Namibia Population-Based HIV Impact Assessment (NAMPHIA) [24]. Census data and population projections were publicly available, while NAMPHIA data were obtained by request from the Centers for Disease Control and Prevention. Program data sources included indicators collected through PEPFAR’s key populations Data for Accountability, Transparency, and Impact Monitoring (DATIM) efforts [25] as well as indicators reported by the partner-led Key Populations—Strengthening Technical Assistance and Response for sustainable HIV prevention and treatment (KP-STAR) program [26].

Population denominators for direct estimates were extracted from Namibia’s Census Population Projections for the years in which data were collected in order to transform size estimates into standardized proportions. For FSW, this included regional estimates of cisgender women aged between 18 and 49 years; for MSM, this comprised adult cisgender men aged between 18 and 49 years. Age bands for each population were selected to align denominators with the age composition of the direct size estimates (numerators) collected through the initial IBBSS respondent-driven sampling survey.

Auxiliary variables identified for potential inclusion in SAE approaches included population density, employment rates, literacy proportions, and HIV prevalence. Population density, literacy, and employment rates were abstracted from the publicly available Namibia 2011 Census, while HIV prevalence estimates came from NAMPHIA (Tables S2 and S3 in Multimedia Appendix 1 provide comparisons of these characteristics across regions, stratified by sex). Variables were selected for inclusion in analyses based on their availability across on- and off-sample regions and through previously identified associations with key population size in the literature [13,14,27]. Population density and HIV prevalence were ultimately selected, given the variation in these data across regions where direct estimates were available. Program data used to inform priors included counts of the number of individuals who accessed services, reported through both DATIM and KP-STAR.

**Use of Program Data to Inform Imputations**

Each method of direct size estimation produces a single estimate. Given the variation between available direct estimates within regions, we used a consensus estimation approach and a publicly available tool (ie, the consensus estimator tool) to generate a single estimate for each region where direct estimates were collected [28]. This allowed for the weighting of the IBBSS-collected direct estimates both by precision and by quality of study implementation. The methods of direct size estimation were ranked by level of confidence, with successive sampling population size estimation (SS-PSE) having the highest confidence, followed by unique object multiplier, mapping, stakeholder consensus, literature review, key informant interview, and lastly, wisdom of the crowds. This initial ranking scheme was based on the rigor and quality of methods, guided by the World Health Organization’s synthesis of these direct size estimation methods and investigator experience implementing these approaches [16,29-31].

Prior beliefs for the distribution of the derived size estimates were defined based on program data. Quarterly data between fiscal year (FY) 2020 quarter 3 and FY 2021 quarter 2 from KP-STAR and between FY 2016 quarter 4 and FY 2021 quarter 1 from DATIM were used. Program data included the number of FSW or MSM that were reached by programs during each quarter. A 2-tailed, 2-sample t test was performed to identify any differences in the underlying distribution between the KP-STAR and PEPFAR data. The data from PEPFAR and KP-STAR were pooled due to similarity in the underlying distribution, and the minimum, maximum, and median numbers were calculated, in addition to the SD for the pooled numbers from 2016 quarter 4 and 2021 quarter 2. These 4 values, along with the assumed log-normal distribution for population sizes, served as the prior beliefs for the consensus estimator tool in order to derive a single direct estimate for each region. Of note, the data availability limited the accessibility of consistently reported direct estimates across regions, such as missing direct estimates collected through SS-PSE for MSM in Karas and Oshana. The USAID team implemented routine data quality assessments of data from DATIM and KP-STAR. This involved a random sample review of data captured in client files in comparison to the implementing partner’s client-level electronic database. A similar comparison was routinely collected at the aggregate level, comparing site-level monthly reports to the quarterly data.

Sensitivity analyses were completed to determine the extent to which adjusting the numerical level of confidence but retaining the rank order affected the weighting scheme and the resulting combined direct estimates. Multiple permutations and values for the confidence levels were assigned to assess the sensitivity of the rankings across the resulting triangulated estimates. The resulting size estimates generated from the consensus estimator were similar across the varying confidence levels as long as rank order was preserved.

**SAE Using Imputation and Regression**

We conducted simple imputation, stratified imputation, and regression modeling to determine the regional proportion of female individuals aged between 18 and 49 years and the proportion of male individuals aged between 18 and 49 years that were FSW and cisgender MSM, respectively. The derived direct estimates from the consensus estimator tool were used in the simple imputation and stratified imputation approaches, whereas all the direct estimates were used in the regression approach to maximize the number of input data points.
For the imputation approaches, the consensus-generated direct estimates were divided by the total cisgender female population aged between 18 and 49 years for FSW and the total cisgender male population aged between 18 and 49 years for MSM to derive proportions. Using simple imputation, the mean of these proportions was applied to each of the regions where direct size estimates were not available. In the stratified imputation, HIV prevalence estimates reported by NAMPHIA were used as the stratification variable. Regions were categorized by whether their HIV prevalence fell above or below the median HIV prevalence of all the regions, as reported by NAMPHIA (17.85% among women and 7.45% among men of reproductive age). The mean of the proportions for each respective category was applied to each of the regions where direct size estimates were not available. In sensitivity analyses, simple and stratified imputations were also conducted using all the available direct size estimates to evaluate how the incorporation of program data as prior beliefs in the consensus estimator tool changed the results.

In a supplemental analysis, multivariable Poisson regression models were fit using the full set of available direct estimates to generate size estimate proportions for FSW and MSM. To ensure a maximum number of available inputs were available to fit the regression models, the consensus estimator tool was not used. Generalized estimating equations accounted for clustering by region, and candidate predictors included HIV prevalence, population density, literacy rate, employment, and annual projected population growth, all overall and stratified by sex. Model selection was determined using Akaike information criterion (AIC) and Bayesian information criterion (BIC) values, with the lowest values indicating the best fit.

The resulting estimated proportions from all approaches were applied to the projected 2021 population of female individuals for FSW and male individuals for MSM aged between 15 and 49 years, resulting in the final PSEs.

Software

Imputations were conducted using Microsoft Excel [32], multivariable Poisson regression was performed using Stata (version 16) [33], and maps were constructed using ArcGIS software [34,35].

Consensus Building With Local Stakeholders

The process of generating the extrapolated size estimates was an iterative process, requiring collaboration and discussion between researchers and government, programs, and community stakeholders in order to refine and select a final set of estimates. Meetings with implementing partners occurred on multiple occasions, with discussion around how these size estimates could be used programmatically to inform service delivery targets. A brief synopsis of these meetings has been provided in Multimedia Appendix 1.

Ethical Considerations

This study comprised a secondary analysis of deidentified surveillance data and routinely collected programmatic data; patient-level data were not shared with the study team nor included in analyses. The Johns Hopkins Bloomberg School of Public Health Institutional Review Board designated this work as not being a human subjects research study (IRB00007442).

Results

Direct PSEs

Direct PSEs collected through the IBBSS varied across direct estimation methods and by region for FSW (Table 1). The largest number of FSW was generally seen in Khomas, ranging from 100 (95% CI 50-1700) using key informant interviews to 5240 (95% CI 3373-11,706) using the unique object multiplier method. Khomas also produced the largest PSEs for MSM, ranging from 300 (95% CI 100-1600) using key informant interviews to 2416 (95% CI 850-4000) using stakeholder consensus. After incorporating program data as priors in the consensus estimator tool, the resulting generated PSEs in Khomas were 1480 (95% CI 1099-1799) for FSW and 511 (95% CI 143-958) for MSM. Direct PSEs for each region, including the resulting weighted estimates from the consensus estimator tool, are presented in Table 1.

**Indirect Estimates**

Extrapolated national estimates for FSW ranged from 4777 (stratified imputation by HIV prevalence) to 13,148 (stratified imputation by population density, preprogrammatic data). For MSM, estimates ranged from 4611 (simple imputation and stratified imputation by HIV prevalence) to 10,171 (stratified imputation by population density). Regional estimates from the imputation approaches are reported in Tables 2 and 3 for FSW and Tables 4 and 5 for MSM. Regional estimates from multivariable Poisson regression models are included in Table S4 in Multimedia Appendix 1.

When program data were incorporated as priors in the imputation models, national extrapolated estimates ranged from 4777 (stratified imputation by HIV prevalence) to 9288 (simple imputation) for FSW. For MSM, these estimates ranged from 2236 (stratified imputation by population density) to 2372 (simple imputation). Regional estimates resulting from the inclusion of programmatic priors are presented by population for each approach in Tables 2-5 and are presented visually in Figures 1 and 2.

Figure 1. Map representing 2021 extrapolated estimates of the number of female sex workers (FSWs) across regions in Namibia. The darker gradations represent a higher number of FSWs in the region. The number of FSWs was calculated through 3 methods of imputation: simple imputation, stratified imputation (by HIV prevalence), and stratified imputation (by population density). Direct estimates used for the imputation were derived from a Bayesian consensus estimation approach incorporating routinely collected program data as priors.
Change in Imputed Estimates Following Inclusion of Program Data

After including program data as priors in the simple imputation model for FSW, the estimated proportion of female individuals aged between 15 and 49 years who were FSW increased from 1.9% to 2.8% (Table 3). Among male individuals aged between 15 and 49 years, the proportion of MSM decreased from 1.5% to 0.75% (Table 5).

In models where HIV prevalence informed stratified imputations, the estimated proportion of women who were FSW increased from 2.6% to 4.0% in regions where HIV prevalence was greater than the median; in regions with less than median HIV prevalence, the estimated proportion decreased from 1.4% to 1.2%. Among MSM, the proportion decreased from 2.1% to 0.8% in regions where the HIV prevalence was greater than the median and decreased from 1.3% to 0.7% in regions where the HIV prevalence was less than the median.

In models where population density informed strata, the estimated proportion of women who were FSW increased from 1.1% to 3.4% in regions with a greater than median population density and decreased from 2.8% to 1.0% in regions with less than median population density. Among MSM, the proportion decreased from 1.4% to 0.45% in regions where the population density was greater than the median and decreased from 1.5% to 1.0% in regions where the population density was less than the median.

Discussion

In this study of key population PSEs in Namibia, we calculated national and regional size estimates for FSW and MSM by incorporating routinely collected program data into established methodological approaches for SAE. These estimates were further refined by engaging implementing partners in consensus-building meetings throughout the estimation process. An iterative qualitative ranking process was used to ground truth estimates with partners. The resulting indirect size estimates varied across SAE approaches, and final estimates were calibrated to population-level data, stakeholder knowledge, and data routinely collected through HIV prevention and treatment programs in Namibia.

The inclusion of program data as previous knowledge increased the estimated proportion of reproductive-age women that were sex workers in regions with high HIV prevalence, suggesting that network-based surveys may have underestimated the true size of the sex worker population in Namibia [36]. Methods to collect direct PSEs vary in rigor and quality, but the quality of implementation and reporting of these estimates can be highly variable irrespective of method, making estimates difficult to compare [30]. Existing direct estimates for FSW from the IBBSS studies included in this analysis were also highly uneven across PSE approaches, necessitating a systematic approach to combine estimates into an interpretable and usable estimate for each region [18,36,37]. This approach may be relevant to similar settings in which direct size estimates are derived from multiple epidemiologic studies and necessitate a formalized approach for consolidation.

Historically, key population program data have not been included in size estimation exercises, given concerns around external validity. While these data are imperfect, in the case of SAEs, the number of sex workers accessing services through established key population programs can potentially serve as a lower bound for these estimates in a given region. This approach demonstrates the potential of including program data in SAE efforts to better align PSEs with real-world data in countries where surveillance efforts may be limited [14,18].

Indirect estimates for MSM were also highly sensitive to the inclusion of programmatic priors, producing smaller than expected population proportions for all regions. Despite efforts in Namibia to reach MSM with targeted HIV prevention and treatment services, including investments in peer navigators and community health workers [38], MSM remain largely marginalized from existing HIV programs relative to FSW. Provision of services to MSM remains a challenge amid Namibia’s legal framework, and as a result, the majority of MSM living with HIV are thought to be unaware of their HIV status. This is particularly true for younger MSM, who are significantly less likely to access HIV testing services relative to older MSM despite a high concentration of risk during
adolescence and early adulthood [39]. While age-oriented and culturally relevant HIV testing programs may increase the uptake of HIV services for young MSM in Namibia, in the absence of larger structural interventions that reduce stigmas and discriminatory policies, these innovations may result in only modest progress in reducing the burden of HIV among MSM [40]. As size estimation is often used for allocating funding and setting targets, methods that harmonize direct PSEs with real-world data in the context of these structural barriers are needed to develop realistic targets for epidemic control. Inclusion of program data in indirect size estimation methods such as SAE could potentially allow programs to implement more informed targets for the delivery of HIV prevention and treatment services, which is ultimately one of the key purposes of population size estimation studies.

These analyses were also grounded in a systematic consensus-building approach, bridging a gap in the coordination and integration of size estimation approaches between researchers and implementing partners [41]. Meetings with key stakeholders were highly influential in the development of indirect estimates, as the limited number of data inputs challenged the precise selection of a universal best-fitting model for each population. Results for up to 3 models were presented to stakeholders to ground-truth potential estimates and serve as an additional appraisal tool. Historically, consensus-building approaches have been used to guide the triangulation of direct PSEs resulting from multiple data collection methods [42-44]. Collaborative efforts that extend beyond the initial data collection processes are seemingly less common. While ideal estimates may vary for different stakeholders, particularly when estimates are used for program target setting, this approach may provide a way forward for ensuring that size estimates are ultimately used to guide practice, programming, and resource allocation.

There are several notable strengths in this study. First, we demonstrated the potential of program data as an underused data source to understand the size of key populations in Namibia, thus opening the possibility of routinizing this approach for size estimation activities in other settings. Second, we systematically engaged with external partners to understand the cultural and on-the-ground implementation context for SAE, which provided a robust understanding of the results and interpretation. Lastly, there was a wide availability of various program and auxiliary data sources spanning multiple regions and years. This enabled the use of longitudinal data to generate prior beliefs regarding the distribution of FSW and MSM in this specific context and to use characteristics specific to each region in order to predict size estimates, which has not been done previously in Namibia.

This study also had several limitations. Despite widely available auxiliary data, there was a lack of available direct size estimates for key populations in Namibia, and those that were available were limited to more urban regions and were from the mid-2010s. As these estimates informed the primary inputs for our imputation approaches and regression modeling, it is possible that extrapolated size estimates were upwardly biased in more rural settings or in communities where outmigration is common [45]. Furthermore, the direct estimates included in analyses may have been sensitive to other unmeasured characteristics, which could have subsequently impacted the size and direction of the resulting indirect estimates. Similarly, we were only able to use programmatic data from regions where size estimates had also been collected to inform our models, as these data informed triangulation of the available direct estimates. While these data may have improved the validity of extrapolated size estimates in regions where direct estimates were available, it is possible that their inclusion introduced additional biases in regions where these data were not available [15]. Moreover, there was limited regional heterogeneity in the availability of direct estimates and program data, resulting in a lack of nuanced indirect estimates in more rural areas.

In this study of indirect PSEs in Namibia, data routinely collected by key population implementing partners were incorporated as prior information into imputation models to produce updated regional and national FSW and MSM estimates. The findings provide a potential roadmap for the systematic integration of program data in generating HIV estimates for key populations and align size estimation efforts with best practices by UNAIDS and others that rely heavily on both sentinel surveillance and national service delivery data to inform general population HIV projections. Further, as PEPFAR and other international donors move toward a model of sustainable HIV programming in sub-Saharan Africa, integrating routinely collected data into SAE approaches can support a more precise calculation of costs and allow for an expanded evidence base for supporting targeted programmatic scale up. Finally, as funding and resources for large epidemiologic studies become increasingly scarce, harnessing underused data sources, such as routinely collected programmatic data, will be critical for improving the validity of PSEs and meeting the needs of key populations in Namibia and elsewhere.

Acknowledgments

The authors would like to thank all participants who generously donated their time to the data collection efforts that informed the present analysis. Additionally, the authors would like to acknowledge the important role of community groups and implementing partners in meeting the needs of those most marginalized in the HIV response. Abstract

Background: In the United States, both drug overdose mortality and injection-involved drug overdose mortality have increased nationally over the past 25 years. Despite documented geographic differences in overdose mortality and substances implicated in overdose mortality trends, injection-involved overdose mortality has not been summarized at a subnational level.

Objective: We aimed to estimate the annual number of injection-involved overdose deaths in each US state from 2000 to 2020.

Methods: We conducted a stratified analysis that used data from drug treatment admissions (Treatment Episodes Data Set–Admissions; TEDS-A) and the National Vital Statistics System (NVSS) to estimate state-specific percentages of reported drug overdose deaths that were injection-involved from 2000 to 2020. TEDS-A collects data on the route of administration and the type of substance used upon treatment admission. We used these data to calculate the percentage of reported injections for each drug type by demographic group (race or ethnicity, sex, and age group), year, and state. Additionally, using NVSS mortality data, the annual number of overdose deaths involving selected drug types was identified by the following specific multiple-cause-of-death codes: heroin or synthetic opioids other than methadone (T40.1, T40.4), natural or semisynthetic opioids and methadone (T40.2, T40.3), cocaine (T40.5), psychostimulants with abuse potential (T43.6), sedatives (T42.3, T42.4), and others (T36-T59.0). We used the probabilities of injection with the annual number of overdose deaths, by year, primary substance, and demographic groups to estimate the number of overdose deaths that were injection-involved.

Results: In 2020, there were 91,071 overdose deaths among adults recorded in the United States, and 93.1% (84,753/91,071) occurred in the 46 jurisdictions that reported data to TEDS-A. Slightly less than half (38,253/84,753, 45.1%; 95% CI 41.1%-49.8%) of those overdose deaths were estimated to be injection-involved, translating to 38,253 (95% CI 34,839-42,181) injection-involved overdose deaths in 2020. There was large variation among states in the estimated injection-involved overdose death rate (median 14.72, range 5.45-31.77 per 100,000 people). The national injection-involved overdose death rate increased by 323% (95% CI 255%-391%) from 2010 (3.78, 95% CI 3.33-4.31) to 2020 (15.97, 95% CI 14.55-17.61). States in which the estimated injection-involved overdose death rate increased faster than the national average were disproportionately concentrated in the Northeast region.

Conclusions: Although overdose mortality and injection-involved overdose mortality have increased dramatically across the country, these trends have been more pronounced in some regions. A better understanding of state-level trends in injection-involved mortality can inform the prioritization of public health strategies that aim to reduce overdose mortality and prevent downstream consequences of injection drug use.

Introduction

Drug overdose mortality has increased dramatically in the United States since 1999, with over 106,000 overdose deaths occurring in 2021 alone [1,2]. Although this trend is often largely attributed to an increase in opioid-involved overdose deaths [3,4], data from toxicology reports indicate that the specific drugs and drug classes that contribute to the burden of overdose mortality have changed over time [5-8]. In addition, primary routes of drug administration have evolved, and recent work suggests much of the recent increase in overdose mortality is likely attributable to increasing injection-involved overdose deaths. From 2007 to 2018, the estimated proportion of all overdose deaths that were injection-involved more than doubled from 18.5% to 42.2% [9]. Increases in injection-involved mortality may indicate an increase in injection behavior, which highlights additional public health concerns. Compared to other routes of substance use (eg, swallowing pills or smoking), injection drug use has the highest risk of overdose and the acquisition of bloodborne infections such as HIV, viral hepatitis, and skin infections [9-13].

National trends in injection-involved overdose mortality likely mask important geographic differences at subnational levels. Previous analysis of mortality data has identified regional differences in the substances implicated in overdose mortality trends [14-16]. Additionally, analyses of infectious disease surveillance data reveal geographic differences in both the rates of acute hepatitis B virus (HBV) and hepatitis C virus (HCV) infections [17] and the trends in HCV-related death rates among persons aged 40 years or younger [18], which are all likely related to the prevalence of injection drug use [19,20]. An understanding of subnational trends in injection-involved overdose mortality has implications both for local resource allocation and the types of interventions needed to prevent overdose mortality, as well as for public health strategies to address additional adverse health outcomes related to injection behavior. For example, the availability of naloxone [21-23] and the implementation of supervised injection sites [24] have both been shown to prevent overdoses, specifically among people who inject drugs. Syringe services programs can prevent infections through the provision of sterile needles and other injection equipment [25-27]. In this study, we aimed to estimate the annual number of injection-involved overdose deaths and the injection death rate within each US state from 2000 to 2020.

Methods

Overview

Our approach used and extended a previously published method for estimating the burden of injection-involved mortality [9]. Briefly, we conducted a stratified analysis that used data from drug treatment admissions to estimate the percentage of persons injecting by reported drug type within demographic strata. Using this estimated percentage along with counts of overdose deaths from the National Vital Statistics System (NVSS), we estimated the number of persons that died from an injection-involved drug overdose death within each state and year.

Data Sources

Drug treatment admissions data were from the Treatment Episode Data Set–Admissions (TEDS-A; from 2000 to 2020) [28]. TEDS-A is a national data set that includes client-level data routinely collected from all publicly funded, and some privately funded, facilities that are licensed to provide substance abuse treatment in the United States. The national data set compiles data from individual state systems into a standardized format. Each record in TEDS-A represents an admission to a treatment program and includes demographic information, along with data on the substances used and the usual route of administration for each substance.

Data on the annual number of overdose deaths were from the NVSS detailed multiple cause of death mortality microdata files, obtained through a data request from the National Center for Health Statistics (NCHS) [29]. The NVSS microdata include a line-listing of all deaths that occurred in the United States from 2000 to 2020. Mortality data include the International Classification of Diseases, Tenth Revision (ICD-10) codes for multiple underlying causes of deaths. To align with previous definitions, overdose deaths were classified using the following ICD-10 codes: X40-X44, X60-X64, X85, and Y10-Y14 [1,30]. Additionally, overdose deaths involving selected drug types were identified by the following specific multiple-cause-of-death codes: heroin or synthetic opioids other than methadone (T40.1, T40.4), natural or semisynthetic opioids and methadone (T40.2, T40.3), cocaine (T40.5), psychostimulants with abuse potential (T43.6), sedatives (T42.3, T42.4), and others (T36-T59.0). We used National Center for Health Statistics bridged-race annual population estimates [31] for denominators in all population death rates.

Analysis

All analyses were limited to adults aged 18 years or older within 50 US states and the District of Columbia. Using TEDS-A data from 2000 to 2020, we identified all treatment admissions that included the following drugs: heroin or synthetic opioids (excluding methadone), stimulants (including methamphetamine, other amphetamines, and other stimulants), natural or semisynthetic opioids and methadone, cocaine (including crack), and sedatives (including benzodiazepines, other tranquilizers, barbiturates, and other sedatives). For each year and within each state, TEDS-A treatment admissions data were categorized into 16 strata defined by all combinations of sex (male and female), age group (18-39 years and ≥40 years), and race or ethnicity (Hispanic, non-Hispanic Black, non-Hispanic White, and non-Hispanic other). For each of the 5 drug types, within the analytic strata, we estimated the percentage of injection by calculating the percentage of admissions with data on the route of administration that reported injection as the usual route of administration. The number of treatment admissions and
percentage of reported injections for each state, year, and drug type are reported in Table S1 in Multimedia Appendix 1.

Overdose deaths from NVSS that included toxicology data were categorized into the same 5 mutually exclusive drug categories. Deaths that indicated multiple drugs were categorized based on the drug that had the highest overall percentage of persons reporting injection, as estimated from the TEDS-A treatment data [9]. This approach was used because we were interested in the percentage of any drug having been injected rather than in classifying deaths as attributable to a single drug type. Overdose deaths that did not have a specific T-code listed (ie, only listed T50.9) were distributed to the 6 categories (the 5 defined drug use categories described above and any other T-codes) based on the nonmissing distribution within each year and demographic strata [32,33]. The percentage of all overdose deaths that were categorized into each drug category for each state and year is reported in Table S2 in Multimedia Appendix 2 [1,9,29,30,32,33].

To estimate the number of injection-involved overdose deaths, we multiplied the drug-specific probabilities of injection by the respective number of reported overdose deaths within each drug type, state, year, and demographic strata. We then collapsed the results to report the estimated number of injection-involved overdose deaths for each state and year. To estimate population-level rates, we summed the bridged-race population estimates as denominators. The CIs were estimated by calculating the Clopper-Pearson confidence limits for all estimates of drug-specific probabilities of injection. If the annual number of treatment admissions that reported any of the 5 drug types was less than 50 within any state, we suppressed the results for that state and year. Additionally, if more than 15% of treatment admissions that reported a drug of interest were missing, we suppressed the results for that state and year.

To demonstrate how changes in injection-involved overdose mortality differed by state and over time, we present state-level results from 3 years: 2000, 2010, and 2020. We also calculated the relative percentage change in the national injection-involved overdose death rate from 2010 to 2020 with CIs for multiyear percentage change [34]. If a state had a suppressed rate for either 2010 or 2020, we suppressed the estimated trend. We then compared the state-level trends to the national trend during the same time period to identify states that had more or less pronounced trends.

**Ethical Considerations**

This study did not receive a review or a formal determination from an institutional review board because this analysis is not human-participant research, according to Regulation 45 CFR 46 [35].

**Results**

In 2020, 90% (46/51) of jurisdictions reported treatment data and were included in the national TEDS-A data set (states not included were Idaho, Maryland, New Mexico, Oregon, and Washington). Overall, there were 91,071 overdose deaths among adults recorded in the United States in 2020. Of those, 93.1% (84,753/91,071) occurred in the 46 jurisdictions that reported data to TEDS-A. Slightly less than half (38,253/84,753, 45.1%, 95% CI 41.1%-49.8%) of those were estimated to be injection-involved, translating to 38,253 (95% CI 34,839-42,181) injection-involved overdose deaths (Table 1). In 2020, the national injection overdose death rate was 15.97 (95% CI 14.55-17.61) per 100,000 people.
Table 1. Estimated number of injection-involved overdose deaths among adults by US state, 2020. State-level results were suppressed if the annual number of treatment admissions that reported any of the 5 drug types was <50 or if ≥15% of treatment admissions that reported a drug of interest were missing data on route of administration.

\(^a\)Not available. These states did not report data to Treatment Episodes Data Set–Admissions.

\(^b\)National rate does not include populations from states that did not report data to Treatment Episodes Data Set–Admissions (Idaho, Maryland, New Mexico, Oregon, and Washington).

In addition to the 5 states that did not report TEDS-A data, we suppressed data from 7 states, resulting in 39 (77%) states with estimated results for 2020. In 2020, the estimated number of injection-involved overdose deaths by state ranged from 37 (95% CI 26–49) in South Dakota to 3767 (95% CI 3475–4073) in Florida (Table 2). There was large variation in the estimated injection-involved overdose death rate by state (median 14.72, range 5.45–31.77 per 100,000 people). Of the 10 states with the highest estimated injection overdose death rate, 5 were located in the South (Kentucky, Tennessee, Louisiana, Delaware, and Florida), 3 were in the Northeast (Pennsylvania, Massachusetts, and Rhode Island), and 2 (Ohio and Indiana) were in the Midwest Census regions. Of the 8 states in the Northeast that have results, 7 (86%) had an estimated injection overdose death rate higher than the national rate (Figure 1). All 6 states with results in the West had an estimated injection overdose death rate lower than the national rate. Over half (19682/38253, 51.5%) of the total number of estimated injection-involved overdoses occurred in 8 states (Florida, California, Pennsylvania, Ohio, New York, Texas, Tennessee, and North Carolina).
Table 2. Estimated number of injection-involved overdose deaths among adults, by US state and year, 2000-2020. State-level results were suppressed if the annual number of treatment admissions that reported any of the 5 drug types was <50 or if ≥15% of treatment admissions that reported a drug of interest were missing data on route of administration.

aNot available. These states did not report data to Treatment Episodes Data Set–Admissions.
Figure 1. Estimated injection-involved overdose death rate among adults, by state and region, United States, 2020. The vertical line represents the national estimated injection overdose death rate for 2020. States without an estimate either did not report data to TEDS-A or were suppressed. State-level results were suppressed if the annual number of treatment admissions that reported any of the 5 drug types was <50 or if ≥15% of treatment admissions that reported a drug of interest were missing data on route of administration.

The number of overdose deaths among adults increased more than 5-fold from 2000 (n=17,196) to 2020 (n=91,071; Table 2). Among jurisdictions that reported TEDS-A data, the estimated number of injection-involved overdose deaths increased more than 10-fold from 2000 (50/51 states reported TEDS-A data; n=3549, 95% CI 3103-4248) to 2020 (46/51 states reported TEDS-A data; n=38,253, 95% CI 34,839-42,181). Over the same time period, the national injection overdose death rate increased from 1.72 (95% CI 1.51-2.05) to 15.97 (95% CI 14.55-17.61). Much of that increase occurred from 2010 to 2020, in which the injection overdose death rate increased by 323% (95% CI 255%-391%). We estimated a state-level relative percentage change in the injection overdose death rate from 2010 to 2020 for 38 states. States that experienced the largest relative increase in injection overdose death rates were disproportionately concentrated in the Northeast (Figure 2). The injection overdose death rate increased more than 6-fold in Massachusetts (733% relative increase), Maine (678% relative increase), New York (610% relative increase), Virginia (600% relative increase), New Jersey (573% relative increase), Louisiana (545% relative increase), Florida (523% relative increase), and Connecticut (507% relative increase). There were 6 states (Utah, Texas, Arkansas, Missouri, Nebraska, and Iowa) that experienced a more gradual increase in the injection overdose death rate than the national increase. The estimated number of injection-involved overdose deaths and injection overdose death rate for each state and year are reported in Table S3 in Multimedia Appendix 3. Additionally, Figure S1 in Multimedia Appendix 4 visualizes the relationship between state-level overdose death rates and the percentage of overdose deaths that were estimated to be injection-involved for each year.
Figure 2. Estimated injection-involved overdose death rate among adults, by state and year, United States, from 2000 to 2020. The state-level results were suppressed if the annual number of treatment admissions that reported any of the 5 drug types was <50 or if ≥15% of treatment admissions that reported a drug of interest were missing data on route of administration.

Discussion

This work provides additional evidence that drug overdose mortality and other adverse outcomes related to injection drug use continue to be growing public health challenges across the United States. We previously demonstrated that much of the increase in overdose mortality since 2000 [1] has been attributable to injection-involved overdose deaths [9], and this analysis indicates that trend continued through 2020. We estimated that over half (34,704/67,986, 51%) of the increase in overdose deaths between 2000 and 2020 were injection-involved deaths. Importantly, these results provide additional granularity that reveals geographic differences in the magnitude of that trend. Although the injection-involved overdose death rate has increased dramatically in all states, the increase in injection overdose mortality is most pronounced in the Northeast and Appalachia regions, further emphasizing the need to prioritize harm reduction strategies in these areas. These geographic differences may be indicative of differences in the drug supply [36], an ongoing shift from prescription opioid mortality to injection-involved mortality [37], or geographic differences in access to overdose prevention interventions.

The estimated injection-involved overdose death rate for any jurisdiction is driven by both trends in overdose deaths (the total number and distribution of substances involved) and trends in reported injection behavior by substance type. Nationally, the likelihood of injecting heroin or synthetic opioids steadily increased before peaking in 2014 at 69.4% and declining to 58.3% in 2020 (Table S1 in Multimedia Appendix 1). However, during the same time period, the number of overdose deaths (46,764 in 2014 and 91,071 in 2020) and the proportion of overdose deaths attributable to heroin or synthetic opioids (39.6% in 2014 and 70.4% in 2020; Table S2 in Multimedia Appendix 2) continually increased, resulting in an increase in the overall injection-involved overdose death rate. As seen in Figure 2, some states have experienced a slight decrease in the estimated injection-involved overdose death rate in recent years due to slightly different temporal trends. For example, in Massachusetts, the injection-involved overdose death rate peaked in 2016. Similar to the national trend, the likelihood of injecting heroin or synthetic opioids has declined in recent years (79.6% in 2016 and 68.8% in 2020). This decrease outweighed the corresponding gradual increase in the percent of overdose deaths attributable to heroin or synthetic opioids (80.0% in 2016 and 85.8% in 2020), resulting in a decrease in the injection-involved overdose death rate. Similarly, recent trends in stimulant use and, subsequently, deaths attributed to stimulant use also influence these estimates. Generally, areas with a higher proportion of deaths attributable to stimulant use are estimated to have relatively fewer injection-involved overdose deaths.
based on a lower probability of injecting stimulants compared to heroin or synthetic opioids. In Tables S1 and S2 in Multimedia Appendices 1 and 2, we present both the probability of injecting by substance type and the percentage of deaths attributable to each substance as components of trends in injection-involved overdose in each state. Disaggregating the drivers of state-level trends in injection-involved overdose death rates can help inform the composition of harm reduction strategies.

Understanding changes in injection-involved overdose mortality provides additional value for designing overdose prevention and intervention strategies that cannot be gained from overall trends in overdose mortality alone. For example, states that are experiencing a particularly sharp increase in injection-involved overdose mortality may prioritize strategies that focus on injection harm reduction, such as naloxone access or supervised injection sites. Although the Centers for Disease Control and Prevention (CDC) has started to implement efforts to expand overdose surveillance and collect better data on the evidence of injection through the development of the State Unintentional Drug Overdose Report System (SUDORS) [38], the system does not yet have complete data on the route of administration and is too new to investigate temporal trends in injection-drug use.

Beyond the implications for overdose mortality prevention, these results can inform efforts to reduce infectious disease transmission due to injection drug use. From a public health surveillance perspective, injection drug use behavior, which is associated with an increased risk of transmission of several viruses and bacteria, is extremely difficult to measure and monitor [39]. These results can help state health departments and researchers better understand the burden of injection drug use in their jurisdiction. Recently, our team developed an approach that built upon this methodology to estimate that there were 3.7 million “people who injected drugs” in the United States in 2018 [40]. Following that framework, researchers could use these results, along with their own local data, to estimate the population size of people who injected drugs at the state level. There has been an increase in federal and state-led efforts to eliminate HCV [41] and HIV [42] infections, both of which disproportionately occur among people who injected drugs in the United States. The results from this analysis can be interpreted alongside data on the prevalence of HCV [17,43] or HIV [44] to highlight areas in most need of infectious disease prevention and treatment efforts. The comparison across states can inform the allocation of federal funding to scale up infectious disease prevention interventions [25,26,45] (eg, syringe service programs, substance use treatment centers, and hepatitis B vaccination clinics) or screening and treatment resources (eg, testing for acute viral hepatitis or HIV infections and providing linkage to care) [46,47].

As previously described in the development of this method [9], we note that we assumed the likelihood of injection within demographic strata and drug type is the same among living persons that enter treatment and persons who died of a drug overdose. This is a conservative approach because if the injection of any of these substances is more lethal than other routes of administration, these results would be an underestimate of the true burden of injection-involved mortality. Additionally, the selection of TEDS-A data to estimate the likelihood of injection comes with strengths and limitations. TEDS-A is the most comprehensive and complete single data source on substance abuse treatment admissions across the country. TEDS-A data collection has been an ongoing systematic activity for more than 30 years, which enables us to look at changes in reported behaviors over time. However, there may be differences in the data collection systems or the use of public funding for substance use treatment within each state [48]. As a result, the degree to which TEDS-A captures all treatment admissions may differ between states. However, this methodology does not depend on the complete enumeration of substance use treatment admissions but rather on the probability of reporting injection among those that are captured by TEDS-A data systems. In 2020, 99.2% of all admissions for a drug of interest reported data on the route of administration. The state-level response rate ranged from 44.6% in Wyoming to >99% in many states. After Wyoming, the second-lowest response rate was 95.2% in North Dakota.

Additionally, the analytic decision to categorize overdose deaths with multiple substances recorded for the drug with the highest likelihood of injection could result in an overestimate if polydrug use is less likely to involve injection than just using one of the drugs independently. In general, this assumption becomes more important, and the use of these estimates may be more limited in time periods or areas in which there is a high proportion of polysubstance use. A future analysis could validate these estimates with an analysis of reported injections from SUDORS [38] as those data become available. Finally, we assumed overdose deaths without T-codes were missing at random within strata and followed the same distribution as overdose deaths with recorded T-codes. However, the potential for this assumption to bias results has been reduced in recent years, as the completeness of these data has increased substantially over time [49].

Measuring trends in injection behavior and understanding how those trends impact the ongoing overdose mortality epidemic remains a huge public health challenge. These estimates provide longitudinal data points that reveal additional understanding of geographic heterogeneity in recent trends of injection-involved overdose mortality. As state and local public health departments continue to implement programs aimed at reducing overdose mortality and preventing infectious disease transmission, innovative and timely data sources can help inform the development of strategies best suited for their particular setting.

Abstract

Background: The COVID-19 pandemic has exerted a significant toll on individual health and the efficacy of health care systems. However, the influence of COVID-19 on the frequency and outcomes of out-of-hospital cardiac arrest (OHCA) within the Chinese population, both before and throughout the entire pandemic period, remains to be clarified.

Objective: This study aimed to fill the gaps by investigating the prevalence and outcomes of OHCA in Hong Kong (HK) both before and during the whole pandemic period.

Methods: This is a retrospective regional registry study. The researchers matched OHCA data with COVID-19–confirmed case records between December 2017 and May 2023. The data included information on response times, location of OHCA, witness presence, initial rhythm, bystander cardiopulmonary resuscitation (CPR), use of public-access defibrillation, resuscitation in the accident and emergency department, and survival to admission. Descriptive analyses were conducted, and statistical tests such as analysis of variance and $\chi^2$ were used to examine differences between variables. The incidence of OHCA and survival rates were calculated, and logistic regression analysis was performed to assess associations. The prevalence of OHCA and COVID-19 during the peak of the pandemic was also described.

Results: A total of 43,882 cases of OHCA were reported in HK and included in our analysis. Around 13,946 cases were recorded during the prepandemic period (2017-2019), and the remaining 29,936 cases were reported during the pandemic period (2020-2023). During the pandemic period, the proportion of female patients increased to 44.1% (13,215/29,936), and the average age increased slightly to 76.5 (SD 18.5) years. The majority of OHCAs (n=18,143, 61.1% cases) occurred at home. A witness was present in 45.9% (n=10,723) of the cases, and bystander CPR was initiated in 44.6% (n=13,318) of the cases. There was a significant increase in OHCA incidence, with a corresponding decrease in survival rates compared to the prepandemic period. The location of OHCA shifted, with a decrease in incidents in public places and a potential increase in incidents at home. We found that CPR (odds ratio 1.48, 95% CI 1.17-1.86) and public-access defibrillation (odds ratio 1.16, 95% CI 1.05-1.28) were significantly associated with a high survival to admission rate during the pandemic period. There was a correlation between the development of OHCA and the prevalence of COVID-19 in HK.

Conclusions: The COVID-19 pandemic has had a significant impact on OHCA in HK, resulting in increased incidence and decreased survival rates. The findings highlight the importance of addressing the indirect effects of the pandemic, such as increased stress levels and strain on health care systems, on OHCA outcomes. Strategies should be developed to improve OHCA prevention, emergency response systems, and health care services during public health emergencies to mitigate the impact on population health.

(JMIR Public Health Surveill 2024;10:e56054) doi:10.2196/56054
Introduction

Out-of-hospital cardiac arrest (OHCA) refers to the sudden cessation of cardiac activity outside a hospital setting. It is a critical medical emergency that poses significant challenges to individuals’ health and health care systems. The escalating prevalence of OHCA in recent years has become a pressing concern. OHCA can affect individuals across all age groups and backgrounds, making it a universal health issue. According to data from 2020, the incidence of OHCA ranges from 30.0 to 97.1 per 100,000 population, with survival to hospital discharge varying from 3.1% to 20.4% worldwide [1]. This highlights the urgent need for effective preventive measures and improved emergency response systems.
